The most fundamental command for correcting erroneous editing is the undo command, C-x u or C-_. This command undoes a single command (usually), a part of a command (in the case of `query-replace`), or several consecutive self-inserting characters. Consecutive repetitions of C-_ or C-x u undo earlier and earlier changes, back to the limit of the undo information available. See section Undoing Changes, for for more information.

Killing Your Mistakes

DEL
: Delete last character (`delete-backward-char`).

M-DEL
: Kill last word (`backward-kill-word`).

C-x DEL
: Kill to beginning of sentence (`backward-kill-sentence`).

The DEL character (`delete-backward-char`) is the most important correction command. It deletes the character before point. When DEL follows a self-inserting character command, you can think of it as canceling that command. However, avoid the mistake of thinking of DEL as a general way to cancel a command!

When your mistake is longer than a couple of characters, it might be more convenient to use M-DEL or C-x DEL. M-DEL kills back to the start of the last word, and C-x DEL kills back to the start of the last sentence. C-x DEL is particularly useful when you change your mind about the phrasing of the text you are writing. M-DEL and C-x DEL save the killed text for C-y and M-y to retrieve. See section Yanking.

M-DEL is often useful even when you have typed only a few characters wrong, if you know you are confused in your typing and aren't sure exactly what you typed. At such a time, you cannot correct with DEL except by looking at the screen to see what you did. Often it requires less thought to kill the whole word and start again.

Transposing Text

C-t
: Transpose two characters (`transpose-chars`).

M-t

Transpose two words (`transpose-words`).

C-M-t

Transpose two balanced expressions (`transpose-sexps`).

C-x C-t

Transpose two lines (`transpose-lines`).

The common error of transposing two characters can be fixed, when they are adjacent, with the C-t command (`transpose-chars`). Normally, C-t transposes the two characters on either side of point. When given at the end of a line, rather than transposing the last character of the line with the newline, which would be useless, C-t transposes the last two characters on the line. So, if you catch your transposition error right away, you can fix it with just a C-t. If you don't catch it so fast, you must move the cursor back to between the two transposed characters. If you transposed a space with the last character of the word before it, the word motion commands are a good way of getting there. Otherwise, a reverse search (C-r) is often the best way. See section Searching and Replacement.

M-t (`transpose-words`) transposes the word before point with the word after point. It moves point forward over a word, dragging the word preceding or containing point forward as well. The punctuation characters between the words do not move. For example, `FOO, BAR' transposes into `BAR, FOO' rather than `BAR FOO,'.

C-M-t (`transpose-sexps`) is a similar command for transposing two expressions (see section Lists and Sexps), and C-x C-t (`transpose-lines`) exchanges lines. They work like M-t except in determining the division of the text into syntactic units.

A numeric argument to a transpose command serves as a repeat count: it tells the transpose command to move the character (word, sexp, line) before or containing point across several other characters (words, sexps, lines). For example, C-u 3 C-t moves the character before point forward across three other characters. It would change `f-!-oobar' into `oobf-!-ar'. This is equivalent to repeating C-t three times. C-u - 4 M-t moves the word before point backward across four words. C-u - C-M-t would cancel the effect of plain C-M-t.

A numeric argument of zero is assigned a special meaning (because otherwise a command with a repeat count of zero would do nothing): to transpose the character (word, sexp, line) ending after point with the one ending after the mark.

Case Conversion

M-- M-l

Convert last word to lower case. Note Meta-- is Meta-minus.

M-- M-u

Convert last word to all upper case.

M-- M-c

Convert last word to lower case with capital initial.

A very common error is to type words in the wrong case. Because of this, the word case-conversion commands M-l, M-u and M-c have a special feature when used with a negative argument: they do not move the cursor. As soon as you see you have mistyped the last word, you can simply case-convert it and go on typing. See section Case Conversion Commands.

Checking and Correcting Spelling

This section describes the commands to check the spelling of a single word or of a portion of a buffer. These commands work with the spelling checker program Ispell, which is not part of Emacs.

M-$
: Check and correct spelling of word at point (`ispell-word`).

M-TAB
: Complete the word before point based on the spelling dictionary (`ispell-complete-word`).

M-x ispell-buffer
: Check and correct spelling of each word in the buffer.

M-x ispell-region
: Check and correct spelling of each word in the region.

M-x ispell-message
: Check and correct spelling of each word in a draft mail message, excluding cited material.

M-x ispell-change-dictionary RET dict RET
: Restart the ispell process, using dict as the dictionary.

M-x ispell-kill-ispell
: Kill the Ispell subprocess.

To check the spelling of the word around or next to point, and optionally correct it as well, use the command M-$ (`ispell-word`). If the word is not correct, the command offers you various alternatives for what to do about it.

To check the entire current buffer, use M-x ispell-buffer. Use M-x ispell-region to check just the current region. To check spelling in an email message you are writing, use M-x ispell-message; that checks the whole buffer, but does not check material that is indented or appears to be cited from other messages.

Each time these commands encounter an incorrect word, they ask you what to do. It displays a list of alternatives, usually including several "near-misses"---words that are close to the word being checked. Then you must type a character. Here are the valid responses:

SPC
: Skip this word--continue to consider it incorrect, but don't change it here.

r new RET
: Replace the word (just this time) with new.

R new RET
: Replace the word with new, and do a `query-replace` so you can replace it elsewhere in the

buffer if you wish.

digit

Replace the word (just this time) with one of the displayed near-misses. Each near-miss is listed with a digit; type that digit to select it.

a

Accept the incorrect word--treat it as correct, but only in this editing session.

A

Accept the incorrect word--treat it as correct, but only in this editing session and for this buffer.

i

Insert this word in your private dictionary file so that Ispell will consider it correct it from now on, even in future sessions.

u

Insert a lower-case version of this word in your private dictionary file.

m

Like i, but you can also specify dictionary completion information.

l word RET

Look in the dictionary for words that match word. These words become the new list of "near-misses"; you can select one of them to replace with by typing a digit. You can use `*' in word as a wildcard.

C-g

Quit interactive spell checking. You can restart it again afterward with C-u M-$.

X

Same as C-g.

x

Quit interactive spell checking and move point back to where it was when you started spell checking.

q

Quit interactive spell checking and kill the Ispell subprocess.

C-l

Refresh the screen.

C-z

This key has its normal command meaning (suspend Emacs or iconify this frame).

The command `ispell-complete-word`, which is bound to the key M-TAB in Text mode and related modes, shows a list of completions based on spelling correction. Insert the beginning of a word, and then type M-TAB; the command displays a completion list window. To choose one of the completions listed, click Mouse-2 on it, or move the cursor there in the completions window and type RET. See section Text Mode.

Once started, the Ispell subprocess continues to run (waiting for something to do), so that subsequent

spell checking commands complete more quickly. If you want to get rid of the Ispell process, use M-ispell-kill-ispell. This is not usually necessary, since the process uses no time except when you do spelling correction.

Ispell uses two dictionaries: the standard dictionary and your private dictionary. The variable `ispell-dictionary` specifies the file name of the standard dictionary to use. A value of `nil` says to use the default dictionary. The command M-x ispell-change-dictionary sets this variable and then restarts the Ispell subprocess, so that it will use a different dictionary.

Go to the previous, next section.

Go to the previous, next section.

File Handling

The operating system stores data permanently in named files. So most of the text you edit with Emacs comes from a file and is ultimately stored in a file.

To edit a file, you must tell Emacs to read the file and prepare a buffer containing a copy of the file's text. This is called visiting the file. Editing commands apply directly to text in the buffer; that is, to the copy inside Emacs. Your changes appear in the file itself only when you save the buffer back into the file.

In addition to visiting and saving files, Emacs can delete, copy, rename, and append to files, keep multiple versions of them, and operate on file directories.

File Names

Most Emacs commands that operate on a file require you to specify the file name. (Saving and reverting are exceptions; the buffer knows which file name to use for them.) You enter the file name using the minibuffer (see section The Minibuffer). Completion is available, to make it easier to specify long file names. See section Completion.

For most operations, there is a default file name which is used if you type just RET to enter an empty argument. Normally the default file name is the name of the file visited in the current buffer; this makes it easy to operate on that file with any of the Emacs file commands.

Each buffer has a default directory, normally the same as the directory of the file visited in that buffer. When you enter a file name without a directory, the default directory is used. If you specify a directory in a relative fashion, with a name that does not start with a slash, it is interpreted with respect to the default directory. The default directory is kept in the variable `default-directory`, which has a separate value in every buffer.

For example, if the default file name is `` `/u/rms/gnu/gnu.tasks' `` then the default directory is `` `/u/rms/gnu/' ``. If you type just `foo', which does not specify a directory, it is short for `` `/u/rms/gnu/foo' ``. `../.login' would stand for `` `/u/rms/.login' ``. `new/foo' would stand for the file name `` `/u/rms/gnu/new/foo' ``.

The command M-x pwd prints the current buffer's default directory, and the command M-x cd sets it (to a value read using the minibuffer). A buffer's default directory changes only when the `cd` command is used. A file-visiting buffer's default directory is initialized to the directory of the file that is visited there. If you create a buffer with C-x b, its default directory is copied from that of the buffer that was current at the time.

The default directory actually appears in the minibuffer when the minibuffer becomes active to read a file name. This serves two purposes: it *shows* you what the default is, so that you can type a relative file name and know with certainty what it will mean, and it allows you to *edit* the default to specify a different directory. This insertion of the default directory is inhibited if the variable

`insert-default-directory` is set to `nil`.

Note that it is legitimate to type an absolute file name after you enter the minibuffer, ignoring the presence of the default directory name as part of the text. The final minibuffer contents may look invalid, but that is not so. For example, if the minibuffer starts out with `/usr/tmp/' and you add `/x1/rms/foo', you get `/usr/tmp//x1/rms/foo'; but Emacs ignores everything through the first slash in the double slash; the result is `/x1/rms/foo'. See section Minibuffers for File Names.

You can refer to files on other machines using a special file name syntax:

```
/host:filename
/user@host:filename
```

When you do this, Emacs uses the FTP program to read and write files on the specified host. It logs in through FTP using your user name or the name user. It may ask you for a password from time to time; this is used for logging in on host.

You can turn off the FTP file name feature by setting the variable `file-name-handler-alist` to `nil`.

`$' in a file name is used to substitute environment variables. For example, if you have used the shell command `export FOO=rms/hacks' to set up an environment variable named `FOO`, then you can use `/u/$FOO/test.c'` or `/u/${FOO}/test.c'` as an abbreviation for `/u/rms/hacks/test.c'`. The environment variable name consists of all the alphanumeric characters after the `$'; alternatively, it may be enclosed in braces after the `$'. Note that shell commands to set environment variables affect Emacs only if done before Emacs is started.

To access a file with `$' in its name, type `$$'. This pair is converted to a single `$' at the same time as variable substitution is performed for single `$'. The Lisp function that performs the substitution is called `substitute-in-file-name`. The substitution is performed only on file names read as such using the minibuffer.

Visiting Files

C-x C-f
: Visit a file (`find-file`).

C-x C-r
: Visit a file for viewing, without allowing changes to it (`find-file-read-only`).

C-x C-v
: Visit a different file instead of the one visited last (`find-alternate-file`).

C-x 4 C-f
: Visit a file, in another window (`find-file-other-window`). Don't change the selected window.

C-x 5 C-f

Visit a file, in a new frame (`find-file-other-frame`). Don't change the selected frame.

M-x auto-compression-mode

Toggle automatic uncompression and recompression for compressed files.

Visiting a file means copying its contents into an Emacs buffer so you can edit them. Emacs makes a new buffer for each file that you visit. We say that this buffer is visiting the file that it was created to hold. Emacs constructs the buffer name from the file name by throwing away the directory, keeping just the name proper. For example, a file named `` `/usr/rms/emacs.tex' `` would get a buffer named `emacs.tex'. If there is already a buffer with that name, a unique name is constructed by appending `<2>', `<3>', or so on, using the lowest number that makes a name that is not already in use.

Each window's mode line shows the name of the buffer that is being displayed in that window, so you can always tell what buffer you are editing.

The changes you make with editing commands are made in the Emacs buffer. They do not take effect in the file that you visited, or any place permanent, until you save the buffer. Saving the buffer means that Emacs writes the current contents of the buffer into its visited file. See section Saving Files.

If a buffer contains changes that have not been saved, we say the buffer is modified. This is important because it implies that some changes will be lost if the buffer is not saved. The mode line displays two stars near the left margin to indicate that the buffer is modified.

To visit a file, use the command C-x C-f (`find-file`). Follow the command with the name of the file you wish to visit, terminated by a RET.

The file name is read using the minibuffer (see section The Minibuffer), with defaulting and completion in the standard manner (see section File Names). While in the minibuffer, you can abort C-x C-f by typing C-g.

Your confirmation that C-x C-f has completed successfully is the appearance of new text on the screen and a new buffer name in the mode line. If the specified file does not exist and could not be created, or cannot be read, then you get an error, with an error message displayed in the echo area.

If you visit a file that is already in Emacs, C-x C-f does not make another copy. It selects the existing buffer containing that file. However, before doing so, it checks that the file itself has not changed since you visited or saved it last. If the file has changed, a warning message is printed. See section Protection against Simultaneous Editing.

What if you want to create a new file? Just visit it. Emacs prints `(New File)' in the echo area, but in other respects behaves as if you had visited an existing empty file. If you make any changes and save them, the file is created.

If the file you specify is actually a directory, C-x C-f invokes Dired, the Emacs directory browser so that you can "edit" the contents of the directory (see section Dired, the Directory Editor). Dired is a convenient way to delete, look at, or operate on the files in the directory. However, if the variable `find-file-run-dired` is `nil`, then it is an error to try to visit a directory.

If you visit a file that the operating system won't let you modify, Emacs makes the buffer read-only, so

that you won't go ahead and make changes that you'll have trouble saving afterward. You can make t buffer writable with C-x C-q (`vc-toggle-read-only`). See section Miscellaneous Buffer Operations.

Occasionally you might want to visit a file as read-only in order to protect yourself from entering changes accidentally; do so by visiting the file with the command C-x C-r (`find-file-read-only`).

If you visit a nonexistent file unintentionally (because you typed the wrong file name), use the C-x C-v command (`find-alternate-file`) to visit the file you really wanted. C-x C-v is similar to C-x C-f, but it kills the current buffer (after first offering to save it if it is modified). When it reads the file name to visit, it inserts the entire default file name in the buffer, with point just after the directory part; this is convenient if you made a slight error in typing the name.

C-x 4 f (`find-file-other-window`) is like C-x C-f except that the buffer containing the specified file is selected in another window. The window that was selected before C-x 4 f continues to show the same buffer it was already showing. If this command is used when only one window is being displayed, that window is split in two, with one window showing the same buffer as before, and the other one showing the newly requested file. See section Multiple Windows.

C-x 5 f (`find-file-other-frame`) is similar, but opens a new frame, or makes visible any existing frame showing the file you seek. This feature is available only when you are using a window system. See section Frames and X Windows.

Two special hook variables allow extensions to modify the operation of visiting files. Visiting a file that does not exist runs the functions in the list `find-file-not-found-hooks`; this variable holds a list of functions, and the functions are called one by one until one of them returns non-`nil`. Any visiting of a file, whether extant or not, expects `find-file-hooks` to contain a list of functions and calls them all, one by one. In both cases the functions receive no arguments. Of these two variables, `find-file-not-found-hooks` takes effect first. These variables are *not* normal hooks, and their names end in `-hooks' rather than `-hook' to indicate that fact. See section Hooks.

The command M-x auto-compression-mode toggles a mode in which visiting a compressed file automatically uncompresses it. (Editing the file and saving it automatically recompresses it.)

There are several ways to specify automatically the major mode for editing the file (see section How Major Modes are Chosen), and to specify local variables defined for that file (see section Local Variables in Files).

Saving Files

Saving a buffer in Emacs means writing its contents back into the file that was visited in the buffer.

C-x C-s

: Save the current buffer in its visited file (`save-buffer`).

C-x s

: Save any or all buffers in their visited files (`save-some-buffers`).

M-~
: Forget that the current buffer has been changed (`not-modified`).

C-x C-w
: Save the current buffer in a specified file (`write-file`).

M-x set-visited-file-name
: Change file the name under which the current buffer will be saved.

When you wish to save the file and make your changes permanent, type C-x C-s (`save-buffer`). After saving is finished, C-x C-s displays a message like this:

```
Wrote /u/rms/gnu/gnu.tasks
```

If the selected buffer is not modified (no changes have been made in it since the buffer was created or last saved), saving is not really done, because it would have no effect. Instead, C-x C-s displays a message like this in the echo area:

```
(No changes need to be saved)
```

The command C-x s (`save-some-buffers`) offers to save any or all modified buffers. It asks you what to do with each buffer. The possible responses are analogous to those of `query-replace`:

y
: Save this buffer and ask about the rest of the buffers.

n
: Don't save this buffer, but ask about the rest of the buffers.

!
: Save this buffer and all the rest with no more questions.

RET
: Terminate `save-some-buffers` without any more saving.

.
: Save this buffer, then exit `save-some-buffers` without even asking about other buffers.

C-r
: View the buffer that you are currently being asked about. When you exit View mode, you get back to `save-some-buffers`, which asks the question again.

C-h
: Display a help message about these options.

C-x C-c, the key sequence to exit Emacs, invokes `save-some-buffers` and therefore asks the same questions.

If you have changed a buffer but you do not want to save the changes, you should take some action to prevent it. Otherwise, each time you use C-x s or C-x C-c, you are liable to save this buffer by mistake. One thing you can do is type M-~ (`not-modified`), which clears out the indication that the buffer is

modified. If you do this, none of the save commands will believe that the buffer needs to be saved. (`~' is often used as a mathematical symbol for `not'; thus M-~ is `not', metafied.) You could also use `set-visited-file-name' (see below) to mark the buffer as visiting a different file name, one which is not in use for anything important. Alternatively, you can cancel all the changes made since the file was visited or saved, by reading the text from the file again. This is called reverting. See section Reverting a Buffer. You could also undo all the changes by repeating the undo command C-x u until you have undone all the changes; but reverting is easier.

M-x set-visited-file-name alters the name of the file that the current buffer is visiting. It reads the new file name using the minibuffer. Then it specifies the visited file name and changes the buffer name correspondingly (as long as the new name is not in use). `set-visited-file-name` does not save the buffer in the newly visited file; it just alters the records inside Emacs in case you do save later. It also marks the buffer as "modified" so that C-x C-s in that buffer *will* save.

If you wish to mark the buffer as visiting a different file and save it right away, use C-x C-w (`write-file`). It is precisely equivalent to `set-visited-file-name` followed by C-x C-s. C-x C-s used on a buffer that is not visiting with a file has the same effect as C-x C-w; that is, it reads a file name, marks the buffer as visiting that file, and saves it there. The default file name in a buffer that is not visiting a file is made by combining the buffer name with the buffer's default directory.

If Emacs is about to save a file and sees that the date of the latest version on disk does not match what Emacs last read or wrote, Emacs notifies you of this fact, because it probably indicates a problem caused by simultaneous editing and requires your immediate attention. See section Protection against Simultaneous Editing.

If the variable `require-final-newline` is non-`nil`, Emacs puts a newline at the end of any file that doesn't already end in one, every time a file is saved or written.

Backup Files

On most operating systems, rewriting a file automatically destroys all record of what the file used to contain. Thus, saving a file from Emacs throws away the old contents of the file--or it would, except that Emacs carefully copies the old contents to another file, called the backup file, before actually saving. (This assumes that the variable `make-backup-files` is non-`nil`. Backup files are not written if this variable is `nil`.) Emacs does not normally make backup files for files in `/tmp'.

At your option, Emacs can keep either a single backup file or a series of numbered backup files for each file that you edit.

Emacs makes a backup for a file only the first time the file is saved from one buffer. No matter how many times you save a file, its backup file continues to contain the contents from before the file was visited. Normally this means that the backup file contains the contents from before the current editing session; however, if you kill the buffer and then visit the file again, a new backup file will be made by the next save.

Single or Numbered Backups

If you choose to have a single backup file (this is the default), the backup file's name is constructed by appending `~' to the file name being edited; thus, the backup file for `eval.c' would be `eval.c~'.

If you choose to have a series of numbered backup files, backup file names are made by appending `.~', the number, and another `~' to the original file name. Thus, the backup files of `eval.c' would be called `eval.c.~1~', `eval.c.~2~', and so on, through names like `eval.c.~259~' and beyond.

If protection stops you from writing backup files under the usual names, the backup file is written as `%backup%~' in your home directory. Only one such file can exist, so only the most recently made such backup is available.

The choice of single backup or numbered backups is controlled by the variable `version-control`. Its possible values are

`t`
: Make numbered backups.

`nil`
: Make numbered backups for files that have numbered backups already. Otherwise, make single backups.

`never`
: Do not in any case make numbered backups; always make single backups.

You can set `version-control` locally in an individual buffer to control the making of backups for that buffer's file. For example, Rmail mode locally sets `version-control` to `never` to make sure that there is only one backup for an Rmail file. See section Local Variables.

If you set the environment variable `VERSION_CONTROL`, to tell various GNU utilities what to do with backup files, Emacs also obeys the environment variable by setting the Lisp variable `version-control` accordingly at startup. If the environment variable's value is `t' or `numbered', then `version-control` becomes `t`; if the value is `nil' or `existing', then `version-control` becomes `nil`; if it is `never' or `simple', then `version-control` becomes `never`.

For files under version control (see section Version Control), the variable `vc-make-backup-files` determines whether to make backup files. By default, it is `nil`, since backup files are redundant when you store all the previous versions in a version control system. See section Editing with Version Control.

Automatic Deletion of Backups

To prevent unlimited consumption of disk space, Emacs can delete numbered backup versions automatically. Generally Emacs keeps the first few backups and the latest few backups, deleting any in between. This happens every time a new backup is made.

The two variables `kept-old-versions` and `kept-new-versions` control this deletion. Their values are, respectively the number of oldest (lowest-numbered) backups to keep and the number of newest (highest-numbered) ones to keep, each time a new backup is made. Recall that these values are used just after a new backup version is made; that newly made backup is included in the count in

`kept-new-versions`. By default, both variables are 2.

If `delete-old-versions` is non-`nil`, the excess middle versions are deleted without a murmur. If it is `nil`, the default, then you are asked whether the excess middle versions should really be deleted.

Dired's . (Period) command can also be used to delete old versions. See section Deleting Files with Dired.

Copying vs. Renaming

Backup files can be made by copying the old file or by renaming it. This makes a difference when the old file has multiple names. If the old file is renamed into the backup file, then the alternate names become names for the backup file. If the old file is copied instead, then the alternate names remain names for the file that you are editing, and the contents accessed by those names will be the new contents.

The method of making a backup file may also affect the file's owner and group. If copying is used, these do not change. If renaming is used, you become the file's owner, and the file's group becomes the default (different operating systems have different defaults for the group).

Having the owner change is usually a good idea, because then the owner always shows who last edited the file. Also, the owners of the backups show who produced those versions. Occasionally there is a file whose owner should not change; it is a good idea for such files to contain local variable lists to set `backup-by-copying-when-mismatch` locally (see section Local Variables in Files).

The choice of renaming or copying is controlled by three variables. Renaming is the default choice. If the variable `backup-by-copying` is non-`nil`, copying is used. Otherwise, if the variable `backup-by-copying-when-linked` is non-`nil`, then copying is used for files that have multiple names, but renaming may still used when the file being edited has only one name. If the variable `backup-by-copying-when-mismatch` is non-`nil`, then copying is used if renaming would cause the file's owner or group to change.

Protection against Simultaneous Editing

Simultaneous editing occurs when two users visit the same file, both make changes, and then both save them. If nobody were informed that this was happening, whichever user saved first would later find that his changes were lost. On some systems, Emacs notices immediately when the second user starts to change the file, and issues an immediate warning.

For the sake of systems where that is not possible, and in case someone else proceeds to change the file despite the warning, Emacs also checks when the file is saved, and issues a second warning if you are about to overwrite a file containing another user's changes. You can prevent loss of the other user's work by taking the proper corrective action at that time.

When you make the first modification in an Emacs buffer that is visiting a file, Emacs records that the file is locked by you. (It does this by writing another file in a directory reserved for this purpose.) The lock is removed when you save the changes. The idea is that the file is locked whenever an Emacs buffer visiting it has unsaved changes.

If you begin to modify the buffer while the visited file is locked by someone else, this constitutes a collision. When Emacs detects a collision, it asks you what to do, by calling the Lisp function `ask-user-about-lock`. You can redefine this function for the sake of customization. The standard definition of this function asks you a question and accepts three possible answers:

s
: Steal the lock. Whoever was already changing the file loses the lock, and you gain the lock.

p
: Proceed. Go ahead and edit the file despite its being locked by someone else.

q
: Quit. This causes an error (`file-locked`) and the modification you were trying to make in the buffer does not actually take place.

Note that locking works on the basis of a file name; if a file has multiple names, Emacs does not realize that the two names are the same file and cannot prevent two users from editing it simultaneously under different names. However, basing locking on names means that Emacs can interlock the editing of new files that will not really exist until they are saved.

Some systems are not configured to allow Emacs to make locks. On these systems, Emacs cannot detect trouble in advance, but it still can detect the collision when you try to save a file and overwrite someone else's changes.

Every time Emacs saves a buffer, it first checks the last-modification date of the existing file on disk to verify that it has not changed since the file was last visited or saved. If the date does not match, it implies that changes were made in the file in some other way, and these changes are about to be lost if Emacs actually does save. To prevent this, Emacs prints a warning message and asks for confirmation before saving. Occasionally you will know why the file was changed and know that it does not matter; then you can answer yes and proceed. Otherwise, you should cancel the save with C-g and investigate the situation.

The first thing you should do when notified that simultaneous editing has already taken place is to list the directory with C-u C-x C-d (see section File Directories). This shows the file's current author. You should attempt to contact him to warn him not to continue editing. Often the next step is to save the contents of your Emacs buffer under a different name, and use `diff` to compare the two files.

Simultaneous editing checks are also made when you visit with C-x C-f a file that is already visited and when you start to modify a file. This is not strictly necessary, but it can cause you to find out about the collision earlier, when perhaps correction takes less work.

Reverting a Buffer

If you have made extensive changes to a file and then change your mind about them, you can get rid of them by reading in the previous version of the file. To do this, use M-x revert-buffer, which operates on the current buffer. Since reverting a buffer unintentionally could lose a lot of work, you must confirm this command with yes.

`revert-buffer` keeps point at the same distance (measured in characters) from the beginning of the file. If the file was edited only slightly, you will be at approximately the same piece of text after reverting as before. If you have made drastic changes, the same value of point in the old file may address a totally different piece of text.

Reverting marks the buffer as "not modified" until another change is made.

Some kinds of buffers whose contents reflect data bases other than files, such as Dired buffers, can also be reverted. For them, reverting means recalculating their contents from the appropriate data base. Buffers created randomly with C-x b cannot be reverted; `revert-buffer` reports an error when asked to do so.

Auto-Saving: Protection Against Disasters

Emacs saves all the visited files from time to time (based on counting your keystrokes) without being asked. This is called auto-saving. It prevents you from losing more than a limited amount of work if the system crashes.

When Emacs determines that it is time for auto-saving, each buffer is considered, and is auto-saved if auto-saving is turned on for it and it has been changed since the last time it was auto-saved. The message `Auto-saving...' is displayed in the echo area during auto-saving, if any files are actually auto-saved. Errors occurring during auto-saving are caught so that they do not interfere with the execution of commands you have been typing.

Auto-Save Files

Auto-saving does not normally save in the files that you visited, because it can be very undesirable to save a program that is in an inconsistent state when you have made half of a planned change. Instead, auto-saving is done in a different file called the auto-save file, and the visited file is changed only when you request saving explicitly (such as with C-x C-s).

Normally, the auto-save file name is made by appending `#' to the front and rear of the visited file name. Thus, a buffer visiting file `` `foo.c' `` is auto-saved in a file `` `#foo.c#' ``. Most buffers that are not visiting files are auto-saved only if you request it explicitly; when they are auto-saved, the auto-save file name is made by appending `#%' to the front and `#' to the rear of buffer name. For example, the `*mail*' buffer in which you compose messages to be sent is auto-saved in a file named `` `#%*mail*#' ``. Auto-save file names are made this way unless you reprogram parts of Emacs to do something different (the functions `make-auto-save-file-name` and `auto-save-file-name-p`). The file name to be used for auto-saving in a buffer is calculated when auto-saving is turned on in that buffer.

When you delete a substantial part of the text in a large buffer, auto save turns off temporarily in that buffer. This is because if you deleted the text unintentionally, you might find the auto-save file more useful if it contains the deleted text. To reenable auto-saving after this happens, save the buffer with C-x C-s, or use C-u 1 M-x auto-save.

If you want auto-saving to be done in the visited file, set the variable `auto-save-visited-file-name` to be non-`nil`. In this mode, there is really no difference

between auto-saving and explicit saving.

A buffer's auto-save file is deleted when you save the buffer in its visited file. To inhibit this, set the variable `delete-auto-save-files` to `nil`. Changing the visited file name with C-x C-w or `set-visited-file-name` renames any auto-save file to go with the new visited name.

Controlling Auto-Saving

Each time you visit a file, auto-saving is turned on for that file's buffer if the variable `auto-save-default` is non-`nil` (but not in batch mode; see section Entering and Exiting Emacs). The default for this variable is `t`, so auto-saving is the usual practice for file-visiting buffers. Auto-saving can be turned on or off for any existing buffer with the command M-x auto-save-mode. Like other minor mode commands, M-x auto-save-mode turns auto-saving on with a positive argument, off with a zero or negative argument; with no argument, it toggles.

Emacs does auto-saving periodically based on counting how many characters you have typed since the last time auto-saving was done. The variable `auto-save-interval` specifies how many characters there are between auto-saves. By default, it is 300.

Auto-saving also takes place when you stop typing for a while. The variable `auto-save-timeout` says how many seconds Emacs should wait before it does an auto save (and perhaps also a garbage collection). (The actual time period is longer if the current buffer is long; this is a heuristic which aims to keep out of your way when you are editing long buffers in which auto-save takes an appreciable amount of time.) Auto-saving during idle periods accomplishes two things: first, it makes sure all your work is saved if you go away from the terminal for a while; second, it may avoid some auto-saving while you are actually typing.

Emacs also does auto-saving whenever it gets a fatal error. This includes killing the Emacs job with a shell command such as `kill %emacs', or disconnecting a phone line or network connection.

You can request an auto-save explicitly with the command M-x do-auto-save.

Recovering Data from Auto-Saves

You can use the contents of an auto-save file to recover from a loss of data with the command M-x recover-file RET file RET. This visits file and then (after your confirmation) restores the contents from from its auto-save file `` `#file#' ``. You can then save with C-x C-s to put the recovered text into file itself. For example, to recover file `` `foo.c' `` from its auto-save file `` `#foo.c#' ``, do:

```
M-x recover-file RET foo.c RET
yes RET
C-x C-s
```

Before asking for confirmation, M-x recover-file displays a directory listing describing the specified file and the auto-save file, so you can compare their sizes and dates. If the auto-save file is older, M-x recover-file does not offer to read it.

If Emacs or the computer crashes, you can recover all the files you were editing from their auto save with the command M-x recover-session. This first shows you a list of recorded interrupted sessions. Move point to the one you choose, and type C-c C-c.

Then `recover-session` asks about each of the files that were being edited during that session, asking whether to recover that file. If you answer y, it calls `recover-file`, which works in its normal fashion. It shows the dates of the original file and its auto-save file, and asks once again whether to recover that file.

When `recover-session` is done, the files you've chosen to recover are present in Emacs buffers. You should then save them. Only this--saving them--updates the files themselves.

Interrupted sessions are recorded for later recovery in files named `` `~/.saves-pid-hostname' ``. The `~/.saves' portion of these names comes from the value of `auto-save-list-file-prefix`. You can arrange to record sessions in a different place by setting that variable in your `` `.emacs' `` file, but you'll have to redefine `recover-session` as well to make it look in the new place. If you set `auto-save-list-file-prefix` to `nil` in your `` `.emacs' `` file, sessions are not recorded for recovery.

File Name Aliases

Symbolic links and hard links both make it possible for several file names to refer to the same file. Hard links are alternate names that refer directly to the file; all the names are equally valid, and no one of them is preferred. By contrast, a symbolic link is a kind of defined alias: when `` `foo' `` is a symbolic link to `` `bar' ``, you can use either name to refer to the file, but `` `bar' `` is the real name, while `` `foo' `` is just an alias. More complex cases occur when symbolic links point to directories.

If you visit two names for the same file, normally Emacs makes two different buffers, but it warns you about the situation.

If you wish to avoid visiting the same file in two buffers under different names, set the variable `find-file-existing-other-name` to a non-`nil` value. Then `find-file` uses the existing buffer visiting the file, no matter which of the file's names you specify.

If the variable `find-file-visit-truename` is non-`nil`, then the file name recorded for a buffer is the file's truename (made by replacing all symbolic links with their target names), rather than the name you specify. Setting `find-file-visit-truename` also implies the effect of `find-file-existing-other-name`.

Version Control

Version control systems are packages that can record multiple versions of a source file, usually storing the unchanged parts of the file just once. Version control systems also record history information such as the creation time of each version, who created it, and a description of what was changed in that version.

The Emacs version control commands work with three version control systems--RCS, CVS and SCCS. The GNU project recommends RCS and CVS, which are free software and available from the Free

Software Foundation.

Supported Version Control Systems

VC currently works with three different version control systems or "back ends": RCS, CVS, and SCCS.

RCS is a free version control system that is available from the Free Software Foundation. It is perhaps the most mature of the supported back ends, and the VC commands are conceptually closest to RCS. Almost everything you can do with RCS can be done through VC.

CVS is built on top of RCS, and extends the features of RCS, allowing for more sophisticated release management, and concurrent multi-user development. VC supports basic editing operations under CVS, but for some less common tasks you still need to call CVS from the command line. Note also that before using CVS you must set up a repository, which is a subject too complex to treat here. See section Using VC with CVS.

SCCS is a proprietary but widely used version control system. In terms of capabilities, it is the weakest of the the three that VC supports. VC compensates for certain features missing in SCCS (snapshots, for example) by implementing them itself, but some other VC features, such as multiple branches, are not available with SCCS. You should use SCCS only if for some reason you cannot use RCS.

Concepts of Version Control

When a file is under version control, we also say that it is registered in the version control system. Each registered file has a corresponding master file which represents the file's present state plus its change history, so that you can reconstruct from it either the current version or any specified earlier version. Usually the master file also records a log entry for each version describing what was changed in that version.

The file that is maintained under version control is sometimes called the work file corresponding to its master file.

To examine a file, you check it out. This extracts a version of the source file (typically, the most recent) from the master file. If you want to edit the file, you must check it out locked. Only one user can do this at a time for any given source file. (This kind of locking is completely unrelated to the locking that Emacs uses to detect simultaneous editing of a file.)

When you are done with your editing, you must check in the new version. This records the new version in the master file, and unlocks the source file so that other people can lock it and thus modify it.

Checkin and checkout are the basic operations of version control. You can do both of them with a single Emacs command: C-x C-q (`vc-toggle-read-only`).

There are variants of this basic pattern, though. CVS, for example, has no such thing as locking, and therefore you can normally edit files right away, without having to check them out first. See section Using VC with CVS. With RCS, you can optionally select non-strict locking for a particular source file; then you can edit the file in Emacs without explicitly locking it.

A snapshot is a coherent collection of versions of the various files that make up a program. See sect
Snapshots.

Editing with Version Control

These are the commands for editing a file maintained with version control:

C-x C-q

C-x v v

Check the visited file in or out.

C-x v u

Revert the buffer and the file to the last checked in version.

C-x v c

Remove the last-entered change from the master for the visited file. This undoes your last check-in.

C-x v i

Register the visited file for version control.

(C-x v is the prefix key for version control commands; all of these commands except for C-x C-q start with C-x v.)

Check-Out

When you want to modify a file maintained with version control, type C-x C-q (`vc-toggle-read-only`). This checks out the file, and tells RCS or SCCS to lock the file. This means making the file writable for you (but not for anyone else).

If you specify a prefix argument (C-u C-x C-q) for checkout, Emacs asks you for a version number, and checks out that version *unlocked*. This lets you move to old versions, or existing branches of the file (see section Multiple Branches of a File). You can then start editing the selected version by typing C-x C-q again. (If you edit an old version of a file this way, checking it in again creates a new branch.)

Under CVS, you normally don't need to check out files explicitly. CVS does not have locking; multiple users can edit their copies of a file whenever they want. (If two users make conflicting changes, they need to reconcile their changes when checking them in.) We therefore say that an implicit check-out happens when you make the first change in the file.

CVS has an alternative mode in which explicit check-out is required. And RCS has an alternative mode called non-strict locking in which explicit check-out is not required. Selecting these modes is done outside of VC, but once you have selected them, VC obeys them. With RCS, you can select non-strict locking for a particular file using the `rcs -U' command. See section Using VC with CVS, for an explanation of how to do this with CVS.

Check-In

When you are finished editing the file, type C-x C-q again. When used on a file that is checked out, t command checks the file in. But check-in does not start immediately; first, you must enter the log entry---a description of the changes in the new version. C-x C-q pops up a buffer for you to enter this in. When you are finished typing in the log entry, type C-c C-c to terminate it; this is when actual check-in takes place. See section Log Entries.

With RCS and SCCS, a checked-out file is also locked, which means it is writable for you, but not for anyone else. As long as you own the lock on the file, nobody else can modify it, and nobody can check in any changes to that particular version. Checking in your changes unlocks the file, so that other users can lock it and modify it.

CVS, on the contrary, doesn't have a concept of locking. The working files are always modifiable, allowing concurrent development, with possible conflicts being resolved at check-in time. See section Using VC with CVS.

To specify the version number for the new version, type C-u C-x C-q to check in a file. Then Emacs asks you for the new version number in the minibuffer. This can be used to create a new branch of the file (see section Multiple Branches of a File), or to increment the file's major version number.

It is not impossible to lock a file that someone else has locked. If you try to check out a file that is locked, C-x C-q asks you whether you want to "steal the lock." If you say yes, the file becomes locked by you, but a message is sent to the person who had formerly locked the file, to inform him of what has happened. The mode line indicates that a file is locked by someone else by displaying the login name of that person, before the version number.

Registering a File for Version Control

C-x v i

Register the visited file for version control.

You can put any file under version control by simply visiting it, and then typing C-x v i (`vc-register`). After C-x v i, the file is unlocked and read-only. Type C-x C-q if you wish to start editing it.

When you register the file, Emacs must choose which version control system to use for it. You can specify your choice explicitly by setting `vc-default-back-end` to `RCS`, `CVS` or `SCCS`. Otherwise, if there is a subdirectory named `` `RCS' ``, `` `SCCS' ``, or `` `CVS' ``, Emacs uses the corresponding version control system. In the absence of any specification, the default choice is RCS if RCS is installed, otherwise SCCS.

After registering a file with CVS, you must subsequently commit the initial version by typing C-x C-q. See section Using VC with CVS.

The initial version number for a newly registered file is 1.1, by default. To specify a different number, give C-x v i a numeric argument; then it reads the initial version number using the minibuffer.

If `vc-initial-comment` is non-`nil`, C-x v i reads an initial comment (much like a log entry) to describe the purpose of this source file.

Undoing Version Control Actions

C-x v u
: Revert the buffer and the file to the last checked in version.

C-x v c
: Remove the last-entered change from the master for the visited file. This undoes your last checkin.

If you want to discard your current set of changes and revert to the last version checked in, use C-x v u (`vc-revert-buffer`). This cancels your last check-out, leaving the file unlocked. If you want to make a different set of changes, you must first check the file out again. C-x v u requires confirmation, unless it sees that you haven't made any changes since the last checked-in version.

C-x v u is also the command to use to unlock a file if you lock it and then decide not to change it.

You can cancel a change after checking it in, with C-x v c (`vc-cancel-version`). This command discards all record of the most recent checked in version. C-x v c also offers to revert your work file and buffer to the previous version (the one that precedes the version that is deleted). If you say no, then VC keeps your changes in the buffer and locks the file.

The no-revert option is useful when you have checked in a change and then discover a trivial error in it; you can cancel the erroneous check-in, fix the error, and check the file in again.

When C-x v c does not revert the buffer, it unexpands all version control headers in the buffer instead (see section Inserting Version Control Headers). This is because the buffer no longer corresponds to any existing version. If you check it in again, the checkin process will expand the headers properly for the new version number.

However, it is impossible to unexpand the RCS `Log' header automatically. If you use that header feature, you have to unexpand it by hand--by deleting the entry for the version that you just canceled.

Be careful when invoking C-x v c, as it is easy to throw away a lot of work with it. To help you be careful, this command always requires confirmation with yes. Note also that this command is disabled under CVS, because canceling versions is very dangerous and discouraged with this back end.

The VC Mode Line

When you visit a file that is under version control, the mode line indicates the current status of the file: the name of the version control back end system, the locking state, and the version.

The locking state is displayed as a single character, which can be either `-' or `:'. `-' means the file is not locked or not modified by you. Once you lock the file, the state indicator changes to `:'. If the file is locked by someone else, that user's name appears after the version number.

For example, `RCS-1.3' means you are looking at RCS version 1.3, which is not locked. `RCS:1.3' means that you have locked the file, and possibly already changed it. `RCS:jim:1.3' means that the file is locked by jim.

Using VC with CVS

In CVS, files are never locked. Two users can check out the same file at the same time; each user has a separate copy and can edit it. Work files are always writable; once you have one, you need not type a VC command to start editing the file. You can edit it at any time.

When using RCS and SCCS, you normally use C-x C-q twice for each change; once before the change, for checkout, and once after, for checkin. With CVS, it's different: you normally use C-x C-q just once for each change, to commit the change when it is done. The work file remains writable, so you can begin editing again with no special commands.

One way to understand this is that VC does an implicit check-out when you save the modified file for the first time. VC indicates this on the mode line: the status indicator changes from `-' to `:' as soon as you save a modified version, telling you that you are not in sync with the repository anymore (see section The VC Mode Line). The file stays "checked out" until you check it back in, even if you kill the buffer and visit the file again.

If, instead, you would like to use explicit check-out with CVS, set the `CVSREAD` environment variable to some value. (It does not matter what value you use.) CVS then makes your work files read-only by default, and VC requires you to check them out explicitly with C-x C-q. When setting `CVSREAD` for the first time, make sure to check out all your modules anew, so that the file protections are set correctly.

VC does not provide a way to check out a working copy of an existing file in the repository. You have to use the CVS shell commands to do that. Once you have a work file, you can start using VC for that file.

CVS terminology speaks of committing a change rather than checking it in. But in practical terms they work the same way: Emacs asks you to type in a log entry, and you finish it with C-c C-c.

When you try to commit a change in a file, but someone else has committed another change in the meanwhile, that creates a conflict. VC detects this situation and offers to merge your changes and those of the other user, creating a new local version of the file, which you can then commit to the repository. This works smoothly if the changes are in different parts of the file, although it is wise to check the resulting file for semantic consistency.

However, if you and the other user changed the same parts of the file, the conflict cannot be resolved automatically. In this case, CVS inserts both variants of the conflicting regions into your working file, and puts so-called conflict markers around them. They indicate how the region looks in the respective user's version. You must resolve the conflict manually, for example by choosing one of the two variants and deleting the other one (and the conflict markers). Then you can commit the resulting file into the repository. The example below shows how a conflict region looks; the file is called `name' and the current repository version with user B's changes in it is 1.11.

```
<<<<<<< name
  User A's version
=======
  User B's version
>>>>>>> 1.11
```

You can turn off use of VC for CVS-managed files by setting the variable `vc-handle-cvs` to `nil`. If

you do this, Emacs treats these files as if they were not managed, and the VC commands are not available for them. You must do all CVS operations manually.

Log Entries

When you're editing an initial comment or log entry for inclusion in a master file, finish your entry by typing C-c C-c.

C-c C-c

Finish the comment edit normally (`vc-finish-logentry`). This finishes check-in.

To abort check-in, just **don't** type C-c C-c in that buffer. You can switch buffers and do other editing. As long as you don't try to check in another file, the entry you were editing remains in its buffer, and you can go back to that buffer at any time to complete the check-in.

If you change several source files for the same reason, it is often convenient to specify the same log entry for many of the files. To do this, use the history of previous log entries. The commands M-n, M-p, M-s and M-r for doing this work just like the minibuffer history commands (except that these versions are used outside the minibuffer).

Each time you check in a file, the log entry buffer is put into VC Log mode, which involves running two hooks: `text-mode-hook` and `vc-log-mode-hook`. See section Hooks.

Change Logs and VC

If you use RCS for a program and also maintain a change log file for it (see section Change Logs), you can generate change log entries automatically from the version control log entries:

C-x v a

Visit the current directory's change log file and create new entries for versions checked in since the most recent entry in the change log file (`vc-update-change-log`).

This command works with RCS only; it does not work with CVS or SCCS.

For example, suppose the first line of `` `ChangeLog' `` is dated 10 April 1992, and that the only check-in since then was by Nathaniel Bowditch to `` `rcs2log' `` on 8 May 1992 with log text `Ignore log messages that start with `#'.'. Then C-x v a visits `` `ChangeLog' `` and inserts text like this:

@medbreak

```
Fri May  8 21:45:00 1992  Nathaniel Bowditch  <nat@apn.org>

        * rcs2log: Ignore log messages that start with `#'.
```

@medbreak

You can then edit the new change log entry further as you wish.

Normally, the log entry for file `` `foo' `` is displayed as `* foo: text of log entry'. The `:' after `` `foo' `` is

omitted if the text of the log entry starts with `(functionname): '. For example, if the log entry for `vc.el' is `(vc-do-command): Check call-process status.', then the text in `ChangeLog' looks like this:

@medbreak

```
Wed May  6 10:53:00 1992  Nathaniel Bowditch  <nat@apn.org>

        * vc.el (vc-do-command): Check call-process status.
```

@medbreak

When C-x v a adds several change log entries at once, it groups related log entries together if they all are checked in by the same author at nearly the same time. If the log entries for several such files all have the same text, it coalesces them into a single entry. For example, suppose the most recent checkins have the following log entries:

```
* For `vc.texinfo': `Fix expansion typos.'
* For `vc.el': `Don't call expand-file-name.'
* For `vc-hooks.el': `Don't call expand-file-name.'
```

They appear like this in `ChangeLog':

@medbreak

```
Wed Apr  1 08:57:59 1992  Nathaniel Bowditch  <nat@apn.org>

        * vc.texinfo: Fix expansion typos.

        * vc.el, vc-hooks.el: Don't call expand-file-name.
```

@medbreak

Normally, C-x v a separates log entries by a blank line, but you can mark several related log entries to be clumped together (without an intervening blank line) by starting the text of each related log entry with a label of the form `{clumpname} '. The label itself is not copied to `ChangeLog'. For example, suppose the log entries are:

```
* For `vc.texinfo': `{expand} Fix expansion typos.'
* For `vc.el': `{expand} Don't call expand-file-name.'
* For `vc-hooks.el': `{expand} Don't call expand-file-name.'
```

Then the text in `ChangeLog' looks like this:

@medbreak

```
Wed Apr  1 08:57:59 1992  Nathaniel Bowditch  <nat@apn.org>
```

```
        * vc.texinfo: Fix expansion typos.
        * vc.el, vc-hooks.el: Don't call expand-file-name.
```

@medbreak

A log entry whose text begins with `#' is not copied to `ChangeLog'. For example, if you merely fix some misspellings in comments, you can log the change with an entry beginning with `#' to avoid putting such trivia into `ChangeLog'.

Examining And Comparing Old Versions

C-u C-x C-q version RET

Select version version as the current work file version.

C-x v ~ version RET

Examine version version of the visited file, in a buffer of its own.

C-x v =

Compare the current buffer contents with the latest checked-in version of the file.

C-u C-x v = file RET oldvers RET newvers RET

Compare the specified two versions of file.

There are two ways to work with an old version of a file. You can make the old version your current work file, for example if you want to reproduce a former stage of development, or if you want to create a branch from the old version (see section Multiple Branches of a File). To do this, visit the file and type C-u C-x C-q version RET. (This works only with RCS.)

If you want only to examine an old version, without changing your work file, visit the file and then type C-x v ~ version RET (`vc-version-other-window`). This puts the text of version version in a file named `filename.~version~', and visits it in its own buffer in a separate window.

To compare two versions of a file, use the command C-x v = (`vc-diff`). Plain C-x v = compares the current buffer contents (saving them in the file if necessary) with the last checked-in version of the file. C-u C-x v =, with a numeric argument, reads a file name and two version numbers, then compares those versions of the specified file.

If you supply a directory name instead of the name of a work file, this command compares the two specified versions of all registered files in that directory and its subdirectories. You can also specify a snapshot name (see section Snapshots) instead of one or both version numbers.

You can specify a checked-in version by its number; an empty input specifies the current contents of the work file (which may be different from all the checked-in versions).

This command works by running the `diff` utility, getting the options from the variable `diff-switches`. It displays the output in a special buffer in another window. Unlike the M-x diff command, C-x v = does not try to locate the changes in the old and new versions. This is because normally one or both versions do not exist as files when you compare them; they exist only in the records of the master file. See section Comparing Files, for more information about M-x diff.

Multiple Branches of a File

One use of version control is to maintain multiple "current" versions of a file. For example, you might have different versions of a program in which you are gradually adding various unfinished new features. Each such independent line of development is called a branch. VC allows you to create branches, and switch between existing branches. Note, however, that branches are supported only with RCS.

A file's main line of development is usually called the trunk. The versions on the trunk are normally numbered 1.1, 1.2, 1.3, etc. At any such version, you may start an independent branch. A branch starting at version 1.2 would have version number 1.2.1.1. Consecutive versions on this branch would have numbers 1.2.1.2, 1.2.1.3, 1.2.1.4, and so on. If there is a second branch also starting at version 1.2; it would consist of versions 1.2.2.1, 1.2.2.2, 1.2.2.3, and so on.

If you omit the final component of a version number, that is called a branch number. It refers to the highest existing version on that branch. The branches in the example above have branch numbers 1.2.1 and 1.2.2.

A version which is the last in its branch is called a head version.

Switching between Branches

To switch between branches, type C-u C-x C-q and specify the version number you want to select. This version is then checked out *unlocked* (write-protected), so you can examine it before really checking it out. Switching branches in this way is allowed only when the file is not locked.

You may omit the minor version number, thus giving only the branch number; this takes you to the highest version on the indicated branch. If you only type RET, Emacs goes to the highest version on the trunk.

After you have switched to any branch (including the main branch), you stay on it for subsequent VC commands, until you explicitly select some other branch.

Creating New Branches

To create a new branch from a head version (one that is the latest in the branch that contains it), first select that version if necessary, lock it with C-x C-q, and make whatever changes you want. Then, when you check in the changes, use C-u C-x C-q. This lets you specify the version number for the new version. You should specify a suitable branch number for a branch starting at the current version. For example, if the current version is 2.5, the branch number should be 2.5.1, 2.5.2, and so on, depending on the number of existing branches at that point.

To create a new branch at an older version (one that is no longer the head of a branch), first select that version, then lock it with C-x C-q. You'll be asked to confirm, when you lock the old version, that you really mean to create a new branch--if you say no, you'll be offered a chance to lock the latest version instead.

Then make your changes and type C-x C-q again to check in a new version. This automatically creates a new branch starting from the selected version. You need not specially request a new branch, because

that's the only way to add a new version at a point that is not the head of a branch.

After the branch is created, you "stay" on it. That means that subsequent checkouts and checkins create new versions on that branch. To leave the branch, you must explicitly select a different version with C-u C-x C-q for checkout.

Multi-User Branching

It is sometimes useful for multiple developers to work simultaneously on different branches of a file. This is possible if you create multiple source directories. Each source directory should have a link named `RCS' which points to a common directory of RCS master files. Then each source directory can have its own choice of versions checked out, but all share the same common RCS records.

This technique works reliably and automatically, provided that the source files contain RCS version headers (see section Inserting Version Control Headers). The headers enable Emacs to be sure, at all times, which version number is present in the work file.

If the files do not have version headers, you must instead tell Emacs explicitly in each session which branch you are working on. To do this, first find the file, then type C-u C-x C-q and specify the correct branch number. This ensures that Emacs knows which branch it is using during this particular editing session.

VC Status Commands

To view the detailed version control status and history of a file, type C-x v l (`vc-print-log`). It displays the history of changes to the current file, including the text of the log entries. The output appears in a separate window.

When you are working on a large program, it's often useful to find all the files that are currently locked, or all the files maintained in version control at all. You can use C-x v d (`vc-directory`) to show all the locked files in or beneath a certain directory. This includes all files that are locked by any user. C-u C-x v d lists all files in or beneath the specified directory that are maintained with version control.

The list of files is displayed as a buffer that uses an augmented Dired mode. The names of the users locking various files are shown (in parentheses) in place of the owner and group. (With CVS, a more detailed status is shown for each file.) All the normal Dired commands work in this buffer. Most interactive VC commands work also, and apply to the file name on the current line.

The C-x v v command (`vc-next-action`), when used in the augmented Dired buffer, operates on all the marked files (or the file on the current line). If it operates on more than one file, it handles each file according to its current state; thus, it may check out one file and check in another (because it is already checked out). If it has to check in any files, it reads a single log entry, then uses that text for all the files being checked in. This can be convenient for registering or checking in several files at once, as part of the same change.

Renaming VC Work Files and Master Files

When you rename a registered file, you must also rename its master file correspondingly to get proper results. Use `vc-rename-file` to rename the source file as you specify, and rename its master file accordingly. It also updates any snapshots (see section Snapshots) that mention the file, so that they use the new name; despite this, the snapshot thus modified may not completely work (see section Snapshot Caveats).

You cannot use `vc-rename-file` on a file that is locked by someone else.

Snapshots

A snapshot is a named set of file versions (one for each registered file) that you can treat as a unit. One important kind of snapshot is a release, a (theoretically) stable version of the system that is ready for distribution to users.

Making and Using Snapshots

There are two basic commands for snapshots; one makes a snapshot with a given name, the other retrieves a named snapshot.

`C-x v s name RET`

Define the last saved versions of every registered file in or under the current directory as a snapshot named name (`vc-create-snapshot`).

`C-x v r name RET`

Check out all registered files at or below the current directory level using whatever versions correspond to the snapshot name (`vc-retrieve-snapshot`).

This command reports an error if any files are locked at or below the current directory, without changing anything; this is to avoid overwriting work in progress.

A snapshot uses a very small amount of resources--just enough to record the list of file names and which version belongs to the snapshot. Thus, you need not hesitate to create snapshots whenever they are useful.

You can give a snapshot name as an argument to C-x v = or C-x v ~ (see section Examining And Comparing Old Versions). Thus, you can use it to compare a snapshot against the current files, or two snapshots against each other, or a snapshot against a named version.

Snapshot Caveats

VC's snapshot facilities are modeled on RCS's named-configuration support. They use RCS's native facilities for this, so under VC snapshots made using RCS are visible even when you bypass VC.

For SCCS, VC implements snapshots itself. The files it uses contain name/file/version-number triples. These snapshots are visible only through VC.

A snapshot is a set of checked-in versions. So make sure that all the files are checked in and not locked when you make a snapshot.

File renaming and deletion can create some difficulties with snapshots. This is not a VC-specific problem, but a general design issue in version control systems that no one has solved very well yet.

If you rename a registered file, you need to rename its master along with it (the command `vc-rename-file` does this automatically). If you are using SCCS, you must also update the records of the snapshot, to mention the file by its new name (`vc-rename-file` does this, too). An old snapshot that refers to a master file that no longer exists under the recorded name is invalid; VC can no longer retrieve it. It would be beyond the scope of this manual to explain enough about RCS and SCCS to explain how to update the snapshots by hand.

Using `vc-rename-file` makes the snapshot remain valid for retrieval, but it does not solve all problems. For example, some of the files in the program probably refer to others by name. At the very least, the makefile probably mentions the file that you renamed. If you retrieve an old snapshot, the renamed file is retrieved under its new name, which is not the name that the makefile expects. So the program won't really work as retrieved.

Inserting Version Control Headers

Sometimes it is convenient to put version identification strings directly into working files. Certain special strings called version headers are replaced in each successive version by the number of that version.

If you are using RCS, and version headers are present in your working files, Emacs can use them to determine the current version and the locking state of the files. This is more reliable than referring to the master files, which is done when there are no version headers. Note that in a multi-branch environment, version headers are necessary to make VC behave correctly (see section Multi-User Branching).

Searching for version headers is controlled by the variable `vc-consult-headers`. If it is non-`nil`, Emacs searches for headers to determine the version number you are editing. Setting it to `nil` disables this feature.

You can use the C-x v h command (`vc-insert-headers`) to insert a suitable header string.

C-x v h

Insert headers in a file for use with your version-control system.

The default header string is `$Id$' for RCS and `%W%' for SCCS. You can specify other headers to insert by setting the variable `vc-header-alist`. Its value is a list of elements of the form `(program . string)` where program is `RCS` or `SCCS` and string is the string to use.

Instead of a single string, you can specify a list of strings; then each string in the list is inserted as a separate header on a line of its own.

It is often necessary to use "superfluous" backslashes when writing the strings that you put in this variable. This is to prevent the string in the constant from being interpreted as a header itself if the Emacs Lisp file containing it is maintained with version control.

Each header is inserted surrounded by tabs, inside comment delimiters, on a new line at the start of the buffer. Normally the ordinary comment start and comment end strings of the current mode are used, but for certain modes, there are special comment delimiters for this purpose; the variable `vc-comment-alist` specifies them. Each element of this list has the form `(mode starter ender)`.

The variable `vc-static-header-alist` specifies further strings to add based on the name of the buffer. Its value should be a list of elements of the form `(regexp . format)`. Whenever regexp matches the buffer name, format is inserted as part of the header. A header line is inserted for each element that matches the buffer name, and for each string specified by `vc-header-alist`. The header line is made by processing the string from `vc-header-alist` with the format taken from the element. The default value for `vc-static-header-alist` is as follows:

```
(("\\.c$" .
  "\n#ifndef lint\nstatic char vcid[] = \"\%s\";\n\
#endif /* lint */\n"))
```

It specifies insertion of text of this form:

```
#ifndef lint
static char vcid[] = "string";
#endif /* lint */
```

Note that the text above starts with a blank line.

If you use more than one version header in a file, put them close together in the file. The mechanism in `revert-buffer` that preserves markers may not handle markers positioned between two version headers.

Customizing VC

There are many ways of customizing VC. The variables that control its behavior fall into three categories, described in the following sections.

VC Workfile Handling

Emacs normally does not save backup files for source files that are maintained with version control. If you want to make backup files even for files that use version control, set the variable `vc-make-backup-files` to a non-`nil` value.

Normally the work file exists all the time, whether it is locked or not. If you set `vc-keep-workfiles` to `nil`, then checking in a new version with C-x C-q deletes the work file; but any attempt to visit the file with Emacs creates it again. (With CVS, work files are always kept.)

Editing a version-controlled file through a symbolic link can be dangerous. It bypasses the version control system--you can edit the file without checking it out, and fail to check your changes in. Also,

your changes might overwrite those of another user. To protect against this, VC checks each symbolic link that you visit, to see if it points to a file under version control.

The variable `vc-follow-symlinks` controls what to do when a symbolic link points to a version-controlled file. If it is `nil`, VC only displays a warning message. If it is `t`, VC automatically follows the link, and visits the real file instead, telling you about this in the echo area. If the value is `ask` (the default), VC asks you each time whether to follow the link.

VC Status Retrieval

When deducing the locked/unlocked state of a file, VC first looks for an RCS version header string in the file (see section Inserting Version Control Headers). If there is no header string (or if the backend system is SCCS), VC normally looks at the file permissions of the work file; this is fast. But there might be situations when the file permissions cannot be trusted. In this case the master file has to be consulted, which is rather expensive. Also the master file can only tell you *if* there's any lock on the file, but not whether your work file really contains that locked version.

You can tell VC not to use version headers to determine lock status by setting `vc-consult-headers` to `nil`. VC then always uses the file permissions (if it can trust them), or else checks the master file.

You can specify the criterion for whether to trust the file permissions by setting the variable `vc-mistrust-permissions`. Its value may be `t` (always mistrust the file permissions and check the master file), `nil` (always trust the file permissions), or a function of one argument which makes the decision. The argument is the directory name of the `` `RCS' ``, `` `CVS' `` or `` `SCCS' `` subdirectory. A non-`nil` value from the function says to mistrust the file permissions. If you find that the file permissions of work files are changed erroneously, set `vc-mistrust-permissions` to `t`. Then VC always checks the master file to determine the file's status.

VC Command Execution

If `vc-suppress-confirm` is non-`nil`, then C-x C-q and C-x v i can save the current buffer without asking, and C-x v u also operates without asking for confirmation. (This variable does not affect C-x v c; that operation is so drastic that it should always ask for confirmation.)

VC mode does much of its work by running the shell commands for RCS, CVS and SCCS. If `vc-command-messages` is non-`nil`, VC displays messages to indicate which shell commands it runs, and additional messages when the commands finish.

You can specify additional directories to search for version control programs by setting the variable `vc-path`. These directories are searched before the usual search path. But the proper files are usually found automatically.

File Directories

The file system groups files into directories. A directory listing is a list of all the files in a directory. Emacs provides commands to create and delete directories, and to make directory listings in brief format (file names only) and verbose format (sizes, dates, and authors included). There is also a directory

browser called Dired; see section Dired, the Directory Editor.

C-x C-d dir-or-pattern RET

Display a brief directory listing (`list-directory`).

C-u C-x C-d dir-or-pattern RET

Display a verbose directory listing.

M-x make-directory RET dirname RET

Create a new directory named dirname.

M-x delete-directory RET dirname RET

Delete the directory named dirname. It must be empty, or you get an error.

The command to display a directory listing is C-x C-d (`list-directory`). It reads using the minibuffer a file name which is either a directory to be listed or a wildcard-containing pattern for the files to be listed. For example,

```
C-x C-d /u2/emacs/etc RET
```

lists all the files in directory `` `/u2/emacs/etc' ``. Here is an example of specifying a file name pattern:

```
C-x C-d /u2/emacs/src/*.c RET
```

Normally, C-x C-d prints a brief directory listing containing just file names. A numeric argument (regardless of value) tells it to make a verbose listing including sizes, dates, and authors (like `ls -l').

The text of a directory listing is obtained by running `ls` in an inferior process. Two Emacs variables control the switches passed to `ls`: `list-directory-brief-switches` is a string giving the switches to use in brief listings (`"-CF"` by default), and `list-directory-verbose-switches` is a string giving the switches to use in a verbose listing (`"-l"` by default).

Comparing Files

The command M-x diff compares two files, displaying the differences in an Emacs buffer named `*Diff*'. It works by running the `diff` program, using options taken from the variable `diff-switches`, whose value should be a string.

The buffer `*Diff*' has Compilation mode as its major mode, so you can use C-x ` to visit successive changed locations in the two source files. You can also move to a particular hunk of changes and type RET or C-c C-c, or click Mouse-2 on it, to move to the corresponding source location. You can also use the other special commands of Compilation mode: SPC and DEL for scrolling, and M-p and M-n for cursor motion. See section Running Compilations under Emacs.

The command M-x diff-backup compares a specified file with its most recent backup. If you specify the name of a backup file, `diff-backup` compares it with the source file that it is a backup of.

The command M-x compare-windows compares the text in the current window with that in the next window. Comparison starts at point in each window, and each starting position is pushed on the mark

ring in its respective buffer. Then point moves forward in each window, a character at a time, until a mismatch between the two windows is reached. Then the command is finished. For more information about windows in Emacs, section Multiple Windows.

With a numeric argument, `compare-windows` ignores changes in whitespace. If the variable `compare-ignore-case` is non-`nil`, it ignores differences in case as well.

See also section Merging Files with Emerge, for convenient facilities for merging two similar files.

Miscellaneous File Operations

Emacs has commands for performing many other operations on files. All operate on one file; they do not accept wild card file names.

M-x view-file allows you to scan or read a file by sequential screenfuls. It reads a file name argument using the minibuffer. After reading the file into an Emacs buffer, `view-file` displays the beginning. You can then type SPC to scroll forward one windowful, or DEL to scroll backward. Various other commands are provided for moving around in the file, but none for changing it; type ? while viewing for a list of them. They are mostly the same as normal Emacs cursor motion commands. To exit from viewing, type q. The commands for viewing are defined by a special major mode called View mode.

A related command, M-x view-buffer, views a buffer already present in Emacs. See section Miscellaneous Buffer Operations.

M-x insert-file inserts a copy of the contents of the specified file into the current buffer at point, leaving point unchanged before the contents and the mark after them.

M-x write-region is the inverse of M-x insert-file; it copies the contents of the region into the specified file. M-x append-to-file adds the text of the region to the end of the specified file. See section Accumulating Text.

M-x delete-file deletes the specified file, like the `rm` command in the shell. If you are deleting many files in one directory, it may be more convenient to use Dired (see section Dired, the Directory Editor).

M-x rename-file reads two file names old and new using the minibuffer, then renames file old as new. If a file named new already exists, you must confirm with yes or renaming is not done; this is because renaming causes the old meaning of the name new to be lost. If old and new are on different file systems, the file old is copied and deleted.

The similar command M-x add-name-to-file is used to add an additional name to an existing file without removing its old name. The new name must belong on the same file system that the file is on.

M-x copy-file reads the file old and writes a new file named new with the same contents. Confirmation is required if a file named new already exists, because copying has the consequence of overwriting the old contents of the file new.

M-x make-symbolic-link reads two file names old and linkname, then creates a symbolic link named linkname and pointing at old. The effect is that future attempts to open file linkname will refer to

whatever file is named old at the time the opening is done, or will get an error if the name old is not in use at that time. This command does not expand the argument filename, so that it allows you to specify a relative name as the target of the link.

Confirmation is required when creating the link if linkname is in use. Note that not all systems support symbolic links.

Accessing Compressed Files

Emacs comes with a library that can automatically uncompress compressed files when you visit them, and automatically recompress them if you alter them and save them. To enable this feature, type the command M-x auto-compression-mode.

When automatic compression (which implies automatic uncompression as well) is enabled, Emacs recognizes compressed files by their file names. File names ending in `.gz' indicate a file compressed with `gzip`. Other endings indicate other compression programs.

Automatic uncompression and compression apply to all the operations in which Emacs uses the contents of a file. This includes visiting it, saving it, inserting its contents into a buffer, loading it, and byte compiling it.

Go to the previous, next section.

Go to the previous, next section.

Using Multiple Buffers

The text you are editing in Emacs resides in an object called a buffer. Each time you visit a file, a buffer is created to hold the file's text. Each time you invoke Dired, a buffer is created to hold the directory listing. If you send a message with C-x m, a buffer named `*mail*' is used to hold the text of the message. When you ask for a command's documentation, that appears in a buffer called `*Help*'.

At any time, one and only one buffer is selected. It is also called the current buffer. Often we say that a command operates on "the buffer" as if there were only one; but really this means that the command operates on the selected buffer (most commands do).

When Emacs has multiple windows, each window has a chosen buffer which is displayed there, but at any time only one of the windows is selected and its chosen buffer is the selected buffer. Each window's mode line displays the name of the buffer that the window is displaying (see section Multiple Windows).

Each buffer has a name, which can be of any length, and you can select any buffer by giving its name. Most buffers are made by visiting files, and their names are derived from the files' names. But you can also create an empty buffer with any name you want. A newly started Emacs has a buffer named `*scratch*' which can be used for evaluating Lisp expressions in Emacs. The distinction between upper and lower case matters in buffer names.

Each buffer records individually what file it is visiting, whether it is modified, and what major mode and minor modes are in effect in it (see section Major Modes). Any Emacs variable can be made local to a particular buffer, meaning its value in that buffer can be different from the value in other buffers. See section Local Variables.

Creating and Selecting Buffers

C-x b buffer RET

: Select or create a buffer named buffer (`switch-to-buffer`).

C-x 4 b buffer RET

: Similar, but select buffer in another window (`switch-to-buffer-other-window`).

C-x 5 b buffer RET

: Similar, but select buffer in a separate frame (`switch-to-buffer-other-frame`).

To select the buffer named bufname, type C-x b bufname RET. This runs the command `switch-to-buffer` with argument bufname. You can use completion on an abbreviation for the buffer name you want (see section Completion). An empty argument to C-x b specifies the most recently selected buffer that is not displayed in any window.

Most buffers are created by visiting files, or by Emacs commands that want to display some text, but you can also create a buffer explicitly by typing C-x b bufname RET. This makes a new, empty buffer which

is not visiting any file, and selects it for editing. Such buffers are used for making notes to yourself. I you try to save one, you are asked for the file name to use. The new buffer's major mode is determi by the value of `default-major-mode` (see section Major Modes).

Note that C-x C-f, and any other command for visiting a file, can also be used to switch to an existing file-visiting buffer. See section Visiting Files.

Emacs uses buffer names that start with a space for internal purposes. It treats these buffers specially in minor ways--for example, by default they do not record undo information. It is best to avoid using such buffer names yourself.

Listing Existing Buffers

C-x C-b

List the existing buffers (`list-buffers`).

To display a list of all the buffers that exist, type C-x C-b. Each line in the list shows one buffer's name, major mode and visited file. The buffers are listed in the order, most recently visited first.

`*' at the beginning of a line indicates the buffer is "modified". If several buffers are modified, it may be time to save some with C-x s (see section Saving Files). `%' indicates a read-only buffer. `.' marks the selected buffer. Here is an example of a buffer list:

```
 MR Buffer          Size  Mode            File
 -- ------          ----  ----            ----
.*  emacs.tex       383402 Texinfo        /u2/emacs/man/emacs.tex
    *Help*          1287  Fundamental
    files.el        23076 Emacs-Lisp      /u2/emacs/lisp/files.el
  % RMAIL           64042 RMAIL           /u/rms/RMAIL
 *% man             747   Dired           /u2/emacs/man/
    net.emacs       343885 Fundamental    /u/rms/net.emacs
    fileio.c        27691 C               /u2/emacs/src/fileio.c
    NEWS            67340 Text            /u2/emacs/etc/NEWS
    *scratch*       0     Lisp Interaction
```

Note that the buffer `*Help*' was made by a help request; it is not visiting any file. The buffer `man` was made by Dired on the directory `/u2/emacs/man/'.

Miscellaneous Buffer Operations

C-x C-q

Toggle read-only status of buffer (`vc-toggle-read-only`).

M-x rename-buffer RET name RET

Change the name of the current buffer.

M-x rename-uniquely

Rename the current buffer by adding `<number>' to the end.

M-x view-buffer RET buffer RET

Scroll through buffer buffer.

A buffer can be read-only, which means that commands to change its contents are not allowed. The mode line indicates read-only buffers with `%%' or `%*' near the left margin. Read-only buffers are usually made by subsystems such as Dired and Rmail that have special commands to operate on the text; also by visiting a file whose access control says you cannot write it.

If you wish to make changes in a read-only buffer, use the command C-x C-q (`vc-toggle-read-only`). It makes a read-only buffer writable, and makes a writable buffer read-only. In most cases, this works by setting the variable `buffer-read-only`, which has a local value in each buffer and makes the buffer read-only if its value is non-`nil`. If the file is maintained with version control, C-x C-q works through the version control system to change the read-only status of the file as well as the buffer. See section Version Control.

M-x rename-buffer changes the name of the current buffer. Specify the new name as a minibuffer argument. There is no default. If you specify a name that is in use for some other buffer, an error happens and no renaming is done.

M-x rename-uniquely renames the current buffer to a similar name with a numeric suffix added to make it both different and unique. This command does not need an argument. It is useful for creating multiple shell buffers: if you rename the `*Shell*' buffer, then do M-x shell again, it makes a new shell buffer named `*Shell*'; meanwhile, the old shell buffer continues to exist under its new name. This method is also good for mail buffers, compilation buffers, and most Emacs features that create special buffers with particular names.

M-x view-buffer is much like M-x view-file (see section Miscellaneous File Operations) except that it examines an already existing Emacs buffer. View mode provides commands for scrolling through the buffer conveniently but not for changing it. When you exit View mode, the value of point that resulted from your perusal remains in effect.

The commands M-x append-to-buffer and M-x insert-buffer can be used to copy text from one buffer to another. See section Accumulating Text.

Killing Buffers

If you continue an Emacs session for a while, you may accumulate a large number of buffers. You may then find it convenient to kill the buffers you no longer need. On most operating systems, killing a buffer releases its space back to the operating system so that other programs can use it. Here are some commands for killing buffers:

C-x k bufname RET

Kill buffer bufname (`kill-buffer`).

M-x kill-some-buffers

Offer to kill each buffer, one by one.

C-x k (`kill-buffer`) kills one buffer, whose name you specify in the minibuffer. The default, used if you type just RET in the minibuffer, is to kill the current buffer. If you kill the current buffer, another buffer is selected; one that has been selected recently but does not appear in any window now. If you ask to kill a file-visiting buffer that is modified (has unsaved editing), then you must confirm with yes before the buffer is killed.

The command M-x kill-some-buffers asks about each buffer, one by one. An answer of y means to kill the buffer. Killing the current buffer or a buffer containing unsaved changes selects a new buffer or asks for confirmation just like `kill-buffer`.

The buffer menu feature (see section Operating on Several Buffers) is also convenient for killing various buffers.

If you want to do something special every time a buffer is killed, you can add hook functions to the hook `kill-buffer-hook` (see section Hooks).

Operating on Several Buffers

The buffer-menu facility is like a "Dired for buffers"; it allows you to request operations on various Emacs buffers by editing an Emacs buffer containing a list of them. You can save buffers, kill them (here called deleting them, for consistency with Dired), or display them.

M-x buffer-menu

Begin editing a buffer listing all Emacs buffers.

The command `buffer-menu` writes a list of all Emacs buffers into the buffer `*Buffer List*', and selects that buffer in Buffer Menu mode. The buffer is read-only, and can be changed only through the special commands described in this section. The usual Emacs cursor motion commands can be used in the `*Buffer List*' buffer. The following commands apply to the buffer described on the current line.

d

Request to delete (kill) the buffer, then move down. The request shows as a `D' on the line, before the buffer name. Requested deletions take place when you type the x command.

C-d

Like d but move up afterwards instead of down.

s

Request to save the buffer. The request shows as an `S' on the line. Requested saves take place when you type the x command. You may request both saving and deletion for the same buffer.

x

Perform previously requested deletions and saves.

u

Remove any request made for the current line, and move down.

DEL

Move to previous line and remove any request made for that line.

The d, C-d, s and u commands to add or remove flags also move down (or up) one line. They accept a numeric argument as a repeat count.

These commands operate immediately on the buffer listed on the current line:

~
: Mark the buffer "unmodified". The command ~ does this immediately when you type it.

%
: Toggle the buffer's read-only flag. The command % does this immediately when you type it.

t
: Visit the buffer as a tags table. See section Selecting a Tags Table.

There are also commands to select another buffer or buffers:

q
: Quit the buffer menu--immediately display the most recent formerly visible buffer in its place.

RET

f
: Immediately select this line's buffer in place of the `*Buffer List*' buffer.

o
: Immediately select this line's buffer in another window as if by C-x 4 b, leaving `*Buffer List*' visible.

C-o
: Immediately display this line's buffer in another window, but don't select the window.

1
: Immediately select this line's buffer in a full-screen window.

2
: Immediately set up two windows, with this line's buffer in one, and the previously selected buffer (aside from the buffer `*Buffer List*') in the other.

m
: Mark this line's buffer to be displayed in another window if you exit with the v command. The request shows as a `>' at the beginning of the line. (A single buffer may not have both a delete request and a display request.)

v
: Immediately select this line's buffer, and also display in other windows any buffers previously marked with the m command. If you have not marked any buffers, this command is equivalent to 1.

All that `buffer-menu` does directly is create and switch to a suitable buffer, and turn on Buffer Menu mode. Everything else described above is implemented by the special commands provided in Buffer Menu mode. One consequence of this is that you can switch from the `*Buffer List*' buffer to another

Emacs buffer, and edit there. You can reselect the `*Buffer List*' buffer later, to perform the operati already requested, or you can kill it, or pay no further attention to it.

The only difference between `buffer-menu` and `list-buffers` is that `buffer-menu` switches to the `*Buffer List*' buffer in the selected window; `list-buffers` displays it in another window. If you run `list-buffers` (that is, type C-x C-b) and select the buffer list manually, you can use all of the commands described here.

The buffer `*Buffer List*' is not updated automatically when buffers are created and killed; its contents are just text. If you have created, deleted or renamed buffers, the way to update `*Buffer List*' to show what you have done is to type g (`revert-buffer`) or repeat the `buffer-menu` command.

Indirect Buffers

An indirect buffer shares the text of some other buffer, which is called the base buffer of the indirect buffer. In some ways it is the analogue, for buffers, of a symbolic link between files.

M-x make-indirect-buffer base-buffer RET indirect-name RET

> Create an indirect buffer named indirect-name whose base buffer is base-buffer.

The text of the indirect buffer is always identical to the text of its base buffer; changes made by editing either one are visible immediately in the other. But in all other respects, the indirect buffer and its base buffer are completely separate. They have different names, different values of point, different narrowing, different markers, different major modes, and different local variables.

An indirect buffer cannot visit a file, but its base buffer can. If you try to save the indirect buffer, that actually works by saving the base buffer. Killing the base buffer effectively kills the indirect buffer, but killing an indirect buffer has no effect on its base buffer.

One way to use indirect buffers is to display multiple views of an outline. See section Viewing One Outline in Multiple Views.

Go to the previous, next section.

Go to the previous, next section.

Multiple Windows

Emacs can split a frame into two or many windows. Multiple windows can display parts of different buffers, or different parts of one buffer. Multiple frames always imply multiple windows, because each frame has its own set of windows. Each window belongs to one and only one frame.

Concepts of Emacs Windows

Each Emacs window displays one Emacs buffer at any time. A single buffer may appear in more than one window; if it does, any changes in its text are displayed in all the windows where it appears. But the windows showing the same buffer can show different parts of it, because each window has its own value of point.

At any time, one of the windows is the selected window; the buffer this window is displaying is the current buffer. The terminal's cursor shows the location of point in this window. Each other window has a location of point as well, but since the terminal has only one cursor there is no way to show where those locations are. When multiple frames are visible in X Windows, each frame has a cursor which appears in the frame's selected window. The cursor in the selected frame is solid; the cursor in other frames is a hollow box.

Commands to move point affect the value of point for the selected Emacs window only. They do not change the value of point in any other Emacs window, even one showing the same buffer. The same is true for commands such as C-x b to change the selected buffer in the selected window; they do not affect other windows at all. However, there are other commands such as C-x 4 b that select a different window and switch buffers in it. Also, all commands that display information in a window, including (for example) C-h f (`describe-function`) and C-x C-b (`list-buffers`), work by switching buffers in a nonselected window without affecting the selected window.

When multiple windows show the same buffer, they can have different regions, because they can have different values of point. This means that in Transient Mark mode, each window highlights a different part of the buffer. The part that is highlighted in the selected window is the region that editing commands use.

Each window has its own mode line, which displays the buffer name, modification status and major and minor modes of the buffer that is displayed in the window. See section The Mode Line, for full details on the mode line.

@break

Splitting Windows

C-x 2

Split the selected window into two windows, one above the other (`split-window-vertically`).

C-x 3

Split the selected window into two windows positioned side by side (`split-window-horizontally`).

C-Mouse-2

In the mode line or scroll bar of a window, split that window.

The command C-x 2 (`split-window-vertically`) breaks the selected window into two windows, one above the other. Both windows start out displaying the same buffer, with the same value of point. By default the two windows each get half the height of the window that was split; a numeric argument specifies how many lines to give to the top window.

C-x 3 (`split-window-horizontally`) breaks the selected window into two side-by-side windows. A numeric argument specifies how many columns to give the one on the left. A line of vertical bars separates the two windows. Windows that are not the full width of the screen have mode lines, but they are truncated; also, they do not always appear in inverse video, because the Emacs display routines have not been taught how to display a region of inverse video that is only part of a line on the screen.

You can split a window horizontally or vertically by clicking C-Mouse-2 in the mode line or the scroll bar. The line of splitting goes through the place where you click: if you click on the mode line, the new scroll bar goes above the spot; if you click in the scroll bar, the mode line of the split window is side by side with your click.

When a window is less than the full width, text lines too long to fit are frequent. Continuing all those lines might be confusing. The variable `truncate-partial-width-windows` can be set non-`nil` to force truncation in all windows less than the full width of the screen, independent of the buffer being displayed and its value for `truncate-lines`. See section Continuation Lines.

Horizontal scrolling is often used in side-by-side windows. See section Controlling the Display.

If `split-window-keep-point` is non-nil, C-x 2 tries to avoid shifting any text on the screen by putting point in whichever window happens to contain the screen line the cursor is already on. The default is that `split-window-keep-point` is non-nil on slow terminals.

Using Other Windows

C-x o

Select another window (`other-window`). That is o, not zero.

C-M-v

Scroll the next window (`scroll-other-window`).

M-x compare-windows

Find next place where the text in the selected window does not match the text in the next window.

Mouse-1

Mouse-1, in a window's mode line, selects that window but does not move point in it (`mouse-select-region`).

To select a different window, click with Mouse-1 on its mode line. With the keyboard, you can switch windows by typing C-x o (`other-window`). That is an o, for `other', not a zero. When there are more than two windows, this command moves through all the windows in a cyclic order, generally top to bottom and left to right. After the rightmost and bottommost window, it goes back to the one at the upper left corner. A numeric argument means to move several steps in the cyclic order of windows. A negative argument moves around the cycle in the opposite order. When the minibuffer is active, the minibuffer is the last window in the cycle; you can switch from the minibuffer window to one of the other windows, and later switch back and finish supplying the minibuffer argument that is requested. See section Editing in the Minibuffer.

The usual scrolling commands (see section Controlling the Display) apply to the selected window only, but there is one command to scroll the next window. C-M-v (`scroll-other-window`) scrolls the window that C-x o would select. It takes arguments, positive and negative, like C-v. (In the minibuffer, C-M-v scrolls the window that contains the minibuffer help display, if any, rather than the next window in the standard cyclic order.)

The command `M-x compare-windows` lets you compare two files or buffers visible in two windows, by moving through them to the next mismatch. See section Comparing Files, for details.

Displaying in Another Window

C-x 4 is a prefix key for commands that select another window (splitting the window if there is only one) and select a buffer in that window. Different C-x 4 commands have different ways of finding the buffer to select.

C-x 4 b bufname RET

Select buffer bufname in another window. This runs `switch-to-buffer-other-window`.

C-x 4 C-o bufname RET

Display buffer bufname in another window, but don't select that buffer or that window. This runs `display-buffer`.

C-x 4 f filename RET

Visit file filename and select its buffer in another window. This runs `find-file-other-window`. See section Visiting Files.

C-x 4 d directory RET

Select a Dired buffer for directory directory in another window. This runs `dired-other-window`. See section Dired, the Directory Editor.

C-x 4 m

Start composing a mail message in another window. This runs `mail-other-window`; its same-window analogue is C-x m (see section Sending Mail).

C-x 4 .

Find a tag in the current tags table, in another window. This runs `find-tag-other-window`, the multiple-window variant of M-. (see section Tags Tables).

C-x 4 r filename RET

Visit file filename read-only, and select its buffer in another window. This runs `find-file-read-only-other-window`. See section Visiting Files.

Forcing Display in the Same Window

Certain Emacs commands switch to a specific buffer with special contents. For example, M-x shell switches to a buffer named `*Shell*'. By convention, all these commands are written to pop up the buffer in a separate window. But you can specify that certain of these buffers should appear in the selected window.

If you add a buffer name to the list `same-window-buffer-names`, the effect is that such commands display that particular buffer by switching to it in the selected window. For example, if you add the element `"*grep*"` to the list, the `grep` command will display its output buffer in the selected window.

The default value of `same-window-buffer-names` is not `nil`. It specifies the buffers `*info*', `*mail*' and `*shell*'. This is why M-x shell normally switches to the `*shell*' buffer in the selected window. If you delete this element from the value of `same-window-buffer-names`, the behavior of M-x shell will change--it will pop up the buffer in another window instead.

You can specify these buffers more generally with the variable `same-window-regexps`. Set it to a list of regular expressions; then any buffer whose name matches one of those regular expressions is displayed by switching to it in the selected window. (Once again, this applies only to buffers that normally get displayed for you in a separate window.) The default value of this variable specifies Telnet and rlogin buffers.

An analogous feature lets you specify buffers which should be displayed in their own individual frames. See section Special Buffer Frames.

Deleting and Rearranging Windows

C-x 0

Delete the selected window (`delete-window`). That is a zero.

C-x 1

Delete all windows in the selected frame except the selected window (`delete-other-windows`).

C-x ^

Make selected window taller (`enlarge-window`).

C-x }

Make selected window wider (`enlarge-window-horizontally`).

Drag-Mouse-1

Dragging a window's mode line up or down with Mouse-1 changes window heights.

Mouse-2

Mouse-2 in a window's mode line deletes all other windows in the frame (`mouse-delete-other-windows`).

Mouse-3

Mouse-3 in a window's mode line deletes that window (`mouse-delete-window`).

To delete a window, type C-x 0 (`delete-window`). (That is a zero.) The space occupied by the deleted window is given to an adjacent window (but not the minibuffer window, even if that is active at the time). Once a window is deleted, its attributes are forgotten; only restoring a window configuration can bring it back. Deleting the window has no effect on the buffer it used to display; the buffer continues to exist, and you can select it in any window with C-x b.

C-x 1 (`delete-other-windows`) is more powerful than C-x 0; it deletes all the windows except the selected one (and the minibuffer); the selected window expands to use the whole frame except for the echo area.

You can also delete a window by clicking on its mode line with Mouse-2, and expand a window to fill its frame by clicking on its mode line with Mouse-3.

The easiest way to adjust window heights is with a mouse. If you press Mouse-1 on a mode line, you can drag that mode line up or down, changing the heights of the windows above and below it.

To readjust the division of space among vertically adjacent windows, use C-x ^ (`enlarge-window`). It makes the currently selected window get one line bigger, or as many lines as is specified with a numeric argument. With a negative argument, it makes the selected window smaller. C-x } (`enlarge-window-horizontally`) makes the selected window wider by the specified number of columns. The extra screen space given to a window comes from one of its neighbors, if that is possible. If this makes any window too small, it is deleted and its space is given to an adjacent window. The minimum size is specified by the variables `window-min-height` and `window-min-width`.

See section Editing in the Minibuffer, for information about the Resize-Minibuffer mode, which automatically changes the size of the minibuffer window to fit the text in the minibuffer.

Go to the previous, next section.

Go to the previous, next section.

Frames and X Windows

When using the X Window System, you can create multiple windows at the X level in a single Emacs session. Each X window that belongs to Emacs displays a frame which can contain one or several Emacs windows. A frame initially contains a single general-purpose Emacs window which you can subdivide vertically or horizontally into smaller windows. A frame normally contains its own echo area and minibuffer, but you can make frames that don't have these--they use the echo area and minibuffer of another frame.

Editing you do in one frame also affects the other frames. For instance, if you put text in the kill ring in one frame, you can yank it in another frame. If you exit Emacs through C-x C-c in one frame, it terminates all the frames. To delete just one frame, use C-x 5 0.

To avoid confusion, we reserve the word "window" for the subdivisions that Emacs implements, and never use it to refer to a frame.

Mouse Commands for Editing

The mouse commands for selecting and copying a region are mostly compatible with the `xterm` program. You can use the same mouse commands for copying between Emacs and other X client programs.

Mouse-1

Move point to where you click (`mouse-set-point`). This is normally the left button.

Drag-Mouse-1

Set the region to the text you select by dragging, and copy it to the kill ring (`mouse-set-region`). You can specify both ends of the region with this single command.

If you move the mouse off the top or bottom of the window while dragging, the window scrolls at a steady rate until you move the mouse back into the window. This way, you can select regions that don't fit entirely on the screen. The number of lines scrolled per step depends on how far away from the window edge the mouse has gone; the variable `mouse-scroll-min-lines` specifies a minimum step size.

Mouse-2

Yank the last killed text, where you click (`mouse-yank-at-click`). This is normally the middle button.

Mouse-3

This command, `mouse-save-then-kill`, has several functions depending on where you click and the status of the region.

The most basic case is when you click Mouse-1 in one place and then Mouse-3 in another. This selects the text between those two positions as the region. It also copies the new region to the kill

ring, so that you can copy it to someplace else.

If you click Mouse-1, scroll with the scroll bar, and then click Mouse-3, it remembers where point was before scrolling (where you put it with Mouse-1), and uses that position as the other end of the region. This is so that you can select a region that doesn't fit entirely on the screen.

More generally, if you do not have a highlighted region, Mouse-3 selects the text between point and the click position as the region. It does this by setting the mark where point was, and moving point to where you click.

If you have a highlighted region, or if the region was set just before by dragging button 1, Mouse-3 adjusts the nearer end of the region by moving it to where you click. The adjusted region's text also replaces the old region's text in the kill ring.

If you originally specified the region using a double or triple Mouse-1, so that the region is defined to consist of entire words or lines, then adjusting the region with Mouse-3 also proceeds by entire words or lines.

If you use Mouse-3 a second time consecutively, at the same place, that kills the region already selected.

Double-Mouse-1

This key sets the region around the word which you click on. If you click on a character with "symbol" syntax (such as underscore, in C mode), it sets the region around the symbol surrounding that character.

If you click on a character with open-parenthesis or close-parenthesis syntax, it sets the region around the parenthetical grouping (sexp) which that character starts or ends. If you click on a character with string-delimiter syntax (such as a singlequote or doublequote in C), it sets the region around the string constant (using heuristics to figure out whether that character is the beginning or the end of it).

Double-Drag-Mouse-1

This key selects a region made up of the words that you drag across.

Triple-Mouse-1

This key sets the region around the line which you click on.

Triple-Drag-Mouse-1

This key selects a region made up of the lines that you drag across.

The simplest way to kill text with the mouse is to press Mouse-1 at one end, then press Mouse-3 twice at the other end. See section Deletion and Killing. To copy the text into the kill ring without deleting it from the buffer, press Mouse-3 just once--or just drag across the text with Mouse-1. Then you can copy it elsewhere by yanking it.

To yank the killed or copied text somewhere else, move the mouse there and press Mouse-2. See section Yanking. However, if `mouse-yank-at-point` is non-`nil`, Mouse-2 yanks at point. Then it does not matter precisely where you click; all that matters is which window you click on. The default value is `nil`. This variable also effects yanking the secondary selection.

To copy text to another X window, kill it or save it in the kill ring. Under X, this also sets the primary selection. Then use the "paste" or "yank" command of the program operating the other window to insert the text from the selection.

To copy text from another X window, use the "cut" or "copy" command of the program operating the other window, to select the text you want. Then yank it in Emacs with C-y or Mouse-2.

When Emacs puts text into the kill ring, or rotates text to the front of the kill ring, it sets the primary selection in the X server. This is how other X clients can access the text. Emacs also stores the text in the cut buffer, but only if the text is short enough (`x-cut-buffer-max` specifies the maximum number of characters); putting long strings in the cut buffer can be slow.

The commands to yank the first entry in the kill ring actually check first for a primary selection in another program; after that, they check for text in the cut buffer. If neither of those sources provides text to yank, the kill ring contents are used.

Secondary Selection

The secondary selection is another way of selecting text using X. It does not use point or the mark, so you can use it to kill text without setting point or the mark.

M-Drag-Mouse-1

> Set the secondary selection, with one end at the place where you press down the button, and the other end at the place where you release it (`mouse-set-secondary`). The highlighting appears and changes as you drag.
>
> If you move the mouse off the top or bottom of the window while dragging, the window scrolls at a steady rate until you move the mouse back into the window. This way, you can mark regions that don't fit entirely on the screen.

M-Mouse-1

> Set one endpoint for the secondary selection (`mouse-start-secondary`).

M-Mouse-3

> Make a secondary selection, using the place specified with M-Mouse-1 as the other end (`mouse-secondary-save-then-kill`). A second click at the same place kills the secondary selection just made.

M-Mouse-2

> Insert the secondary selection where you click (`mouse-kill-secondary`). This places point at the end of the yanked text.

Double or triple clicking of M-Mouse-1 operates on words and lines, much like Mouse-1.

If `mouse-yank-at-point` is non-`nil`, M-Mouse-2 yanks at point. Then it does not matter precisely where you click; all that matters is which window you click on. See section Mouse Commands for Editing.

Following References with the Mouse

Some Emacs buffers display lists of various sorts. These include lists of files, of buffers, of possible completions, of matches for a pattern, and so on.

Since yanking text into these buffers is not very useful, most of them define Mouse-2 specially, as a command to use or view the item you click on.

For example, if you click Mouse-2 on a file name in a Dired buffer, you visit the that file. If you click Mouse-2 on an error message in the `*Compilation*' buffer, you go to the source code for that error message. If you click Mouse-2 on a completion in the `*Completions*' buffer, you choose that completion.

You can usually tell when Mouse-2 has this special sort of meaning because the sensitive text highlights when you move the mouse over it.

Mouse Clicks for Menus

Mouse clicks modified with the CONTROL and SHIFT keys bring up menus.

C-Mouse-1

> This menu is for selecting a buffer.

C-Mouse-2

> This menu is for specifying faces and other text properties for editing formatted text. See section Editing Formatted Text.

C-Mouse-3

> This menu is mode-specific. For most modes, this menu has the same items as all the mode-specific menu bar menus put together. Some modes may specify a different menu for this button.(2)

S-mouse-1

> This menu is for specifying the frame's default font.

Mode Line Mouse Commands

You can use mouse clicks on window mode lines to select and manipulate windows.

Mouse-1

> Mouse-1 on a mode line selects the window above. By dragging Mouse-1 on the mode line, you can move it, thus changing the height of the windows above and below.

Mouse-2

> Mouse-2 on a mode line expands that window to fill its frame.

Mouse-3

> Mouse-3 on a mode line deletes the window above.

C-Mouse-2

C-Mouse-2 on a mode line splits the window above horizontally, above the place in the mode line where you click.

C-Mouse-2 on a scroll bar splits the corresponding window vertically. See section Splitting Windows.

Creating Frames

The prefix key C-x 5 is analogous to C-x 4, with parallel subcommands. The difference is that C-x 5 commands create a new frame rather than just a new window in the selected frame (See section Displaying in Another Window). If an existing visible or iconified frame already displays the requested material, these commands use the existing frame, after raising or deiconifying as necessary.

The various C-x 5 commands differ in how they find or create the buffer to select:

C-x 5 2

Create a new frame (`make-frame`).

C-x 5 b bufname RET

Select buffer bufname in another window. This runs `switch-to-buffer-other-frame`.

C-x 5 f filename RET

Visit file filename and select its buffer in another frame. This runs `find-file-other-frame`. See section Visiting Files.

C-x 5 d directory RET

Select a Dired buffer for directory directory in another frame. This runs `dired-other-frame`. See section Dired, the Directory Editor.

C-x 5 m

Start composing a mail message in another frame. This runs `mail-other-frame`. It is the other-frame variant of C-x m. See section Sending Mail.

C-x 5 .

Find a tag in the current tag table in another frame. This runs `find-tag-other-frame`, the multiple-frame variant of M-.. See section Tags Tables.

C-x 5 r filename RET

Visit file filename read-only, and select its buffer in another frame. This runs `find-file-read-only-other-frame`. See section Visiting Files.

You can control the appearance of new frames you create by setting the frame parameters in `default-frame-alist`. You can use the variable `initial-frame-alist` to specify parameters that affect only the initial frame. See section 'Initial Parameters' in The Emacs Lisp Manual, for more information.

Multiple Displays

A single Emacs can talk to more than one X Windows display. Initially, Emacs uses just one display--the one specified with the `DISPLAY` environment variable or with the `--display' option (see section Initial Options). To connect to another display, use the command `make-frame-on-display`:

M-x make-frame-on-display RET display RET

Create a new frame on display display.

A single X server can handle more than one screen. When you open frames on two screens belonging to one server, Emacs knows they share a single keyboard, and it treats all the commands arriving from these screens as a single stream of input.

When you open frames on different X servers, Emacs makes a separate input stream for each server. This way, two users can type simultaneously on the two displays, and Emacs will not garble their input. Each server also has its own selected frame. The commands you enter with a particular X server apply to that server's selected frame.

Despite these features, people using the same Emacs job from different displays can still interfere with each other if they are not careful. For example, if any one types C-x C-c, that exits the Emacs job for all of them!

Special Buffer Frames

You can make certain chosen buffers, for which Emacs normally creates a second window when you have just one window, appear in special frames of their own. To do this, set the variable `special-display-buffer-names` to a list of buffer names; any buffer whose name is in that list automatically gets a special frame, when an Emacs command wants to display it "in another window."

For example, if you set the variable this way,

```
(setq special-display-buffer-names
      '("*Completions*" "*grep*" "*tex-shell*"))
```

then completion lists, `grep` output and the TeX mode shell buffer get individual frames of their own. These frames, and the windows in them, are never automatically split or reused for any other buffers. They continue to show the buffers they were created for, unless you alter them by hand. Killing the special buffer deletes its frame automatically.

More generally, you can set `special-display-regexps` to a list of regular expressions; then a buffer gets its own frame if its name matches any of those regular expressions. (Once again, this applies only to buffers that normally get displayed for you in a separate window.)

The variable `special-display-frame-alist` specifies the frame parameters for these frames. It has a default value, so you don't need to set it.

For those who know Lisp, an element of `special-display-buffer-names` or

`special-display-regexps` can also be a list. Then the first element is the buffer name or regu expression; the rest of the list specifies how to create the frame. It can be an association list specifyi frame parameter values; these values take precedence over parameter values specified in `special-display-frame-alist`. Alternatively, it can have this form:

```
(function args...)
```

where function is a symbol. Then the frame is constructed by calling function; its first argument is the buffer, and its remaining arguments are args.

Setting Frame Parameters

This section describes commands for altering the display style and window management behavior of the selected frame.

M-x set-foreground-color RET color RET

Specify color color for the foreground of the selected frame.

M-x set-background-color RET color RET

Specify color color for the background of the selected frame. This changes the foreground color of the `modeline` face also, so that it remains in inverse video compared with the default.

M-x set-cursor-color RET color RET

Specify color color for the cursor of the selected frame.

M-x set-mouse-color RET color RET

Specify color color for the mouse cursor when it is over the selected frame.

M-x set-border-color RET color RET

Specify color color for the border of the selected frame.

M-x list-colors-display

Display the defined color names and show what the colors look like. This command is somewhat slow.

M-x auto-raise-mode

Toggle whether or not the selected frame should auto-raise. Auto-raise means that every time you move the mouse onto the frame, it raises the frame.

Note that this auto-raise feature is implemented by Emacs itself. Some window managers also implement auto-raise. If you enable auto-raise for Emacs frames in your X window manager, it should work, but it is beyond Emacs's control and therefore `auto-raise-mode` has no effect on it.

M-x auto-lower-mode

Toggle whether or not the selected frame should auto-lower. Auto-lower means that every time you move the mouse off of the frame, the frame moves to the bottom of the stack of X windows.

The command `auto-lower-mode` has no effect on auto-lower implemented by the X window manager. To control that, you must use the appropriate window manager features.

M-x set-default-font RET font RET

Specify font font as the default for the selected frame. See section Font Specification Options, for ways to list the available fonts on your system.

You can also set a frame's default font through a pop-up menu. Press S-Mouse-1 to activate this menu.

In Emacs versions that use an X toolkit, the color-setting and font-setting functions don't affect menus and the menu bar, since they are displayed by their own widget classes. To change the appearance of the menus and menu bar, you must use X resources (see section X Resources). See section Window Color Options, regarding colors. See section Font Specification Options, regarding choice of font.

For information on frame parameters and customization, see section 'Frame Parameters' in The Emacs Lisp Manual.

Scroll Bars

When using X, Emacs normally makes a scroll bar at the right of each Emacs window. The scroll bar runs the height of the window, and shows a moving rectangular inner box which represents the portion of the buffer currently displayed. The entire height of the scroll bar represents the entire length of the buffer.

You can use Mouse-2 (normally, the middle button) in the scroll bar to move or drag the inner box up and down. If you move it to the top of the scroll bar, you see the top of the buffer. If you move it to the bottom of the scroll bar, you see the bottom of the buffer.

The left and right buttons in the scroll bar scroll by controlled increments. Mouse-1 (normally, the left button) moves the line at the level where you click up to the top of the window. Mouse-3 (normally, the right button) moves the line at the top of the window down to the level where you click. By clicking repeatedly in the same place, you can scroll by the same distance over and over.

Aside from scrolling, you can also click C-Mouse-2 in the scroll bar to split a window vertically. The split occurs on the line where you click.

You can enable or disable Scroll Bar mode with the command M-x scroll-bar-mode. With no argument, it toggles the use of scroll bars. With an argument, it turns use of scroll bars on if and only if the argument is positive. This command applies to all frames, including frames yet to be created. You can use the X resource `verticalScrollBars' to control the initial setting of Scroll Bar mode. See section X Resources.

To enable or disable scroll bars for just the selected frame, use the M-x toggle-scroll-bar command.

Menu Bars

By default, each Emacs frame has a menu bar at the top which you can use to perform certain common operations. There's no need to describe them in detail here, as you can more easily see for yourself; also, we may change them and add to them in subsequent Emacs versions.

When you are using a window system, you can use the mouse to choose a command from the menu bar. On text-only terminals, you can use the menu bar by typing M-` (`tmm-menubar`). This enters a mode in which you can select a menu item from the keyboard. Either type the initial of the item you want, or use the left and right arrow keys to choose an item and use RET to finalize the choice.

Each of the operations in the menu bar is bound to an ordinary Emacs command which you can invoke equally well with M-x or with its own key bindings. The menu lists one equivalent key binding (if the command has any) at the right margin. To see the command's name and documentation, type C-h k and then select the menu bar item you are interested in.

You can turn display of menu bars on or off with M-x menu-bar-mode. With no argument, this command toggles Menu Bar mode, a minor mode. With an argument, the command turns Menu Bar mode on if the argument is positive, off if the argument is not positive. You can use the X resource `menuBarLines' to control the initial setting of Menu Bar mode. See section X Resources. Expert users often turn off the menu bar, especially on text-only terminals where this makes one additional line available for text.

Using Multiple Typefaces

When using Emacs with X, you can set up multiple styles of displaying characters. The aspects of style that you can control are the type font, the foreground color, the background color, and whether to underline. Emacs on MS-DOS supports faces partially by letting you control the foreground and background colors of each face (see section MS-DOS Issues).

The way you control display style is by defining named faces. Each face can specify a type font, a foreground color, a background color, and an underline flag; but it does not have to specify all of them.

The style of display used for a given character in the text is determined by combining several faces. Any aspect of the display style that isn't specified by overlays or text properties comes from the frame itself.

Enriched mode, the mode for editing formatted text, includes several commands and menus for specifying faces. See section Faces in Formatted Text, for how to specify the font for text in the buffer. See section Colors in Formatted Text, for how to specify the foreground and background color.

To see what faces are currently defined, and what they look like, type M-x list-faces-display. It's possible for a given face to look different in different frames; this command shows the appearance in the frame in which you type it. Here's a list of the standardly defined faces:

`default`

This face is used for ordinary text that doesn't specify any other face.

`modeline`

This face is used for mode lines. By default, it's set up as the inverse of the default face. See section Variables Controlling Display.

`highlight`
: This face is used for highlighting portions of text, in various modes.

`region`
: This face is used for displaying a selected region (when Transient Mark mode is enabled--see below).

`secondary-selection`
: This face is used for displaying a secondary selection (see section Secondary Selection).

`bold`
: This face uses a bold variant of the default font, if it has one.

`italic`
: This face uses an italic variant of the default font, if it has one.

`bold-italic`
: This face uses a bold italic variant of the default font, if it has one.

`underline`
: This face underlines text.

When Transient Mark mode is enabled, the text of the region is highlighted when the mark is active. This uses the face named `region`; you can control the style of highlighting by changing the style of this face (see section Modifying Faces). See section Transient Mark Mode, for more information about Transient Mark mode and activation and deactivation of the mark.

One easy way to use faces is to turn on Font Lock mode. This minor mode, which is always local to a particular buffer, arranges to choose faces according to the syntax of the text you are editing. It can recognize comments and strings in most languages; in several languages, it can also recognize and properly highlight various other important constructs. See section Font Lock mode, for more information about Font Lock mode and syntactic highlighting.

You can print out the buffer with the highlighting that appears on your screen using the command `ps-print-buffer-with-faces`. See section Postscript Hardcopy.

Modifying Faces

Here are the commands for changing the font of a face:

M-x set-face-font RET face RET font RET
: Change face face to use font font. See section Font Specification Options, for more information about font naming under X.

M-x make-face-bold RET face RET
: Convert face face to use a bold version of its current font.

M-x make-face-italic RET face RET

Convert face face to use a italic version of its current font.

M-x make-face-bold-italic RET face RET

Convert face face to use a bold-italic version of its current font.

M-x make-face-unbold RET face RET

Convert face face to use a non-bold version of its current font.

M-x make-face-unitalic RET face RET

Convert face face to use a non-italic version of its current font.

Here are the commands for setting the colors and underline flag of a face:

M-x set-face-foreground RET face RET color RET

Use color color for the foreground of characters in face face.

M-x set-face-background RET face RET color RET

Use color color for the background of characters in face face.

On a black-and-white display, the colors you can use for the background are `black', `white', `gray', `gray1' and `gray3'. Emacs supports the gray colors by using background stipple patterns instead of a color.

M-x set-face-stipple RET face RET pattern RET

Use stipple pattern pattern for the background of characters in face face.

M-x list-colors-display

Display the defined color names and show what the colors look like.

M-x set-face-underline-p RET face RET flag RET

Specify whether to underline characters in face face.

M-x invert-face RET face RET

Swap the foreground and background colors of face face.

M-x modify-face RET face RET attributes...

Change various attributes of face face. This command prompts for all the attribute of the face, one attribute at a time. For the color and stipple attributes, the attribute's current value is the default--type just RET if you don't want to change that attribute. Type `none' if you want to clear out the attribute.

You can also use X resources to specify attributes of particular faces. See section X Resources.

Font Lock mode

Font Lock mode is a minor mode, always local to a particular buffer, which highlights (or "fontifies") using various faces according to the syntax of the text you are editing. It can recognize comments and strings in most languages; in several languages, it can also recognize and properly highlight various other important constructs--for example, names of functions being defined or reserved keywords.

The command M-x font-lock-mode turns Font Lock mode on or off according to the argument, and toggles the mode when it has no argument. The function `turn-on-font-lock` unconditionally enables Font Lock mode. This is useful in mode-hook functions. For example, to enable Font Lock mode whenever you edit a C file, you can do this:

```
(add-hook 'c-mode-hook 'turn-on-font-lock)
```

To turn on Font Lock mode automatically in all modes which support it, use the function `global-font-lock-mode`, like this:

```
(global-font-lock-mode t)
```

In Font Lock mode, when you edit the text, the highlighting updates automatically in the line that you changed. Most changes don't affect the highlighting of subsequent lines, but occasionally they do. To rehighlight a range of lines, use the command C-M-g (`font-lock-fontify-block`).

In certain major modes, C-M-g refontifies the entire current function. (The variable `font-lock-mark-block-function` controls how to find the current function.) In other major modes, C-M-g refontifies 16 lines above and below point.

With a prefix argument n, C-M-g refontifies n lines above and below point, regardless of the mode.

To get the full benefit of Font Lock mode, you need to choose a default font which has bold, italic, and bold-italic variants; or else you need to have a color or grayscale screen. The variable `font-lock-display-type` specifies whether Font Lock mode should use font styles, colors, or shades of gray to distinguish the various kinds of text. Emacs chooses the default value according to the characteristics of your display.

The variable `font-lock-maximum-decoration` specifies the preferred level of fontification for modes that provide multiple levels. The normal default is 1; larger numbers request more fontification, and some modes support levels as high as 3. These variables can also specify different numbers for particular major modes; for example, to use level 3 for C/C++ modes, and the default level otherwise, use this:

```
(setq font-lock-maximum-decoration
      '((c-mode . 3) (c++-mode . 3)))
```

Fontification can be too slow for large buffers, so you can suppress it. The variable `font-lock-maximum-size` specifies a buffer size, beyond which buffer fontification is suppressed.

Font Lock Support Modes

Font Lock support modes make Font Lock mode faster for large buffers. There are two support modes: Fast Lock mode and Lazy Lock mode. They use two different methods of speeding up Font Lock mode.

Fast Lock Mode

To make Font Lock mode faster for buffers visiting large files, you can use Fast Lock mode. Fast Lock mode saves the font information for each file in a separate cache file; each time you visit the file, it rereads the font information from the cache file instead of refontifying the text from scratch.

The command M-x fast-lock-mode turns Fast Lock mode on or off, according to the argument (with no argument, it toggles). You can also arrange to enable Fast Lock mode whenever you use Font Lock mode, like this:

```
(setq font-lock-support-mode 'fast-lock-mode)
```

It is not worth writing a cache file for small buffers. Therefore, the variable `fast-lock-minimum-size` specifies a minimum file size for caching font information.

The variable `fast-lock-cache-directories` specifies where to put the cache files. Its value is a list of directories to try; `"."` means the same directory as the file being edited. The default value is `("." "~/.emacs-flc")`, which means to use the same directory if possible, and otherwise the directory `` `~/.emacs-flc' ``.

The variable `fast-lock-save-others` specifies whether Fast Lock mode should save cache files for files that you do not own. A non-`nil` value means yes (and that is the default).

Lazy Lock Mode

To make Font Lock mode faster for large buffers, you can use Lazy Lock mode to reduce the amount of text that is fontified. In Lazy Lock mode, buffer fontification is demand-driven; it happens to portions of the buffer that are about to be displayed. And fontification of your changes is deferred; it happens only when Emacs has been idle for a certain short period of time.

The command M-x lazy-lock-mode turns Lazy Lock mode on or off, according to the argument (with no argument, it toggles). You can also arrange to enable Lazy Lock mode whenever you use Font Lock mode, like this:

```
(setq font-lock-support-mode 'lazy-lock-mode)
```

It is not worth avoiding buffer fontification for small buffers. Therefore, the variable `lazy-lock-minimum-size` specifies a minimum buffer size for demand-driven buffer fontification. Buffers smaller than that are fontified all at once, as in plain Font Lock mode.

When you alter the buffer, Lazy Lock mode defers fontification of the text you changed. The variable `lazy-lock-defer-time` specifies how many seconds Emacs must be idle before it starts fontifying your changes. If the value is `nil`, then changes are fontified immediately, as in plain Font Lock mode.

Lazy Lock mode normally fontifies newly visible portions of the buffer before they are first displayed. However, if the value of `lazy-lock-defer-driven` is non-`nil`, newly visible text is fontified only when Emacs is idle for `lazy-lock-defer-time` seconds.

When Emacs is idle for a long time, Lazy Lock fontifies additional portions of the buffer, not yet displayed, in case you will display them later. This is called stealth fontification.

The variable `lazy-lock-stealth-time` specifies how many seconds Emacs has to be idle before stealth fontification starts. A value of `nil` means no stealth fontification. The variables `lazy-lock-stealth-lines` and `lazy-lock-stealth-verbose` specify the granularity and verbosity of stealth fontification.

Fast Lock or Lazy Lock?

Here is a simple guide to help you choose one of the Font Lock support modes.

- Fast Lock mode only intervenes during file visiting and buffer killing (and related events); therefore buffer editing and window scrolling are no faster or slower than plain Font Lock mode.
- Fast Lock mode is slower at reading a cache file than Lazy Lock mode is at fontifying a window; therefore Fast Lock mode is slower at visiting a file than Lazy Lock mode.
- Lazy Lock mode intervenes during window scrolling to fontify text that scrolls onto the screen; therefore, scrolling is slower than in plain Font Lock mode.
- Lazy Lock mode doesn't fontify during buffer editing (it defers fontification of changes); therefore, editing is faster than in plain Font Lock mode.
- Fast Lock mode can be fooled by a file that is kept under version control software; therefore buffer fontification may occur even when a cache file exists for the file.
- Fast Lock mode only works with a buffer visiting a file; Lazy Lock mode works with any buffer.
- Fast Lock mode generates cache files; Lazy Lock mode does not.

The variable `font-lock-support-mode` specifies which of these support modes to use; for example, to specify that Fast Lock mode is used for C/C++ modes, and Lazy Lock mode otherwise, set the variable like this:

```
(setq font-lock-support-mode
      '((c-mode . fast-lock-mode) (c++-mode . fast-lock-mode)
        (t . lazy-lock-mode)))
```

Miscellaneous X Window Features

The following commands let you create, delete and operate on frames:

C-z

To iconify the selected Emacs frame, type C-z (`iconify-or-deiconify-frame`). The normal meaning of C-z, to suspend Emacs, is not useful under a window system, so it has a different binding in that case.

If you type this command on an Emacs frame's icon, it deiconifies the frame.

C-x 5 0

To delete the selected frame, type C-x 5 0 (`delete-frame`). This is not allowed if there is only

one frame.

C-x 5 o

Select another frame, raise it, and warp the mouse to it so that it stays selected. If you repeat this command, it cycles through all the frames on your terminal.

M-x transient-mark-mode

Under X Windows, when Transient Mark mode is enabled, Emacs highlights the region when the mark is active. This feature is the main motive for using Transient Mark mode. To toggle the state of this mode, use the command M-x transient-mark-mode. See section The Mark and the Region.

Non-Window Terminals

If your terminal does not have a window system that Emacs supports, then it can display only one Emacs frame at a time. However, you can still create multiple Emacs frames, and switch between them. Switching frames on these terminals is much like switching between different window configurations.

Use C-x 5 2 to create a new frame and switch to it; use C-x 5 o to cycle through the existing frames; use C-x 5 0 to delete the current frame.

Each frame has a number to distinguish it. The selected frame's number appears in the mode line after `Emacs', except when frame 1 is selected.

Go to the previous, next section.

Go to the previous, next section.

Major Modes

Emacs provides many alternative major modes, each of which customizes Emacs for editing text of a particular sort. The major modes are mutually exclusive, and each buffer has one major mode at any time. The mode line normally shows the name of the current major mode, in parentheses (see section The Mode Line).

The least specialized major mode is called Fundamental mode. This mode has no mode-specific redefinitions or variable settings, so that each Emacs command behaves in its most general manner, and each option is in its default state. For editing text of a specific type that Emacs knows about, such as Lisp code or English text, you should switch to the appropriate major mode, such as Lisp mode or Text mode.

Selecting a major mode changes the meanings of a few keys to become more specifically adapted to the language being edited. The ones which are changed frequently are TAB, DEL, and LFD. The prefix key C-c normally contains mode-specific commands. In addition, the commands which handle comments use the mode to determine how comments are to be delimited. Many major modes redefine the syntactical properties of characters appearing in the buffer. See section The Syntax Table.

The major modes fall into three major groups. Lisp mode (which has several variants), C mode, Fortran mode and others are for specific programming languages. Text mode, Nroff mode, TeX mode and Outline mode are for editing English text. The remaining major modes are not intended for use on users' files; they are used in buffers created for specific purposes by Emacs, such as Dired mode for buffers made by Dired (see section Dired, the Directory Editor), and Mail mode for buffers made by C-x m (see section Sending Mail), and Shell mode for buffers used for communicating with an inferior shell process (see section Interactive Inferior Shell).

Most programming language major modes specify that only blank lines separate paragraphs. This is to make the paragraph commands useful. (See section Paragraphs.) They also cause Auto Fill mode to use the definition of TAB to indent the new lines it creates. This is because most lines in a program are usually indented. (See section Indentation.)

How Major Modes are Chosen

You can select a major mode explicitly for the current buffer, but most of the time Emacs determines which mode to use based on the file name or on special text in the file.

Explicit selection of a new major mode is done with a M-x command. From the name of a major mode, add `-mode` to get the name of a command to select that mode. Thus, you can enter Lisp mode by executing M-x lisp-mode.

When you visit a file, Emacs usually chooses the right major mode based on the file's name. For example, files whose names end in `.c' are edited in C mode. The correspondence between file names and

major modes is controlled by the variable `auto-mode-alist`. Its value is a list in which each ele has this form,

```
(regexp . mode-function)
```

or this form,

```
(regexp mode-function flag)
```

For example, one element normally found in the list has the form `("\\.c\\'" . c-mode)`, and it is responsible for selecting C mode for files whose names end in `.c'`. (Note that `\\' is needed in Lisp syntax to include a `\' in the string, which is needed to suppress the special meaning of `.' in regexps.) If the element has the form `(regexp mode-function flag)` and flag is non-nil, then after calling function, the suffix that matched regexp is deleted and the list is searched again for another match.

You can specify which major mode should be used for editing a certain file by a special sort of text in the first nonblank line of the file. The mode name should appear in this line both preceded and followed by `-*-'. Other text may appear on the line as well. For example,

```
;-*-Lisp-*-
```

tells Emacs to use Lisp mode. Such an explicit specification overrides any defaulting based on the file name. Note how the semicolon is used to make Lisp treat this line as a comment.

Another format of mode specification is

```
-*-Mode: modename;-*-
```

which allows you to specify local variables as well, like this:

```
-*- mode: modename; var: value; ... -*-
```

See section Local Variables in Files, for more information about this.

When a file's contents begin with `#!', it can serve as an executable shell command, which works by running an interpreter named on the file's first line. The rest of the file is used as input to the interpreter.

When you visit such a file in Emacs, if the file's name does not specify a major mode, Emacs uses the interpreter name on the first line to choose a mode. If the first line is the name of a recognized interpreter program, such as `perl' or `tcl', Emacs uses a mode appropriate for programs for that interpreter. The variable `interpreter-mode-alist` specifies the correspondence between interpreter program names and major modes.

When you visit a file that does not specify a major mode to use, or when you create a new buffer with C-x b, the variable `default-major-mode` specifies which major mode to use. Normally its value is the symbol `fundamental-mode`, which specifies Fundamental mode. If `default-major-mode` is `nil`, the major mode is taken from the previously selected buffer.

TOC

If you change the major mode of a buffer, you can go back to the major mode Emacs would choose automatically: use the command M-x normal-mode to do this. This is the same function that `find-file` calls to choose the major mode. It also processes the file's local variables list if any.

Go to the previous, next section.

Go to the previous, next section.

TOC

Indentation

This chapter describes the Emacs commands that add, remove, or adjust indentation.

TAB

Indent current line "appropriately" in a mode-dependent fashion.

LFD

Perform RET followed by TAB (`newline-and-indent`).

M-^

Merge two lines (`delete-indentation`). This would cancel out the effect of LFD.

C-M-o

Split line at point; text on the line after point becomes a new line indented to the same column that it now starts in (`split-line`).

M-m

Move (forward or back) to the first nonblank character on the current line (`back-to-indentation`).

C-M-\

Indent several lines to same column (`indent-region`).

C-x TAB

Shift block of lines rigidly right or left (`indent-rigidly`).

M-i

Indent from point to the next prespecified tab stop column (`tab-to-tab-stop`).

M-x indent-relative

Indent from point to under an indentation point in the previous line.

Most programming languages have some indentation convention. For Lisp code, lines are indented according to their nesting in parentheses. The same general idea is used for C code, though many details are different.

Whatever the language, to indent a line, use the TAB command. Each major mode defines this command to perform the sort of indentation appropriate for the particular language. In Lisp mode, TAB aligns the line according to its depth in parentheses. No matter where in the line you are when you type TAB, it aligns the line as a whole. In C mode, TAB implements a subtle and sophisticated indentation style that knows about many aspects of C syntax.

In Text mode, TAB runs the command `tab-to-tab-stop`, which indents to the next tab stop column. You can set the tab stops with M-x edit-tab-stops.

Indentation Commands and Techniques

To move over the indentation on a line, do M-m (`back-to-indentation`). This command, given anywhere on a line, positions point at the first nonblank character on the line.

To insert an indented line before the current line, do C-a C-o TAB. To make an indented line after the current line, use C-e LFD.

If you just want to insert a tab character in the buffer, you can type C-q TAB.

C-M-o (`split-line`) moves the text from point to the end of the line vertically down, so that the current line becomes two lines. C-M-o first moves point forward over any spaces and tabs. Then it inserts after point a newline and enough indentation to reach the same column point is on. Point remains before the inserted newline; in this regard, C-M-o resembles C-o.

To join two lines cleanly, use the M-^ (`delete-indentation`) command. It deletes the indentation at the front of the current line, and the line boundary as well, replacing them with a single space. As a special case (useful for Lisp code) the single space is omitted if the characters to be joined are consecutive open parentheses or closing parentheses, or if the junction follows another newline. To delete just the indentation of a line, go to the beginning of the line and use M-\ (`delete-horizontal-space`), which deletes all spaces and tabs around the cursor.

If you have a fill prefix, M-^ deletes the fill prefix if it appears after the newline that is deleted. See section The Fill Prefix.

There are also commands for changing the indentation of several lines at once. C-M-\ (`indent-region`) applies to all the lines that begin in the region; it indents each line in the "usual" way, as if you had typed TAB at the beginning of the line. A numeric argument specifies the column to indent to, and each line is shifted left or right so that its first nonblank character appears in that column. C-x TAB (`indent-rigidly`) moves all of the lines in the region right by its argument (left, for negative arguments). The whole group of lines moves rigidly sideways, which is how the command gets its name.

M-x indent-relative indents at point based on the previous line (actually, the last nonempty line). It inserts whitespace at point, moving point, until it is underneath an indentation point in the previous line. An indentation point is the end of a sequence of whitespace or the end of the line. If point is farther right than any indentation point in the previous line, the whitespace before point is deleted and the first indentation point then applicable is used. If no indentation point is applicable even then, `indent-relative` runs `tab-to-tab-stop` (see next section).

`indent-relative` is the definition of TAB in Indented Text mode. See section Commands for Human Languages.

See section Indentation in Formatted Text, for another way of specifying the indentation for part of your text.

Tab Stops

For typing in tables, you can use Text mode's definition of TAB, `tab-to-tab-stop`. This command inserts indentation before point, enough to reach the next tab stop column. If you are not in Text mode, this command can be found on the key M-i.

You can specify the tab stops used by M-i. They are stored in a variable called `tab-stop-list`, as a list of column-numbers in increasing order.

The convenient way to set the tab stops is with M-x edit-tab-stops, which creates and selects a buffer containing a description of the tab stop settings. You can edit this buffer to specify different tab stops, and then type C-c C-c to make those new tab stops take effect. In the tab stop buffer, C-c C-c runs the function `edit-tab-stops-note-changes` rather than its usual definition `save-buffer`. `edit-tab-stops` records which buffer was current when you invoked it, and stores the tab stops back in that buffer; normally all buffers share the same tab stops and changing them in one buffer affects all, but if you happen to make `tab-stop-list` local in one buffer then `edit-tab-stops` in that buffer will edit the local settings.

Here is what the text representing the tab stops looks like for ordinary tab stops every eight columns.

```
        :       :       :       :       :       :
0         1         2         3         4
0123456789012345678901234567890123456789012345678
To install changes, type C-c C-c
```

The first line contains a colon at each tab stop. The remaining lines are present just to help you see where the colons are and know what to do.

Note that the tab stops that control `tab-to-tab-stop` have nothing to do with displaying tab characters in the buffer. See section Variables Controlling Display, for more information on that.

Tabs vs. Spaces

Emacs normally uses both tabs and spaces to indent lines. If you prefer, all indentation can be made from spaces only. To request this, set `indent-tabs-mode` to `nil`. This is a per-buffer variable; altering the variable affects only the current buffer, but there is a default value which you can change as well. See section Local Variables.

There are also commands to convert tabs to spaces or vice versa, always preserving the columns of all nonblank text. M-x tabify scans the region for sequences of spaces, and converts sequences of at least three spaces to tabs if that can be done without changing indentation. M-x untabify changes all tabs in the region to appropriate numbers of spaces.

Go to the previous, next section.

Go to the previous, next section.

Commands for Human Languages

The term text has two widespread meanings in our area of the computer field. One is data that is a sequence of characters. Any file that you edit with Emacs is text, in this sense of the word. The other meaning is more restrictive: a sequence of characters in a human language for humans to read (possibly after processing by a text formatter), as opposed to a program or commands for a program.

Human languages have syntactic/stylistic conventions that can be supported or used to advantage by editor commands: conventions involving words, sentences, paragraphs, and capital letters. This chapter describes Emacs commands for all of these things. There are also commands for filling, which means rearranging the lines of a paragraph to be approximately equal in length. The commands for moving over and killing words, sentences and paragraphs, while intended primarily for editing text, are also often useful for editing programs.

Emacs has several major modes for editing human language text. If the file contains text pure and simple, use Text mode, which customizes Emacs in small ways for the syntactic conventions of text. Outline mode provides special commands for operating on text with an outline structure. See section Outline Mode.

For text which contains embedded commands for text formatters, Emacs has other major modes, each for a particular text formatter. Thus, for input to TeX, you would use TeX mode (see section TeX Mode). For input to nroff, use Nroff mode.

Instead of using a text formatter, you can edit formatted text in WYSIWYG style ("what you see is what you get"), with Enriched mode. Then the formatting appears on the screen in Emacs while you edit. See section Editing Formatted Text.

Words

Emacs has commands for moving over or operating on words. By convention, the keys for them are all Meta characters.

M-f
: Move forward over a word (`forward-word`).

M-b
: Move backward over a word (`backward-word`).

M-d
: Kill up to the end of a word (`kill-word`).

M-DEL
: Kill back to the beginning of a word (`backward-kill-word`).

M-@

Mark the end of the next word (`mark-word`).

M-t

Transpose two words or drag a word across other words (`transpose-words`).

Notice how these keys form a series that parallels the character-based C-f, C-b, C-d, C-t and DEL. M-@ is cognate to C-@, which is an alias for C-SPC.

The commands M-f (`forward-word`) and M-b (`backward-word`) move forward and backward over words. These Meta characters are thus analogous to the corresponding control characters, C-f and C-b, which move over single characters in the text. The analogy extends to numeric arguments, which serve as repeat counts. M-f with a negative argument moves backward, and M-b with a negative argument moves forward. Forward motion stops right after the last letter of the word, while backward motion stops right before the first letter.

M-d (`kill-word`) kills the word after point. To be precise, it kills everything from point to the place M-f would move to. Thus, if point is in the middle of a word, M-d kills just the part after point. If some punctuation comes between point and the next word, it is killed along with the word. (If you wish to kill only the next word but not the punctuation before it, simply do M-f to get the end, and kill the word backwards with M-DEL.) M-d takes arguments just like M-f.

M-DEL (`backward-kill-word`) kills the word before point. It kills everything from point back to where M-b would move to. If point is after the space in `FOO, BAR', then `FOO, ' is killed. (If you wish to kill just `FOO', do M-b M-d instead of M-DEL.)

M-t (`transpose-words`) exchanges the word before or containing point with the following word. The delimiter characters between the words do not move. For example, `FOO, BAR' transposes into `BAR, FOO' rather than `BAR FOO,'. See section Transposing Text, for more on transposition and on arguments to transposition commands.

To operate on the next n words with an operation which applies between point and mark, you can either set the mark at point and then move over the words, or you can use the command M-@ (`mark-word`) which does not move point, but sets the mark where M-f would move to. M-@ accepts a numeric argument that says how many words to scan for the place to put the mark. In Transient Mark mode, this command activates the mark.

The word commands' understanding of syntax is completely controlled by the syntax table. Any character can, for example, be declared to be a word delimiter. See section The Syntax Table.

Sentences

The Emacs commands for manipulating sentences and paragraphs are mostly on Meta keys, so as to be like the word-handling commands.

M-a

Move back to the beginning of the sentence (`backward-sentence`).

M-e

Move forward to the end of the sentence (`forward-sentence`).

M-k

Kill forward to the end of the sentence (`kill-sentence`).

C-x DEL

Kill back to the beginning of the sentence (`backward-kill-sentence`).

The commands M-a and M-e (`backward-sentence` and `forward-sentence`) move to the beginning and end of the current sentence, respectively. They were chosen to resemble C-a and C-e, which move to the beginning and end of a line. Unlike them, M-a and M-e if repeated or given numeric arguments move over successive sentences.

Moving backward over a sentence places point just before the first character of the sentence; moving forward places point right after the punctuation that ends the sentence. Neither one moves over the whitespace at the sentence boundary.

Just as C-a and C-e have a kill command, C-k, to go with them, so M-a and M-e have a corresponding kill command M-k (`kill-sentence`) which kills from point to the end of the sentence. With minus one as an argument it kills back to the beginning of the sentence. Larger arguments serve as a repeat count. There is also a command, C-x DEL (`backward-kill-sentence`), for killing back to the beginning of a sentence. This command is useful when you change your mind in the middle of composing text.

The sentence commands assume that you follow the American typist's convention of putting two spaces at the end of a sentence; they consider a sentence to end wherever there is a `.', `?' or `!' followed by the end of a line or two spaces, with any number of `)', `]', `', or `"' characters allowed in between. A sentence also begins or ends wherever a paragraph begins or ends.

The variable `sentence-end` controls recognition of the end of a sentence. It is a regexp that matches the last few characters of a sentence, together with the whitespace following the sentence. Its normal value is

```
"[.?!][]\"')]*\\($\\|\t\\|  \\)[ \t\n]*"
```

This example is explained in the section on regexps. See section Syntax of Regular Expressions.

If you want to use just one space between sentences, you should set `sentence-end` to this value:

```
"[.?!][]\"')]*\\($\\|\t\\| \\)[ \t\n]*"
```

You should also set the variable `sentence-end-double-space` to `nil` so that the fill commands expect and leave just one space at the end of a sentence. Note that this makes it impossible to distinguish between periods that end sentences and those that indicate abbreviations.

Paragraphs

The Emacs commands for manipulating paragraphs are also Meta keys.

M-{
: Move back to previous paragraph beginning (`backward-paragraph`).

M-}
: Move forward to next paragraph end (`forward-paragraph`).

M-h
: Put point and mark around this or next paragraph (`mark-paragraph`).

M-{ moves to the beginning of the current or previous paragraph, while M-} moves to the end of the current or next paragraph. Blank lines and text formatter command lines separate paragraphs and are not considered part of any paragraph. Also, an indented line starts a new paragraph.

In major modes for programs (as opposed to Text mode), paragraphs begin and end only at blank lines. This makes the paragraph commands continue to be useful even though there are no paragraphs per se.

When there is a fill prefix, then paragraphs are delimited by all lines which don't start with the fill prefix. See section Filling Text.

When you wish to operate on a paragraph, you can use the command M-h (`mark-paragraph`) to set the region around it. Thus, for example, M-h C-w kills the paragraph around or after point. The M-h command puts point at the beginning and mark at the end of the paragraph point was in. In Transient Mark mode, it activates the mark. If point is between paragraphs (in a run of blank lines, or at a boundary), the paragraph following point is surrounded by point and mark. If there are blank lines preceding the first line of the paragraph, one of these blank lines is included in the region.

The precise definition of a paragraph boundary is controlled by the variables `paragraph-separate` and `paragraph-start`. The value of `paragraph-start` is a regexp that should match any line that either starts or separates paragraphs. The value of `paragraph-separate` is another regexp that should match only lines that separate paragraphs without being part of any paragraph. Lines that start a new paragraph and are contained in it must match only `paragraph-start`, not `paragraph-separate`. For example, normally `paragraph-start` is `"[ \t\n\f]"` and `paragraph-separate` is `"[ \t\f]*$"`.

Normally it is desirable for page boundaries to separate paragraphs. The default values of these variables recognize the usual separator for pages.

Pages

Files are often thought of as divided into pages by the formfeed character (ASCII control-L, octal code 014). When you print hardcopy for a file, this character forces a page break; thus, each page of the file goes on a separate page on paper. Most Emacs commands treat the page-separator character just like any other character: you can insert it with C-q C-l, and delete it with DEL. Thus, you are free to paginate your file or not. However, since pages are often meaningful divisions of the file, Emacs provides

commands to move over them and operate on them.

C-x [
: Move point to previous page boundary (`backward-page`).

C-x]
: Move point to next page boundary (`forward-page`).

C-x C-p
: Put point and mark around this page (or another page) (`mark-page`).

C-x l
: Count the lines in this page (`count-lines-page`).

The C-x [(`backward-page`) command moves point to immediately after the previous page delimiter. If point is already right after a page delimiter, it skips that one and stops at the previous one. A numeric argument serves as a repeat count. The C-x] (`forward-page`) command moves forward past the next page delimiter.

The C-x C-p command (`mark-page`) puts point at the beginning of the current page and the mark at the end. The page delimiter at the end is included (the mark follows it). The page delimiter at the front is excluded (point follows it). C-x C-p C-w is a handy way to kill a page to move it elsewhere. If you move to another page delimiter with C-x [and C-x], then yank the killed page, all the pages will be properly delimited once again. The reason C-x C-p includes only the following page delimiter in the region is to ensure that.

A numeric argument to C-x C-p is used to specify which page to go to, relative to the current one. Zero means the current page. One means the next page, and -1 means the previous one.

The C-x l command (`count-lines-page`) is good for deciding where to break a page in two. It prints in the echo area the total number of lines in the current page, and then divides it up into those preceding the current line and those following, as in

```
Page has 96 (72+25) lines
```

Notice that the sum is off by one; this is correct if point is not at the beginning of a line.

The variable `page-delimiter` controls where pages begin. Its value is a regexp that matches the beginning of a line that separates pages. The normal value of this variable is `"^\f"`, which matches a formfeed character at the beginning of a line.

Filling Text

Filling text means breaking it up into lines that fit a specified width. Emacs does filling in two ways. In Auto Fill mode, inserting text with self-inserting characters also automatically fills it. There are also explicit fill commands that you can use when editing text leaves it unfilled. When you edit formatted text, you can specify a style of filling for each portion of the text (see section Editing Formatted Text).

Auto Fill Mode

Auto Fill mode is a minor mode in which lines are broken automatically when they become too wide. Breaking happens only when you type a SPC or RET.

M-x auto-fill-mode

Enable or disable Auto Fill mode.

SPC

RET

In Auto Fill mode, break lines when appropriate.

M-x auto-fill-mode turns Auto Fill mode on if it was off, or off if it was on. With a positive numeric argument it always turns Auto Fill mode on, and with a negative argument always turns it off. You can see when Auto Fill mode is in effect by the presence of the word `Fill' in the mode line, inside the parentheses. Auto Fill mode is a minor mode which is enabled or disabled for each buffer individually. See section Minor Modes.

In Auto Fill mode, lines are broken automatically at spaces when they get longer than the desired width. Line breaking and rearrangement takes place only when you type SPC or RET. If you wish to insert a space or newline without permitting line-breaking, type C-q SPC or C-q LFD (recall that a newline is really a linefeed). Also, C-o inserts a newline without line breaking.

Auto Fill mode works well with Lisp mode, because when it makes a new line in Lisp mode it indents that line with TAB. If a line ending in a comment gets too long, the text of the comment is split into two comment lines. Optionally new comment delimiters are inserted at the end of the first line and the beginning of the second so that each line is a separate comment; the variable `comment-multi-line` controls the choice (see section Manipulating Comments).

Adaptive filling (see the following section) works for Auto Filling as well as for explicit fill commands. It takes a fill prefix automatically from the second or first line of a paragraph.

Auto Fill mode does not refill entire paragraphs; it can break lines but cannot merge lines. So editing in the middle of a paragraph can result in a paragraph that is not correctly filled. The easiest way to make the paragraph properly filled again is usually with the explicit fill commands.

Many users like Auto Fill mode and want to use it in all text files. The section on init files says how to arrange this permanently for yourself. See section The Init File, `~/.emacs'.

Explicit Fill Commands

M-q

Fill current paragraph (`fill-paragraph`).

C-x f

Set the fill column (`set-fill-column`).

M-x fill-region

Fill each paragraph in the region (`fill-region`).

M-x fill-region-as-paragraph.

Fill the region, considering it as one paragraph.

M-s

Center a line.

To refill a paragraph, use the command M-q (`fill-paragraph`). This operates on the paragraph that point is inside, or the one after point if point is between paragraphs. Refilling works by removing all the line-breaks, then inserting new ones where necessary.

To refill many paragraphs, use M-x fill-region, which divides the region into paragraphs and fills each of them.

M-q and `fill-region` use the same criteria as M-h for finding paragraph boundaries (see section Paragraphs). For more control, you can use M-x fill-region-as-paragraph, which refills everything between point and mark. This command deletes any blank lines within the region, so separate blocks of text end up combined into one block.

A numeric argument to M-q causes it to justify the text as well as filling it. This means that extra spaces are inserted to make the right margin line up exactly at the fill column. To remove the extra spaces, use M-q with no argument. (Likewise for `fill-region`.) Another way to control justification, and choose other styles of filling, is with the `justification` text property; see section Justification in Formatted Text.

The fill commands can deduce the proper fill prefix for a paragraph automatically in certain cases: either whitespace or certain punctuation characters at the beginning of a line are treated as a fill prefix. They take the fill prefix from the paragraph's second line, unless the paragraph has just one line. You can turn off this feature by setting `adaptive-fill-mode` to `nil`.

Some major modes, including Text mode, treat whitespace at the beginning of a line as a signal that this line starts a new paragraph. It would be a mistake to copy text which implies the start of a paragraph onto each line of the paragraph when filling it. Therefore, adaptive filling does not accept a fill prefix from a line which is a paragraph-starter. In particular, adaptive filling in Text mode does not accept a fill prefix consisting of just whitespace.

However, other modes including Indented Text mode (see section Text Mode) do not consider whitespace as a signal to start a new paragraph. In these modes, adaptive filling does accept a fill prefix consisting of just whitespace, if the first or second line of a paragraph begins with whitespace.

The variable `adaptive-fill-regexp` determines what kinds of line beginnings can serve as a fill prefix: any characters at the start of the line which match this regular expression are used.

You can specify more complex ways of choosing a fill prefix automatically by setting the variable `adaptive-fill-function` to a function. This function is called with point after the left margin of a line, and it should return the appropriate fill prefix based on that line. If it returns `nil`, that means it sees no fill prefix in that line.

The command M-s (`center-line`) centers the current line within the current fill column. With an

argument n, it centers n lines individually and moves past them.

The maximum line width for filling is in the variable `fill-column`. Altering the value of `fill-column` makes it local to the current buffer; until that time, the default value is in effect. The default is initially 70. See section Local Variables. The easiest way to set `fill-column` is to use the command C-x f (`set-fill-column`). With a numeric argument, it uses that as the new fill column. With just C-u as argument, it sets `fill-column` to the current horizontal position of point.

Emacs commands normally consider a period followed by two spaces or by a newline as the end of a sentence; a period followed by just one space indicates an abbreviation and not the end of a sentence. To preserve the distinction between these two ways of using a period, the fill commands do not break a line after a period followed by just one space.

If the variable `sentence-end-double-space` is `nil`, the fill commands expect and leave just one space at the end of a sentence. Ordinarily this variable is `t`, so the fill commands insist on two spaces for the end of a sentence, as explained above. See section Sentences.

If the variable `colon-double-space` is non-`nil`, the fill commands put two spaces after a colon.

The Fill Prefix

To fill a paragraph in which each line starts with a special marker (which might be a few spaces, giving an indented paragraph), use the fill prefix feature. The fill prefix is a string which Emacs expects every line to start with, and which is not included in filling.

C-x .
: Set the fill prefix (`set-fill-prefix`).

M-q
: Fill a paragraph using current fill prefix (`fill-paragraph`).

M-x fill-individual-paragraphs
: Fill the region, considering each change of indentation as starting a new paragraph.

M-x fill-nonuniform-paragraphs
: Fill the region, considering only paragraph-separator lines as starting a new paragraph.

To specify a fill prefix, move to a line that starts with the desired prefix, put point at the end of the prefix, and give the command C-x . (`set-fill-prefix`). That's a period after the C-x. To turn off the fill prefix, specify an empty prefix: type C-x . with point at the beginning of a line.

When a fill prefix is in effect, the fill commands remove the fill prefix from each line before filling and insert it on each line after filling. Auto Fill mode also inserts the fill prefix automatically when it makes a new line. The C-o command inserts the fill prefix on new lines it creates, when you use it at the beginning of a line (see section Blank Lines). Conversely, the command M-^ deletes the prefix (if it occurs) after the newline that it deletes (see section Indentation).

For example, if `fill-column` is 40 and you set the fill prefix to `;; ', then M-q in the following text

```
;; This is an
;; example of a paragraph
;; inside a Lisp-style comment.
```

produces this:

```
;; This is an example of a paragraph
;; inside a Lisp-style comment.
```

Lines that do not start with the fill prefix are considered to start paragraphs, both in M-q and the paragraph commands; this gives good results for paragraphs with hanging indentation (every line indented except the first one). Lines which are blank or indented once the prefix is removed also separate or start paragraphs; this is what you want if you are writing multi-paragraph comments with a comment delimiter on each line.

You can use M-x fill-individual-paragraphs to set the fill prefix for each paragraph automatically. This command divides the region into paragraphs, treating every change in the amount of indentation as the start of a new paragraph, and fills each of these paragraphs. Thus, all the lines in one "paragraph" have the same amount of indentation. That indentation serves as the fill prefix for that paragraph.

M-x fill-nonuniform-paragraphs is a similar command that divides the region into paragraphs in a different way. It considers only paragraph-separating lines (as defined by `paragraph-separate`) as starting a new paragraph. Since this means that the lines of one paragraph may have different amounts of indentation, the fill prefix used is the smallest amount of indentation of any of the lines of the paragraph. This gives good results with styles that indent a paragraph's first line more or less that the rest of the paragraph.

The fill prefix is stored in the variable `fill-prefix`. Its value is a string, or `nil` when there is no fill prefix. This is a per-buffer variable; altering the variable affects only the current buffer, but there is a default value which you can change as well. See section Local Variables.

The `indentation` text property provides another way to control the amount of indentation paragraphs receive. See section Indentation in Formatted Text.

Case Conversion Commands

Emacs has commands for converting either a single word or any arbitrary range of text to upper case or to lower case.

M-l
: Convert following word to lower case (`downcase-word`).

M-u
: Convert following word to upper case (`upcase-word`).

M-c
: Capitalize the following word (`capitalize-word`).

C-x C-l

Convert region to lower case (`downcase-region`).

C-x C-u

Convert region to upper case (`upcase-region`).

The word conversion commands are the most useful. M-l (`downcase-word`) converts the word after point to lower case, moving past it. Thus, repeating M-l converts successive words. M-u (`upcase-word`) converts to all capitals instead, while M-c (`capitalize-word`) puts the first letter of the word into upper case and the rest into lower case. All these commands convert several words at once if given an argument. They are especially convenient for converting a large amount of text from all upper case to mixed case, because you can move through the text using M-l, M-u or M-c on each word as appropriate, occasionally using M-f instead to skip a word.

When given a negative argument, the word case conversion commands apply to the appropriate number of words before point, but do not move point. This is convenient when you have just typed a word in the wrong case: you can give the case conversion command and continue typing.

If a word case conversion command is given in the middle of a word, it applies only to the part of the word which follows point. This is just like what M-d (`kill-word`) does. With a negative argument, case conversion applies only to the part of the word before point.

The other case conversion commands are C-x C-u (`upcase-region`) and C-x C-l (`downcase-region`), which convert everything between point and mark to the specified case. Point and mark do not move.

The region case conversion commands `upcase-region` and `downcase-region` are normally disabled. This means that they ask for confirmation if you try to use them. When you confirm, you may enable the command, which means it will not ask for confirmation again. See section Disabling Commands.

Text Mode

When you edit files of text in a human language, it's more convenient to use Text mode rather than Fundamental mode. Invoke M-x text-mode to enter Text mode. In Text mode, TAB runs the function `tab-to-tab-stop`, which allows you to use arbitrary tab stops set with M-x edit-tab-stops (see section Tab Stops). Features concerned with comments in programs are turned off in Text mode except when explicitly invoked. The syntax table is changed so that periods are not considered part of a word, while apostrophes, backspaces and underlines are part of words.

A similar variant mode is Indented Text mode, intended for editing text in which most lines are indented. This mode defines TAB to run `indent-relative` (see section Indentation), and makes Auto Fill indent the lines it creates. The result is that normally a line made by Auto Filling, or by LFD, is indented just like the previous line. In Indented Text mode, only blank lines separate paragraphs--indented lines continue the current paragraph. Use M-x indented-text-mode to select this mode.

Text mode, and all the modes based on it, define M-TAB as the command `ispell-complete-word`, which performs completion of the partial word in the buffer before point, using the spelling dictionary as

the space of possible words. See section Checking and Correcting Spelling.

Entering Text mode or Indented Text mode runs the hook `text-mode-hook`. Other major modes related to Text mode also run this hook, followed by hooks of their own; this includes Nroff mode, TeX mode, Outline mode and Mail mode. Hook functions on `text-mode-hook` can look at the value of `major-mode` to see which of these modes is actually being entered. See section Hooks.

Outline Mode

Outline mode is a major mode much like Text mode but intended for editing outlines. It allows you to make parts of the text temporarily invisible so that you can see the outline structure. Type M-x outline-mode to switch to Outline mode as the major mode of the current buffer.

When Outline mode makes a line invisible, the line does not appear on the screen. The screen appears exactly as if the invisible line were deleted, except that an ellipsis (three periods in a row) appears at the end of the previous visible line (only one ellipsis no matter how many invisible lines follow).

All editing commands treat the text of the invisible line as part of the previous visible line. For example, C-n moves onto the next visible line. Killing an entire visible line, including its terminating newline, really kills all the following invisible lines along with it; yanking it all back yanks the invisible lines and they remain invisible.

Outline minor mode provides the same commands as the major mode, Outline mode, but you can use it in conjunction with other major modes. Type M-x outline-minor-mode to enable the Outline minor mode in the current buffer. You can also specify this in the text of a file, with a file local variable of the form `mode: outline-minor' (see section Local Variables in Files).

The major mode, Outline mode, provides special key bindings on the C-c prefix. Outline minor mode provides similar bindings with C-c @ as the prefix; this is to reduce the conflicts with the major mode's special commands. (The variable `outline-minor-mode-prefix` controls the prefix used.)

Entering Outline mode runs the hook `text-mode-hook` followed by the hook `outline-mode-hook` (see section Hooks).

Format of Outlines

Outline mode assumes that the lines in the buffer are of two types: heading lines and body lines. A heading line represents a topic in the outline. Heading lines start with one or more stars; the number of stars determines the depth of the heading in the outline structure. Thus, a heading line with one star is a major topic; all the heading lines with two stars between it and the next one-star heading are its subtopics; and so on. Any line that is not a heading line is a body line. Body lines belong with the preceding heading line. Here is an example:

```
* Food

This is the body,
```

```
which says something about the topic of food.

** Delicious Food

This is the body of the second-level header.

** Distasteful Food

This could have
a body too, with
several lines.

*** Dormitory Food

* Shelter

Another first-level topic with its header line.
```

A heading line together with all following body lines is called collectively an entry. A heading line together with all following deeper heading lines and their body lines is called a subtree.

You can customize the criterion for distinguishing heading lines by setting the variable `outline-regexp`. Any line whose beginning has a match for this regexp is considered a heading line. Matches that start within a line (not at the left margin) do not count. The length of the matching text determines the level of the heading; longer matches make a more deeply nested level. Thus, for example, if a text formatter has commands `@chapter', `@section' and `@subsection' to divide the document into chapters and sections, you could make those lines count as heading lines by setting `outline-regexp` to `"@chap\\|@\\(sub\\)*section"'. Note the trick: the two words `chapter' and `section' are equally long, but by defining the regexp to match only `chap' we ensure that the length of the text matched on a chapter heading is shorter, so that Outline mode will know that sections are contained in chapters. This works as long as no other command starts with `@chap'.

It is possible to change the rule for calculating the level of a heading line by setting the variable `outline-level`. The value of `outline-level` should be a function that takes no arguments and returns the level of the current heading. Some major modes such as C, Nroff, and Emacs Lisp mode set this variable in order to work with Outline minor mode.

Outline mode makes a line invisible by changing the newline before it into an ASCII control-M (code 015). Most editing commands that work on lines treat an invisible line as part of the previous line because, strictly speaking, it *is* part of that line, since there is no longer a newline in between. When you save the file in Outline mode, control-M characters are saved as newlines, so the invisible lines become ordinary lines in the file. But saving does not change the visibility status of a line inside Emacs.

Outline Motion Commands

Outline mode provides special motion commands that move backward and forward to heading lines

C-c C-n
: Move point to the next visible heading line (`outline-next-visible-heading`).

C-c C-p
: Move point to the previous visible heading line (`outline-previous-visible-heading`).

C-c C-f
: Move point to the next visible heading line at the same level as the one point is on (`outline-forward-same-level`).

C-c C-b
: Move point to the previous visible heading line at the same level (`outline-backward-same-level`).

C-c C-u
: Move point up to a lower-level (more inclusive) visible heading line (`outline-up-heading`).

C-c C-n (`outline-next-visible-heading`) moves down to the next heading line. C-c C-p (`outline-previous-visible-heading`) moves similarly backward. Both accept numeric arguments as repeat counts. The names emphasize that invisible headings are skipped, but this is not really a special feature. All editing commands that look for lines ignore the invisible lines automatically.

More powerful motion commands understand the level structure of headings. C-c C-f (`outline-forward-same-level`) and C-c C-b (`outline-backward-same-level`) move from one heading line to another visible heading at the same depth in the outline. C-c C-u (`outline-up-heading`) moves backward to another heading that is less deeply nested.

Outline Visibility Commands

The other special commands of outline mode are used to make lines visible or invisible. Their names all start with `hide` or `show`. Most of them fall into pairs of opposites. They are not undoable; instead, you can undo right past them. Making lines visible or invisible is simply not recorded by the undo mechanism.

C-c C-t
: Make all body lines in the buffer invisible (`hide-body`).

C-c C-a
: Make all lines in the buffer visible (`show-all`).

C-c C-d
: Make everything under this heading invisible, not including this heading itself (`hide-subtree`).

C-c C-s
: Make everything under this heading visible, including body, subheadings, and their bodies

(`show-subtree`).

C-c C-l

Make the body of this heading line, and of all its subheadings, invisible (`hide-leaves`).

C-c C-k

Make all subheadings of this heading line, at all levels, visible (`show-branches`).

C-c C-i

Make immediate subheadings (one level down) of this heading line visible (`show-children`).

C-c C-c

Make this heading line's body invisible (`hide-entry`).

C-c C-e

Make this heading line's body visible (`show-entry`).

C-c C-q

Hide everything except the top n levels of heading lines (`hide-sublevels`).

C-c C-o

Hide everything except for the heading or body that point is in, plus the headings leading up from there to the top level of the outline (`hide-other`).

Two commands that are exact opposites are C-c C-c (`hide-entry`) and C-c C-e (`show-entry`). They are used with point on a heading line, and apply only to the body lines of that heading. Subheadings and their bodies are not affected.

Two more powerful opposites are C-c C-d (`hide-subtree`) and C-c C-s (`show-subtree`). Both expect to be used when point is on a heading line, and both apply to all the lines of that heading's subtree: its body, all its subheadings, both direct and indirect, and all of their bodies. In other words, the subtree contains everything following this heading line, up to and not including the next heading of the same or higher rank.

Intermediate between a visible subtree and an invisible one is having all the subheadings visible but none of the body. There are two commands for doing this, depending on whether you want to hide the bodies or make the subheadings visible. They are C-c C-l (`hide-leaves`) and C-c C-k (`show-branches`).

A little weaker than `show-branches` is C-c C-i (`show-children`). It makes just the direct subheadings visible--those one level down. Deeper subheadings remain invisible, if they were invisible.

Two commands have a blanket effect on the whole file. C-c C-t (`hide-body`) makes all body lines invisible, so that you see just the outline structure. C-c C-a (`show-all`) makes all lines visible. These commands can be thought of as a pair of opposites even though C-c C-a applies to more than just body lines.

The command C-c C-q (`hide-sublevels`) hides all but the top level headings. With a numeric argument n, it hides everything except the top n levels of heading lines.

The command C-c C-o (`hide-other`) hides everything except the heading or body text that point is in, plus its parents (the headers leading up from there to top level in the outline).

You can turn off the use of ellipses at the ends of visible lines by setting `selective-display-ellipses` to `nil`. Then there is no visible indication of the presence of invisible lines.

Viewing One Outline in Multiple Views

You can display two views of a single outline at the same time, in different windows, by means of an alternative implementation of Outline mode called `noutline`.

To do this, first load the library `noutline` with M-x load-library RET noutline RET. This loads the alternative implementation of Outline mode. It provides the same command names and key bindings as regular Outline mode, but it implements them differently.

Then, to display a second view of an outline buffer, you must create an indirect buffer using M-x make-indirect-buffer. The first argument of this command is the existing outline buffer name, and its second argument is the name to use for the new indirect buffer. See section Indirect Buffers.

Once the indirect buffer exists, you can display it in a window in the normal fashion, with C-x 4 b or other Emacs commands. The Outline mode commands to show and hide parts of the text operate on each buffer independently; as a result, each buffer can have its own view. If you want more than two views on the same outline, create additional indirect buffers.

In a future Emacs version, the alternative `noutline` implementation will probably become the principal implementation.

TeX Mode

TeX is a powerful text formatter written by Donald Knuth; it is also free, like GNU Emacs. LaTeX is a simplified input format for TeX, implemented by TeX macros; it comes with TeX. SliTeX is a special form of LaTeX.

Emacs has a special TeX mode for editing TeX input files. It provides facilities for checking the balance of delimiters and for invoking TeX on all or part of the file.

TeX mode has three variants, Plain TeX mode, LaTeX mode, and SliTeX mode (these three distinct major modes differ only slightly). They are designed for editing the three different formats. The command M-x tex-mode looks at the contents of the buffer to determine whether the contents appear to be either LaTeX input or SliTeX input; if so, it selects the appropriate mode. If the file contents do not appear to be LaTeX or SliTeX, it selects Plain TeX mode. If the contents are insufficient to determine this, the variable `tex-default-mode` controls which mode is used.

When M-x tex-mode does not guess right, you can use the commands M-x plain-tex-mode, M-x latex-mode, and M-x slitex-mode to select explicitly the particular variants of TeX mode.

TeX Editing Commands

Here are the special commands provided in TeX mode for editing the text of the file.

"

Insert, according to context, either `"' or `"' or `"' (`tex-insert-quote').

LFD

Insert a paragraph break (two newlines) and check the previous paragraph for unbalanced braces or dollar signs (`tex-terminate-paragraph').

M-x validate-tex-region

Check each paragraph in the region for unbalanced braces or dollar signs.

C-c {

Insert `{}' and position point between them (`tex-insert-braces').

C-c }

Move forward past the next unmatched close brace (`up-list').

In TeX, the character `"' is not normally used; we use `"' to start a quotation and `"' to end one. To make editing easier under this formatting convention, TeX mode overrides the normal meaning of the key " with a command that inserts a pair of single-quotes or backquotes (`tex-insert-quote'). To be precise, this command inserts `"' after whitespace or an open brace, `"' after a backslash, and `"' after any other character.

If you need the character `"' itself in unusual contexts, use C-q to insert it. Also, " with a numeric argument always inserts that number of `"' characters.

In TeX mode, `$' has a special syntax code which attempts to understand the way TeX math mode delimiters match. When you insert a `$' that is meant to exit math mode, the position of the matching `$' that entered math mode is displayed for a second. This is the same feature that displays the open brace that matches a close brace that is inserted. However, there is no way to tell whether a `$' enters math mode or leaves it; so when you insert a `$' that enters math mode, the previous `$' position is shown as if it were a match, even though they are actually unrelated.

TeX uses braces as delimiters that must match. Some users prefer to keep braces balanced at all times, rather than inserting them singly. Use C-c { (`tex-insert-braces') to insert a pair of braces. It leaves point between the two braces so you can insert the text that belongs inside. Afterward, use the command C-c } (`up-list') to move forward past the close brace.

There are two commands for checking the matching of braces. LFD (`tex-terminate-paragraph') checks the paragraph before point, and inserts two newlines to start a new paragraph. It prints a message in the echo area if any mismatch is found. M-x validate-tex-region checks a region, paragraph by paragraph. When it finds a paragraph that contains a mismatch, it displays point at the beginning of the paragraph for a few seconds and sets the mark at that spot. Scanning continues until the whole buffer has been checked or until you type another key. Afterward, you can use the mark ring to find the last several paragraphs that had mismatches (see section The Mark Ring).

Note that Emacs commands count square brackets and parentheses in TeX mode, not just braces. This is

not strictly correct for the purpose of checking TeX syntax. However, parentheses and square brackets are likely to be used in text as matching delimiters and it is useful for the various motion commands and automatic match display to work with them.

LaTeX Editing Commands

LaTeX mode, and its variant, SliTeX mode, provide a few extra features not applicable to plain TeX.

C-c C-o

Insert `\begin' and `\end' for LaTeX block and position point on a line between them. (`tex-latex-block`).

C-c C-e

Close the last unended block for LaTeX (`tex-close-latex-block`).

In LaTeX input, `\begin' and `\end' commands are used to group blocks of text. To insert a `\begin' and a matching `\end' (on a new line following the `\begin'), use C-c C-o (`tex-latex-block`). A blank line is inserted between the two, and point is left there. You can use completion when you enter the block type; to specify additional block type names beyond the standard list, set the variable `latex-block-names`. For example, here's how to add `theorem', `corollary', and `proof':

```
(setq latex-block-names '("theorem" "corollary" "proof"))
```

In LaTeX input, `\begin' and `\end' commands must balance. You can use C-c C-e (`tex-close-latex-block`) to insert automatically a matching `\end' to match the last unmatched `\begin'. It indents the `\end' to match the corresponding `\begin'. It inserts a newline after `\end' if point is at the beginning of a line.

TeX Printing Commands

You can invoke TeX as an inferior of Emacs on either the entire contents of the buffer or just a region at a time. Running TeX in this way on just one chapter is a good way to see what your changes look like without taking the time to format the entire file.

C-c C-r

Invoke TeX on the current region, together with the buffer's header (`tex-region`).

C-c C-b

Invoke TeX on the entire current buffer (`tex-buffer`).

C-c TAB

Invoke BibTeX on the current file (`tex-bibtex-file`).

C-c C-f

Invoke TeX on the current file (`tex-file`).

C-c C-l

Recenter the window showing output from the inferior TeX so that the last line can be seen (`tex-recenter-output-buffer`).

C-c C-k
: Kill the TeX subprocess (`tex-kill-job`).

C-c C-p
: Print the output from the last C-c C-r, C-c C-b, or C-c C-f command (`tex-print`).

C-c C-v
: Preview the output from the last C-c C-r, C-c C-b, or C-c C-f command (`tex-view`).

C-c C-q
: Show the printer queue (`tex-show-print-queue`).

You can pass the current buffer through an inferior TeX by means of C-c C-b (`tex-buffer`). The formatted output appears in a temporary file; to print it, type C-c C-p (`tex-print`). Afterward, you can use C-c C-q (`tex-show-print-queue`) to view the progress of your output towards being printed. If your terminal has the ability to display TeX output files, you can preview the output on the terminal with C-c C-v (`tex-view`).

You can specify the directory to use for running TeX by setting the variable `tex-directory`. `"."` is the default value. If your environment variable `TEXINPUTS` contains relative directory names, or if your files contains `\input' commands with relative file names, then `tex-directory` *must* be `"."` or you will get the wrong results. Otherwise, it is safe to specify some other directory, such as `"/tmp"`.

If you want to specify which shell commands are used in the inferior TeX, you can do so by setting the values of the variables `tex-run-command`, `latex-run-command`, `slitex-run-command`, `tex-dvi-print-command`, `tex-dvi-view-command`, and `tex-show-queue-command`. You *must* set the value of `tex-dvi-view-command` for your particular terminal; this variable has no default value. The other variables have default values that may (or may not) be appropriate for your system.

Normally, the file name given to these commands comes at the end of the command string; for example, `latex filename'. In some cases, however, the file name needs to be embedded in the command; an example is when you need to provide the file name as an argument to one command whose output is piped to another. You can specify where to put the file name with `*' in the command string. For example,

```
(setq tex-dvi-print-command "dvips -f * | lpr")
```

The terminal output from TeX, including any error messages, appears in a buffer called `*tex-shell*'. If TeX gets an error, you can switch to this buffer and feed it input (this works as in Shell mode; see section Interactive Inferior Shell). Without switching to this buffer you can scroll it so that its last line is visible by typing C-c C-l.

Type C-c C-k (`tex-kill-job`) to kill the TeX process if you see that its output is no longer useful. Using C-c C-b or C-c C-r also kills any TeX process still running.

You can also pass an arbitrary region through an inferior TeX by typing C-c C-r (`tex-region`). This is tricky, however, because most files of TeX input contain commands at the beginning to set parameters and define macros, without which no later part of the file will format correctly. To solve this problem,

C-c C-r allows you to designate a part of the file as containing essential commands; it is included bef the specified region as part of the input to TeX. The designated part of the file is called the header.

To indicate the bounds of the header in Plain TeX mode, you insert two special strings in the file. Insert `%**start of header' before the header, and `%**end of header' after it. Each string must appear entirely on one line, but there may be other text on the line before or after. The lines containing the two strings are included in the header. If `%**start of header' does not appear within the first 100 lines of the buffer, C-c C-r assumes that there is no header.

In LaTeX mode, the header begins with `\documentstyle' and ends with `\begin{document}'. These are commands that LaTeX requires you to use in any case, so nothing special needs to be done to identify the header.

The commands (`tex-buffer`) and (`tex-region`) do all of their work in a temporary directory, and do not have available any of the auxiliary files needed by TeX for cross-references; these commands are generally not suitable for running the final copy in which all of the cross-references need to be correct. When you want the auxiliary files, use C-c C-f (`tex-file`) which runs TeX on the current buffer's file, in that file's directory. Before TeX runs, you will be asked about saving any modified buffers. Generally, you need to use (`tex-file`) twice to get cross-references correct.

For LaTeX files, you can use BibTeX to process the auxiliary file for the current buffer's file. BibTeX looks up bibliographic citations in a data base and prepares the cited references for the bibliography section. The command C-c TAB (`tex-bibtex-file`) runs the shell command (`tex-bibtex-command`) to produce a `.bbl' file for the current buffer's file. Generally, you need to do C-c C-f (`tex-file`) once to generate the `.aux' file, then do C-c TAB (`tex-bibtex-file`), and then repeat C-c C-f (`tex-file`) twice more to get the cross-references correct.

Entering any kind of TeX mode runs the hooks `text-mode-hook` and `tex-mode-hook`. Then it runs either `plain-tex-mode-hook` or `latex-mode-hook`, whichever is appropriate. For SliTeX files, it calls `slitex-mode-hook`. Starting the TeX shell runs the hook `tex-shell-hook`. See section Hooks.

Unix TeX Distribution

TeX for Unix systems can be obtained from the University of Washington for a distribution fee.

To order a full distribution, specify whether you prefer 1/4 inch QIC-24 or 4mm DAT tape (9-track reel-to-reel is no longer available) and send $210.00 for a (tar or cpio) cartridge, payable to the University of Washington to:

```
Pierre MacKay
Department of Classics
Denny Hall, Mail Stop DH-10
University of Washington
Seattle, Washington 98195
```

Purchase orders are acceptable, but there is an extra charge of $10.00, to pay for processing charges.

For overseas orders please add $20.00 to the base cost for shipment via air parcel post, or $30.00 for shipment via courier.

The normal distribution is a tar tape, blocked 20, 1600 bpi, on an industry standard 2400 foot half-inch reel. The physical format for the 1/4 inch streamer cartridges is QIC-24. System V tapes can be written in cpio format, blocked 5120 bytes, with ASCII headers.

Nroff Mode

Nroff mode is a mode like Text mode but modified to handle nroff commands present in the text. Invoke M-x nroff-mode to enter this mode. It differs from Text mode in only a few ways. All nroff command lines are considered paragraph separators, so that filling will never garble the nroff commands. Pages are separated by `.bp' commands. Comments start with backslash-doublequote. Also, three special commands are provided that are not in Text mode:

M-n

Move to the beginning of the next line that isn't an nroff command (`forward-text-line`). An argument is a repeat count.

M-p

Like M-n but move up (`backward-text-line`).

M-?

Prints in the echo area the number of text lines (lines that are not nroff commands) in the region (`count-text-lines`).

The other feature of Nroff mode is that you can turn on Electric Nroff mode. This is a minor mode that you can turn on or off with M-x electric-nroff-mode (see section Minor Modes). When the mode is on, each time you use RET to end a line that contains an nroff command that opens a kind of grouping, the matching nroff command to close that grouping is automatically inserted on the following line. For example, if you are at the beginning of a line and type . (b RET, this inserts the matching command `.)b' on a new line following point.

If you use Outline minor mode with Nroff mode (see section Outline Mode), heading lines are lines of the form `.H' followed by a number (the header level).

Entering Nroff mode runs the hook `text-mode-hook`, followed by the hook `nroff-mode-hook` (see section Hooks).

Editing Formatted Text

Enriched mode is a minor mode for editing files that contain formatted text in WYSIWYG fashion, as in a word processor. Currently, formatted text in Enriched mode can specify fonts, colors, underlining, margins, and types of filling and justification. In the future, we plan to implement other formatting features as well.

Enriched mode is a minor mode (see section Minor Modes). Typically it is used in conjunction with Text

mode (see section Text Mode). However, you can also use it with other major modes such as Outline mode and Indented Text mode.

Potentially, Emacs can store formatted text files in various file formats. Currently, only one format is implemented: text/enriched format, which is defined by the MIME protocol. See section 'Format Conversion' in the Emacs Lisp Reference Manual, for details of how Emacs recognizes and converts file formats.

The Emacs distribution contains a formatted text file that can serve as an example. Its name is `etc/enriched.doc'. It contains samples illustrating all the features described in this section. It also contains a list of ideas for future enhancements.

Requesting to Edit Formatted Text

Whenever you visit a file that Emacs saved in the text/enriched format, Emacs automatically converts the formatting information in the file into Emacs's own internal format (text properties), and turns on Enriched mode.

To create a new file of formatted text, first visit the nonexistent file, then type M-x enriched-mode before you start inserting text. This command turns on Enriched mode. Do this before you begin inserting text, to ensure that the text you insert is handled properly.

More generally, the command `enriched-mode` turns Enriched mode on if it was off, and off if it was on. With a prefix argument, this command turns Enriched mode on if the argument is positive, and turns the mode off otherwise.

When you save a buffer while Enriched mode is enabled in it, Emacs automatically converts the text to text/enriched format while writing it into the file. When you visit the file again, Emacs will automatically recognize the format, reconvert the text, and turn on Enriched mode again.

Normally, after reading a file in text/enriched format, Emacs refills each paragraph to fit the width of the window. You can turn off this refilling, to save time, by setting the variable `enriched-fill-after-visiting` to `nil` or to `ask`.

In any case, if the window width is the same as the width with which the file was saved, Emacs trusts that the file is already properly filled.

You can add annotations for saving additional text properties, which Emacs normally does not save, by adding to `enriched-translations`. Note that the text/enriched standard requires any non-standard annotations to have names starting with `x-', as in `x-read-only'. This ensures that they will not conflict with standard annotations that may be added later.

Hard and Soft Newlines

In formatted text, Emacs distinguishes between two different kinds of newlines, hard newlines and soft newlines.

Hard newlines are used to separate paragraphs, or items in a list, or anywhere that there should always be

a line break regardless of the margins. The RET command (`newline`) and C-o (`open-line`) insert hard newlines.

Soft newlines are used to make text fit between the margins. All the fill commands, including Auto Fill, insert soft newlines--and they delete only soft newlines.

Although hard and soft newlines look the same, it is important to bear the difference in mind. Do not use RET to break lines in the middle of filled paragraphs, or else you will get hard newlines that are barriers to further filling. Instead, let Auto Fill mode break lines, so that if the text or the margins change, Emacs can refill the lines properly. See section Auto Fill Mode.

On the other hand, in tables and lists, where the lines should always remain as you type them, you can use RET to end lines. For these lines, you may also want to set the justification style to `unfilled`. See section Justification in Formatted Text.

Editing Format Information

There are two ways to alter the formatting information for a formatted text file: with keyboard commands, and with the mouse.

The easiest way to add properties to your document is by using the Text Properties menu. You can get to this menu in two ways: from the Edit menu in the menu bar, or with C-mouse-2 (hold the CTRL key and press the middle mouse button).

Most of the items in the Text Properties menu lead to other submenus. These are described in the sections that follow. Some items run commands directly:

`Remove Properties`
: Delete from the region all the text properties that the Text Properties menu works with (`facemenu-remove-props`).

`Remove All`
: Delete *all* text properties from the region (`facemenu-remove-all`).

`List Properties`
: List all the text properties of the character following point (`list-text-properties-at`).

`Display Faces`
: Display a list of all the defined faces.

`Display Colors`
: Display a list of all the defined colors.

Faces in Formatted Text

The Faces submenu lists various Emacs faces including `bold`, `italic`, and `underline`. Selecting one of these adds the chosen face to the region. See section Using Multiple Typefaces. You can also specify a face with these keyboard commands:

M-g d

Set the region, or the next inserted character, to the `default` face (`facemenu-set-default`).

M-g b

Set the region, or the next inserted character, to the `bold` face (`facemenu-set-bold`).

M-g i

Set the region, or the next inserted character, to the `italic` face (`facemenu-set-italic`).

M-g l

Set the region, or the next inserted character, to the `bold-italic` face (`facemenu-set-bold-italic`).

M-g u

Set the region, or the next inserted character, to the `underline` face (`facemenu-set-underline`).

M-g o face RET

Set the region, or the next inserted character, to the face face (`facemenu-set-face`).

If you use these commands with a prefix argument--or, in Transient Mark mode, if the region is not active--then these commands specify a face to use for your next self-inserting input. See section Transient Mark Mode. This applies to both the keyboard commands and the menu commands.

Enriched mode defines two additional faces: `excerpt` and `fixed`. These correspond to codes used in the text/enriched file format.

The `excerpt` face is intended for quotations. This face is the same as `italic` unless you customize it (see section Modifying Faces).

The `fixed` face is meant to say, "Use a fixed-width font for this part of the text." Emacs currently supports only fixed-width fonts; therefore, the `fixed` annotation is not necessary now. However, we plan to support variable width fonts in future Emacs versions, and other systems that display text/enriched format may not use a fixed-width font as the default. So if you specifically want a certain part of the text to use a fixed-width font, you should specify the `fixed` face for that part.

The `fixed` face is normally defined to use a different font from the default. However, systems have different fonts installed, you may need to customize this.

If your terminal cannot display different faces, you will not be able to see them, but you can still edit documents containing faces. You can even add faces and colors to documents. They will be visible when the file is viewed on a terminal that can display them.

Colors in Formatted Text

You can specify foreground and background colors for portions of the text. There is a menu for specifying the foreground color and a menu for specifying the background color. Each color menu lists all the colors that you have used in Enriched mode in the current Emacs session.

If you specify a color with a prefix argument--or, in Transient Mark mode, if the region is not

active--then it applies to your next self-inserting input. See section Transient Mark Mode. Otherwise command applies to the region.

Each color menu contains one additional item: `Other'. You can use this item to specify a color that is not listed in the menu; it reads the color name with the minibuffer. To display list of available colors and their names, use the `Display Colors' menu item in the Text Properties menu (see section Editing Format Information).

Any color that you specify in this way, or that is mentioned in a formatted text file that you read in, is added to both color menus for the duration of the Emacs session.

There are no key bindings for specifying colors, but you can do so with the extended commands M-x facemenu-set-foreground and M-x facemenu-set-background. Both of these commands read the name of the color with the minibuffer.

Indentation in Formatted Text

When editing formatted text, you can specify different amounts of indentation for the right or left margin of an entire paragraph or a part of a paragraph. The margins you specify automatically affect the Emacs fill commands (see section Filling Text) and line-breaking commands.

The Indentation submenu provides a convenient interface for specifying these properties. The submenu contains four items:

`Indent More`

Indent the region by 4 columns (`increase-left-margin`). In Enriched mode, this command is also available on C-x TAB; if you supply a numeric argument, that says how many columns to add to the margin (a negative argument reduces the number of columns).

`Indent Less`

Remove 4 columns of indentation from the region.

`Indent Right More`

Make the text narrower by indenting 4 columns at the right margin.

`Indent Right Less`

Remove 4 columns of indentation from the right margin.

You can use these commands repeatedly to increase or decrease the indentation.

The most common way to use these commands is to change the indentation of an entire paragraph. However, that is not the only use. You can change the margins at any point; the new values take effect at the end of the line (for right margins) or the beginning of the next line (for left margins).

This makes it possible to format paragraphs with hanging indents, which means that the first line is indented less than subsequent lines. To set up a hanging indent, increase the indentation of the region starting after the first word of the paragraph and running until the end of the paragraph.

Indenting the first line of a paragraph is easier. Set the margin for the whole paragraph where you want it to be for the body of the paragraph, then indent the first line by inserting extra spaces or tabs.

Sometimes, as a result of editing, the filling of a paragraph becomes messed up--parts of the paragraph may extend past the left or right margins. When this happens, use M-q (`fill-paragraph`) to refill the paragraph.

The variable `standard-indent` specifies how many columns these commands should add to or subtract from the indentation. The default value is 4.

Enriched mode automatically sets the variable `fill-column` based on the window width: it leaves a certain number of columns for the right margin. The variable `enriched-default-right-margin` says how many columns. The default value is 10.

Justification in Formatted Text

When editing formatted text, you can specify various styles of justification for a paragraph. The style you specify automatically affects the Emacs fill commands.

The Justification submenu provides a convenient interface for specifying the style. The submenu contains five items:

`Flush Left`

This is the most common style of justification (at least for English). Lines are aligned at the left margin but left uneven at the right.

`Flush Right`

This aligns each line with the right margin. Spaces and tabs are added on the left, if necessary, to make lines line up on the right.

`Full`

This justifies the text, aligning both edges of each line. Justified text looks very nice in a printed book, where the spaces can all be adjusted equally, but it does not look as nice with a fixed-width font on the screen. Perhaps a future version of Emacs will be able to adjust the width of spaces in a line to achieve elegant justification.

`Center`

This centers every line between the current margins.

`None`

This turns off filling entirely. Each line will remain as you wrote it; the fill and auto-fill functions will have no effect on text which has this setting. You can, however, still indent the left margin. In unfilled regions, all newlines are treated as hard newlines (see section Hard and Soft Newlines) .

In Enriched mode, you can also specify justification from the keyboard using the M-j prefix character:

M-j l

Make the region left-filled (`set-justification-left`).

M-j r

Make the region right-filled (`set-justification-right`).

M-j f

Make the region fully-justified (`set-justification-full`).

M-j c

M-S

Make the region centered (`set-justification-center`).

M-j u

Make the region unfilled (`set-justification-none`).

Justification styles apply to entire paragraphs. All the justification-changing commands operate on the paragraph containing point, or, if the region is active, on all paragraphs which overlap the region.

The default justification style is specified by the variable `default-justification`. Its value should be one of the symbols `left`, `right`, `full`, `center`, or `none`.

Setting Other Text Properties

The Other Properties menu lets you add or remove three other useful text properties: `read-only`, `invisible` and `intangible`. The `intangible` property disallows moving point within the text, the `invisible` text property hides text from display, and the `read-only` property disallows alteration of the text.

Each of these special properties has a menu item to add it to the region. The last menu item, `Remove Special', removes all of these special properties from the text in the region.

Currently, the `invisible` and `intangible` properties are *not* saved in the text/enriched format. The `read-only` property is saved, but it is not a standard part of the text/enriched format, so other editors may not respect it.

Forcing Enriched Mode

Normally, Emacs knows when you are editing formatted text because it recognizes the special annotations used in the file that you visited. However, there are situations in which you must take special actions to convert file contents or turn on Enriched mode:

- When you visit a file that was created with some other editor, Emacs may not recognize the file as being in the text/enriched format. In this case, when you visit the file you will see the formatting commands rather than the formatted text. Type M-x format-decode-buffer to translate it.
- When you *insert* a file into a buffer, rather than visiting it. Emacs does the necessary conversions on the text which you insert, but it does not enable Enriched mode. If you wish to do that, type M-x enriched-mode.

The command `format-decode-buffer` translates text in various formats into Emacs's internal format. It asks you to specify the format to translate from; however, normally you can type just RET, which tells Emacs to guess the format.

If you wish to look at a file in text/enriched format in its raw form, as a sequence of characters with no formatting, use M-x format-find-file RET filename RET RET. The empty second argument means, "read without format conversion."

Go to the previous, next section.

Editing Programs

Emacs has many commands designed to understand the syntax of programming languages such as Lisp and C. These commands can

- Move over or kill balanced expressions or sexps (see section Lists and Sexps).
- Move over or mark top-level expressions---defuns, in Lisp; functions, in C (see section Defuns).
- Show how parentheses balance (see section Automatic Display Of Matching Parentheses).
- Insert, kill or align comments (see section Manipulating Comments).
- Follow the usual indentation conventions of the language (see section Indentation for Programs).

The commands for words, sentences and paragraphs are very useful in editing code even though their canonical application is for editing human language text. Most symbols contain words (see section Words); sentences can be found in strings and comments (see section Sentences). Paragraphs per se don't exist in code, but the paragraph commands are useful anyway, because programming language major modes define paragraphs to begin and end at blank lines (see section Paragraphs). Judicious use of blank lines to make the program clearer will also provide useful chunks of text for the paragraph commands to work on.

The selective display feature is useful for looking at the overall structure of a function (see section Selective Display). This feature causes only the lines that are indented less than a specified amount to appear on the screen.

Major Modes for Programming Languages

Emacs also has major modes for the programming languages Lisp, Scheme (a variant of Lisp), Awk, C, C++, Fortran, Icon, Java, Objective-C, Pascal, Perl and Tcl. There is also a major mode for makefiles, called Makefile mode.

Ideally, a major mode should be implemented for each programming language that you might want to edit with Emacs; but often the mode for one language can serve for other syntactically similar languages. The language modes that exist are those that someone decided to take the trouble to write.

There are several forms of Lisp mode, which differ in the way they interface to Lisp execution. See section Executing Lisp Expressions.

Each of the programming language modes defines the TAB key to run an indentation function that knows the indentation conventions of that language and updates the current line's indentation accordingly. For example, in C mode TAB is bound to `c-indent-line`. LFD is normally defined to do RET followed by TAB; thus, it too indents in a mode-specific fashion.

In most programming languages, indentation is likely to vary from line to line. So the major modes for

those languages rebind DEL to treat a tab as if it were the equivalent number of spaces (using the command `backward-delete-char-untabify`). This makes it possible to rub out indentation one column at a time without worrying whether it is made up of spaces or tabs. Use C-b C-d to delete a tab character before point, in these modes.

Programming language modes define paragraphs to be separated only by blank lines, so that the paragraph commands remain useful. Auto Fill mode, if enabled in a programming language major mode, indents the new lines which it creates.

Turning on a major mode runs a normal hook called the mode hook, which is the value of a Lisp variable. Each major mode has a mode hook, and the hook's name is always made from the mode command's name by adding `-hook'. For example, turning on C mode runs the hook `c-mode-hook`, while turning on Lisp mode runs the hook `lisp-mode-hook`. See section Hooks.

Lists and Sexps

By convention, Emacs keys for dealing with balanced expressions are usually Control-Meta characters. They tend to be analogous in function to their Control and Meta equivalents. These commands are usually thought of as pertaining to expressions in programming languages, but can be useful with any language in which some sort of parentheses exist (including human languages).

These commands fall into two classes. Some deal only with lists (parenthetical groupings). They see nothing except parentheses, brackets, braces (whichever ones must balance in the language you are working with), and escape characters that might be used to quote those.

The other commands deal with expressions or sexps. The word `sexp' is derived from s-expression, the ancient term for an expression in Lisp. But in Emacs, the notion of `sexp' is not limited to Lisp. It refers to an expression in whatever language your program is written in. Each programming language has its own major mode, which customizes the syntax tables so that expressions in that language count as sexps.

Sexps typically include symbols, numbers, and string constants, as well as anything contained in parentheses, brackets or braces.

In languages that use prefix and infix operators, such as C, it is not possible for all expressions to be sexps. For example, C mode does not recognize `foo + bar' as a sexp, even though it *is* a C expression; it recognizes `foo' as one sexp and `bar' as another, with the `+' as punctuation between them. This is a fundamental ambiguity: both `foo + bar' and `foo' are legitimate choices for the sexp to move over if point is at the `f'. Note that `(foo + bar)' is a single sexp in C mode.

Some languages have obscure forms of expression syntax that nobody has bothered to make Emacs understand properly.

List And Sexp Commands

C-M-f

Move forward over a sexp (`forward-sexp`).

C-M-b
: Move backward over a sexp (`backward-sexp`).

C-M-k
: Kill sexp forward (`kill-sexp`).

C-M-DEL
: Kill sexp backward (`backward-kill-sexp`).

C-M-u
: Move up and backward in list structure (`backward-up-list`).

C-M-d
: Move down and forward in list structure (`down-list`).

C-M-n
: Move forward over a list (`forward-list`).

C-M-p
: Move backward over a list (`backward-list`).

C-M-t
: Transpose expressions (`transpose-sexps`).

C-M-@
: Put mark after following expression (`mark-sexp`).

To move forward over a sexp, use C-M-f (`forward-sexp`). If the first significant character after point is an opening delimiter (`(' in Lisp; `(', `[' or `{' in C), C-M-f moves past the matching closing delimiter. If the character begins a symbol, string, or number, C-M-f moves over that.

The command C-M-b (`backward-sexp`) moves backward over a sexp. The detailed rules are like those above for C-M-f, but with directions reversed. If there are any prefix characters (single-quote, backquote and comma, in Lisp) preceding the sexp, C-M-b moves back over them as well. The sexp commands move across comments as if they were whitespace in most modes.

C-M-f or C-M-b with an argument repeats that operation the specified number of times; with a negative argument, it moves in the opposite direction.

Killing a sexp at a time can be done with C-M-k (`kill-sexp`) or C-M-DEL (`backward-kill-sexp`). C-M-k kills the characters that C-M-f would move over, and C-M-DEL kills the characters that C-M-b would move over.

The list commands move over lists like the sexp commands but skip blithely over any number of other kinds of sexps (symbols, strings, etc). They are C-M-n (`forward-list`) and C-M-p (`backward-list`). The main reason they are useful is that they usually ignore comments (since the comments usually do not contain any lists).

C-M-n and C-M-p stay at the same level in parentheses, when that's possible. To move *up* one (or n) levels, use C-M-u (`backward-up-list`). C-M-u moves backward up past one unmatched opening delimiter. A positive argument serves as a repeat count; a negative argument reverses direction of motion

and also requests repetition, so it moves forward and up one or more levels.

To move *down* in list structure, use C-M-d (`down-list`). In Lisp mode, where `(' is the only opening delimiter, this is nearly the same as searching for a `('. An argument specifies the number of levels of parentheses to go down.

A somewhat random-sounding command which is nevertheless handy is C-M-t (`transpose-sexps`), which drags the previous sexp across the next one. An argument serves as a repeat count, and a negative argument drags backwards (thus canceling out the effect of C-M-t with a positive argument). An argument of zero, rather than doing nothing, transposes the sexps ending after point and the mark.

To set the region around the next sexp in the buffer, use C-M-@ (`mark-sexp`), which sets mark at the same place that C-M-f would move to. C-M-@ takes arguments like C-M-f. In particular, a negative argument is useful for putting the mark at the beginning of the previous sexp.

The list and sexp commands' understanding of syntax is completely controlled by the syntax table. Any character can, for example, be declared to be an opening delimiter and act like an open parenthesis. See section The Syntax Table.

Defuns

In Emacs, a parenthetical grouping at the top level in the buffer is called a defun. The name derives from the fact that most top-level lists in a Lisp file are instances of the special form `defun`, but any top-level parenthetical grouping counts as a defun in Emacs parlance regardless of what its contents are, and regardless of the programming language in use. For example, in C, the body of a function definition is a defun.

C-M-a
: Move to beginning of current or preceding defun (`beginning-of-defun`).

C-M-e
: Move to end of current or following defun (`end-of-defun`).

C-M-h
: Put region around whole current or following defun (`mark-defun`).

The commands to move to the beginning and end of the current defun are C-M-a (`beginning-of-defun`) and C-M-e (`end-of-defun`).

If you wish to operate on the current defun, use C-M-h (`mark-defun`) which puts point at the beginning and mark at the end of the current or next defun. For example, this is the easiest way to get ready to move the defun to a different place in the text. In C mode, C-M-h runs the function `mark-c-function`, which is almost the same as `mark-defun`; the difference is that it backs up over the argument declarations, function name and returned data type so that the entire C function is inside the region. See section Commands to Mark Textual Objects.

Emacs assumes that any open-parenthesis found in the leftmost column is the start of a defun. Therefore, **never put an open-parenthesis at the left margin in a Lisp file unless it is the start of a top level list. Never put an open-brace or other opening delimiter at the beginning of a line of C code unless it**

starts the body of a function. The most likely problem case is when you want an opening delimiter at the start of a line inside a string. To avoid trouble, put an escape character (`\', in C and Emacs Lisp, some other Lisp dialects) before the opening delimiter. It will not affect the contents of the string.

In the remotest past, the original Emacs found defuns by moving upward a level of parentheses until there were no more levels to go up. This always required scanning all the way back to the beginning of the buffer, even for a small function. To speed up the operation, Emacs was changed to assume that any `(' (or other character assigned the syntactic class of opening-delimiter) at the left margin is the start of a defun. This heuristic is nearly always right and avoids the costly scan; however, it mandates the convention described above.

Indentation for Programs

The best way to keep a program properly indented is to use Emacs to re-indent it as you change it. Emacs has commands to indent properly either a single line, a specified number of lines, or all of the lines inside a single parenthetical grouping.

Emacs also provides a Lisp pretty-printer in the library `pp`. This program prints a Lisp object with indentation chosen to look nice.

Basic Program Indentation Commands

TAB
: Adjust indentation of current line.

LFD
: Equivalent to RET followed by TAB (`newline-and-indent`).

The basic indentation command is TAB, which gives the current line the correct indentation as determined from the previous lines. The function that TAB runs depends on the major mode; it is `lisp-indent-line` in Lisp mode, `c-indent-line` in C mode, etc. These functions understand different syntaxes for different languages, but they all do about the same thing. TAB in any programming language major mode inserts or deletes whitespace at the beginning of the current line, independent of where point is in the line. If point is inside the whitespace at the beginning of the line, TAB leaves it at the end of that whitespace; otherwise, TAB leaves point fixed with respect to the characters around it.

Use C-q TAB to insert a tab at point.

When entering lines of new code, use LFD (`newline-and-indent`), which is equivalent to a RET followed by a TAB. LFD creates a blank line, and then gives it the appropriate indentation.

TAB indents the second and following lines of the body of a parenthetical grouping each under the preceding one; therefore, if you alter one line's indentation to be nonstandard, the lines below will tend to follow it. This behavior is convenient in cases where you have overridden the standard result of TAB because you find it unaesthetic for a particular line.

Remember that an open-parenthesis, open-brace or other opening delimiter at the left margin is assumed

by Emacs (including the indentation routines) to be the start of a function. Therefore, you must never have an opening delimiter in column zero that is not the beginning of a function, not even inside a string. This restriction is vital for making the indentation commands fast; you must simply accept it. See section Defuns, for more information on this.

Indenting Several Lines

When you wish to re-indent several lines of code which have been altered or moved to a different level in the list structure, you have several commands available.

C-M-q

Re-indent all the lines within one list (`indent-sexp`).

C-u TAB

Shift an entire list rigidly sideways so that its first line is properly indented.

C-M-\

Re-indent all lines in the region (`indent-region`).

You can re-indent the contents of a single list by positioning point before the beginning of it and typing C-M-q (`indent-sexp` in Lisp mode, `indent-c-exp` in C mode; also bound to other suitable commands in other modes). The indentation of the line the sexp starts on is not changed; therefore, only the relative indentation within the list, and not its position, is changed. To correct the position as well, type a TAB before the C-M-q.

If the relative indentation within a list is correct but the indentation of its first line is not, go to that line and type C-u TAB. TAB with a numeric argument reindents the current line as usual, then reindents by the same amount all the lines in the grouping starting on the current line. In other words, it reindents the whole grouping rigidly as a unit. It is clever, though, and does not alter lines that start inside strings, or C preprocessor lines when in C mode.

Another way to specify the range to be re-indented is with the region. The command C-M-\ (`indent-region`) applies TAB to every line whose first character is between point and mark.

Customizing Lisp Indentation

The indentation pattern for a Lisp expression can depend on the function called by the expression. For each Lisp function, you can choose among several predefined patterns of indentation, or define an arbitrary one with a Lisp program.

The standard pattern of indentation is as follows: the second line of the expression is indented under the first argument, if that is on the same line as the beginning of the expression; otherwise, the second line is indented underneath the function name. Each following line is indented under the previous line whose nesting depth is the same.

If the variable `lisp-indent-offset` is non-`nil`, it overrides the usual indentation pattern for the second line of an expression, so that such lines are always indented `lisp-indent-offset` more columns than the containing list.

The standard pattern is overridden for certain functions. Functions whose names start with `def` alwa indent the second line by `lisp-body-indent` extra columns beyond the open-parenthesis startin expression.

The standard pattern can be overridden in various ways for individual functions, according to the `lisp-indent-function` property of the function name. There are four possibilities for this property:

`nil`

This is the same as no property; the standard indentation pattern is used.

`defun`

The pattern used for function names that start with `def` is used for this function also.

a number, number

The first number arguments of the function are distinguished arguments; the rest are considered the body of the expression. A line in the expression is indented according to whether the first argument on it is distinguished or not. If the argument is part of the body, the line is indented `lisp-body-indent` more columns than the open-parenthesis starting the containing expression. If the argument is distinguished and is either the first or second argument, it is indented *twice* that many extra columns. If the argument is distinguished and not the first or second argument, the standard pattern is followed for that line.

a symbol, symbol

symbol should be a function name; that function is called to calculate the indentation of a line within this expression. The function receives two arguments:

state

The value returned by `parse-partial-sexp` (a Lisp primitive for indentation and nesting computation) when it parses up to the beginning of this line.

pos

The position at which the line being indented begins.

It should return either a number, which is the number of columns of indentation for that line, or a list whose car is such a number. The difference between returning a number and returning a list is that a number says that all following lines at the same nesting level should be indented just like this one; a list says that following lines might call for different indentations. This makes a difference when the indentation is being computed by C-M-q; if the value is a number, C-M-q need not recalculate indentation for the following lines until the end of the list.

Commands for C Indentation

Here are the commands for indentation in C mode and related modes:

`C-c C-q`

Reindent the current top-level function definition or aggregate type declaration (`c-indent-defun`).

`C-M-q`

Reindent each line in the balanced expression that follows point (`c-indent-exp`). A prefix argument inhibits error checking and warning messages about invalid syntax.

`TAB`

Reindent the current line, and/or in some cases insert a tab character (`c-indent-command`).

If `c-tab-always-indent` is `t`, this command always reindents the current line and does nothing else. This is the default.

If that variable is `nil`, this command reindents the current line only if point is at the left margin or in the line's indentation; otherwise, it inserts a tab.

Any other value (not `nil` or `t`) means always reindent the line, and also insert a tab if within a comment, a string, or a preprocessor directive.

`C-u TAB`

Reindent the current line according to its syntax; also rigidly reindent any other lines of the expression that starts on the current line. See section Indenting Several Lines.

To reindent the whole current buffer, type C-x h C-M-\. This first selects the whole buffer as the region, then reindents that region.

To reindent the current block, use C-M-u C-M-q. This moves to the front of the block and then reindents it all.

Customizing C Indentation

C mode and related modes use a simple yet flexible mechanism for customizing indentation. The mechanism works in two steps: first it classifies the line syntactically according to its contents and context; second, it associates each kind of syntactic construct with an indentation offset which you can customize.

Step 1--Syntactic Analysis

In the first step, the C indentation mechanism looks at the line you are currently indenting and determines the syntactic components of the construct on that line. It builds a list of these syntactic components, where each component on the list contains a syntactic symbol and a relative buffer position. Syntactic symbols describe grammatical elements such as statement, substatement, class-open, class-close, knr-argdecl, etc.

Conceptually, a line of C code is always indented relative to the indentation of some line higher up in the buffer. This is represented by the relative buffer positions in the syntactic component list.

Here is an example. Suppose we have the following code in a C++ mode buffer (the line numbers don't actually appear in the buffer):

```
1: void swap (int& a, int& b)
2: {
3:   int tmp = a;
```

```
4:    a = b;
5:    b = tmp;
6: }
```

If you type C-c C-s (which runs the command `c-show-syntactic-information`) on line 4, it shows the result of the indentation mechanism for that line:

```
((statement . 32))
```

This indicates that the line is a statement and it is indented relative to buffer position 32, which happens to be the `i' in `int` on line 3. If you move the cursor to line 3 and type C-c C-s, it displays this:

```
((defun-block-intro . 28))
```

This indicates that the `int` line is the first statement in a block, and is indented relative to buffer position 28, which is the brace just after the function header.

Here is another example:

```
1: int add (int val, int incr, int doit)
2: {
3:   if (doit)
4:     {
5:       return (val + incr);
6:     }
7:   return (val);
8: }
```

Typing C-c C-s on line 4 displays this:

```
((substatement-open . 43))
```

This says that the brace *opens* a substatement block. By the way, a substatement indicates the line after an `if`, `else`, `while`, `do`, `switch`, and `for` statements.

After a line has been analyzed syntactically for indentation, the global variable `c-syntactic-context` contains a list that describes the results. Each element in this list is a a syntactic component: a cons cell containing a syntactic symbol and (optionally) its corresponding buffer position. There may be several elements in a component list; typically only one element has a buffer position.

Step 2--Indentation Calculation

The C indentation mechanism calculates the indentation for the current line using the list of syntactic components, `c-syntactic-context`, derived from syntactic analysis. Each component is a cons cell that contains a syntactic symbol and may also contain a pointer to a location in the buffer.

Each component contributes to the final total indentation of the line in two ways. First, the syntactic

symbol identifies an element of `c-offsets-alist`, which is an association list mapping syntacti symbols into indentation offsets. Each syntactic symbol's offset adds to the total indentation. Second, if the component includes a buffer position, the column number of that position adds to the indentation. All these offsets and column numbers, added together, give the total indentation.

The following examples demonstrate the workings of the C indentation mechanism:

```
1: void swap (int& a, int& b)
2: {
3:   int tmp = a;
4:   a = b;
5:   b = tmp;
6: }
```

Suppose that point is on line 3 and you type TAB to reindent the line. As explained above (see section Step 1--Syntactic Analysis), the syntactic component list for that line is:

```
((defun-block-intro . 28))
```

In this case, the indentation calculation first looks up `defun-block-intro` in the `c-offsets-alist` alist. Suppose that it finds the integer 2; it adds this to the running total (initialized to zero), yielding a updated total indentation of 2 spaces.

The next step is to find the column number of buffer position 28. Since the brace at buffer position 28 is in column zero, this adds 0 to the running total. Since this line has only one syntactic component, the total indentation for the line is 2 spaces.

```
1: int add (int val, int incr, int doit)
2: {
3:   if (doit)
4:     {
5:       return(val + incr);
6:     }
7:   return(val);
8: }
```

If you type TAB on line 4, the same process is performed, but with different data. The syntactic component list for this line is:

```
((substatement-open . 43))
```

Here, the indentation calculation's first job is to look up the symbol `substatement-open` in `c-offsets-alist`. Let's assume that the offset for this symbol is 2. At this point the running total is 2 (0 + 2 = 2). Then it adds the column number of buffer position 43, which is the `i' in `if` on line 3. This character is in column 2 on that line. Adding this yields a total indentation of 4 spaces.

If a syntactic symbol in the analysis of a line does not appear in `c-offsets-alist`, it is ignored; if in

addition the variable `c-strict-syntax-p` is non-`nil`, it is an error.

Changing Indentation Style

There are two ways to customize the indentation style for the C modes. First, you can select one of several predefined styles, each of which specifies offsets for all the syntactic symbols. For more flexibility, you can customize the handling of individual syntactic symbols. See section Syntactic Symbols, for a list of all defined syntactic symbols.

M-x c-set-style RET style RET

> Select predefined indentation style style. Type ? when entering style to see a list of supported styles; to find out what a style looks like, select it and reindent some C code.

C-c C-o symbol RET offset RET

> Set the indentation offset for syntactic symbol symbol (`c-set-offset`). The second argument offset specifies the new indentation offset.

The `c-offsets-alist` variable controls the amount of indentation to give to each syntactic symbol. Its value is an association list, and each element of the list has the form `(syntactic-symbol . offset)`. By changing the offsets for various syntactic symbols, you can customize indentation in fine detail.

Each offset value in `c-offsets-alist` can be an integer, a function or variable name, or one of the following symbols: `+`, `-`, `++`, or `--`, indicating positive or negative multiples of the variable `c-basic-offset`. Thus, if you want to change the levels of indentation to be 3 spaces instead of 2 spaces, set `c-basic-offset` to 3.

Using a function as the offset value provides the ultimate flexibility in customizing indentation. The function is called with a single argument containing the `cons` of the syntactic symbol and the relative indent point. The function should return an integer offset.

The command C-c C-o (`c-set-offset`) is the easiest way to set offsets, both interactively or in your `` `~/.emacs' `` file. First specify the syntactic symbol, then the offset you want. See section Syntactic Symbols, for a list of valid syntactic symbols and their meanings.

The variable `c-offsets-alist-default` holds the default settings for the offsets of the syntactic symbols. *Do not change this value!*

Syntactic Symbols

Here is a table of valid syntactic symbols for C mode indentation, with their syntactic meanings. Normally, most of these symbols are assigned offsets in `c-offsets-alist`.

`string`

> Inside a multi-line string.

`c`

> Inside a multi-line C style block comment.

`defun-open`

On a brace that opens a function definition.

`defun-close`
: On a brace that closes a function definition.

`defun-block-intro`
: In the first line in a top-level defun.

`class-open`
: On a brace that opens a class definition.

`class-close`
: On a brace that closes a class definition.

`inline-open`
: On a brace that opens an in-class inline method.

`inline-close`
: On a brace that closes an in-class inline method.

`ansi-funcdecl-cont`
: In the nether region between an ANSI function declaration and the defun opening brace.

`knr-argdecl-intro`
: On the first line of a K&R C argument declaration.

`knr-argdecl`
: In one of the subsequent lines in a K&R C argument declaration.

`topmost-intro`
: On the first line in a topmost construct definition.

`topmost-intro-cont`
: On the topmost definition continuation lines.

`member-init-intro`
: On the first line in a member initialization list.

`member-init-cont`
: On one of the subsequent member initialization list lines.

`inher-intro`
: On the first line of a multiple inheritance list.

`inher-cont`
: On one of the subsequent multiple inheritance lines.

`block-open`
: On a statement block open brace.

`block-close`
: On a statement block close brace.

`brace-list-open`

On the opening brace of an `enum` or `static` array list.

`brace-list-close`
: On the closing brace of an `enum` or `static` array list.

`brace-list-intro`
: On the first line in an `enum` or `static` array list.

`brace-list-entry`
: On one of the subsequent lines in an `enum` or `static` array list.

`statement`
: On an ordinary statement.

`statement-cont`
: On a continuation line of a statement.

`statement-block-intro`
: On the first line in a new statement block.

`statement-case-intro`
: On the first line in a `case` "block".

`statement-case-open`
: On the first line in a `case` block starting with brace.

`substatement`
: On the first line after an `if`, `while`, `for`, `do`, or `else`.

`substatement-open`
: On the brace that opens a substatement block.

`case-label`
: On a `case` or `default` label.

`access-label`
: On a C++ `private`, `protected`, or `public` access label.

`label`
: On any ordinary label.

`do-while-closure`
: On the `while` that ends a `do-while` construct.

`else-clause`
: On the `else` of an `if-else` construct.

`comment-intro`
: On a line containing only a comment introduction.

`arglist-intro`
: On the first line in an argument list.

`arglist-cont`

On one of the subsequent argument list lines when no arguments follow on the same line as th arglist opening parenthesis.

`arglist-cont-nonempty`

On one of the subsequent argument list lines when at least one argument follows on the same line as the arglist opening parenthesis.

`arglist-close`

On the closing parenthesis of an argument list.

`stream-op`

On one of the lines continuing a stream operator construct.

`inclass`

On a construct which is nested inside a class definition.

`cpp-macro`

On the start of a cpp macro.

`friend`

On a C++ `friend` declaration.

`objc-method-intro`

On the first line of an Objective-C method definition.

`objc-method-args-cont`

On one of the lines continuing an Objective-C method definition.

`objc-method-call-cont`

On one of the lines continuing an Objective-C method call.

Variables for C Indentation

This section describes additional variables which control the indentation behavior of C mode and related mode.

`c-offsets-alist`

Association list of syntactic symbols and their indentation offsets. See section Changing Indentation Style, for details.

`c-offsets-alist-default`

Default settings for the offsets of the syntactic symbols. See section Changing Indentation Style.

`c-style-alist`

Variable for specifying styles of indentation; see below.

`c-basic-offset`

Amount of basic offset used by `+` and `-` symbols in `c-offsets-alist`.

`c-recognize-knr-p`

If this variable is non-`nil`, C mode and Objective C mode recognize K&R constructs. This variable is needed because of ambiguities in C syntax that make recognition of K&R constructs

problematic and slow. If you always use ANSI C prototype syntax, set this variable to `nil` to speed up C indentation.

This variable is `nil` by default in C++ mode, and `t` by default in C mode and Objective C mode.

`c-special-indent-hook`

Hook for user-defined special indentation adjustments. This hook is called after a line is indented by C mode and related modes.

The variable `c-style-alist` specifies the predefined indentation styles. Each element has form `(name variable-setting...)`, where name is the name of the style. Each variable-setting has the form `(variable . value)`; variable is one of the customization variables used by C mode, and value is the value for that variable when using the selected style.

When variable is `c-offsets-alist`, that is a special case: value is appended to the front of the value of `c-offsets-alist` instead of replacing that value outright. Therefore, it is not necessary for value to specify each and every syntactic symbol--only those for which the style differs from the default.

The indentation of lines containing only comments is also affected by the variable `c-comment-only-line-offset` (see section Comments in C Modes).

C Indentation Styles

A C style is a collection of indentation style customizations. Emacs comes with several predefined indentation styles for C code including `gnu`, `k&r`, `bsd`, `stroustrup` `whitesmith`, `ellemtel`, and `cc-mode`. The default style is `gnu`.

To choose the style you want, use the command M-x c-set-style. Specify a style name as an argument (case is not significant in C style names). The chosen style only affects newly visited buffers, not those you are already editing.

To define a new C indentation style, call the function `c-add-style`:

```
(c-add-style name values use-now)
```

Here name is the name of the new style (a string), and values is an alist whose elements have the form `(variable . value)`. The variables you specify should be among those documented in section Variables for C Indentation.

If use-now is non-`nil`, `c-add-style` switches to the new style after defining it.

Automatic Display Of Matching Parentheses

The Emacs parenthesis-matching feature is designed to show automatically how parentheses match in the text. Whenever you type a self-inserting character that is a closing delimiter, the cursor moves momentarily to the location of the matching opening delimiter, provided that is on the screen. If it is not on the screen, some text near it is displayed in the echo area. Either way, you can tell what grouping is being closed off.

In Lisp, automatic matching applies only to parentheses. In C, it applies to braces and brackets too. Emacs knows which characters to regard as matching delimiters based on the syntax table, which is set by the major mode. See section The Syntax Table.

If the opening delimiter and closing delimiter are mismatched--such as in `[x)'---a warning message is displayed in the echo area. The correct matches are specified in the syntax table.

Three variables control parenthesis match display. `blink-matching-paren` turns the feature on or off; `nil` turns it off, but the default is `t` to turn match display on. `blink-matching-delay` says how many seconds to wait; the default is 1, but on some systems it is useful to specify a fraction of a second. `blink-matching-paren-distance` specifies how many characters back to search to find the matching opening delimiter. If the match is not found in that far, scanning stops, and nothing is displayed. This is to prevent scanning for the matching delimiter from wasting lots of time when there is no match. The default is 12,000.

When using X Windows, you can request a more powerful kind of automatic parenthesis matching by loading the `paren` library. To load it, type M-x load-library RET paren RET. This library turns off the usual kind of matching parenthesis display and substitutes another: whenever point is after a close parenthesis, the close parenthesis and its matching open parenthesis are both highlighted; otherwise, if point is before an open parenthesis, the matching close parenthesis is highlighted. (There is no need to highlight the open parenthesis after point because the cursor appears on top of that character.)

Manipulating Comments

Because comments are such an important part of programming, Emacs provides special commands for editing and inserting comments.

Comment Commands

The comment commands insert, kill and align comments.

M-;
: Insert or align comment (`indent-for-comment`).

C-x ;
: Set comment column (`set-comment-column`).

C-u - C-x ;
: Kill comment on current line (`kill-comment`).

M-LFD
: Like RET followed by inserting and aligning a comment (`indent-new-comment-line`).

M-x comment-region
: Add or remove comment delimiters on all the lines in the region.

The command that creates a comment is M-; (`indent-for-comment`). If there is no comment already on the line, a new comment is created, aligned at a specific column called the comment column.

The comment is created by inserting the string Emacs thinks comments should start with (the value of `comment-start`; see below). Point is left after that string. If the text of the line extends past the comment column, then the indentation is done to a suitable boundary (usually, at least one space is inserted). If the major mode has specified a string to terminate comments, that is inserted after point, to keep the syntax valid.

M-; can also be used to align an existing comment. If a line already contains the string that starts comments, then M-; just moves point after it and re-indents it to the conventional place. Exception: comments starting in column 0 are not moved.

Some major modes have special rules for indenting certain kinds of comments in certain contexts. For example, in Lisp code, comments which start with two semicolons are indented as if they were lines of code, instead of at the comment column. Comments which start with three semicolons are supposed to start at the left margin. Emacs understands these conventions by indenting a double-semicolon comment using TAB, and by not changing the indentation of a triple-semicolon comment at all.

```
;; This function is just an example
;;; Here either two or three semicolons are appropriate.
(defun foo (x)
;;; And now, the first part of the function:
  ;; The following line adds one.
  (1+ x))           ; This line adds one.
```

In C code, a comment preceded on its line by nothing but whitespace is indented like a line of code.

Even when an existing comment is properly aligned, M-; is still useful for moving directly to the start of the comment.

C-u - C-x ; (`kill-comment`) kills the comment on the current line, if there is one. The indentation before the start of the comment is killed as well. If there does not appear to be a comment in the line, nothing is done. To reinsert the comment on another line, move to the end of that line, do C-y, and then do M-; to realign it. Note that C-u - C-x ; is not a distinct key; it is C-x ; (`set-comment-column`) with a negative argument. That command is programmed so that when it receives a negative argument it calls `kill-comment`. However, `kill-comment` is a valid command which you could bind directly to a key if you wanted to.

Multiple Lines of Comments

If you are typing a comment and wish to continue it on another line, you can use the command M-LFD (`indent-new-comment-line`). This terminates the comment you are typing, creates a new blank line afterward, and begins a new comment indented under the old one. When Auto Fill mode is on, going past the fill column while typing a comment causes the comment to be continued in just this fashion. If point is not at the end of the line when M-LFD is typed, the text on the rest of the line becomes part of the new comment line.

To turn existing lines into comment lines, use the M-x comment-region command. It adds comment delimiters to the lines that start in the region, thus commenting them out. With a negative argument, it

does the opposite--it deletes comment delimiters from the lines in the region.

With a positive argument, `comment-region` duplicates the last character of the comment start sequence it adds; the argument specifies how many copies of the character to insert. Thus, in Lisp mode, C-u 2 M-x comment-region adds `;;' to each line. Duplicating the comment delimiter is a way of calling attention to the comment. It can also affect how the comment is indented. In Lisp, for proper indentation, you should use an argument of two, if between defuns, and three, if within a defun.

Options Controlling Comments

The comment column is stored in the variable `comment-column`. You can set it to a number explicitly. Alternatively, the command C-x ; (`set-comment-column`) sets the comment column to the column point is at. C-u C-x ; sets the comment column to match the last comment before point in the buffer, and then does a M-; to align the current line's comment under the previous one. Note that C-u - C-x ; runs the function `kill-comment` as described above.

The variable `comment-column` is per-buffer: setting the variable in the normal fashion affects only the current buffer, but there is a default value which you can change with `setq-default`. See section Local Variables. Many major modes initialize this variable for the current buffer.

The comment commands recognize comments based on the regular expression that is the value of the variable `comment-start-skip`. Make sure this regexp does not match the null string. It may match more than the comment starting delimiter in the strictest sense of the word; for example, in C mode the value of the variable is `"/\\*+ *"`, which matches extra stars and spaces after the `/*' itself. (Note that `\\' is needed in Lisp syntax to include a `\' in the string, which is needed to deny the first star its special meaning in regexp syntax. See section Syntax of Regular Expressions.)

When a comment command makes a new comment, it inserts the value of `comment-start` to begin it. The value of `comment-end` is inserted after point, so that it will follow the text that you will insert into the comment. In C mode, `comment-start` has the value `"/* "` and `comment-end` has the value `" */"`.

The variable `comment-multi-line` controls how M-LFD (`indent-new-comment-line`) behaves when used inside a comment. If `comment-multi-line` is `nil`, as it normally is, then the comment on the starting line is terminated and a new comment is started on the new following line. If `comment-multi-line` is not `nil`, then the new following line is set up as part of the same comment that was found on the starting line. This is done by not inserting a terminator on the old line, and not inserting a starter on the new line. In languages where multi-line comments work, the choice of value for this variable is a matter of taste.

The variable `comment-indent-function` should contain a function that will be called to compute the indentation for a newly inserted comment or for aligning an existing comment. It is set differently by various major modes. The function is called with no arguments, but with point at the beginning of the comment, or at the end of a line if a new comment is to be inserted. It should return the column in which the comment ought to start. For example, in Lisp mode, the indent hook function bases its decision on how many semicolons begin an existing comment, and on the code in the preceding lines.

Editing Without Unbalanced Parentheses

M-(

Put parentheses around next sexp(s) (`insert-parentheses`).

M-)

Move past next close parenthesis and re-indent (`move-over-close-and-reindent`).

The commands M-((`insert-parentheses`) and M-) (`move-over-close-and-reindent`) are designed to facilitate a style of editing which keeps parentheses balanced at all times. M-(inserts a pair of parentheses, either together as in `()', or, if given an argument, around the next several sexps. It leaves point after the open parenthesis. The command M-) moves past the close parenthesis, deleting any indentation preceding it (in this example there is none), and indenting with LFD after it.

For example, instead of typing (F O O), you can type M-(F O O, which has the same effect except for leaving the cursor before the close parenthesis.

M-(may insert a space before the open parenthesis, depending on the syntax class of the preceding character. Set `parens-dont-require-spaces` to a non-`nil` value if you wish to inhibit this.

Completion for Symbol Names

Usually completion happens in the minibuffer. But one kind of completion is available in all buffers: completion for symbol names.

The character M-TAB runs a command to complete the partial symbol before point against the set of meaningful symbol names. Any additional characters determined by the partial name are inserted at point.

If the partial name in the buffer has more than one possible completion and they have no additional characters in common, a list of all possible completions is displayed in another window.

There are two ways of determining the set of legitimate symbol names to complete against. In most major modes, this uses a tags table (see section Tags Tables); the legitimate symbol names are the tag names listed in the tags table file. The command which implements this is `complete-tag`.

In Emacs-Lisp mode, the name space for completion normally consists of nontrivial symbols present in Emacs--those that have function definitions, values or properties. However, if there is an open-parenthesis immediately before the beginning of the partial symbol, only symbols with function definitions are considered as completions. The command which implements this is `lisp-complete-symbol`.

In Text mode and related modes, M-TAB completes words based on the spell-checker's dictionary. See section Checking and Correcting Spelling.

Documentation Commands

As you edit Lisp code to be run in Emacs, the commands C-h f (`describe-function`) and C-h v (`describe-variable`) can be used to print documentation of functions and variables that you want to call. These commands use the minibuffer to read the name of a function or variable to document, and display the documentation in a window.

For extra convenience, these commands provide default arguments based on the code in the neighborhood of point. C-h f sets the default to the function called in the innermost list containing point. C-h v uses the symbol name around or adjacent to point as its default.

Documentation on operating system commands, library functions and system calls can be obtained with the M-x manual-entry command. This reads a topic as an argument, and displays the "man page" on that topic. `manual-entry` starts a background process that formats the manual page, by running the `man` program. The result goes in a buffer named `*man topic*'. These buffers use a special major mode, Man mode, that facilitates scrolling and examining other manual pages. For details, type C-h m while in a man page buffer.

For a long man page, setting the faces properly can take substantial time. By default, Emacs uses faces in man pages if you are using X Windows. You can turn off use of faces in man pages by setting the variable `Man-fontify-manpage-flag` to `nil`.

If you insert the text of a man page into an Emacs buffer in some other fashion, you can use the command M-x Man-fontify-manpage to perform the same conversions that M-x manual-entry does.

Eventually the GNU project hopes to replace most man pages with better-organized manuals that you can browse with Info. See section Other Help Commands. Since this process is only partially completed, it is still useful to read manual pages.

Change Logs

The Emacs command C-x 4 a adds a new entry to the change log file for the file you are editing (`add-change-log-entry-other-window`).

A change log file contains a chronological record of when and why you have changed a program, consisting of a sequence of entries describing individual changes. Normally it is kept in a file called `` `ChangeLog' `` in the same directory as the file you are editing, or one of its parent directories. A single `` `ChangeLog' `` file can record changes for all the files in its directory and all its subdirectories.

A change log entry starts with a header line that contains your name, your email address (taken from the variable `user-mail-address`), and the current date and time. Aside from these header lines, every line in the change log starts with a space or a tab. The bulk of the entry consists of items, each of which starts with a line starting with whitespace and a star. Here are two entries, each with two items:

@medbreak

```
Wed May  5 14:11:45 1993  Richard Stallman  <rms@gnu.ai.mit.edu>
```

```
        * man.el: Rename symbols `man-*' to `Man-*'.
        (manual-entry): Make prompt string clearer.

        * simple.el (blink-matching-paren-distance):
        Change default to 12,000.

Tue May  4 12:42:19 1993  Richard Stallman  <rms@gnu.ai.mit.edu>

        * vc.el (minor-mode-map-alist): Don't use it if it's void.
        (vc-cancel-version): Doc fix.
```

One entry can describe several changes; each change should have its own item. Normally there should be a blank line between items. When items are related (parts of the same change, in different places), group them by leaving no blank line between them. The second entry above contains two items grouped in this way.

C-x 4 a visits the change log file and creates a new entry unless the most recent entry is for today's date and your name. It also creates a new item for the current file. For many languages, it can even guess the name of the function or other object that was changed.

The change log file is visited in Change Log mode. In this major mode, each bunch of grouped items counts as one paragraph, and each entry is considered a page. This facilitates editing the entries. LFD and auto-fill indent each new line like the previous line; this is convenient for entering the contents of an entry.

Version control systems are another way to keep track of changes in your program and keep a change log. See section Log Entries.

Tags Tables

A tags table is a description of how a multi-file program is broken up into files. It lists the names of the component files and the names and positions of the functions (or other named subunits) in each file. Grouping the related files makes it possible to search or replace through all the files with one command. Recording the function names and positions makes possible the M-. command which finds the definition of a function by looking up which of the files it is in.

Tags tables are stored in files called tags table files. The conventional name for a tags table file is `TAGS'.

Each entry in the tags table records the name of one tag, the name of the file that the tag is defined in (implicitly), and the position in that file of the tag's definition.

Just what names from the described files are recorded in the tags table depends on the programming language of the described file. They normally include all functions and subroutines, and may also include global variables, data types, and anything else convenient. Each name recorded is called a tag.

Source File Tag Syntax

- In Lisp code, any function defined with `defun`, any variable defined with `defvar` or `defconst`, and in general the first argument of any expression that starts with `(def' in column zero, is a tag.
- In Scheme code, tags include anything defined with `def` or with a construct whose name starts with `def'. They also include variables set with `set!` at top level in the file.
- In C code, any C function or typedef is a tag, and so are definitions of struct, union and enum. Any `#define` is also a tag, unless `--no-defines' is specified when the tags table is constructed, which sometimes makes the tags file much smaller. In C++ code, member functions are also recognized.
- In Yacc or Bison input files, each rule defines as a tag the nonterminal it constructs. The portions of the file that contain C code are parsed as C code.
- In Fortran code, functions and subroutines are tags.
- In Pascal code, the tags are the functions and procedures defined in the file.
- In Perl code, the tags are the procedures defined by the `sub` keyword.
- In Prolog code, a tag name appears at the left margin.
- In Erlang code, the tags are the functions, records, and macros defined in the file.
- In assembler code, labels appearing at the beginning of a line, followed by a colon, are tags.
- In LaTeX text, the argument of any of the commands `\chapter`, `\section`, `\subsection`, `\subsubsection`, `\eqno`, `\label`, `\ref`, `\cite`, `\bibitem`, `\part`, `\appendix`, `\entry`, or `\index`, is a tag.

  Other commands can make tags as well, if you specify them in the environment variable `TEXTAGS` before invoking `etags`. The value of this environment variable should be a colon-separated list of commands names. For example,

  ```
  TEXTAGS="def:newcommand:newenvironment"
  export TEXTAGS
  ```

  specifies (using Bourne shell syntax) that the commands `\def', `\newcommand' and `\newenvironment' also define tags.
- You can also generate tags based on regexp matching (see section Creating Tags Tables) for any text file.

Creating Tags Tables

The `etags` program is used to create a tags table file. It knows the syntax of several languages, as described in the previous section. Here is how to run `etags`:

```
etags inputfiles...
```

The `etags` program reads the specified files, and writes a tags table named `TAGS' in the current working directory. `etags` recognizes the language used in an input file based on its file name and

contents. You can specify the language with the `--language=name' option, described below.

If the tags table data become outdated due to changes in the files described in the table, the way to update the tags table is the same way it was made in the first place. It is not necessary to do this often.

If the tags table fails to record a tag, or records it for the wrong file, then Emacs cannot possibly find its definition. However, if the position recorded in the tags table becomes a little bit wrong (due to some editing in the file that the tag definition is in), the only consequence is a slight delay in finding the tag. Even if the stored position is very wrong, Emacs will still find the tag, but it must search the entire file for it.

So you should update a tags table when you define new tags that you want to have listed, or when you move tag definitions from one file to another, or when changes become substantial. Normally there is no need to update the tags table after each edit, or even every day.

One tags table can effectively include another. Specify the included tags file name with the `--include=file' option when creating the file that is to include it. The latter file then acts as if it contained all the files specified in the included file, as well as the files it directly contains.

If you specify the source files with relative file names when you run `etags`, the tags file will contain file names relative to the directory where the tags file was initially written. This way, you can move an entire directory tree containing both the tags file and the source files, and the tags file will still refer correctly to the source files.

If you specify absolute file names as arguments to `etags`, then the tags file will contain absolute file names. This way, the tags file will still refer to the same files even if you move it, as long as the source files remain in the same place. Absolute file names start with `/', or with `device:/' on MS-DOS and Windows.

When you want to make a tags table from a great number of files, you may have problems listing them on the command line, because some systems have a limit on its length. The simplest way to circumvent this limit is to tell `etags` to read the file names from its standard input, by typing a dash in place of the file names, like this:

```
find . -name "*.[chCH]" -print | etags -
```

Use the option `--language=name' to specify the language explicitly. You can intermix these options with file names; each one applies to the file names that follow it. Specify `--language=auto' to tell `etags` to resume guessing the language from the file names and file contents. Specify `--language=none' to turn off language-specific processing entirely; then `etags` recognizes tags by regexp matching alone. `etags --help' prints the list of the languages `etags` knows, and the file name rules for guessing the language.

The `--regex' option provides a general way of recognizing tags based on regexp matching. You can freely intermix it with file names. Each `--regex' option adds to the preceding ones, and applies only to the following files. The syntax is:

```
--regex=/tagregexp[/nameregexp]/
```

where tagregexp is used to match the lines to tag. It is always anchored, that is, it behaves as if preceded

by `^'. If you want to account for indentation, just match any initial number of blanks by beginning y regular expression with `[\t]*'. In the regular expressions, `\' quotes the next character, and `\t' stands the tab character. Note that `etags` does not handle the other C escape sequences for special characters.

You should not match more characters with tagregexp than that needed to recognize what you want to tag. If the match is such that more characters than needed are unavoidably matched by tagregexp, you may find useful to add a nameregexp, in order to narrow the tag scope. You can find some examples below.

The `-R' option deletes all the regexps defined with `--regex' options. It applies to the file names following it, as you can see from the following example:

```
etags --regex=/reg1/ voo.doo --regex=/reg2/ \
    bar.ber -R --lang=lisp los.er
```

Here `etags` chooses the parsing language for `voo.doo' and `bar.ber' according to their contents. `etags` also uses reg1 to recognize additional tags in `voo.doo', and both reg1 and reg2 to recognize additional tags in `bar.ber'. `etags` uses the Lisp tags rules, and no regexp matching, to recognize tags in `los.er'.

Here are some more examples. The regexps are quoted to protect them from shell interpretation.

Tag the `DEFVAR` macros in the emacs source files:

```
--regex='/[ \t]*DEFVAR_[A-Z_ \t(]+"\([^"]+\)"/'
```

Tag VHDL files (this example is a single long line, broken here for formatting reasons):

```
--language=none
--regex='/[ \t]*\(ARCHITECTURE\|CONFIGURATION\) +[^ ]* +OF/'
--regex='/[ \t]*\(ATTRIBUTE\|ENTITY\|FUNCTION\|PACKAGE\
\( BODY\)?\|PROCEDURE\|PROCESS\|TYPE\)[ \t]+\([^ \t(]+\)/\3/'
```

Tag Cobol files (every label starting in column seven):

```
--language=none --regex='/.......[a-zA-Z0-9-]+\./'
```

Tag Postscript files (every label starting in column one):

```
--language=none --regex='#/[^ \t{]+#/'
```

Tag TCL files (this last example shows the usage of a nameregexp):

```
--lang=none --regex='/proc[ \t]+\([^ \t]+\)/\1/'
```

For a list of the other available `etags` options, execute `etags --help`.

Selecting a Tags Table

Emacs has at any time one selected tags table, and all the commands for working with tags tables use the selected one. To select a tags table, type M-x visit-tags-table, which reads the tags table file name as an argument. The name `TAGS' in the default directory is used as the default file name.

All this command does is store the file name in the variable `tags-file-name`. Emacs does not actually read in the tags table contents until you try to use them. Setting this variable yourself is just as good as using `visit-tags-table`. The variable's initial value is `nil`; that value tells all the commands for working with tags tables that they must ask for a tags table file name to use.

Using `visit-tags-table` when a tags table is already loaded gives you a choice: you can add the new tags table to the current list of tags tables, or start a new list. The tags commands use all the tags tables in the current list. If you start a new list, the new tags table is used *instead* of others. If you add the new table to the current list, it is used *as well as* the others. When the tags commands scan the list of tags tables, they don't always start at the beginning of the list; they start with the first tags table (if any) that describes the current file, proceed from there to the end of the list, and then scan from the beginning of the list until they have covered all the tables in the list.

You can specify a precise list of tags tables by setting the variable `tags-table-list` to a list of strings, like this:

```
(setq tags-table-list
      '("~/emacs" "/usr/local/lib/emacs/src"))
```

This tells the tags commands to look at the `TAGS' files in your `~/emacs' directory and in the `/usr/local/lib/emacs/src' directory. The order depends on which file you are in and which tags table mentions that file, as explained above.

Do not set both `tags-file-name` and `tags-table-list`.

Finding a Tag

The most important thing that a tags table enables you to do is to find the definition of a specific tag.

M-. tag RET
: Find first definition of tag (`find-tag`).

C-u M-.
: Find next alternate definition of last tag specified.

C-u - M-.
: Go back to previous tag found.

C-M-. pattern RET
: Find a tag whose name matches pattern (`find-tag-regexp`).

C-u C-M-.
: Find the next tag whose name matches the last pattern used.

C-x 4 . tag RET

Find first definition of tag, but display it in another window (`find-tag-other-window`).

C-x 5 . tag RET

Find first definition of tag, and create a new frame to select the buffer (`find-tag-other-frame`).

M-. (`find-tag`) is the command to find the definition of a specified tag. It searches through the tags table for that tag, as a string, and then uses the tags table info to determine the file that the definition is in and the approximate character position in the file of the definition. Then `find-tag` visits that file, moves point to the approximate character position, and searches ever-increasing distances away to find the tag definition.

If an empty argument is given (just type RET), the sexp in the buffer before or around point is used as the tag argument. See section Lists and Sexps, for info on sexps.

You don't need to give M-. the full name of the tag; a part will do. This is because M-. finds tags in the table which contain tag as a substring. However, it prefers an exact match to a substring match. To find other tags that match the same substring, give `find-tag` a numeric argument, as in C-u M-.; this does not read a tag name, but continues searching the tags table's text for another tag containing the same substring last used. If you have a real META key, M-0 M-. is an easier alternative to C-u M-..

Like most commands that can switch buffers, `find-tag` has a variant that displays the new buffer in another window, and one that makes a new frame for it. The former is C-x 4 ., which invokes the command `find-tag-other-window`. The latter is C-x 5 ., which invokes `find-tag-other-frame`.

To move back to places you've found tags recently, use C-u - M-.; more generally, M-. with a negative numeric argument. This command can take you to another buffer. C-x 4 . with a negative argument finds the previous tag location in another window.

The command C-M-. (`find-tag-regexp`) visits the tags that match a specified regular expression. It is just like M-. except that it does regexp matching instead of substring matching.

Searching and Replacing with Tags Tables

The commands in this section visit and search all the files listed in the selected tags table, one by one. For these commands, the tags table serves only to specify a sequence of files to search.

M-x tags-search RET regexp RET

Search for regexp through the files in the selected tags table.

M-x tags-query-replace RET regexp RET replacement RET

Perform a `query-replace-regexp` on each file in the selected tags table.

M-,

Restart one of the commands above, from the current location of point (`tags-loop-continue`).

M-x tags-search reads a regexp using the minibuffer, then searches for matches in all the files in the

selected tags table, one file at a time. It displays the name of the file being searched so you can follow progress. As soon as it finds an occurrence, `tags-search` returns.

Having found one match, you probably want to find all the rest. To find one more match, type M-, (`tags-loop-continue`) to resume the `tags-search`. This searches the rest of the current buffer, followed by the remaining files of the tags table.

M-x tags-query-replace performs a single `query-replace-regexp` through all the files in the tags table. It reads a regexp to search for and a string to replace with, just like ordinary M-x query-replace-regexp. It searches much like M-x tags-search, but repeatedly, processing matches according to your input. See section Replacement Commands, for more information on query replace.

It is possible to get through all the files in the tags table with a single invocation of M-x tags-query-replace. But often it is useful to exit temporarily, which you can do with any input event that has no special query replace meaning. You can resume the query replace subsequently by typing M-,; this command resumes the last tags search or replace command that you did.

The commands in this section carry out much broader searches than the `find-tag` family. The `find-tag` commands search only for definitions of tags that match your substring or regexp. The commands `tags-search` and `tags-query-replace` find every occurrence of the regexp, as ordinary search commands and replace commands do in the current buffer.

These commands create buffers only temporarily for the files that they have to search (those which are not already visited in Emacs buffers). Buffers in which no match is found are quickly killed; the others continue to exist.

It may have struck you that `tags-search` is a lot like `grep`. You can also run `grep` itself as an inferior of Emacs and have Emacs show you the matching lines one by one. This works much like running a compilation; finding the source locations of the `grep` matches works like finding the compilation errors. See section Running Compilations under Emacs.

Tags Table Inquiries

M-x list-tags RET file RET

Display a list of the tags defined in the program file `` `file' ``.

M-x tags-apropos RET regexp RET

Display a list of all tags matching regexp.

M-x list-tags reads the name of one of the files described by the selected tags table, and displays a list of all the tags defined in that file. The "file name" argument is really just a string to compare against the file names recorded in the tags table; it is read as a string rather than as a file name. Therefore, completion and defaulting are not available, and you must enter the file name the same way it appears in the tags table. Do not include a directory as part of the file name unless the file name recorded in the tags table includes a directory.

M-x tags-apropos is like `apropos` for tags (see section Apropos). It reads a regexp, then finds all the tags in the selected tags table whose entries match that regexp, and displays the tag names found.

You can also perform completion in the buffer on the name space of tag names in the current tags tat
See section Completion for Symbol Names.

Merging Files with Emerge

It's not unusual for programmers to get their signals crossed and modify the same program in two different directions. To recover from this confusion, you need to merge the two versions. Emerge makes this easier. See also section Comparing Files.

Overview of Emerge

To start Emerge, run one of these four commands:

M-x emerge-files

Merge two specified files.

M-x emerge-files-with-ancestor

Merge two specified files, with reference to a common ancestor.

M-x emerge-buffers

Merge two buffers.

M-x emerge-buffers-with-ancestor

Merge two buffers with reference to a common ancestor in a third buffer.

The Emerge commands compare two files or buffers, and display the comparison in three buffers: one for each input text (the A buffer and the B buffer), and one (the merge buffer) where merging takes place. The merge buffer shows the full merged text, not just the differences. Wherever the two input texts differ, you can choose which one of them to include in the merge buffer.

The Emerge commands that take input from existing buffers use only the accessible portions of those buffers, if they are narrowed (see section Narrowing).

If a common ancestor version is available, from which the two texts to be merged were both derived, Emerge can use it to guess which alternative is right. Wherever one current version agrees with the ancestor, Emerge presumes that the other current version is a deliberate change which should be kept in the merged version. Use the `with-ancestor' commands if you want to specify a common ancestor text. These commands read three file or buffer names--variant A, variant B, and the common ancestor.

After the comparison is done and the buffers are prepared, the interactive merging starts. You control the merging by typing special merge commands in the merge buffer. The merge buffer shows you a full merged text, not just differences. For each run of differences between the input texts, you can choose which one of them to keep, or edit them both together.

The merge buffer uses a special major mode, Emerge mode, with commands for making these choices. But you can also edit the buffer with ordinary Emacs commands.

At any given time, the attention of Emerge is focused on one particular difference, called the selected

difference. This difference is marked off in the three buffers like this:

```
vvvvvvvvvvvvvvvvvvvv
text that differs
^^^^^^^^^^^^^^^^^^^^
```

Emerge numbers all the differences sequentially and the mode line always shows the number of the selected difference.

Normally, the merge buffer starts out with the A version of the text. But when the A version of a difference agrees with the common ancestor, then the B version is initially preferred for that difference.

Emerge leaves the merged text in the merge buffer when you exit. At that point, you can save it in a file with C-x C-w. If you give a numeric argument to `emerge-files` or `emerge-files-with-ancestor`, it reads the name of the output file using the minibuffer. (This is the last file name those commands read.) Then exiting from Emerge saves the merged text in the output file.

Normally, Emerge commands save the output buffer in its file when you exit. If you abort Emerge with C-], the Emerge command does not save the output buffer, but you can save it yourself if you wish.

Submodes of Emerge

You can choose between two modes for giving merge commands: Fast mode and Edit mode. In Fast mode, basic merge commands are single characters, but ordinary Emacs commands are disabled. This is convenient if you use only merge commands. In Edit mode, all merge commands start with the prefix key C-c C-c, and the normal Emacs commands are also available. This allows editing the merge buffer, but slows down Emerge operations.

Use e to switch to Edit mode, and C-c C-c f to switch to Fast mode. The mode line indicates Edit and Fast modes with `E' and `F'.

Emerge has two additional submodes that affect how particular merge commands work: Auto Advance mode and Skip Prefers mode.

If Auto Advance mode is in effect, the a and b commands advance to the next difference. This lets you go through the merge faster as long as you simply choose one of the alternatives from the input. The mode line indicates Auto Advance mode with `A'.

If Skip Prefers mode is in effect, the n and p commands skip over differences in states prefer-A and prefer-B (see section State of a Difference). Thus you see only differences for which neither version is presumed "correct". The mode line indicates Skip Prefers mode with `S'.

Use the command s a (`emerge-auto-advance-mode`) to set or clear Auto Advance mode. Use s s (`emerge-skip-prefers-mode`) to set or clear Skip Prefers mode. These commands turn on the mode with a positive argument, turns it off with a negative or zero argument, and toggle the mode with no argument.

State of a Difference

In the merge buffer, a difference is marked with lines of `v' and `^' characters. Each difference has one of these seven states:

A

The difference is showing the A version. The a command always produces this state; the mode line indicates it with `A'.

B

The difference is showing the B version. The b command always produces this state; the mode line indicates it with `B'.

default-A

default-B

The difference is showing the A or the B state by default, because you haven't made a choice. All differences start in the default-A state (and thus the merge buffer is a copy of the A buffer), except those for which one alternative is "preferred" (see below).

When you select a difference, its state changes from default-A or default-B to plain A or B. Thus, the selected difference never has state default-A or default-B, and these states are never displayed in the mode line.

The command d a chooses default-A as the default state, and d b chooses default-B. This chosen default applies to all differences which you haven't ever selected and for which no alternative is preferred. If you are moving through the merge sequentially, the differences you haven't selected are those following the selected one. Thus, while moving sequentially, you can effectively make the A version the default for some sections of the merge buffer and the B version the default for others by using d a and d b between sections.

prefer-A

prefer-B

The difference is showing the A or B state because it is preferred. This means that you haven't made an explicit choice, but one alternative seems likely to be right because the other alternative agrees with the common ancestor. Thus, where the A buffer agrees with the common ancestor, the B version is preferred, because chances are it is the one that was actually changed.

These two states are displayed in the mode line as `A*' and `B*'.

combined

The difference is showing a combination of the A and B states, as a result of the x c or x C commands.

Once a difference is in this state, the a and b commands don't do anything to it unless you give them a numeric argument.

The mode line displays this state as `comb'.

Merge Commands

Here are the Merge commands for Fast mode; in Edit mode, precede them with C-c C-c:

p
: Select the previous difference.

n
: Select the next difference.

a
: Choose the A version of this difference.

b
: Choose the B version of this difference.

C-u n j
: Select difference number n.

.
: Select the difference containing point. You can use this command in the merge buffer or in the A or B buffer.

q
: Quit--finish the merge.

C-]
: Abort--exit merging and do not save the output.

f
: Go into Fast mode. (In Edit mode, this is actually C-c C-c f.)

e
: Go into Edit mode.

l
: Recenter (like C-l) all three windows.

-
: Specify part of a prefix numeric argument.

digit
: Also specify part of a prefix numeric argument.

d a
: Choose the A version as the default from here down in the merge buffer.

d b
: Choose the B version as the default from here down in the merge buffer.

c a
: Copy the A version of this difference into the kill ring.

c b

Copy the B version of this difference into the kill ring.

i a

Insert the A version of this difference at point.

i b

Insert the B version of this difference at point.

m

Put point and mark around the difference.

^

Scroll all three windows down (like M-v).

v

Scroll all three windows up (like C-v).

<

Scroll all three windows left (like C-x <).

>

Scroll all three windows right (like C-x >).

|

Reset horizontal scroll on all three windows.

x 1

Shrink the merge window to one line. (Use C-u l to restore it to full size.)

x c

Combine the two versions of this difference (see section Combining the Two Versions).

x f

Show the names of the files/buffers Emerge is operating on, in a Help window. (Use C-u l to restore windows.)

x j

Join this difference with the following one. (C-u x j joins this difference with the previous one.)

x s

Split this difference into two differences. Before you use this command, position point in each of the three buffers at the place where you want to split the difference.

x t

Trim identical lines off top and bottom of the difference. Such lines occur when the A and B versions are identical but differ from the ancestor version.

Exiting Emerge

The q command (`emerge-quit`) finishes the merge, storing the results into the output file if you specified one. It restores the A and B buffers to their proper contents, or kills them if they were created by Emerge and you haven't changed them. It also disables the Emerge commands in the merge buffer,

since executing them later could damage the contents of the various buffers.

C-] aborts the merge. This means exiting without writing the output file. If you didn't specify an output file, then there is no real difference between aborting and finishing the merge.

If the Emerge command was called from another Lisp program, then its return value is `t` for successful completion, or `nil` if you abort.

Combining the Two Versions

Sometimes you want to keep *both* alternatives for a particular difference. To do this, use x c, which edits the merge buffer like this:

```
#ifdef NEW
version from A buffer
#else /* NEW */
version from B buffer
#endif /* NEW */
```

While this example shows C preprocessor conditionals delimiting the two alternative versions, you can specify the strings to use by setting the variable `emerge-combine-versions-template` to a string of your choice. In the string, `%a' says where to put version A, and `%b' says where to put version B. The default setting, which produces the results shown above, looks like this:

```
"#ifdef NEW\n%a#else /* NEW */\n%b#endif /* NEW */\n"
```

Fine Points of Emerge

During the merge, you mustn't try to edit the A and B buffers yourself. Emerge modifies them temporarily, but ultimately puts them back the way they were.

You can have any number of merges going at once--just don't use any one buffer as input to more than one merge at once, since the temporary changes made in these buffers would get in each other's way.

Starting Emerge can take a long time because it needs to compare the files fully. Emacs can't do anything else until `diff` finishes. Perhaps in the future someone will change Emerge to do the comparison in the background when the input files are large--then you could keep on doing other things with Emacs until Emerge is ready to accept commands.

After setting up the merge, Emerge runs the hook `emerge-startup-hook` (see section Hooks).

C Mode

This section describes special features available in C, C++, Objective-C and Java modes.

C Mode Motion Commands

This section commands for moving point, in C mode and related modes.

`C-c C-u`

Move point back to the containing preprocessor conditional, leaving the mark behind. A prefix argument acts as a repeat count. With a negative argument, move point forward to the end of the containing preprocessor conditional. When going backwards, `#elif` is treated like `#else` followed by `#if`. When going forwards, `#elif` is ignored.

`C-c C-p`

Move point back over a preprocessor conditional, leaving the mark behind. A prefix argument acts as a repeat count. With a negative argument, move forward.

`C-c C-n`

Move point forward across a preprocessor conditional, leaving the mark behind. A prefix argument acts as a repeat count. With a negative argument, move backward.

`M-a`

Move point to the beginning of the innermost C statement. If point is already at the beginning of a statement, move to the beginning of the preceding statement. With prefix argument n, move back n - 1 statements.

If point is within a string or comment, or next to a comment (only whitespace between them), this command moves by sentences instead of statements.

When called from a program, this function takes two optional arguments: the numeric prefix argument, and a buffer position limit (don't move back before that place).

`M-e`

Move point to the end of the innermost C statement. If point is at the end of a statement, move to the end of the next statement. With prefix argument n, move forward n - 1 statements.

If point is within a string or comment, or next to a comment (only whitespace between them), this command moves by sentences instead of statements.

When called from a program, this function takes two optional arguments: the numeric prefix argument, and a buffer position limit (don't move past that place).

`M-x c-backward-into-nomenclature`

Move point backward to beginning of a C++ nomenclature section or word. With prefix argument n, move n times. If n is negative, move forward. C++ nomenclature means a symbol name in the style of NamingSymbolsWithMixedCaseAndNoUnderlines; each capital letter begins a section or word.

In the GNU project, we recommend using underscores to separate words within an identifier in C or C++, rather than using case distinctions.

`M-x c-forward-into-nomenclature`

Move point forward to end of a C++ nomenclature section or word. With prefix argument n, move n times.

Electric C Characters

In C mode and related modes, certain printing characters are "electric"---in addition to inserting themselves, they also reindent the current line and may insert newlines. This feature is controlled by the variable `c-auto-newline`. The "electric" characters are {, }, :, #, ;, ,, <, >, / and *.

Electric characters insert newlines only when the auto-newline feature is enabled (indicated by `/a' in the mode line after the mode name). This feature is controlled by the variable `c-auto-newline`. You can turn this feature on or off with the command C-c C-a:

C-c C-a

> Toggle the auto-newline feature (`c-toggle-auto-state`). With a prefix argument, this command turns the auto-newline feature on if the argument is positive, and off if it is negative.

The colon character is electric because that is appropriate for a single colon. But when you want to insert a double colon in C++, the electric behavior of colon is inconvenient. You can insert a double colon with no reindentation or newlines by typing C-c ::

C-c :

> Insert a double colon scope operator at point, without reindenting the line or adding any newlines (`c-scope-operator`).

The electric # key reindents the line if it appears to be the beginning of a preprocessor directive. This happens when the value of `c-electric-pound-behavior` is `(alignleft)`. You can turn this feature off by setting `c-electric-pound-behavior` to `nil`.

The variable `c-hanging-braces-alist` controls the insertion of newlines before and after inserted braces. It is an association list with elements of the following form: `(syntactic-symbol . nl-list)`. Most of the syntactic symbols that appear in `c-offsets-alist` are meaningful here as well.

The list nl-list may contain either of the symbols `before` or `after`, or both; or it may be `nil`. When a brace is inserted, the syntactic context it defines is looked up in `c-hanging-braces-alist`; if it is found, the nl-list is used to determine where newlines are inserted: either before the brace, after, or both. If not found, the default is to insert a newline both before and after braces.

The variable `c-hanging-colons-alist` controls the insertion of newlines before and after inserted colons. It is an association list with elements of the following form: `(syntactic-symbol . nl-list)`. The list nl-list may contain either of the symbols `before` or `after`, or both; or it may be `nil`.

When a colon is inserted, the syntactic symbol it defines is looked up in this list, and if found, the nl-list is used to determine where newlines are inserted: either before the brace, after, or both. If the syntactic symbol is not found in this list, no newlines are inserted.

Electric characters can also delete newlines automatically when the auto-newline feature is enabled. This feature makes auto-newline more acceptable, by deleting the newlines in the most common cases where you do not want them. Emacs can recognize several cases in which deleting a newline might be

desirable; by setting the variable `c-cleanup-list`, you can specify *which* of these cases that sho happen. The variable's value is a list of symbols, each describing one case for possible deletion of a newline. Here are the meaningful symbols, and their meanings:

`brace-else-brace`

Clean up `} else {' constructs by placing entire construct on a single line. The clean-up occurs when you type the `{' after the `else`, but only if there is nothing but white space between the braces and the `else`.

`empty-defun-braces`

Clean up empty defun braces by placing the braces on the same line. Clean-up occurs when you type the closing brace.

`defun-close-semi`

Clean up the semicolon after a `struct` or similar type declaration, by placing the semicolon on the same line as the closing brace. Clean-up occurs when you type the semicolon.

`list-close-comma`

Clean up commas following braces in array and aggregate initializers. Clean-up occurs when you type the comma.

`scope-operator`

Clean up double colons which may designate a C++ scope operator, by placing the colons together. Clean-up occurs when you type the second colon, but only when the two colons are separated by nothing but whitespace.

Hungry Delete Feature in C

When the hungry-delete feature is enabled (indicated by `/h' or `/ah' in the mode line after the mode name), a single DEL command deletes all preceding whitespace, not just one space. To turn this feature on or off, use C-c C-d:

C-c C-d

Toggle the hungry-delete feature (`c-toggle-hungry-state`). With a prefix argument, this command turns the hungry-delete feature on if the argument is positive, and off if it is negative.

C-c C-t

Toggle the auto-newline and hungry-delete features, both at once (`c-toggle-auto-hungry-state`).

The variable `c-hungry-delete-key` controls whether the hungry-delete feature is enabled.

Other Commands for C Mode

C-M-h

Put mark at the end of a function definition, and put point at the beginning (`c-mark-function`).

M-q

Fill a paragraph, handling C and C++ comments (`c-fill-paragraph`). If any part of the current line is a comment or within a comment, this command fills the comment or the paragraph of it that point is in, preserving the comment indentation and comment delimiters.

C-c C-e

Run the C preprocessor on the text in the region, and show the result, which includes the expansion of all the macro calls (`c-macro-expand`). The buffer text before the region is also included in preprocessing, for the sake of macros defined there, but the output from this part isn't shown.

When you are debugging C code that uses macros, sometimes it is hard to figure out precisely how the macros expand. With this command, you don't have to figure it out; you can see the expansions.

C-c C-\

Insert or align `\' characters at the ends of the lines of the region (`c-backslash-region`). This is useful after writing or editing a C macro definition.

If a line already ends in `\', this command adjusts the amount of whitespace before it. Otherwise, it inserts a new `\'. However, the last line in the region is treated specially; no `\' is inserted on that line, and any `\' there is deleted.

M-x cpp-highlight-buffer

Highlight parts of the text according to its preprocessor conditionals. This command displays another buffer named `*CPP Edit*', which serves as a graphic menu for selecting how to display particular kinds of conditionals and their contents. After changing various settings, click on `[A]pply these settings' (or go to that buffer and type a) to rehighlight the C mode buffer accordingly.

C-c C-s

Display the syntactic information about the current source line (`c-show-syntactic-information`). This is the information that directs how the line is indented.

Comments in C Modes

C mode and related modes use a number of variables for controlling comment format.

`c-block-comments-indent-p`

This variable specifies how to reindent block comments. The C modes support five styles of block comments:

```
style 1:    style 2 (GNU):   style 3:    style 4:    style 5:
/*          /* Blah         /*          /*          /*
   blah        blah.  */      * blah     ** blah     blah
   blah                       * blah     ** blah     blah
   */                         */         */          */
```

For the styles 1 through 4, `c-block-comments-indent-p` should be `nil` (the default). If

you want to use style 5, set `c-block-comments-indent-p` to `t`.

This variable has no effect on the indentation of the comment-start itself or on insertion of asterisks when auto-filling C comments. It does not affect M-q either.

`c-comment-only-line-offset`

Extra offset for line which contains only the start of a comment. It can be either an integer or a cons cell of the form `(non-anchored-offset . anchored-offset)`, where non-anchored-offset is the amount of offset given to non-column-zero anchored comment-only lines, and anchored-offset is the amount of offset to give column-zero anchored comment-only lines. Just an integer as value is equivalent to `(val . 0)`.

`c-comment-start-regexp`

This buffer-local variable specifies how to recognize the start of a comment.

`c-hanging-comment-ender-p`

If this variable is `nil`, `c-fill-paragraph` leaves the comment terminator of a block comment on a line by itself. The default value is `t`, which always puts the comment-end delimiter `*/' at the end of the last line of the comment text.

Fortran Mode

Fortran mode provides special motion commands for Fortran statements and subprograms, and indentation commands that understand Fortran conventions of nesting, line numbers and continuation statements. Fortran mode has its own Auto Fill mode that breaks long lines into proper Fortran continuation lines.

Special commands for comments are provided because Fortran comments are unlike those of other languages. Built-in abbrevs optionally save typing when you insert Fortran keywords.

Use M-x fortran-mode to switch to this major mode. This command runs the hook `fortran-mode-hook` (see section Hooks).

Motion Commands

Fortran mode provides special commands to move by subprograms (functions and subroutines) and by statements. There is also a command to put the region around one subprogram, convenient for killing it or moving it.

C-M-a

Move to beginning of subprogram (`beginning-of-fortran-subprogram`).

C-M-e

Move to end of subprogram (`end-of-fortran-subprogram`).

C-M-h

Put point at beginning of subprogram and mark at end (`mark-fortran-subprogram`).

C-c C-n

Move to beginning of current or next statement (`fortran-next-statement`).

C-c C-p

Move to beginning of current or previous statement (`fortran-previous-statement`).

Fortran Indentation

Special commands and features are needed for indenting Fortran code in order to make sure various syntactic entities (line numbers, comment line indicators and continuation line flags) appear in the columns that are required for standard Fortran.

Fortran Indentation Commands

TAB

Indent the current line (`fortran-indent-line`).

LFD

Indent the current and start a new indented line (`fortran-indent-new-line`).

M-LFD

Break the current line and set up a continuation line.

C-M-q

Indent all the lines of the subprogram point is in (`fortran-indent-subprogram`).

Fortran mode redefines TAB to reindent the current line for Fortran (`fortran-indent-line`). This command indents Line numbers and continuation markers to their required columns, and independently indents the body of the statement based on its nesting in the program.

The key LFD runs the command `fortran-indent-new-line`, which reindents the current line then makes and indents a new line. This command is useful to reindent the closing statement of `do' loops and other blocks before starting a new line.

The key C-M-q runs `fortran-indent-subprogram`, a command to reindent all the lines of the Fortran subprogram (function or subroutine) containing point.

The key M-LFD runs `fortran-split-line`, which splits a line in the appropriate fashion for Fortran. In a non-comment line, the second half becomes a continuation line and is indented accordingly. In a comment line, both halves become separate comment lines.

Continuation Lines

Most modern Fortran compilers allow two ways of writing continuation lines. If the first non-space character on a line is in column 5, then that line is a continuation of the previous line. We call this fixed format. (In GNU Emacs we always count columns from 0.) The variable `fortran-continuation-string` specifies what character to put on column 5. A line that starts with a tab character followed by any digit except `0' is also a continuation line. We call this style of continuation tab format.

Fortran mode can make either style of continuation line, but you must specify which one you prefer. The value of the variable `indent-tabs-mode` controls the choice: `nil` for fixed format, and non-`nil` for tab format. You can tell which style is presently in effect by the presence or absence of the string `Tab' in the mode line.

If the text on a line starts with the conventional Fortran continuation marker `$', or if it begins with any non-whitespace character in column 5, Fortran mode treats it as a continuation line. When you indent a continuation line with TAB, it converts the line to the current continuation style. When you split a Fortran statement with M-LFD, the continuation marker on the newline is created according to the continuation style.

The setting of continuation style affects several other aspects of editing in Fortran mode. In fixed format mode, the minimum column number for the body of a statement is 6. Lines inside of Fortran blocks that are indented to larger column numbers always use only the space character for whitespace. In tab format mode, the minimum column number for the statement body is 8, and the whitespace before column 8 must always consist of one tab character.

When you enter Fortran mode for an existing file, it tries to deduce the proper continuation style automatically from the file contents. The first line that begins with either a tab character or six spaces determines the choice. The variable `fortran-analyze-depth` specifies how many lines to consider (at the beginning of the file); if none of those lines indicates a style, then the variable `fortran-tab-mode-default` specifies the style. If it is `nil`, that specifies fixed format, and non-`nil` specifies tab format.

Line Numbers

If a number is the first non-whitespace in the line, Fortran indentation assumes it is a line number and moves it to columns 0 through 4. (Columns always count from 0 in GNU Emacs.)

Line numbers of four digits or less are normally indented one space. The variable `fortran-line-number-indent` controls this; it specifies the maximum indentation a line number can have. Line numbers are indented to right-justify them to end in column 4 unless that would require more than this maximum indentation. The default value of the variable is 1.

Simply inserting a line number is enough to indent it according to these rules. As each digit is inserted, the indentation is recomputed. To turn off this feature, set the variable `fortran-electric-line-number` to `nil`. Then inserting line numbers is like inserting anything else.

Syntactic Conventions

Fortran mode assumes that you follow certain conventions that simplify the task of understanding a Fortran program well enough to indent it properly:

- Two nested `do' loops never share a `continue' statement.
- Fortran keywords such as `if', `else', `then', `do' and others are written without embedded whitespace or line breaks.

Fortran compilers generally ignore whitespace outside of string constants, but Fortran mode d not recognize these keywords if they are not contiguous. Constructs such as `else if' or `end d acceptable, but the second word should be on the same line as the first and not on a continuati line.

If you fail to follow these conventions, the indentation commands may indent some lines unaesthetically. However, a correct Fortran program retains its meaning when reindented even if the conventions are not followed.

Variables for Fortran Indentation

Several additional variables control how Fortran indentation works:

`fortran-do-indent`

Extra indentation within each level of `do' statement (default 3).

`fortran-if-indent`

Extra indentation within each level of `if' statement (default 3). This value is also used for extra indentation within each level of the Fortran 90 `where' statement.

`fortran-structure-indent`

Extra indentation within each level of `structure', `union', or `map' statements (default 3).

`fortran-continuation-indent`

Extra indentation for bodies of continuation lines (default 5).

`fortran-check-all-num-for-matching-do`

If this is `nil`, indentation assumes that each `do' statement ends on a `continue' statement. Therefore, when computing indentation for a statement other than `continue', it can save time by not checking for a `do' statement ending there. If this is non-`nil`, indenting any numbered statement must check for a `do' that ends there. The default is `nil`.

`fortran-blink-matching-if`

If this is `t`, indenting an `endif' statement moves the cursor momentarily to the matching `if' statement to show where it is. The default is `nil`.

`fortran-minimum-statement-indent-fixed`

Minimum indentation for fortran statements when using fixed format continuation line style. Statement bodies are never indented less than this much. The default is 6.

`fortran-minimum-statement-indent-tab`

Minimum indentation for fortran statements for tab format continuation line style. Statement bodies are never indented less than this much. The default is 8.

Fortran Comments

The usual Emacs comment commands assume that a comment can follow a line of code. In Fortran, the standard comment syntax requires an entire line to be just a comment. Therefore, Fortran mode replaces the standard Emacs comment commands and defines some new variables.

Fortran mode can also handle a nonstandard comment syntax where comments start with `!' and can follow other text. Because only some Fortran compilers accept this syntax, Fortran mode will not insert such comments unless you have said in advance to do so. To do this, set the variable `comment-start` to `"!"` (see section Variables).

M-;

Align comment or insert new comment (`fortran-comment-indent`).

C-x ;

Applies to nonstandard `!' comments only.

C-c ;

Turn all lines of the region into comments, or (with argument) turn them back into real code (`fortran-comment-region`).

M-; in Fortran mode is redefined as the command `fortran-comment-indent`. Like the usual M-; command, this recognizes any kind of existing comment and aligns its text appropriately; if there is no existing comment, a comment is inserted and aligned. But inserting and aligning comments are not the same in Fortran mode as in other modes.

When a new comment must be inserted, if the current line is blank, a full-line comment is inserted. On a non-blank line, a nonstandard `!' comment is inserted if you have said you want to use them. Otherwise a full-line comment is inserted on a new line before the current line.

Nonstandard `!' comments are aligned like comments in other languages, but full-line comments are different. In a standard full-line comment, the comment delimiter itself must always appear in column zero. What can be aligned is the text within the comment. You can choose from three styles of alignment by setting the variable `fortran-comment-indent-style` to one of these values:

`fixed`

Align the text at a fixed column, which is the sum of `fortran-comment-line-extra-indent` and the minimum statement indentation. This is the default.

The minimum statement indentation is `fortran-minimum-statement-indent-fixed` for fixed format continuation line style and `fortran-minimum-statement-indent-tab` for tab format style.

`relative`

Align the text as if it were a line of code, but with an additional `fortran-comment-line-extra-indent` columns of indentation.

`nil`

Don't move text in full-line columns automatically at all.

In addition, you can specify the character to be used to indent within full-line comments by setting the variable `fortran-comment-indent-char` to the single-character string you want to use.

Fortran mode introduces two variables `comment-line-start` and `comment-line-start-skip` which play for full-line comments the same roles played by `comment-start` and `comment-start-skip` for ordinary text-following comments. Normally these are set properly by

Fortran mode so you do not need to change them.

The normal Emacs comment command C-x ; has not been redefined. If you use `!' comments, this command can be used with them. Otherwise it is useless in Fortran mode.

The command C-c ; (`fortran-comment-region`) turns all the lines of the region into comments by inserting the string `C$$$' at the front of each one. With a numeric argument, it turns the region back into live code by deleting `C$$$' from the front of each line in it. The string used for these comments can be controlled by setting the variable `fortran-comment-region`. Note that here we have an example of a command and a variable with the same name; these two uses of the name never conflict because in Lisp and in Emacs it is always clear from the context which one is meant.

Fortran Auto Fill Mode

Fortran Auto Fill mode is a minor mode which automatically splits Fortran statements as you insert them when they become too wide. Splitting a statement involves making continuation lines using `fortran-continuation-string` (See section Continuation Lines). This splitting happens when you type SPC, RET, or TAB, and also in the Fortran indentation commands.

M-x fortran-auto-fill-mode turns Fortran Auto Fill mode on if it was off, or off if it was on. This command works the same as M-x auto-fill-mode does for normal Auto Fill mode (see section Filling Text). A positive numeric argument turns Fortran Auto Fill mode on, and a negative argument turns it off. You can see when Fortran Auto Fill mode is in effect by the presence of the word `Fill' in the mode line, inside the parentheses. Fortran Auto Fill mode is a minor mode, turned on or off for each buffer individually. See section Minor Modes.

Fortran Auto Fill mode breaks lines at spaces or delimiters when the lines get longer than the desired width (the value of `fill-column`). The delimiters that Fortran Auto Fill mode may break at are `,', `'', `+', `-', `/', `*', `=', and `)'. The line break comes after the delimiter if the variable `fortran-break-before-delimiters` is `nil`. Otherwise (and by default), the break comes before the delimiter.

By default, Fortran Auto Fill mode is not enabled. If you want this feature turned on permanently, add a hook function to `fortran-mode-hook` to execute `(fortran-auto-fill-mode 1)`. See section Hooks.

Checking Columns in Fortran

C-c C-r

Display a "column ruler" momentarily above the current line (`fortran-column-ruler`).

C-c C-w

Split the current window horizontally temporarily so that it is 72 columns wide. This may help you avoid making lines longer than the 72 character limit that some fortran compilers impose (`fortran-window-create-momentarily`).

The command C-c C-r (`fortran-column-ruler`) shows a column ruler momentarily above the

current line. The comment ruler is two lines of text that show you the locations of columns with spec significance in Fortran programs. Square brackets show the limits of the columns for line numbers, a curly brackets show the limits of the columns for the statement body. Column numbers appear above them.

Note that the column numbers count from zero, as always in GNU Emacs. As a result, the numbers may be one less than those you are familiar with; but the positions they indicate in the line are standard for Fortran.

The text used to display the column ruler depends on the value of the variable `indent-tabs-mode`. If `indent-tabs-mode` is `nil`, then the value of the variable `fortran-column-ruler-fixed` is used as the column ruler. Otherwise, the variable `fortran-column-ruler-tab` is displayed. By changing these variables, you can change the column ruler display.

For even more help, use C-c C-w (`fortran-window-create`), a command which splits the current window horizontally, making a window 72 columns wide. By editing in this window you can immediately see when you make a line too wide to be correct Fortran.

Fortran Keyword Abbrevs

Fortran mode provides many built-in abbrevs for common keywords and declarations. These are the same sort of abbrev that you can define yourself. To use them, you must turn on Abbrev mode. See section Abbrevs.

The built-in abbrevs are unusual in one way: they all start with a semicolon. You cannot normally use semicolon in an abbrev, but Fortran mode makes this possible by changing the syntax of semicolon to "word constituent."

For example, one built-in Fortran abbrev is `;c' for `continue'. If you insert `;c' and then insert a punctuation character such as a space or a newline, the `;c' expands automatically to `continue', provided Abbrev mode is enabled.

Type `;?' or `;C-h' to display a list of all the built-in Fortran abbrevs and what they stand for.

Asm Mode

Asm mode is a major mode for editing files of assembler code. It defines these commands:

TAB
: `tab-to-tab-stop`.

LFD
: Insert a newline and then indent using `tab-to-tab-stop`.

:
: Insert a colon and then remove the indentation from before the label preceding colon. Then do `tab-to-tab-stop`.

;

Insert or align a comment.

The variable `asm-comment-char` specifies which character starts comments in assembler syntax.

Go to the previous, next section.

Go to the previous, next section.

Compiling and Testing Programs

The previous chapter discusses the Emacs commands that are useful for making changes in programs. This chapter deals with commands that assist in the larger process of developing and maintaining programs.

Running Compilations under Emacs

Emacs can run compilers for noninteractive languages such as C and Fortran as inferior processes, feeding the error log into an Emacs buffer. It can also parse the error messages and show you the source lines where compilation errors occurred.

M-x compile

: Run a compiler asynchronously under Emacs, with error messages to `*compilation*' buffer.

M-x grep

: Run `grep` asynchronously under Emacs, with matching lines listed in the buffer named `*grep*'.

M-x kill-compilation

M-x kill-grep

: Kill the running compilation or `grep` subprocess.

C-x `

: Visit the locus of the next compiler error message or `grep` match.

RET

: Visit the locus of the error message that point is on. This command is used in the compilation buffer.

Mouse-2

: Visit the locus of the error message that you click on.

To run `make` or another compilation command, do M-x compile. This command reads a shell command line using the minibuffer, and then executes the command in an inferior shell, putting output in the buffer named `*compilation*'. The current buffer's default directory is used as the working directory for the execution of the command; normally, therefore, the compilation happens in this directory.

When the shell command line is read, the minibuffer appears containing a default command line, which is the command you used the last time you did M-x compile. If you type just RET, the same command line is used again. For the first M-x compile, the default is `make -k'. The default compilation command comes from the variable `compile-command`; if the appropriate compilation command for a file is something other than `make -k', it can be useful for the file to specify a local value for `compile-command` (see section Local Variables in Files).

Starting a compilation displays the buffer `*compilation*' in another window but does not select it. The

buffer's mode line tells you whether compilation is finished, with the word `run' or `exit' inside the parentheses. You do not have to keep this buffer visible; compilation continues in any case. While a compilation is going on, the string `Compiling' appears in the mode lines of all windows. When this string disappears, the compilation is finished.

If you want to watch the compilation transcript as it appears, switch to the `*compilation*' buffer and move point to the end of the buffer. When point is at the end, new compilation output is inserted above point, which remains at the end. If point is not at the end of the buffer, it remains fixed while more compilation output is added at the end of the buffer.

To kill the compilation process, do M-x kill-compilation. When the compiler process terminates, the mode line of the `*compilation*' buffer changes to say `signal' instead of `run'. Starting a new compilation also kills any running compilation, as only one can exist at any time. However, M-x compile asks for confirmation before actually killing a compilation that is running.

The `*compilation*' buffer uses a special major mode, Compilation mode. This mode provides the keys SPC and DEL to scroll by screenfuls, and M-n and M-p to move to the next or previous error message. You can also use M-{ and M-} to move up or down to an error message for a different source file.

You can visit the source for any particular error message by moving point in `*compilation*' to that error message and typing RET (`compile-goto-error`). Or click Mouse-2 on the error message; you need not switch to the `*compilation*' buffer first.

To parse the compiler error messages sequentially, type C-x ` (`next-error`). The character following the C-x is the backquote or "grave accent," not the single-quote. This command is available in all buffers, not just in `*compilation*'; it displays the next error message at the top of one window and source location of the error in another window.

The first time C-x ` is used after the start of a compilation, it moves to the first error's location. Subsequent uses of C-x ` advance down to subsequent errors. If you visit a specific error message with RET or Mouse-2, subsequent C-x ` commands advance from there. When C-x ` gets to the end of the buffer and finds no more error messages to visit, it fails and signals an Emacs error.

C-u C-x ` starts scanning from the beginning of the compilation buffer. This way, you can process the same set of errors again.

Just as you can run a compiler, you can also run `grep` and then visit the lines on which matches were found. To do this, type M-x grep with an argument line that contains the same arguments you would give `grep` when running it normally: a `grep`-style regexp (usually in single-quotes to quote the shell's special characters) followed by file names which may use wildcards. The output from `grep` goes in the `*grep*' buffer, and you can find the matching lines in the source with C-x ` and RET just like compiler errors.

Note: a shell is used to run the compile command, but the shell is told that it should be noninteractive. This means in particular that the shell starts up with no prompt. If you find your usual shell prompt making an unsightly appearance in the `*compilation*' buffer, it means you have made a mistake in your shell's init file by setting the prompt unconditionally. (The init file name may be `.profile', `.cshrc', `.shrc', or various other things, depending on the shell you use.) The shell init file should set the prompt only if there already is a prompt. In csh, here is how to do it:

```
if ($?prompt) set prompt = ...
```

And here's how to do it in bash:

```
if [ "${PS1+set}" = set ]
then prompt=...
fi
```

There may well be other things that your shell's init file ought to do only for an interactive shell. You can use the same method to conditionalize them.

The features of Compilation mode are also available in a minor mode called Compilation Minor mode. This lets you parse error messages in any buffer, not just a normal compilation output buffer. Type M-x compilation-minor-mode to enable the minor mode. This defines the keys RET and Mouse-2, as in the Compilation major mode. In an Rlogin buffer (see section Remote Host Shell), Compilation minor mode automatically accesses remote source files by FTP (see section File Names).

The MS-DOS "operating system" does not support asynchronous subprocesses; to work around this lack, M-x compile runs the compilation command synchronously on MS-DOS. As a consequence, you must wait until the command finishes before you can do anything else in Emacs. See section MS-DOS Issues.

Running Debuggers Under Emacs

The GUD (Grand Unified Debugger) library provides an interface to various symbolic debuggers from within Emacs. We recommend the debugger GDB, which is free software, but you can also run DBX, SDB or XDB if you have them. GUD can also serve as an interface to the Perl's debugging mode.

Starting GUD

There are five commands for starting a debugger, each corresponding to a particular debugger program.

M-x gdb RET file RET

> Run GDB as a subprocess of Emacs. This command creates a buffer for input and output to GDB, and switches to it. If a GDB buffer already exists, it just switches to that buffer.

M-x dbx RET file RET

> Similar, but run DBX instead of GDB.

M-x xdb RET file RET

> Similar, but run XDB instead of GDB. Use the variable `gud-xdb-directories` to specify directories to search for source files.

M-x sdb RET file RET

> Similar, but run SDB instead of GDB.
>
> Some versions of SDB do not mention source file names in their messages. When you use them, you need to have a valid tags table (see section Tags Tables) in order for GUD to find functions in

the source code. If you have not visited a tags table or the tags table doesn't list one of the functions, you get a message saying `The sdb support requires a valid tags table to work'. If this happens, generate a valid tags table in the working directory and try again.

M-x perldb RET file RET

Run the Perl interpreter in debug mode to debug file, a Perl program.

You can only run one debugger process at a time.

Each of these commands takes one argument: a command line to invoke the debugger. In the simplest case, specify just the name of the executable file you want to debug. You may also use options that the debugger supports. However, shell wild cards and variables are not allowed. GUD assumes that the first argument not preceded by a `-' is the executable file name.

Debugger Operation

When you run a debugger with GUD, the debugger uses an Emacs buffer for its ordinary input and output. This is called the GUD buffer. The debugger displays the source files of the program by visiting them in Emacs buffers. An arrow (`=>') in one of these buffers indicates the current execution line. Moving point in this buffer does not move the arrow.

You can start editing these source files at any time in the buffers that were made to display them. The arrow is not part of the file's text; it appears only on the screen. If you do modify a source file, keep in mind that inserting or deleting lines will throw off the arrow's positioning; GUD has no way of figuring out which line corresponded before your changes to the line number in a debugger message. Also, you'll typically have to recompile and restart the program for your changes to be reflected in the debugger's tables.

If you wish, you can control your debugger process entirely through the debugger buffer, which uses a variant of Shell mode. All the usual commands for your debugger are available, and you can use the Shell mode history commands to repeat them. See section Shell Mode.

Commands of GUD

The GUD interaction buffer uses a variant of Shell mode, so the commands of Shell mode are available (see section Shell Mode). GUD mode also provides commands for setting and clearing breakpoints, for selecting stack frames, and for stepping through the program. These commands are available both in the GUD buffer and globally, but with different key bindings.

The breakpoint commands are usually used in source file buffers, because that is the way to specify where to set or clear the breakpoint. Here's the global command to set a breakpoint:

C-x SPC

Set a breakpoint on the source line that point is on.

Here are the other special commands provided by GUD. The keys starting with C-c are available only in the GUD interaction buffer. The bindings that start with C-x C-a are available in the GUD buffer and also in source files.

C-c C-l

C-x C-a C-l

Display in another window the last line referred to in the GUD buffer (that is, the line indicated in the last location message). This runs the command `gud-refresh`.

C-c C-s

C-x C-a C-s

Execute a single line of code (`gud-step`). If the line contains a function call, execution stops after entering the called function.

C-c C-n

C-x C-a C-n

Execute a single line of code, stepping across entire function calls at full speed (`gud-next`).

C-c C-i

C-x C-a C-i

Execute a single machine instruction (`gud-stepi`).

C-c C-r

C-x C-a C-r

Continue execution without specifying any stopping point. The program will run until it hits a breakpoint, terminates, or gets a signal that the debugger is checking for (`gud-cont`).

C-c C-d

C-x C-a C-d

Delete the breakpoint(s) on the current source line, if any (`gud-remove`). If you use this command in the GUD interaction buffer, it applies to the line where the program last stopped.

C-c C-t

C-x C-a C-t

Set a temporary breakpoint on the current source line, if any. If you use this command in the GUD interaction buffer, it applies to the line where the program last stopped.

The above commands are common to all supported debuggers. If you are using GDB or (some versions of) DBX, these additional commands are available:

C-c <

C-x C-a <

Select the next enclosing stack frame (`gud-up`). This is equivalent to the `up' command.

C-c >

C-x C-a >

Select the next inner stack frame (`gud-down`). This is equivalent to the `down' command.

If you are using GDB, these additional key bindings are available:

TAB

With GDB, complete a symbol name (`gud-gdb-complete-command`). This key is available

only in the GUD interaction buffer, and requires GDB versions 4.13 and later.

C-c C-f

C-x C-a C-f

Run the program until the selected stack frame returns (or until it stops for some other reason).

These commands interpret a numeric argument as a repeat count, when that makes sense.

Because TAB serves as a completion command, you can't use it to enter a tab as input to the program you are debugging with GDB. Instead, type C-q TAB to enter a tab.

GUD Customization

On startup, GUD runs one of the following hooks: `gdb-mode-hook`, if you are using GDB; `dbx-mode-hook`, if you are using DBX; `sdb-mode-hook`, if you are using SDB; `xdb-mode-hook`, if you are using XDB; `perldb-mode-hook`, for Perl debugging mode. You can use these hooks to define custom key bindings for the debugger interaction buffer. See section Hooks.

Here is a convenient way to define a command that sends a particular command string to the debugger, and set up a key binding for it in the debugger interaction buffer:

```
(gud-def function cmdstring binding docstring)
```

This defines a command named function which sends cmdstring to the debugger process, and gives it the documentation string docstring. You can use the command thus defined in any buffer. If binding is non-`nil`, `gud-def` also binds the command to C-c binding in the GUD buffer's mode and to C-x C-a binding generally.

The command string cmdstring may contain certain `%'-sequences that stand for data to be filled in at the time function is called:

`%f'

The name of the current source file. If the current buffer is the GUD buffer, then the "current source file" is the file that the program stopped in.

`%l'

The number of the current source line. If the current buffer is the GUD buffer, then the "current source line" is the line that the program stopped in.

`%e'

The text of the C lvalue or function-call expression at or adjacent to point.

`%a'

The text of the hexadecimal address at or adjacent to point.

`%p'

The numeric argument of the called function, as a decimal number. If the command is used without a numeric argument, `%p' stands for the empty string.

If you don't use `%p' in the command string, the command you define ignores any numeric

argument.

Executing Lisp Expressions

Emacs has several different major modes for Lisp and Scheme. They are the same in terms of editing commands, but differ in the commands for executing Lisp expressions. Each mode has its own purpose.

Emacs-Lisp mode

The mode for editing source files of programs to run in Emacs Lisp. This mode defines C-M-x to evaluate the current defun. See section Libraries of Lisp Code for Emacs.

Lisp Interaction mode

The mode for an interactive session with Emacs Lisp. It defines LFD to evaluate the sexp before point and insert its value in the buffer. See section Lisp Interaction Buffers.

Lisp mode

The mode for editing source files of programs that run in Lisps other than Emacs Lisp. This mode defines C-M-x to send the current defun to an inferior Lisp process. See section Running an External Lisp.

Inferior Lisp mode

The mode for an interactive session with an inferior Lisp process. This mode combines the special features of Lisp mode and Shell mode (see section Shell Mode).

Scheme mode

Like Lisp mode but for Scheme programs.

Inferior Scheme mode

The mode for an interactive session with an inferior Scheme process.

Most editing commands for working with Lisp programs are in fact available globally. See section Editing Programs.

Libraries of Lisp Code for Emacs

Lisp code for Emacs editing commands is stored in files whose names conventionally end in `.el'. This ending tells Emacs to edit them in Emacs-Lisp mode (see section Executing Lisp Expressions).

To execute a file of Emacs Lisp code, use M-x load-file. This command reads a file name using the minibuffer and then executes the contents of that file as Lisp code. It is not necessary to visit the file first; in any case, this command reads the file as found on disk, not text in an Emacs buffer.

Once a file of Lisp code is installed in the Emacs Lisp library directories, users can load it using M-x load-library. Programs can load it by calling `load-library`, or with `load`, a more primitive function that is similar but accepts some additional arguments.

M-x load-library differs from M-x load-file in that it searches a sequence of directories and tries three file names in each directory. Suppose your argument is lib; the three names are `lib.elc', `lib.el',

and lastly just `lib'. If `lib.elc' exists, it is by convention the result of compiling `lib.el'; it is better to load the compiled file, since it will load and run faster.

If `load-library' finds that `lib.el' is newer than `lib.elc' file, it prints a warning, because it's likely that somebody made changes to the `.el' file and forgot to recompile it.

Because the argument to `load-library' is usually not in itself a valid file name, file name completion is not available. Indeed, when using this command, you usually do not know exactly what file name will be used.

The sequence of directories searched by M-x load-library is specified by the variable `load-path', a list of strings that are directory names. The default value of the list contains the directory where the Lisp code for Emacs itself is stored. If you have libraries of your own, put them in a single directory and add that directory to `load-path'. `nil' in this list stands for the current default directory, but it is probably not a good idea to put `nil' in the list. If you find yourself wishing that `nil' were in the list, most likely what you really want to do is use M-x load-file this once.

Often you do not have to give any command to load a library, because the commands defined in the library are set up to autoload that library. Trying to run any of those commands calls `load' to load the library; this replaces the autoload definitions with the real ones from the library.

Emacs Lisp code can be compiled into byte-code which loads faster, takes up less space when loaded, and executes faster. See section 'Byte Compilation' in the Emacs Lisp Reference Manual. By convention, the compiled code for a library goes in a separate file whose name consists of the library source file with `c' appended. Thus, the compiled code for `foo.el' goes in `foo.elc'. That's why `load-library' searches for `.elc' files first.

Evaluating Emacs-Lisp Expressions

Lisp programs intended to be run in Emacs should be edited in Emacs-Lisp mode; this happens automatically for file names ending in `.el'. By contrast, Lisp mode itself is used for editing Lisp programs intended for other Lisp systems. To switch to Emacs-Lisp mode explicitly, use the command M-x emacs-lisp-mode.

For testing of Lisp programs to run in Emacs, it is often useful to evaluate part of the program as it is found in the Emacs buffer. For example, after changing the text of a Lisp function definition, evaluating the definition installs the change for future calls to the function. Evaluation of Lisp expressions is also useful in any kind of editing, for invoking noninteractive functions (functions that are not commands).

M-:

> Read a single Lisp expression in the minibuffer, evaluate it, and print the value in the echo area (`eval-expression').

C-x C-e

> Evaluate the Lisp expression before point, and print the value in the echo area (`eval-last-sexp').

C-M-x

Evaluate the defun containing or after point, and print the value in the echo area (`eval-defu`

M-x eval-region

Evaluate all the Lisp expressions in the region.

M-x eval-current-buffer

Evaluate all the Lisp expressions in the buffer.

M-: (`eval-expression`) is the most basic command for evaluating a Lisp expression interactively. It reads the expression using the minibuffer, so you can execute any expression on a buffer regardless of what the buffer contains. When the expression is evaluated, the current buffer is once again the buffer that was current when M-: was typed.

M-: can easily confuse users who do not understand it. Therefore, `eval-expression` is normally a disabled command. Attempting to use this command asks for confirmation and gives you the option of enabling it; once you enable the command, confirmation will no longer be required for it. See section Disabling Commands.

In Emacs-Lisp mode, the key C-M-x is bound to the command `eval-defun`, which parses the defun containing or following point as a Lisp expression and evaluates it. The value is printed in the echo area. This command is convenient for installing in the Lisp environment changes that you have just made in the text of a function definition.

C-M-x treats `defvar` expressions specially. Normally, evaluating a `defvar` expression does nothing if the variable it defines already has a value. But C-M-x unconditionally resets the variable to the initial value specified in the `defvar` expression. This special feature is convenient for debugging Lisp programs.

The command C-x C-e (`eval-last-sexp`) evaluates the Lisp expression preceding point in the buffer, and displays the value in the echo area. It is available in all major modes, not just Emacs-Lisp mode. It does not treat `defvar` specially.

If C-M-x or C-x C-e is given a numeric argument, it inserts the value into the current buffer at point, rather than displaying it in the echo area. The argument's value does not matter.

The most general command for evaluating Lisp expressions from a buffer is `eval-region`. M-x eval-region parses the text of the region as one or more Lisp expressions, evaluating them one by one. M-x eval-current-buffer is similar but evaluates the entire buffer. This is a reasonable way to install the contents of a file of Lisp code that you are just ready to test. Later, as you find bugs and change individual functions, use C-M-x on each function that you change. This keeps the Lisp world in step with the source file.

Lisp Interaction Buffers

The buffer `*scratch*' which is selected when Emacs starts up is provided for evaluating Lisp expressions interactively inside Emacs.

The simplest way to use the `*scratch*' buffer is to insert Lisp expressions and type LFD after each expression. This command reads the Lisp expression before point, evaluates it, and inserts the value in

printed representation before point. The result is a complete typescript of the expressions you have evaluated and their values.

The `*scratch*' buffer's major mode is Lisp Interaction mode, which is the same as Emacs-Lisp mode except for the binding of LFD.

The rationale for this feature is that Emacs must have a buffer when it starts up, but that buffer is not useful for editing files since a new buffer is made for every file that you visit. The Lisp interpreter typescript is the most useful thing I can think of for the initial buffer to do. Type M-x lisp-interaction-mode to put the current buffer in Lisp Interaction mode.

An alternative way of evaluating Emacs Lisp expressions interactively is to use Inferior Emacs-Lisp mode, which provides an interface rather like Shell mode (see section Shell Mode) for evaluating Emacs Lisp expressions. Type M-x ielm to create an `*ielm*' buffer which uses this mode.

Running an External Lisp

Emacs has facilities for running programs in other Lisp systems. You can run a Lisp process as an inferior of Emacs, and pass expressions to it to be evaluated. You can also pass changed function definitions directly from the Emacs buffers in which you edit the Lisp programs to the inferior Lisp process.

To run an inferior Lisp process, type M-x run-lisp. This runs the program named `lisp`, the same program you would run by typing `lisp` as a shell command, with both input and output going through an Emacs buffer named `*lisp*'. That is to say, any "terminal output" from Lisp will go into the buffer, advancing point, and any "terminal input" for Lisp comes from text in the buffer. (You can change the name of the Lisp executable file by setting the variable `inferior-lisp-program`.)

To give input to Lisp, go to the end of the buffer and type the input, terminated by RET. The `*lisp*' buffer is in Inferior Lisp mode, which combines the special characteristics of Lisp mode with most of the features of Shell mode (see section Shell Mode). The definition of RET to send a line to a subprocess is one of the features of Shell mode.

For the source files of programs to run in external Lisps, use Lisp mode. This mode can be selected with M-x lisp-mode, and is used automatically for files whose names end in `.l', `.lsp', or `.lisp', as most Lisp systems usually expect.

When you edit a function in a Lisp program you are running, the easiest way to send the changed definition to the inferior Lisp process is the key C-M-x. In Lisp mode, this runs the function `lisp-eval-defun`, which finds the defun around or following point and sends it as input to the Lisp process. (Emacs can send input to any inferior process regardless of what buffer is current.)

Contrast the meanings of C-M-x in Lisp mode (for editing programs to be run in another Lisp system) and Emacs-Lisp mode (for editing Lisp programs to be run in Emacs): in both modes it has the effect of installing the function definition that point is in, but the way of doing so is different according to where the relevant Lisp environment is found. See section Executing Lisp Expressions.

Go to the previous, next section.

Go to the previous, next section.

Abbrevs

A defined abbrev is a word which expands, if you insert it, into some different text. Abbrevs are defined by the user to expand in specific ways. For example, you might define `foo' as an abbrev expanding to `find outer otter'. Then you would be able to insert `find outer otter ' into the buffer by typing f o o SPC.

A second kind of abbreviation facility is called dynamic abbrev expansion. You use dynamic abbrev expansion with an explicit command to expand the letters in the buffer before point by looking for other words in the buffer that start with those letters. See section Dynamic Abbrev Expansion.

Abbrev Concepts

An abbrev is a word which has been defined to expand into a specified expansion. When you insert a word-separator character following the abbrev, that expands the abbrev--replacing the abbrev with its expansion. For example, if `foo' is defined as an abbrev expanding to `find outer otter', then you can insert `find outer otter.' into the buffer by typing f o o ..

Abbrevs expand only when Abbrev mode (a minor mode) is enabled. Disabling Abbrev mode does not cause abbrev definitions to be forgotten, but they do not expand until Abbrev mode is enabled again. The command M-x abbrev-mode toggles Abbrev mode; with a numeric argument, it turns Abbrev mode on if the argument is positive, off otherwise. See section Minor Modes. `abbrev-mode` is also a variable; Abbrev mode is on when the variable is non-`nil`. The variable `abbrev-mode` automatically becomes local to the current buffer when it is set.

Abbrev definitions can be mode-specific---active only in one major mode. Abbrevs can also have global definitions that are active in all major modes. The same abbrev can have a global definition and various mode-specific definitions for different major modes. A mode specific definition for the current major mode overrides a global definition.

Abbrevs can be defined interactively during the editing session. Lists of abbrev definitions can also be saved in files and reloaded in later sessions. Some users keep extensive lists of abbrevs that they load in every session.

Defining Abbrevs

C-x a g

> Define an abbrev, using one or more words before point as its expansion (`add-global-abbrev`).

C-x a l

> Similar, but define an abbrev specific to the current major mode (`add-mode-abbrev`).

C-x a i g

Define a word in the buffer as an abbrev (`inverse-add-global-abbrev`).

C-x a i l

Define a word in the buffer as a mode-specific abbrev (`inverse-add-mode-abbrev`).

M-x kill-all-abbrevs

This command discards all abbrev definitions currently in effect, leaving a blank slate.

The usual way to define an abbrev is to enter the text you want the abbrev to expand to, position point after it, and type C-x a g (`add-global-abbrev`). This reads the abbrev itself using the minibuffer, and then defines it as an abbrev for one or more words before point. Use a numeric argument to say how many words before point should be taken as the expansion. For example, to define the abbrev `foo' as mentioned above, insert the text `find outer otter' and then type C-u 3 C-x a g f o o RET.

An argument of zero to C-x a g means to use the contents of the region as the expansion of the abbrev being defined.

The command C-x a l (`add-mode-abbrev`) is similar, but defines a mode-specific abbrev. Mode specific abbrevs are active only in a particular major mode. C-x a l defines an abbrev for the major mode in effect at the time C-x a l is typed. The arguments work the same as for C-x a g.

If the text already in the buffer is the abbrev, rather than its expansion, use command C-x a i g (`inverse-add-global-abbrev`) instead of C-x a g, or use C-x a i l (`inverse-add-mode-abbrev`) instead of C-x a l. These commands are called "inverse" because they invert the meaning of the two text strings they use (one from the buffer and one read with the minibuffer).

To change the definition of an abbrev, just define a new definition. When the abbrev has a prior definition, the abbrev definition commands ask for confirmation for replacing it.

To remove an abbrev definition, give a negative argument to the abbrev definition command: C-u - C-x a g or C-u - C-x a l. The former removes a global definition, while the latter removes a mode-specific definition.

M-x kill-all-abbrevs removes all the abbrev definitions there are, both global and local.

Controlling Abbrev Expansion

An abbrev expands whenever it is present in the buffer just before point and you type a self-inserting whitespace or punctuation character (SPC, comma, etc.). More precisely, any character that is not a word constituent expands an abbrev, and any word constituent character can be part of an abbrev. The most common way to use an abbrev is to insert it and then insert a punctuation character to expand it.

Abbrev expansion preserves case; thus, `foo' expands into `find outer otter'; `Foo' into `Find outer otter', and `FOO' into `FIND OUTER OTTER' or `Find Outer Otter' according to the variable `abbrev-all-caps` (a non-`nil` value chooses the first of the two expansions).

These commands are used to control abbrev expansion:

M-'

Separate a prefix from a following abbrev to be expanded (`abbrev-prefix-mark`).

C-x a e

Expand the abbrev before point (`expand-abbrev`). This is effective even when Abbrev mode is not enabled.

M-x expand-region-abbrevs

Expand some or all abbrevs found in the region.

You may wish to expand an abbrev with a prefix attached; for example, if `cnst' expands into `construction', you might want to use it to enter `reconstruction'. It does not work to type recnst, because that is not necessarily a defined abbrev. What you can do is use the command M-' (`abbrev-prefix-mark`) in between the prefix `re' and the abbrev `cnst'. First, insert `re'. Then type M-'; this inserts a hyphen in the buffer to indicate that it has done its work. Then insert the abbrev `cnst'; the buffer now contains `re-cnst'. Now insert a non-word character to expand the abbrev `cnst' into `construction'. This expansion step also deletes the hyphen that indicated M-' had been used. The result is the desired `reconstruction'.

If you actually want the text of the abbrev in the buffer, rather than its expansion, you can accomplish this by inserting the following punctuation with C-q. Thus, foo C-q , leaves `foo,' in the buffer.

If you expand an abbrev by mistake, you can undo the expansion and bring back the abbrev itself by typing C-_ to undo (see section Undoing Changes). This also undoes the insertion of the non-word character that expanded the abbrev. If the result you want is the terminating non-word character plus the unexpanded abbrev, you must reinsert the terminating character, quoting it with C-q.

M-x expand-region-abbrevs searches through the region for defined abbrevs, and for each one found offers to replace it with its expansion. This command is useful if you have typed in text using abbrevs but forgot to turn on Abbrev mode first. It may also be useful together with a special set of abbrev definitions for making several global replacements at once. This command is effective even if Abbrev mode is not enabled.

Expanding an abbrev runs the hook `pre-abbrev-expand-hook` (see section Hooks).

Examining and Editing Abbrevs

M-x list-abbrevs

Display a list of all abbrev definitions.

M-x edit-abbrevs

Edit a list of abbrevs; you can add, alter or remove definitions.

The output from M-x list-abbrevs looks like this:

```
(lisp-mode-abbrev-table)
"dk"            0    "define-key"
(global-abbrev-table)
"dfn"           0    "definition"
```

(Some blank lines of no semantic significance, and some other abbrev tables, have been omitted.)

A line containing a name in parentheses is the header for abbrevs in a particular abbrev table; `global-abbrev-table` contains all the global abbrevs, and the other abbrev tables that are named after major modes contain the mode-specific abbrevs.

Within each abbrev table, each nonblank line defines one abbrev. The word at the beginning of the line is the abbrev. The number that follows is the number of times the abbrev has been expanded. Emacs keeps track of this to help you see which abbrevs you actually use, so that you can eliminate those that you don't use often. The string at the end of the line is the expansion.

M-x edit-abbrevs allows you to add, change or kill abbrev definitions by editing a list of them in an Emacs buffer. The list has the same format described above. The buffer of abbrevs is called `*Abbrevs*', and is in Edit-Abbrevs mode. Type C-c C-c in this buffer to install the abbrev definitions as specified in the buffer--and delete any abbrev definitions not listed.

The command `edit-abbrevs` is actually the same as `list-abbrevs` except that it selects the buffer `*Abbrevs*' whereas `list-abbrevs` merely displays it in another window.

Saving Abbrevs

These commands allow you to keep abbrev definitions between editing sessions.

M-x write-abbrev-file RET file RET

: Write a file file describing all defined abbrevs.

M-x read-abbrev-file RET file RET

: Read the file file and define abbrevs as specified therein.

M-x quietly-read-abbrev-file RET file RET

: Similar but do not display a message about what is going on.

M-x define-abbrevs

: Define abbrevs from definitions in current buffer.

M-x insert-abbrevs

: Insert all abbrevs and their expansions into current buffer.

M-x write-abbrev-file reads a file name using the minibuffer and then writes a description of all current abbrev definitions into that file. This is used to save abbrev definitions for use in a later session. The text stored in the file is a series of Lisp expressions that, when executed, define the same abbrevs that you currently have.

M-x read-abbrev-file reads a file name using the minibuffer and then reads the file, defining abbrevs according to the contents of the file. M-x quietly-read-abbrev-file is the same except that it does not display a message in the echo area saying that it is doing its work; it is actually useful primarily in the `.emacs' file. If an empty argument is given to either of these functions, they use the file name specified in the variable `abbrev-file-name`, which is by default `"~/.abbrev_defs"`.

Emacs will offer to save abbrevs automatically if you have changed any of them, whenever it offers to save all files (for C-x s or C-x C-c). This feature can be inhibited by setting the variable `save-abbrevs` to `nil`.

The commands M-x insert-abbrevs and M-x define-abbrevs are similar to the previous commands but work on text in an Emacs buffer. M-x insert-abbrevs inserts text into the current buffer before point, describing all current abbrev definitions; M-x define-abbrevs parses the entire current buffer and defines abbrevs accordingly.

Dynamic Abbrev Expansion

The abbrev facility described above operates automatically as you insert text, but all abbrevs must be defined explicitly. By contrast, dynamic abbrevs allow the meanings of abbrevs to be determined automatically from the contents of the buffer, but dynamic abbrev expansion happens only when you request it explicitly.

M-/

> Expand the word in the buffer before point as a dynamic abbrev, by searching in the buffer for words starting with that abbreviation (`dabbrev-expand`).

C-M-/

> Complete the word before point as a dynamic abbrev (`dabbrev-completion`).

For example, if the buffer contains `does this follow ' and you type f o M-/, the effect is to insert `follow' because that is the last word in the buffer that starts with `fo'. A numeric argument to M-/ says to take the second, third, etc. distinct expansion found looking backward from point. Repeating M-/ searches for an alternative expansion by looking farther back. After considering the entire buffer before point, it searches the text after point. The variable `dabbrev-limit`, if non-`nil`, specifies how far in the buffer to search for an expansion.

After searching all of the current buffer, M-/ normally searches other buffers, unless you have set `dabbrev-check-all-buffers` to `nil`.

A negative argument to M-/, as in C-u - M-/, says to search first for expansions after point, and second for expansions before point. If you repeat the M-/ to look for another expansion, do not specify an argument. This tries all the expansions after point and then the expansions before point.

After you have expanded a dynamic abbrev, you can copy additional words that follow the expansion in its original context. Simply type SPC M-/ for each word you want to copy. The spacing and punctuation between words is copied along with the words.

The command C-M-/ (`dabbrev-completion`) performs completion of a dynamic abbreviation. Instead of trying the possible expansions one by one, it finds all of them, then inserts the text that they have in common. If they have nothing in common, C-M-/ displays a list of completions, from which you can select a choice in the usual manner. See section Completion.

Dynamic abbrev expansion is completely independent of Abbrev mode; the expansion of a word with M-/ is completely independent of whether it has a definition as an ordinary abbrev.

Customizing Dynamic Abbreviation

Normally, dynamic abbrev expansion ignores case when searching for expansions. That is, the expansion need not agree in case with the word you are expanding. If you set `dabbrev-case-fold-search` to `nil`, then the word and the expansion must match in case.

The value of `dabbrev-case-fold-search` may be any expression. Dynamic abbrev expansion evaluates that expression, and ignores case while searching if its value is not `nil`. The default value of `dabbrev-case-fold-search` is `case-fold-search`, so normally the value of `case-fold-search` controls the decision. The reason why dynamic abbrev expansion normally ignores case when searching for expansions is that normally the value of `case-fold-search` is `t`.

Normally, dynamic abbrev expansion preserves the case pattern *of the word you are expanding*, by converting the expansion to that case pattern. If you set `dabbrev-case-replace` to `nil`, the expansion is copied without conversion.

The variables `dabbrev-case-fold-search` and `dabbrev-case-replace` are handled in a special way. Their values are actually Lisp expressions which are evaluated each time a decision needs to be made. If the expression's value is non-`nil`, then case is ignored in searching, or converted on replacement, respectively. If the expression's value is `nil`, case is not ignored or not converted. The default values let the variables `case-fold-search` (see section Searching and Case) and `case-replace` (see section Replace Commands and Case) control what to do.

The variable `dabbrev-abbrev-char-regexp`, if non-`nil`, controls which characters are considered part of a word, for dynamic expansion purposes. The regular expression must match just one character, never two or more. The same regular expression also determines which characters are part of an expansion. The value `nil` has a special meaning: abbreviations are made of word characters, but expansions are made of word and symbol characters.

In shell scripts and makefiles, a variable name is sometimes prefixed with `$' and sometimes not. Major modes for this kind of text can customize dynamic abbreviation to handle optional prefixes by setting the variable `dabbrev-abbrev-skip-leading-regexp`. Its value should be a regular expression that matches the optional prefix that dynamic abbreviation should ignore.

Go to the previous, next section.

Editing Pictures

To edit a picture made out of text characters (for example, a picture of the division of a register into fields, as a comment in a program), use the command M-x edit-picture to enter Picture mode.

In Picture mode, editing is based on the quarter-plane model of text, according to which the text characters lie studded on an area that stretches infinitely far to the right and downward. The concept of the end of a line does not exist in this model; the most you can say is where the last nonblank character on the line is found.

Of course, Emacs really always considers text as a sequence of characters, and lines really do have ends. But Picture mode replaces the most frequently-used commands with variants that simulate the quarter-plane model of text. They do this by inserting spaces or by converting tabs to spaces.

Most of the basic editing commands of Emacs are redefined by Picture mode to do essentially the same thing but in a quarter-plane way. In addition, Picture mode defines various keys starting with the C-c prefix to run special picture editing commands.

One of these keys, C-c C-c, is pretty important. Often a picture is part of a larger file that is usually edited in some other major mode. M-x edit-picture records the name of the previous major mode so you can use the C-c C-c command (`picture-mode-exit`) later to go back to that mode. C-c C-c also deletes spaces from the ends of lines, unless given a numeric argument.

The special commands of Picture mode all work in other modes (provided the `` `picture' `` library is loaded), but are not bound to keys except in Picture mode. The descriptions below talk of moving "one column" and so on, but all the picture mode commands handle numeric arguments as their normal equivalents do.

Turning on Picture mode runs the hook `picture-mode-hook` (see section Hooks).

Basic Editing in Picture Mode

Most keys do the same thing in Picture mode that they usually do, but do it in a quarter-plane style. For example, C-f is rebound to run `picture-forward-column`, a command which moves point one column to the right, inserting a space if necessary so that the actual end of the line makes no difference. C-b is rebound to run `picture-backward-column`, which always moves point left one column, converting a tab to multiple spaces if necessary. C-n and C-p are rebound to run `picture-move-down` and `picture-move-up`, which can either insert spaces or convert tabs as necessary to make sure that point stays in exactly the same column. C-e runs `picture-end-of-line`, which moves to after the last nonblank character on the line. There is no need to change C-a, as the choice of screen model does not affect beginnings of lines.

Insertion of text is adapted to the quarter-plane screen model through the use of Overwrite mode (see section Minor Modes). Self-inserting characters replace existing text, column by column, rather than

pushing existing text to the right. RET runs `picture-newline`, which just moves to the beginnin the following line so that new text will replace that line.

Picture mode provides erasure instead of deletion and killing of text. DEL (`picture-backward-clear-column`) replaces the preceding character with a space rather than removing it; this moves point backwards. C-d (`picture-clear-column`) replaces the next character or characters with spaces, but does not move point. (If you want to clear characters to spaces and move forward over them, use SPC.) C-k (`picture-clear-line`) really kills the contents of lines, but does not delete the newlines from the buffer.

To do actual insertion, you must use special commands. C-o (`picture-open-line`) creates a blank line after the current line; it never splits a line. C-M-o, `split-line`, makes sense in Picture mode, so it is not changed. LFD (`picture-duplicate-line`) inserts below the current line another line with the same contents.

To do actual deletion in Picture mode, use C-w, C-c C-d (which is defined as `delete-char`, as C-d is in other modes), or one of the picture rectangle commands (see section Picture Mode Rectangle Commands).

Controlling Motion after Insert

Since "self-inserting" characters in Picture mode overwrite and move point, there is no essential restriction on how point should be moved. Normally point moves right, but you can specify any of the eight orthogonal or diagonal directions for motion after a "self-inserting" character. This is useful for drawing lines in the buffer.

C-c <
: Move left after insertion (`picture-movement-left`).

C-c >
: Move right after insertion (`picture-movement-right`).

C-c ^
: Move up after insertion (`picture-movement-up`).

C-c .
: Move down after insertion (`picture-movement-down`).

C-c `
: Move up and left ("northwest") after insertion (`picture-movement-nw`).

C-c '
: Move up and right ("northeast") after insertion (`picture-movement-ne`).

C-c /
: Move down and left ("southwest") after insertion (`picture-movement-sw`).

C-c \
: Move down and right ("southeast") after insertion

(`picture-movement-se`).

Two motion commands move based on the current Picture insertion direction. The command C-c C-f (`picture-motion`) moves in the same direction as motion after "insertion" currently does, while C-c C-b (`picture-motion-reverse`) moves in the opposite direction.

Picture Mode Tabs

Two kinds of tab-like action are provided in Picture mode. Use M-TAB (`picture-tab-search`) for context-based tabbing. With no argument, it moves to a point underneath the next "interesting" character that follows whitespace in the previous nonblank line. "Next" here means "appearing at a horizontal position greater than the one point starts out at." With an argument, as in C-u M-TAB, this command moves to the next such interesting character in the current line. M-TAB does not change the text; it only moves point. "Interesting" characters are defined by the variable `picture-tab-chars`, which should define a set of characters. The syntax for this variable is like the syntax used inside of `[...]' in a regular expression--but without the `[' and the `]'. Its default value is `"!-~"`.

TAB itself runs `picture-tab`, which operates based on the current tab stop settings; it is the Picture mode equivalent of `tab-to-tab-stop`. Normally it just moves point, but with a numeric argument it clears the text that it moves over.

The context-based and tab-stop-based forms of tabbing are brought together by the command C-c TAB, `picture-set-tab-stops`. This command sets the tab stops to the positions which M-TAB would consider significant in the current line. The use of this command, together with TAB, can get the effect of context-based tabbing. But M-TAB is more convenient in the cases where it is sufficient.

It may be convenient to prevent use of actual tab characters in pictures. For example, this prevents C-x TAB from messing up the picture. You can do this by setting the variable `indent-tabs-mode` to `nil`. See section Tabs vs. Spaces.

Picture Mode Rectangle Commands

Picture mode defines commands for working on rectangular pieces of the text in ways that fit with the quarter-plane model. The standard rectangle commands may also be useful (see section Rectangles).

C-c C-k

Clear out the region-rectangle with spaces (`picture-clear-rectangle`). With argument, delete the text.

C-c C-w r

Similar but save rectangle contents in register r first (`picture-clear-rectangle-to-register`).

C-c C-y

Copy last killed rectangle into the buffer by overwriting, with upper left corner at point (`picture-yank-rectangle`). With argument, insert instead.

C-c C-x r

Similar, but use the rectangle in register r (`picture-yank-rectangle-from-register`).

The picture rectangle commands C-c C-k (`picture-clear-rectangle`) and C-c C-w (`picture-clear-rectangle-to-register`) differ from the standard rectangle commands in that they normally clear the rectangle instead of deleting it; this is analogous with the way C-d is changed in Picture mode.

However, deletion of rectangles can be useful in Picture mode, so these commands delete the rectangle if given a numeric argument. C-c C-k either with or without a numeric argument saves the rectangle for C-c C-y.

The Picture mode commands for yanking rectangles differ from the standard ones in overwriting instead of inserting. This is the same way that Picture mode insertion of other text differs from other modes. C-c C-y (`picture-yank-rectangle`) inserts (by overwriting) the rectangle that was most recently killed, while C-c C-x (`picture-yank-rectangle-from-register`) does likewise for the rectangle found in a specified register.

Go to the previous, next section.

Go to the previous, next section.

Sending Mail

To send a message in Emacs, you start by typing a command (C-x m) to select and initialize the `*mail*' buffer. Then you edit the text and headers of the message in this buffer, and type another command (C-c C-s or C-c C-c) to send the message.

C-x m
: Begin composing a message to send (`mail`).

C-x 4 m
: Likewise, but display the message in another window (`mail-other-window`).

C-x 5 m
: Likewise, but make a new frame (`mail-other-frame`).

C-c C-s
: In Mail mode, send the message (`mail-send`).

C-c C-c
: Send the message and bury the mail buffer (`mail-send-and-exit`).

The command C-x m (`mail`) selects a buffer named `*mail*' and initializes it with the skeleton of an outgoing message. C-x 4 m (`mail-other-window`) selects the `*mail*' buffer in a different window, leaving the previous current buffer visible. C-x 5 m (`mail-other-frame`) creates a new frame to select the `*mail*' buffer.

Because the mail composition buffer is an ordinary Emacs buffer, you can switch to other buffers while in the middle of composing mail, and switch back later (or never). If you use the C-x m command again when you have been composing another message but have not sent it, you are asked to confirm before the old message is erased. If you answer n, the `*mail*' buffer is left selected with its old contents, so you can finish the old message and send it. C-u C-x m is another way to do this. Sending the message marks the `*mail*' buffer "unmodified", which avoids the need for confirmation when C-x m is next used.

If you are composing a message in the `*mail*' buffer and want to send another message before finishing the first, rename the `*mail*' buffer using M-x rename-uniquely (see section Miscellaneous Buffer Operations). Then you can use C-x m or its variants described above to make a new `*mail*' buffer. Once you've done that, you can work with each mail buffer independently.

The Format of the Mail Buffer

In addition to the text or body, a message has header fields which say who sent it, when, to whom, why, and so on. Some header fields such as the date and sender are created automatically after the message is sent. Others, such as the recipient names, must be specified by you in order to send the message properly.

Mail mode provides a few commands to help you edit some header fields, and some are preinitialized in

the buffer automatically at times. You can insert and edit header fields using ordinary editing comma

The line in the buffer that says

```
--text follows this line--
```

is a special delimiter that separates the headers you have specified from the text. Whatever follows this line is the text of the message; the headers precede it. The delimiter line itself does not appear in the message actually sent. The text used for the delimiter line is controlled by the variable `mail-header-separator`.

Here is an example of what the headers and text in the mail buffer might look like.

```
To: gnu@prep.ai.mit.edu
CC: lungfish@spam.org, byob@spam.org
Subject: The Emacs Manual
--Text follows this line--
Please ignore this message.
```

Mail Header Fields

A header field in the mail buffer starts with a field name at the beginning of a line, terminated by a colon. Upper and lower case are equivalent in field names (and in mailing addresses also). After the colon and optional whitespace comes the contents of the field.

You can use any name you like for a header field, but normally people use only standard field names with accepted meanings. Here is a table of fields commonly used in outgoing messages.

`To'

This field contains the mailing addresses to which the message is addressed.

`Subject'

The contents of the `Subject' field should be a piece of text that says what the message is about. The reason `Subject' fields are useful is that most mail-reading programs can provide a summary of messages, listing the subject of each message but not its text.

`CC'

This field contains additional mailing addresses to send the message to, but whose readers should not regard the message as addressed to them.

`BCC'

This field contains additional mailing addresses to send the message to, which should not appear in the header of the message actually sent. Copies sent this way are called blind carbon copies.

To send a blind carbon copy of every outgoing message to yourself, set the variable `mail-self-blind` to `t`.

`FCC'

This field contains the name of one file and directs Emacs to append a copy of the message to that

file when you send the message. If the file is in Rmail format, Emacs writes the message to Rmail format; otherwise, Emacs writes the message in system mail file format.

To put a fixed file name as in `FCC' field each time you start editing an outgoing message, set the variable `mail-archive-file-name` to that file name. Unless you remove the `FCC' field before sending, the message will be written into that file when it is sent.

`From'

Use the `From' field to say who you are, when the account you are using to send the mail is not your own. The contents of the `From' field should be a valid mailing address, since replies will normally go there. If you don't specify the `From' field yourself, Emacs uses the value of `user-mail-address` as the default.

`Reply-to'

Use this field to direct replies to a different address. Most mail-reading programs (including Rmail) automatically send replies to the `Reply-to' address in preference to the `From' address. By adding a `Reply-to' field to your header, you can work around any problems your `From' address may cause for replies.

To put a fixed `Reply-to' address into every outgoing message, set the variable `mail-default-reply-to` to that address (as a string). Then `mail` initializes the message with a `Reply-to' field as specified. You can delete or alter that header field before you send the message, if you wish. When Emacs starts up, if the environment variable `REPLYTO` is set, `mail-default-reply-to` is initialized from that environment variable.

`In-reply-to'

This field contains a piece of text describing a message you are replying to. Some mail systems can use this information to correlate related pieces of mail. Normally this field is filled in by Rmail when you reply to a message in Rmail, and you never need to think about it (see section Reading Mail with Rmail).

The `To', `CC', `BCC' and `FCC' fields can appear any number of times, to specify many places to send the message. The `To', `CC', and `BCC' fields can have continuation lines. All the lines starting with whitespace, following the line on which the field starts, are considered part of the field. For example,

```
To: foo@here.net, this@there.net,
  me@gnu.cambridge.mass.usa.earth.spiral3281
```

When you send the message, if you didn't write a `From' field yourself, Emacs puts in one for you. The variable `mail-from-style` controls the format:

`nil`

Just the email address, as in `king@grassland.com'.

`parens`

Both email address and full name, as in `king@grassland.com (Elvis Parsley)'.

`angles`

Both email address and full name, as in `Elvis Parsley <king@grassland.com>'.

Mail Aliases

You can define mail aliases in a file named `~/.mailrc'. These are short mnemonic names which stand for mail addresses or groups of mail addresses. Like many other mail programs, Emacs expands aliases when they occur in the `To', `From', `CC', `BCC', and `Reply-to' fields, plus their `Resent-' variants.

To define an alias in `~/.mailrc', write a line in the following format:

```
alias shortaddress fulladdresses
```

Here fulladdresses stands for one or more mail addresses for shortaddress to expand into. Separate multiple addresses with spaces; if an address contains a space, quote the whole address with a pair of double-quotes.

For instance, to make `maingnu` stand for `gnu@prep.ai.mit.edu` plus a local address of your own, put in this line:

```
alias maingnu gnu@prep.ai.mit.edu local-gnu
```

Emacs also recognizes include commands in `.mailrc' files. They look like this:

```
source filename
```

The file `~/.mailrc' is used primarily by other mail-reading programs; it can contain various other commands. Emacs ignores everything in it except for alias definitions and include commands.

Another way to define a mail alias, within Emacs alone, is with the `define-mail-alias` command. It prompts for the alias and then the full address. You can use it to define aliases in your `.emacs' file, like this:

```
(define-mail-alias "maingnu" "gnu@prep.ai.mit.edu")
```

`define-mail-alias` records aliases by adding them to a variable named `mail-aliases`. If you are comfortable with manipulating Lisp lists, you can set `mail-aliases` directly. The initial value of `mail-aliases` is `t`, which means that Emacs should read `.mailrc' to get the proper value.

You can specify a different file name to use instead of `~/.mailrc' by setting the variable `mail-personal-alias-file`.

Normally, Emacs expands aliases when you send the message. If you like, you can have mail aliases expand as abbrevs, as soon as you type them in (see section Abbrevs). To enable this feature, execute the following:

```
(add-hook 'mail-setup-hook 'mail-abbrevs-setup)
```

This can go in your `.emacs' file. See section Hooks. If you use this feature, you must use

`define-mail-abbrev` instead of `define-mail-alias`; the latter does not work with this package. Note that the mail abbreviation package uses the variable `mail-abbrevs` instead of `mail-aliases`, and that all alias names are converted to lower case.

The mail abbreviation package also provides the C-c C-a (`mail-interactive-insert-alias`) command, which reads an alias name (with completion) and inserts its definition at point. This is useful when editing the message text itself or a header field such as `Subject' in which Emacs does not normally expand aliases.

Note that abbrevs expand only if you insert a word-separator character afterward. However, you can rebind C-n and M-> to cause expansion as well. Here's how to do that:

```
(add-hook 'mail-setup-hook
          '(lambda ()
             (substitute-key-definition
               'next-line 'mail-abbrev-next-line
               mail-mode-map global-map)
             (substitute-key-definition
               'end-of-buffer 'mail-abbrev-end-of-buffer
               mail-mode-map global-map)))
```

Mail Mode

The major mode used in the mail buffer is Mail mode, which is much like Text mode except that various special commands are provided on the C-c prefix. These commands all have to do specifically with editing or sending the message.

C-c C-s
: Send the message, and leave the mail buffer selected (`mail-send`).

C-c C-c
: Send the message, and select some other buffer (`mail-send-and-exit`).

M-TAB
: Complete a mailing address (`mail-complete`).

C-c C-f C-t
: Move to the `To' header field, creating one if there is none (`mail-to`).

C-c C-f C-s
: Move to the `Subject' header field, creating one if there is none (`mail-subject`).

C-c C-f C-c
: Move to the `CC' header field, creating one if there is none (`mail-cc`).

C-c C-f C-b
: Move to the `BCC' header field, creating one if there is none (`mail-bcc`).

C-c C-f C-f

Move to the `FCC' header field, creating one if there is none (`mail-fcc').

C-c C-t

Move to the beginning of the message body text (`mail-text').

C-c C-w

Insert the file `~/.signature' at the end of the message text (`mail-signature').

C-c C-y

Yank the selected message from Rmail (`mail-yank-original'). This command does nothing unless your command to start sending a message was issued with Rmail.

C-c C-q

Fill all paragraphs of yanked old messages, each individually (`mail-fill-yanked-message').

M-x ispell-message

Do spelling correction on the message text, but not on citations from other messages.

There are two ways to send the message. C-c C-s (`mail-send') sends the message and marks the mail buffer unmodified, but leaves that buffer selected so that you can modify the message (perhaps with new recipients) and send it again. C-c C-c (`mail-send-and-exit') sends and then deletes the window or switches to another buffer. It puts the mail buffer at the lowest priority for reselection by default, since you are finished with using it. This is the usual way to send the message.

While editing a header field that contains mailing addresses, such as `To:', `CC:' and `BCC:', you can complete a mailing address by typing M-TAB (`mail-complete'). For completion purposes, the valid mailing addresses are taken to be the local users' names plus your personal mail aliases. Additionally, if your site provides a mail directory or a specific host to use for any unrecognized user name, you can arrange to query that host for completion--see the variables `mail-directory-process' and `mail-directory-stream' in the source code.

If you type M-TAB in the body of the message, it invokes `ispell-complete-word', as in Text mode.

Mail mode provides special commands for editing the headers and text of the message before you send it. There are five commands defined to move point to particular header fields, all based on the prefix C-c C-f (`C-f' is for "field"). They are C-c C-f C-t (`mail-to') to move to the `To' field, C-c C-f C-s (`mail-subject') for the `Subject' field, C-c C-f C-c (`mail-cc') for the `CC' field, C-c C-f C-b (`mail-bcc') for the `BCC' field, and C-c C-f C-f (`mail-fcc') for the `FCC' field. If the field in question does not exist, these commands create one. We provide special motion commands for these particular fields because they are the fields users most often want to edit.

C-c C-t (`mail-text') moves point to just after the header separator line--that is, to the beginning of the message body text.

C-c C-w (`mail-signature') adds a standard piece text at the end of the message to say more about who you are. The text comes from the file `.signature' in your home directory. To insert your signature automatically, set the variable `mail-signature' to `t'; then starting a mail message automatically inserts the contents of your `.signature' file. If you want to omit your signature from

a particular message, delete it from the buffer before you send the message.

You can also set `mail-signature` to a string; then that string is inserted automatically as your signature when you start editing a message to send.

When mail sending is invoked from the Rmail mail reader using an Rmail command, C-c C-y can be used inside the mail buffer to insert the text of the message you are replying to. Normally it indents each line of that message four spaces and eliminates most header fields. A numeric argument specifies the number of spaces to indent. An argument of just C-u says not to indent at all and not to eliminate anything. C-c C-y always uses the current message from the Rmail buffer, so you can insert several old messages by selecting one in Rmail, switching to `*mail*' and yanking it, then switching back to Rmail to select another.

You can specify the text for C-c C-y to insert at the beginning of each line: set `mail-yank-prefix` to the desired string. (A value of `nil` means to use indentation; this is the default.) However, C-u C-c C-y never adds anything at the beginning of the inserted lines, regardless of the value of `mail-yank-prefix`.

After using C-c C-y, you can use the command C-c C-q (`mail-fill-yanked-message`) to fill the paragraphs of the yanked old message or messages. One use of C-c C-q fills all such paragraphs, each one individually. To fill a single paragraph of the quoted message, use M-q, after first setting the fill prefix appropriately to handle the indentation. See section Filling Text.

You can do spelling correction on the message text you have written with the command M-x ispell-message. If you have yanked an incoming message into the outgoing draft, this command skips what was yanked, but it checks the text that you yourself inserted. (It looks for indentation or `mail-yank-prefix` to distinguish the cited lines from your input.) See section Checking and Correcting Spelling.

Mail mode defines the character `%' as a word separator; this is helpful for using the word commands to edit mail addresses.

Mail mode is normally used in buffers set up automatically by the `mail` command and related commands. However, you can also switch to Mail mode in a file-visiting buffer. That is a useful thing to do if you have saved draft message text in a file. In a file-visiting buffer, C-c C-c does not clear the modified flag, because only saving the file should do that. As a result, you don't get a warning about trying to send the same message twice.

Turning on Mail mode (which C-x m does automatically) runs the normal hooks `text-mode-hook` and `mail-mode-hook`. Initializing a new outgoing message runs the normal hook `mail-setup-hook`; if you want to add special fields to your mail header or make other changes to the appearance of the mail buffer, use that hook. See section Hooks.

The main difference between these hooks is just when they are invoked. Whenever you type M-x mail, `mail-mode-hook` runs as soon as the `*mail*' buffer is created. Then the `mail-setup` function puts in the default contents of the buffer. After these default contents are inserted, `mail-setup-hook` runs.

Distracting the NSA

M-x spook adds a line of randomly chosen keywords to an outgoing mail message. The keywords are chosen from a list of words that suggest you are discussing something subversive.

The idea behind this feature is the suspicion that the NSA snoops on all electronic mail messages that contain keywords suggesting they might find them interesting. (The NSA says they don't, but that's what they *would* say.) The idea is that if lots of people add suspicious words to their messages, the NSA will get so busy with spurious input that they will have to give up reading it all.

Here's how to insert spook keywords automatically whenever you start entering an outgoing message:

```
(add-hook 'mail-setup-hook 'spook)
```

Whether or not this confuses the NSA, it at least amuses people.

Go to the previous, next section.

Go to the previous, next section.

Reading Mail with Rmail

Rmail is an Emacs subsystem for reading and disposing of mail that you receive. Rmail stores mail messages in files called Rmail files. Reading the message in an Rmail file is done in a special major mode, Rmail mode, which redefines most letters to run commands for managing mail.

Basic Concepts of Rmail

Using Rmail in the simplest fashion, you have one Rmail file `~/RMAIL' in which all of your mail is saved. It is called your primary Rmail file. The command M-x rmail reads your primary Rmail file, merges new mail in from your inboxes, displays the first message you haven't read yet, and lets you begin reading. The variable `rmail-file-name` specifies the name of the primary Rmail file.

Rmail uses narrowing to hide all but one message in the Rmail file. The message that is shown is called the current message. Rmail mode's special commands can do such things as delete the current message, copy it into another file, send a reply, or move to another message. You can also create multiple Rmail files and use Rmail to move messages between them.

Within the Rmail file, messages are normally arranged sequentially in order of receipt; you can specify other ways to sort them. Messages are assigned consecutive integers as their message numbers. The number of the current message is displayed in Rmail's mode line, followed by the total number of messages in the file. You can move to a message by specifying its message number with the j key (see section Moving Among Messages).

Following the usual conventions of Emacs, changes in an Rmail file become permanent only when the file is saved. You can save it with s (`rmail-save`), which also expunges deleted messages from the file first (see section Deleting Messages). To save the file without expunging, use C-x C-s. Rmail also saves the Rmail file after merging new mail from an inbox file (see section Rmail Files and Inboxes).

You can exit Rmail with q (`rmail-quit`); this expunges and saves the Rmail file and then switches to another buffer. But there is no need to `exit' formally. If you switch from Rmail to editing in other buffers, and never happen to switch back, you have exited. (The Rmail command b, `rmail-bury`, does this for you.) Just make sure to save the Rmail file eventually (like any other file you have changed). C-x s is a good enough way to do this (see section Saving Files).

Scrolling Within a Message

When Rmail displays a message that does not fit on the screen, you must scroll through it to read the rest. You could do this with C-v, M-v and M-<, but in Rmail scrolling is so frequent that it deserves to be easier to type.

SPC

Scroll forward (`scroll-up`).

DEL

Scroll backward (`scroll-down`).

.

Scroll to start of message (`rmail-beginning-of-message`).

Since the most common thing to do while reading a message is to scroll through it by screenfuls, Rmail makes SPC and DEL synonyms of C-v (`scroll-up`) and M-v (`scroll-down`)

The command . (`rmail-beginning-of-message`) scrolls back to the beginning of the selected message. This is not quite the same as M-<: for one thing, it does not set the mark; for another, it resets the buffer boundaries to the current message if you have changed them.

Moving Among Messages

The most basic thing to do with a message is to read it. The way to do this in Rmail is to make the message current. The usual practice is to move sequentially through the file, since this is the order of receipt of messages. When you enter Rmail, you are positioned at the first message that you have not yet made current (that is, the first one that has the `unseen' attribute; see section Labels). Move forward to see the other new messages; move backward to reexamine old messages.

n

Move to the next nondeleted message, skipping any intervening deleted messages (`rmail-next-undeleted-message`).

p

Move to the previous nondeleted message (`rmail-previous-undeleted-message`).

M-n

Move to the next message, including deleted messages (`rmail-next-message`).

M-p

Move to the previous message, including deleted messages (`rmail-previous-message`).

j

Move to the first message. With argument n, move to message number n (`rmail-show-message`).

>

Move to the last message (`rmail-last-message`).

<

Move to the first message (`rmail-first-message`).

M-s regexp RET

Move to the next message containing a match for regexp (`rmail-search`).

- M-s regexp RET

Move to the previous message containing a match for regexp.

n and p are the usual way of moving among messages in Rmail. They move through the messages sequentially, but skip over deleted messages, which is usually what you want to do. Their command definitions are named `rmail-next-undeleted-message` and `rmail-previous-undeleted-message`. If you do not want to skip deleted messages--for example, if you want to move to a message to undelete it--use the variants M-n and M-p (`rmail-next-message` and `rmail-previous-message`). A numeric argument to any of these commands serves as a repeat count.

In Rmail, you can specify a numeric argument by typing just the digits. You don't need to type C-u first.

The M-s (`rmail-search`) command is Rmail's version of search. The usual incremental search command C-s works in Rmail, but it searches only within the current message. The purpose of M-s is to search for another message. It reads a regular expression (see section Syntax of Regular Expressions) nonincrementally, then searches starting at the beginning of the following message for a match. It then selects that message. If regexp is empty, M-s reuses the regexp used the previous time.

To search backward in the file for another message, give M-s a negative argument. In Rmail you can do this with - M-s.

It is also possible to search for a message based on labels. See section Labels.

To move to a message specified by absolute message number, use j (`rmail-show-message`) with the message number as argument. With no argument, j selects the first message. < (`rmail-first-message`) also selects the first message. > (`rmail-last-message`) selects the last message.

Deleting Messages

When you no longer need to keep a message, you can delete it. This flags it as ignorable, and some Rmail commands pretend it is no longer present; but it still has its place in the Rmail file, and still has its message number.

Expunging the Rmail file actually removes the deleted messages. The remaining messages are renumbered consecutively. Expunging is the only action that changes the message number of any message, except for undigestifying (see section Digest Messages).

d

Delete the current message, and move to the next nondeleted message (`rmail-delete-forward`).

C-d

Delete the current message, and move to the previous nondeleted message (`rmail-delete-backward`).

u

Undelete the current message, or move back to a deleted message and undelete it (`rmail-undelete-previous-message`).

x

Expunge the Rmail file (`rmail-expunge`).

There are two Rmail commands for deleting messages. Both delete the current message and select another message. d (`rmail-delete-forward`) moves to the following message, skipping messages already deleted, while C-d (`rmail-delete-backward`) moves to the previous nondeleted message. If there is no nondeleted message to move to in the specified direction, the message that was just deleted remains current.

Whenever Rmail deletes a message, it invokes the function(s) listed in `rmail-delete-message-hook`. When the hook functions are invoked, the message has been marked deleted, but it is still the current message in the Rmail buffer.

To make all the deleted messages finally vanish from the Rmail file, type x (`rmail-expunge`). Until you do this, you can still undelete the deleted messages. The undeletion command, u (`rmail-undelete-previous-message`), is designed to cancel the effect of a d command in most cases. It undeletes the current message if the current message is deleted. Otherwise it moves backward to previous messages until a deleted message is found, and undeletes that message.

You can usually undo a d with a u because the u moves back to and undeletes the message that the d deleted. But this does not work when the d skips a few already-deleted messages that follow the message being deleted; then the u command undeletes the last of the messages that were skipped. There is no clean way to avoid this problem. However, by repeating the u command, you can eventually get back to the message that you intend to undelete. You can also select a particular deleted message with the M-p command, then type u to undelete it.

A deleted message has the `deleted' attribute, and as a result `deleted' appears in the mode line when the current message is deleted. In fact, deleting or undeleting a message is nothing more than adding or removing this attribute. See section Labels.

Rmail Files and Inboxes

The operating system places incoming mail for you in a file that we call your inbox. When you start up Rmail, it runs a C program called `movemail` to copy the new messages from your inbox into your primary Rmail file, which also contains other messages saved from previous Rmail sessions. It is in this file that you actually read the mail with Rmail. This operation is called getting new mail. You can get new mail at any time in Rmail by typing g.

The variable `rmail-primary-inbox-list` contains a list of the files which are inboxes for your primary Rmail file. If you don't set this variable explicitly, it is initialized from the `MAIL` environment variable, or, as a last resort, set to `nil`, which means to use the default inbox. The default inbox is `` `/var/mail/username' ``, `` `/usr/spool/mail/username' ``, or `` `/usr/mail/username' ``, depending on your operating system. You can specify the inbox file(s) for any Rmail file with the command `set-rmail-inbox-list`; see section Multiple Rmail Files.

Some sites use a method called POP for accessing users' inbox data instead of storing the data in inbox files. `movemail` can work with POP if you compile it with the macro `MAIL_USE_POP` defined, and

then install it setuid to `root`. It is safe to install `movemail` in this way. Note: `movemail` only wo with POP3, not with older versions of POP.

Assuming you have compiled and installed `movemail` appropriately, you can specify a POP inbox with a "file name" of the form `po:username'. `movemail` handles such a name by opening a connection to the POP server. The `MAILHOST` environment variable specifies the machine to look for the server on.

Accessing mail via POP may require a password. If the variable `rmail-pop-password` is non-`nil`, it specifies the password to use for POP. Alternatively, if `rmail-pop-password-required` is non-`nil`, then Rmail asks you for the password to use.

There are two reasons for having separate Rmail files and inboxes.

1. The inbox file format varies between operating systems and according to the other mail software in use. Only one part of Rmail needs to know about the alternatives, and it need only understand how to convert all of them to Rmail's own format.
2. It is very cumbersome to access an inbox file without danger of losing mail, because it is necessary to interlock with mail delivery. Moreover, different operating systems use different interlocking techniques. The strategy of moving mail out of the inbox once and for all into a separate Rmail file avoids the need for interlocking in all the rest of Rmail, since only Rmail operates on the Rmail file.

Rmail was written to use Babyl format as its internal format. Since then, we have recognized that the usual inbox format on Unix and GNU systems is adequate for the job, and we plan to change Rmail to use that as its internal format. However, the Rmail file will still be separate from the inbox file, even on systems where their format is the same.

When getting new mail, Rmail first copies the new mail from the inbox file to the Rmail file; then it saves the Rmail file; then it truncates the inbox file. This way, a system crash may cause duplication of mail between the inbox and the Rmail file, but cannot lose mail.

When `movemail` copies mail from an inbox in the system's mailer directory, it actually puts it in an intermediate file `` `~/.newmail-inboxname' ``. Once it finishes, Rmail reads that file, merges the new mail, saves the Rmail file, and only then deletes the intermediate file. If there is a crash at the wrong time, this file continues to exist and Rmail will use it again the next time it gets new mail from that inbox.

Multiple Rmail Files

Rmail operates by default on your primary Rmail file, which is named `` `~/RMAIL' `` and receives your incoming mail from your system inbox file. But you can also have other Rmail files and edit them with Rmail. These files can receive mail through their own inboxes, or you can move messages into them with explicit Rmail commands (see section Copying Messages Out to Files).

i file RET

Read file into Emacs and run Rmail on it (`rmail-input`).

M-x set-rmail-inbox-list RET files RET

Specify inbox file names for current Rmail file to get mail from.

g

Merge new mail from current Rmail file's inboxes (`rmail-get-new-mail`).

C-u g file RET

Merge new mail from inbox file file.

To run Rmail on a file other than your primary Rmail file, you may use the i (`rmail-input`) command in Rmail. This visits the file in Rmail mode. You can use M-x rmail-input even when not in Rmail.

The file you read with i should normally be a valid Rmail file. If it is not, Rmail tries to decompose it into a stream of messages in various known formats. If it succeeds, it converts the whole file to an Rmail file. If you specify a file name that doesn't exist, i initializes a new buffer for creating a new Rmail file.

You can also select an Rmail file from a menu. Choose first the menu bar Classify item, then from the Classify menu choose the Input Rmail File item; then choose the Rmail file you want. The variables `rmail-secondary-file-directory` and `rmail-secondary-file-regexp` specify which files to offer in the menu: the first variable says which directory to find them in; the second says which files in that directory to offer (all those that match the regular expression). These variables also apply to choosing a file for output (see section Copying Messages Out to Files).

Each Rmail file can contain a list of inbox file names; you can specify this list with M-x set-rmail-inbox-list RET files RET. The argument can contain any number of file names, separated by commas. It can also be empty, which specifies that this file should have no inboxes. Once a list of inboxes is specified, the Rmail file remembers it permanently until you specify a different list.

As a special exception, if your primary Rmail file does not specify any inbox files, it uses your standard system inbox.

The g command (`rmail-get-new-mail`) merges mail into the current Rmail file from its specified inboxes. If the Rmail file has no inboxes, g does nothing. The command M-x rmail also merges new mail into your primary Rmail file.

To merge mail from a file that is not the usual inbox, give the g key a numeric argument, as in C-u g. Then it reads a file name and merges mail from that file. The inbox file is not deleted or changed in any way when g with an argument is used. This is, therefore, a general way of merging one file of messages into another.

Copying Messages Out to Files

These commands copy messages from an Rmail file into another file.

o file RET

Append a copy of the current message to the file file, using Rmail file format by default (`rmail-output-to-rmail-file`).

C-o file RET

Append a copy of the current message to the file file, using system inbox file format by default

(`rmail-output`).

The commands o and C-o copy the current message into a specified file. This file may be an Rmail file or it may be in system inbox format; the output commands ascertain the file's format and write the copied message in that format.

The o and C-o commands differ in two ways: each has its own separate default file name, and each specifies a choice of format to use when the file does not already exist. The o command uses Rmail format when it creates a new file, while C-o uses system inbox format for a new file. The default file name for o is the file name used last with o, and the default file name for C-o is the file name used last with C-o.

If the output file is an Rmail file currently visited in an Emacs buffer, the output commands copy the message into that buffer. It is up to you to save the buffer eventually in its file.

You can also output a message to an Rmail file chosen with a menu. Choose first the menu bar Classify item, then from the Classify menu choose the Output Rmail Menu item; then choose the Rmail file you want. This outputs the current message to that file, like the o command. The variables `rmail-secondary-file-directory` and `rmail-secondary-file-regexp` specify which files to offer in the menu: the first variable says which directory to find them in; the second says which files in that directory to offer (all those that match the regular expression).

Copying a message gives the original copy of the message the `filed' attribute, so that `filed' appears in the mode line when such a message is current. If you like to keep just a single copy of every mail message, set the variable `rmail-delete-after-output` to `t`; then the o and C-o commands delete the original message after copying it. (You can undelete the original afterward if you wish.)

Copying messages into files in system inbox format uses the header fields that are displayed in Rmail at the time. Thus, if you use the t command to view the entire header and then copy the message, the entire header is copied. See section Display of Messages.

The variable `rmail-output-file-alist` lets you specify intelligent defaults for the output file, based on the contents of the current message. The value should be a list whose elements have this form:

```
(regexp . name-exp)
```

If there's a match for regexp in the current message, then the default file name for output is name-exp. If multiple elements match the message, the first matching element decides the default file name. The subexpression name-exp may be a string constant giving the file name to use, or more generally it may be any Lisp expression that returns a file name as a string. `rmail-output-file-alist` applies to both o and C-o.

Labels

Each message can have various labels assigned to it as a means of classification. Each label has a name; different names are different labels. Any given label is either present or absent on a particular message. A few label names have standard meanings and are given to messages automatically by Rmail when

appropriate; these special labels are called attributes. All other labels are assigned only by users.

a label RET

Assign the label label to the current message (`rmail-add-label`).

k label RET

Remove the label label from the current message (`rmail-kill-label`).

C-M-n labels RET

Move to the next message that has one of the labels labels (`rmail-next-labeled-message`).

C-M-p labels RET

Move to the previous message that has one of the labels labels (`rmail-previous-labeled-message`).

C-M-l labels RET

Make a summary of all messages containing any of the labels labels (`rmail-summary-by-labels`).

The a (`rmail-add-label`) and k (`rmail-kill-label`) commands allow you to assign or remove any label on the current message. If the label argument is empty, it means to assign or remove the same label most recently assigned or removed.

Once you have given messages labels to classify them as you wish, there are two ways to use the labels: in moving and in summaries.

The command C-M-n labels RET (`rmail-next-labeled-message`) moves to the next message that has one of the labels labels. The argument labels specifies one or more label names, separated by commas. C-M-p (`rmail-previous-labeled-message`) is similar, but moves backwards to previous messages. A numeric argument to either command serves as a repeat count.

The command C-M-l labels RET (`rmail-summary-by-labels`) displays a summary containing only the messages that have at least one of a specified set of labels. The argument labels is one or more label names, separated by commas. See section Summaries, for information on summaries.

If the labels argument to C-M-n, C-M-p or C-M-l is empty, it means to use the last set of labels specified for any of these commands.

Some labels such as `deleted' and `filed' have built-in meanings and are assigned to or removed from messages automatically at appropriate times; these labels are called attributes. Here is a list of Rmail attributes:

`unseen'

Means the message has never been current. Assigned to messages when they come from an inbox file, and removed when a message is made current. When you start Rmail, it initially shows the first message that has this attribute.

`deleted'

Means the message is deleted. Assigned by deletion commands and removed by undeletion commands (see section Deleting Messages).

`filed'

Means the message has been copied to some other file. Assigned by the file output commands (see section Multiple Rmail Files).

`answered'

Means you have mailed an answer to the message. Assigned by the r command (`rmail-reply`). See section Sending Replies.

`forwarded'

Means you have forwarded the message. Assigned by the f command (`rmail-forward`). See section Sending Replies.

`edited'

Means you have edited the text of the message within Rmail. See section Editing Within a Message.

`resent'

Means you have resent the message. Assigned by the command M-x rmail-resend. See section Sending Replies.

All other labels are assigned or removed only by the user, and have no standard meaning.

Sending Replies

Rmail has several commands that use Mail mode to send outgoing mail. See section Sending Mail, for information on using Mail mode. What are documented here are the special commands of Rmail for entering Mail mode. Note that the usual keys for sending mail---C-x m, C-x 4 m, and C-x 5 m---are available in Rmail mode and work just as they usually do.

m

Send a message (`rmail-mail`).

c

Continue editing already started outgoing message (`rmail-continue`).

r

Send a reply to the current Rmail message (`rmail-reply`).

f

Forward current message to other users (`rmail-forward`).

C-u f

Resend the current message to other users (`rmail-resend`).

M-m

Try sending a bounced message a second time (`rmail-retry-failure`).

The most common reason to send a message while in Rmail is to reply to the message you are reading. To do this, type r (`rmail-reply`). This displays the `*mail*' buffer in another window, much like C-x

4 m, but preinitializes the `Subject', `To', `CC' and `In-reply-to' header fields based on the message y are replying to. The `To' field starts out as the address of the person who sent the message you receiv and the `CC' field starts out with all the other recipients of that message.

You can exclude certain recipients from being placed automatically in the `CC', using the variable `rmail-dont-reply-to-names`. Its value should be a regular expression (as a string); any recipient that the regular expression matches, is excluded from the `CC' field. The default value matches your own name, and any name starting with `info-'. (Those names are excluded because there is a convention of using them for large mailing lists to broadcast announcements.)

To omit the `CC' field completely for a particular reply, enter the reply command with a numeric argument: C-u r or 1 r.

Once the `*mail*' buffer has been initialized, editing and sending the mail goes as usual (see section Sending Mail). You can edit the presupplied header fields if they are not right for you. You can also use the commands of Mail mode (see section Mail Mode), including C-c C-y which yanks in the message that you are replying to. You can switch to the Rmail buffer, select a different message there, switch back, and yank the new current message.

Sometimes a message does not reach its destination. Mailers usually send the failed message back to you, enclosed in a failure message. The Rmail command M-m (`rmail-retry-failure`) prepares to send the same message a second time: it sets up a `*mail*' buffer with the same text and header fields as before. If you type C-c C-c right away, you send the message again exactly the same as the first time. Alternatively, you can edit the text or headers and then send it. The variable `rmail-retry-ignored-headers`, in the same format as `rmail-ignored-headers` (see section Display of Messages), controls which headers are stripped from the failed message when retrying it; it defaults to nil.

Another frequent reason to send mail in Rmail is to forward the current message to other users. f (`rmail-forward`) makes this easy by preinitializing the `*mail*' buffer with the current message as the text, and a subject designating a forwarded message. All you have to do is fill in the recipients and send. When you forward a message, recipients get a message which is "from" you, and which has the original message in its contents.

Forwarding a message encloses it between two delimiter lines. It also modifies every line that starts with a dash, by inserting `- ' at the start of the line. When you receive a forwarded message, if it contains something besides ordinary text--for example, program source code--you might find it useful to undo that transformation. You can do this by selecting the forwarded message and typing M-x unforward-rmail-message. This command extracts the original forwarded message, deleting the inserted `- ' strings, and inserts it into the Rmail file as a separate message immediately following the current one.

Resending is an alternative similar to forwarding; the difference is that resending sends a message that is "from" the original sender, just as it reached you--with a few added header fields `Resent-from' and `Resent-to' to indicate that it came via you. To resend a message in Rmail, use C-u f. (f runs `rmail-forward`, which is programmed to invoke `rmail-resend` if you provide a numeric argument.)

The m (`rmail-mail`) command is used to start editing an outgoing message that is not a reply. It

leaves the header fields empty. Its only difference from C-x 4 m is that it makes the Rmail buffer accessible for C-c C-y, just as r does. Thus, m can be used to reply to or forward a message; it can do anything r or f can do.

The c (`rmail-continue`) command resumes editing the `*mail*' buffer, to finish editing an outgoing message you were already composing, or to alter a message you have sent.

If you set the variable `rmail-mail-new-frame` to a non-`nil` value, then all the Rmail commands to start sending a message create a new frame to edit it in. This frame is deleted when you send the message, or when you use the `Don't Send' item in the `Mail' menu.

Summaries

A summary is a buffer containing one line per message to give you an overview of the mail in an Rmail file. Each line shows the message number, the sender, the labels, and the subject. Almost all Rmail commands are valid in the summary buffer also; these apply to the message described by the current line of the summary. Moving point in the summary buffer selects messages as you move to their summary lines.

A summary buffer applies to a single Rmail file only; if you are editing multiple Rmail files, each one can have its own summary buffer. The summary buffer name is made by appending `-summary' to the Rmail buffer's name. Normally only one summary buffer is displayed at a time.

Making Summaries

Here are the commands to create a summary for the current Rmail file. Once the Rmail file has a summary buffer, changes in the Rmail file (such as deleting or expunging messages, and getting new mail) automatically update the summary.

h

C-M-h

> Summarize all messages (`rmail-summary`).

l labels RET

C-M-l labels RET

> Summarize message that have one or more of the specified labels (`rmail-summary-by-labels`).

C-M-r rcpts RET

> Summarize messages that have one or more of the specified recipients (`rmail-summary-by-recipients`).

C-M-t topic RET

> Summarize messages that have a match for the specified regexp topic in their subjects (`rmail-summary-by-topic`).

The h or C-M-h (`rmail-summary`) command fills the summary buffer for the current Rmail file with a summary of all the messages in the file. It then displays and selects the summary buffer in another

window.

C-M-l labels RET (`rmail-summary-by-labels`) makes a partial summary mentioning only the messages that have one or more of the labels labels. labels should contain label names separated by commas.

C-M-r rcpts RET (`rmail-summary-by-recipients`) makes a partial summary mentioning only the messages that have one or more of the recipients rcpts. rcpts should contain mailing addresses separated by commas.

C-M-t topic RET (`rmail-summary-by-topic`) makes a partial summary mentioning only the messages whose subjects have a match for the regular expression topic.

Note that there is only one summary buffer for any Rmail file; making one kind of summary discards any previously made summary.

The variable `rmail-summary-window-size` says how many lines to use for the summary window.

Editing in Summaries

You can use the Rmail summary buffer to do almost anything you can do in the Rmail buffer itself. In fact, once you have a summary buffer, there's no need to switch back to the Rmail buffer.

You can select and display various messages in the Rmail buffer, from the summary buffer, just by moving point in the summary buffer to different lines. It doesn't matter what Emacs command you use to move point; whichever line point is on at the end of the command, that message is selected in the Rmail buffer.

Almost all Rmail commands work in the summary buffer as well as in the Rmail buffer. Thus, d in the summary buffer deletes the current message, u undeletes, and x expunges. o and C-o output the current message to a file; r starts a reply to it. You can scroll the current message while remaining in the summary buffer using SPC and DEL.

The Rmail commands to move between messages also work in the summary buffer, but with a twist: they move through the set of messages included in the summary. They also ensure the Rmail buffer appears on the screen (unlike cursor motion commands, which update the contents of the Rmail buffer but don't display it in a window unless it already appears). Here is a list of these commands:

n
: Move to next line, skipping lines saying `deleted', and select its message.

p
: Move to previous line, skipping lines saying `deleted', and select its message.

M-n
: Move to next line and select its message.

M-p
: Move to previous line and select its message.

>

Move to the last line, and select its message.

<

Move to the first line, and select its message.

M-s pattern RET

Search through messages for pattern starting with the current message; select the message found, and move point in the summary buffer to that message's line.

Deletion, undeletion, and getting new mail, and even selection of a different message all update the summary buffer when you do them in the Rmail buffer. If the variable `rmail-redisplay-summary` is non-`nil`, these actions also bring the summary buffer back onto the screen.

When you are finished using the summary, type w (`rmail-summary-wipe`) to delete the summary buffer's window. You can also exit Rmail while in the summary: q (`rmail-summary-quit`) deletes the summary window, then exits from Rmail by saving the Rmail file and switching to another buffer.

Sorting the Rmail File

M-x rmail-sort-by-date

Sort messages of current Rmail file by date.

M-x rmail-sort-by-subject

Sort messages of current Rmail file by subject.

M-x rmail-sort-by-author

Sort messages of current Rmail file by author's name.

M-x rmail-sort-by-recipient

Sort messages of current Rmail file by recipient's names.

M-x rmail-sort-by-correspondent

Sort messages of current Rmail file by the name of the other correspondent.

M-x rmail-sort-by-lines

Sort messages of current Rmail file by size (number of lines).

M-x rmail-sort-by-keywords RET labels RET

Sort messages of current Rmail file by labels. The argument labels should be a comma-separated list of labels. The order of these labels specifies the order of messages; messages with the first label come first, messages with the second label come second, and so on. Messages which have none of these labels come last.

The Rmail sort commands perform a *stable sort*: if there is no reason to prefer either one of two messages, their order remains unchanged. You can use this to sort by more than one criterion. For example, if you use `rmail-sort-by-date` and then `rmail-sort-by-author`, messages from the same author appear in order by date.

With a numeric argument, all these commands reverse the order of comparison. This means they sort messages from newest to oldest, from biggest to smallest, or in reverse alphabetical order.

Display of Messages

Rmail reformats the header of each message before displaying it for the first time. Reformatting hides uninteresting header fields to reduce clutter. You can use the t command to show the entire header or to repeat the header reformatting operation.

t

Toggle display of complete header (`rmail-toggle-header`).

Reformatting the header involves deleting most header fields, on the grounds that they are not interesting. The variable `rmail-ignored-headers` holds a regular expression that specifies which header fields to hide in this way--if it matches the beginning of a header field, that whole field is hidden.

Rmail saves the complete original header before reformatting; to see it, use the t command (`rmail-toggle-header`). This discards the reformatted headers of the current message and displays it with the original header. Repeating t reformats the message again. Selecting the message again also reformats.

One consequence of this is that if you edit the reformatted header (using e; see section Editing Within a Message), subsequent use of t will discard your edits. On the other hand, if you use e after t, to edit the original (unreformatted) header, those changes are permanent.

When used with a window system that supports multiple fonts, Rmail highlights certain header fields that are especially interesting--by default, the `From' and `Subject' fields. The variable `rmail-highlighted-headers` holds a regular expression that specifies the header fields to highlight; if it matches the beginning of a header field, that whole field is highlighted.

If you specify unusual colors for your text foreground and background, the colors used for highlighting may not go well with them. If so, specify different colors for the `highlight` face. That is worth doing because the `highlight` face is used for other kinds of highlighting as well. See section Using Multiple Typefaces, for how to do this.

To turn off highlighting entirely in Rmail, set `rmail-highlighted-headers` to `nil`.

Editing Within a Message

Most of the usual Emacs commands are available in Rmail mode, though a few, such as C-M-n and C-M-h, are redefined by Rmail for other purposes. However, the Rmail buffer is normally read only, and most of the letters are redefined as Rmail commands. If you want to edit the text of a message, you must use the Rmail command e.

e

Edit the current message as ordinary text.

The e command (`rmail-edit-current-message`) switches from Rmail mode into Rmail Edit mode, another major mode which is nearly the same as Text mode. The mode line indicates this change.

In Rmail Edit mode, letters insert themselves as usual and the Rmail commands are not available. W you are finished editing the message and are ready to go back to Rmail, type C-c C-c, which switche back to Rmail mode. Alternatively, you can return to Rmail mode but cancel all the editing that you have done, by typing C-c C-].

Entering Rmail Edit mode runs the hook `text-mode-hook`; then it runs the hook `rmail-edit-mode-hook` (see section Hooks). It adds the attribute `edited' to the message.

Digest Messages

A digest message is a message which exists to contain and carry several other messages. Digests are used on some moderated mailing lists; all the messages that arrive for the list during a period of time such as one day are put inside a single digest which is then sent to the subscribers. Transmitting the single digest uses much less computer time than transmitting the individual messages even though the total size is the same, because the per-message overhead in network mail transmission is considerable.

When you receive a digest message, the most convenient way to read it is to undigestify it: to turn it back into many individual messages. Then you can read and delete the individual messages as it suits you.

To do this, select the digest message and type the command M-x undigestify-rmail-message. This extracts the submessages as separate Rmail messages, and inserts them following the digest. The digest message itself is flagged as deleted.

Converting an Rmail File to Inbox Format

The command M-x unrmail converts a file in Rmail format to inbox format (also known as the system mailbox format), so that you can use it with other mail-editing tools. You must specify two arguments, the name of the Rmail file and the name to use for the converted file. M-x unrmail does not alter the Rmail file itself.

Reading Rot13 Messages

Mailing list messages that might offend some readers are sometimes encoded in a simple code called rot13---so named because it rotates the alphabet by 13 letters. This code is not for secrecy, as it provides none; rather, it enables those who might be offended to avoid ever seeing the real text of the message.

To view a buffer using the rot13 code, use the command M-x rot13-other-window. This displays the current buffer in another window which applies the code when displaying the text.

Go to the previous, next section.

Go to the previous, next section.

Dired, the Directory Editor

Dired makes an Emacs buffer containing a listing of a directory, and optionally some of its subdirectories as well. You can use the normal Emacs commands to move around in this buffer, and special Dired commands to operate on the files listed.

Entering Dired

To invoke Dired, do C-x d or M-x dired. The command reads a directory name or wildcard file name pattern as a minibuffer argument to specify which files to list. Where `dired` differs from `list-directory` is in putting the buffer into Dired mode so that the special commands of Dired are available.

The variable `dired-listing-switches` specifies the options to give to `ls` for listing directory; this string *must* contain `-l'. If you use a numeric prefix argument with the `dired` command, you can specify the `ls` switches with the minibuffer after you finish entering the directory specification.

To display the Dired buffer in another window rather than in the selected window, use C-x 4 d (`dired-other-window`) instead of C-x d. C-x 5 d (`dired-other-frame`) uses a separate frame to display the Dired buffer.

Commands in the Dired Buffer

The Dired buffer is "read-only", and inserting text in it is not useful, so ordinary printing characters such as d and x are used for special Dired commands. Some Dired commands mark or flag the current file (that is, the file on the current line); other commands operate on the marked files or on the flagged files.

All the usual Emacs cursor motion commands are available in Dired buffers. Some special purpose cursor motion commands are also provided. The keys C-n and C-p are redefined to put the cursor at the beginning of the file name on the line, rather than at the beginning of the line.

For extra convenience, SPC and n in Dired are equivalent to C-n. p is equivalent to C-p. (Moving by lines is so common in Dired that it deserves to be easy to type.) DEL (move up and unflag) is often useful simply for moving up.

Deleting Files with Dired

The primary use of Dired is to flag files for deletion and then delete the files previously flagged.

d

Flag this file for deletion.

u

Remove deletion flag on this line.

DEL

Move point to previous line and remove the deletion flag on that line.

x

Delete the files that are flagged for deletion.

You can flag a file for deletion by moving to the line describing the file and typing d. The deletion flag is visible as a `D' at the beginning of the line. This command moves point to the next line, so that repeated d commands flag successive files. A numeric argument serves as a repeat count.

The files are flagged for deletion rather than deleted immediately to reduce the danger of deleting a file accidentally. Until you direct Dired to expunge the flagged files, you can remove deletion flags using the commands u and DEL. u works just like d, but removes flags rather than making flags. DEL moves upward, removing flags; it is like u with numeric argument automatically negated.

To delete the flagged files, type x (`dired-expunge`). This command first displays a list of all the file names flagged for deletion, and requests confirmation with yes. If you confirm, Dired deletes the flagged files, then deletes their lines from the text of the Dired buffer. The shortened Dired buffer remains selected.

If you answer no or quit with C-g when asked to confirm, you return immediately to Dired, with the deletion flags still present in the buffer, and no files actually deleted.

Flagging Many Files

#

Flag all auto-save files (files whose names start and end with `#') for deletion (see section Auto-Saving: Protection Against Disasters).

~

Flag all backup files (files whose names end with `~') for deletion (see section Backup Files).

. (Period)

Flag excess numeric backup files for deletion. The oldest and newest few backup files of any one file are exempt; the middle ones are flagged.

% d regexp RET

Flag for deletion all files whose names match the regular expression regexp (`dired-flag-files-regexp`).

The #, ~ and . commands flag many files for deletion, based on their file names. These commands are useful precisely because they do not actually delete any files; you can remove the deletion flags from any flagged files that you really wish to keep.

flags for deletion all files whose names look like auto-save files (see section Auto-Saving: Protection

Against Disasters)---that is, files whose names begin and end with `#'. ~ flags for deletion all files wh names say they are backup files (see section Backup Files)---that is, whose names end in `~'.

. (Period) flags just some of the backup files for deletion: all but the oldest few and newest few backups of any one file. Normally `dired-kept-versions` (**not** `kept-new-versions`; that applies only when saving) specifies the number of newest versions of each file to keep, and `kept-old-versions` specifies the number of oldest versions to keep.

Period with a positive numeric argument, as in C-u 3 ., specifies the number of newest versions to keep, overriding `dired-kept-versions`. A negative numeric argument overrides `kept-old-versions`, using minus the value of the argument to specify the number of oldest versions of each file to keep.

The % d command flags all files whose names match a specified regular expression (`dired-flag-files-regexp`). Only the non-directory part of the file name is used in matching. You can use `^' and `$' to anchor matches. You can exclude subdirectories by hiding them (see section Hiding Subdirectories).

Visiting Files in Dired

There are several Dired commands for visiting or examining the files listed in the Dired buffer. All of them apply to the current line's file; if that file is really a directory, these commands invoke Dired on that subdirectory (making a separate Dired buffer).

f

Visit the file described on the current line, like typing C-x C-f and supplying that file name (`dired-find-file`). See section Visiting Files.

RET

Equivalent to f.

o

Like f, but uses another window to display the file's buffer (`dired-find-file-other-window`). The Dired buffer remains visible in the first window. This is like using C-x 4 C-f to visit the file. See section Multiple Windows.

C-o

Visit the file described on the current line, and display the buffer in another window, but do not select that window (`dired-display-file`).

Mouse-2

Visit the file named by the line you click on (`dired-mouse-find-file-other-window`). This uses another window to display the file, like the o command.

v

View the file described on the current line, using M-x view-file (`dired-view-file`).

Viewing a file is like visiting it, but is slanted toward moving around in the file conveniently and

does not allow changing the file. See section Miscellaneous File Operations.

Dired Marks vs. Flags

Instead of flagging a file with `D', you can mark the file with some other character (usually `*'). Most Dired commands to operate on files, aside from "expunge" (x), look for files marked with `*'.

Here are some commands for marking with `*' (and also for unmarking). (See section Deleting Files with Dired, for commands to flag and unflag files.)

m

Mark the current file with `*' (`dired-mark`). With a numeric argument n, mark the next n files starting with the current file. (If n is negative, mark the previous -n files.)

*

Mark all executable files with `*' (`dired-mark-executables`). With a numeric argument, unmark all those files.

@

Mark all symbolic links with `*' (`dired-mark-symlinks`). With a numeric argument, unmark all those files.

/

Mark with `*' all files which are actually directories, except for `.' and `..' (`dired-mark-directories`). With a numeric argument, unmark all those files.

M-DEL markchar

Remove all marks that use the character markchar (`dired-unmark-all-files`). If you specify RET as markchar, this command removes all marks, no matter what the marker character is.

With a numeric argument, this command queries about each marked file, asking whether to remove its mark. You can answer y meaning yes, n meaning no, ! to remove the marks from the remaining files without asking about them.

c old new

Replace all marks that use the character old with marks that use the character new (`dired-change-marks`). This command is the primary way to create or use marks other than `*' or `D'. The arguments are single characters--do not use RET to terminate them.

You can use almost any character as a mark character by means of this command, to distinguish various classes of files. If old is a space (` '), then the command operates on all unmarked files; if new is a space, then the command unmarks the files it acts on.

To illustrate the power of this command, here is how to put `*' marks on all the files that are unmarked, while unmarking all those that have `*' marks:

```
c * t  c SPC *  c t SPC
```

% m regexp RET

Mark (with `*') all files whose names match the regular expression regexp (`dired-mark-files-regexp`). % m is like % d, except that it marks files with `*' instead of flagging with `D'. See section Flagging Many Files.

Only the non-directory part of the file name is used in matching. Use `^' and `$' to anchor matches. Exclude subdirectories by hiding them (see section Hiding Subdirectories).

Operating on Files

This section describes the basic Dired commands to operate on one file or several files. All of these commands are capital letters; all of them use the minibuffer, either to read an argument or to ask for confirmation, before they act. All use the following convention to decide which files to manipulate:

- If you give the command a numeric prefix argument n, it operates on the next n files, starting with the current file. (If n is negative, the command operates on the -n files preceding the current line.)
- Otherwise, if some files are marked with `*', the command operates on all those files.
- Otherwise, the command operates on the current file only.

Here are the file-manipulating commands that operate on files in this way. (Some other Dired commands, such as ! and the `%' commands, also use these conventions to decide which files to work on.)

C new RET

Copy the specified files (`dired-do-copy`). The argument new is the directory to copy into, or (if copying a single file) the new name.

If `dired-copy-preserve-time` is non-`nil`, then copying with this command sets the modification time of the new file to be the same as that of the old file.

R new RET

Rename the specified files (`dired-do-rename`). The argument new is the directory to rename into, or (if renaming a single file) the new name.

Dired automatically changes the visited file name of buffers associated with renamed files so that they refer to the new names.

H new RET

Make hard links to the specified files (`dired-do-hardlink`). The argument new is the directory to make the links in, or (if making just one link) the name to give the link.

S new RET

Make symbolic links to the specified files (`dired-do-symlink`). The argument new is the directory to make the links in, or (if making just one link) the name to give the link.

M modespec RET

Change the mode (also called "permission bits") of the specified files (`dired-do-chmod`). This uses the `chmod` program, so modespec can be any argument that `chmod` can handle.

G newgroup RET

Change the group of the specified files to newgroup (`dired-do-chgrp`).

O newowner RET

Change the owner of the specified files to newowner (`dired-do-chown`). (On most systems, only the superuser can do this.)

The variable `dired-chown-program` specifies the name of the program to use to do the work (different systems put `chown` in different places).

P command RET

Print the specified files (`dired-do-print`). You must specify the command to print them with, but the minibuffer starts out with a suitable guess made using the variables `lpr-command` and `lpr-switches` (the same variables that `lpr-file` uses; see section Hardcopy Output).

Z

Compress or uncompress the specified files (`dired-do-compress`). If the file appears to be a compressed file, it is uncompressed; otherwise, it is compressed.

L

Load the specified Emacs Lisp files (`dired-do-load`). See section Libraries of Lisp Code for Emacs.

B

Byte compile the specified Emacs Lisp files (`dired-do-byte-compile`). See section 'Byte Compilation' in The Emacs Lisp Reference Manual.

A regexp RET

Search all the specified files for the regular expression regexp (`dired-do-search`).

This command is a variant of `tags-search`. The search stops at the first match it finds; use M-, to resume the search and find the next match. See section Searching and Replacing with Tags Tables.

Q from RET to RET

Perform `query-replace-regexp` on each of the specified files, replacing matches for from (a regular expression) with the string to (`dired-do-query-replace`).

This command is a variant of `tags-query-replace`. If you exit the query replace loop, you can use M-, to resume the scan and replace more matches. See section Searching and Replacing with Tags Tables.

One special file-operation command is + (`dired-create-directory`). This command reads a directory name and creates the directory if it does not already exist.

Shell Commands in Dired

The dired command ! (`dired-do-shell-command`) reads a shell command string in the minibuffer and runs that shell command on all the specified files. There are two ways of applying a shell command to multiple files:

- If you use `*' in the shell command, then it runs just once, with the list of file names substituted for the `*'. The order of file names is the order of appearance in the Dired buffer.

  Thus, ! tar cf foo.tar * RET runs `tar` on the entire list of file names, putting them into one tar file `foo.tar'.

- If the command string doesn't contain `*', then it runs once *for each file*, with the file name added at the end.

  For example, ! uudecode RET runs `uudecode` on each file.

What if you want to run the shell command once for each file but with the file name inserted in the middle? Or if you want to use the file names in a more complicated fashion? Use a shell loop. For example, this shell command would run `uuencode` on each of the specified files, writing the output into a corresponding `.uu' file:

```
for file in *; uuencode $file $file >$file.uu; done
```

The working directory for the shell command is the top level directory of the Dired buffer.

The ! command does not attempt to update the Dired buffer to show new or modified files, because it doesn't really understand shell commands, and does not know what files the shell command changed. Use the g command to update the Dired buffer (see section Updating the Dired Buffer).

Transforming File Names in Dired

Here are commands that alter file names in a systematic way:

% u

Rename each of the selected files to an upper case name (`dired-upcase`). If the old file names are `Foo' and `bar', the new names are `FOO' and `BAR'.

% l

Rename each of the selected files to a lower case name (`dired-downcase`). If the old file names are `Foo' and `bar', the new names are `foo' and `bar'.

% R from RET to RET

% C from RET to RET

% H from RET to RET

% S from RET to RET

These four commands rename, copy, make hard links and make soft links, in each case computing the new name by regular expression substitution from the name of the old file.

The four regular expression substitution commands effectively perform a search-and-replace on the selected file names in the Dired buffer. They read two arguments: a regular expression from, and a substitution pattern to.

The commands match each "old" file name against the regular expression from, and then replace the

matching part with to. You can use `\&' and `\digit' in to to refer to all or part of what the pattern mat in the old file name, as in `query-replace-regexp` (see section Query Replace). If the regular expression matches more than once in a file name, only the first match is replaced.

For example, % R ^.*$ RET x-\& RET renames each selected file by prepending `x-' to its name. The inverse of this, removing `x-' from the front of each file name, is also possible: one method is % R ^x-\(.*\)$ RET \1 RET; another is % R ^x- RET RET. (Use `^' and `$' to anchor matches that should span the whole filename.)

Normally, the replacement process does not consider the files' directory names; it operates on the file name within the directory. If you specify a numeric argument of zero, then replacement affects the entire absolute file name including directory name.

Often you will want to apply the command to all files matching the same regexp that you use in the command. To do this, mark those files with % m regexp RET, then use the same regular expression in the command to operate on the files. To make this easier, the % commands to operate on files use the last regular expression specified in any % command as a default.

File Comparison with Dired

Here are two Dired commands that compare specified files using `diff`.

=

Compare the current file (the file at point) with another file (the file at the mark) using the `diff` program (`dired-diff`). The file at the mark is the first argument of `diff`, and the file at point is the second argument.

M-=

Compare the current file with its latest backup file (`dired-backup-diff`). If the current file is itself a backup, compare it with the file it is a backup of; this way, you can compare a file with any backup version of your choice.

The backup file is the first file given to `diff`.

Subdirectories in Dired

A Dired buffer displays just one directory in the normal case; but you can optionally include its subdirectories as well.

The simplest way to include multiple directories in one Dired buffer is to specify the options `-lR' for running `ls`. (If you give a numeric argument when you run Dired, then you can specify these options in the minibuffer.) That produces a recursive directory listing showing all subdirectories at all levels.

But usually all the subdirectories are too many; usually you will prefer to include specific subdirectories only. You can do this with the i command:

i

Insert the contents of a subdirectory later in the buffer.

Use the i (`dired-maybe-insert-subdir`) command on a line that describes a file which is a directory. It inserts the contents of that directory into the same Dired buffer, and moves there. Inserted subdirectory contents follow the top-level directory of the Dired buffer, just as they do in `ls -lR' output.

If the subdirectory's contents are already present in the buffer, the i command just moves to it.

In either case, i sets the Emacs mark before moving, so C-u C-SPC takes you back to the old position in the buffer (the line describing that subdirectory).

Use the l command (`dired-do-redisplay`) to update the subdirectory's contents. Use k to delete the subdirectory. See section Updating the Dired Buffer.

Moving Over Subdirectories

When a Dired buffer lists subdirectories, you can use the page motion commands C-x [and C-x] to move by entire directories.

The following commands move across, up and down in the tree of directories within one Dired buffer. They move to directory header lines, which are the lines that give a directory's name, at the beginning of the directory's contents.

C-M-n
: Go to next subdirectory header line, regardless of level (`dired-next-subdir`).

C-M-p
: Go to previous subdirectory header line, regardless of level (`dired-prev-subdir`).

C-M-u
: Go up to the parent directory's header line (`dired-tree-up`).

C-M-d
: Go down in the directory tree, to the first subdirectory's header line (`dired-tree-down`).

Hiding Subdirectories

Hiding a subdirectory means to make it invisible, except for its header line, via selective display (see section Selective Display).

$
: Hide or reveal the subdirectory that point is in, and move point to the next subdirectory (`dired-hide-subdir`). A numeric argument serves as a repeat count.

M-$
: Hide all subdirectories in this Dired buffer, leaving only their header lines (`dired-hide-all`). Or, if any subdirectory is currently hidden, make all subdirectories visible again. You can use this command to get an overview in very deep directory trees or to move quickly to subdirectories far away.

Ordinary Dired commands never consider files inside a hidden subdirectory. For example, the comm to operate on marked files ignore files in hidden directories even if they are marked. Thus you can us hiding to temporarily exclude subdirectories from operations without having to remove the markers.

The subdirectory hiding commands toggle; that is, they hide what was visible, and show what was hidden.

Updating the Dired Buffer

This section describes commands to update the Dired buffer to reflect outside (non-Dired) changes in the directories and files, and to delete part of the Dired buffer.

g
: Update the entire contents of the Dired buffer (`revert-buffer`).

l
: Update the specified files (`dired-do-redisplay`).

k
: Delete the specified *file lines*---not the files, just the lines (`dired-do-kill-lines`).

s
: Toggle between sorting by file name and sorting by date/time (`dired-sort-toggle-or-edit`).

C-u s switches RET
: Refresh the Dired buffer using switches as `dired-listing-switches`.

Type g (`revert-buffer`) to update the contents of the Dired buffer, based on changes in the files and directories listed. This preserves all marks except for those on files that have vanished. Hidden subdirectories are updated but remain hidden.

To update only some of the files, type l (`dired-do-redisplay`). This command applies to the next n files, or to the marked files if any, or to the current file. Updating them means reading their current status from the file system and changing the buffer to reflect it properly.

If you use l on a subdirectory header line, it updates the contents of the corresponding subdirectory.

To delete the specified *file lines*---not the files, just the lines--type k (`dired-do-kill-lines`). This command applies to the next n files, or to the marked files if any, or to the current file.

If you kill the line for a file that is a directory, the directory's contents are also deleted from the buffer. Typing C-u k on the header line for a subdirectory is another way to delete a subdirectory from the Dired buffer.

The g command brings back any individual lines that you have killed in this way, but not subdirectories--you must use i to reinsert each subdirectory.

The files in a Dired buffers are normally in listed alphabetical order by file names. Alternatively Dired can sort them by date/time. The Dired command s (`dired-sort-toggle-or-edit`) switches

between these two sorting modes. The mode line in a Dired buffer indicates which way it is currently sorted--by name, or by date.

C-u s switches RET lets you specify a new value for `dired-listing-switches`.

Dired and `find`

You can select a set of files for display in a Dired buffer more flexibly by using the `find` utility to choose the files.

To search for files with names matching a wildcard pattern use M-x find-name-dired. It reads arguments directory and pattern, and chooses all the files in directory or its subdirectories whose individual names match pattern.

The files thus chosen are displayed in a Dired buffer in which the ordinary Dired commands are available.

If you want to test the contents of files, rather than their names, use M-x find-grep-dired. This command reads two minibuffer arguments, directory and regexp; it chooses all the files in directory or its subdirectories that contain a match for regexp. It works by running the programs `find` and `grep`.

The most general command in this series is M-x find-dired, which lets you specify any condition that `find` can test. It takes two minibuffer arguments, directory and find-args; it runs `find` in directory, passing find-args to tell `find` what condition to test. To use this command, you need to know how to use `find`.

The format of listing produced by these commands is controlled by the variable `find-ls-option`, whose default value specifies using options `-ldi' for `ls`. If your listings are corrupted, you may need to change the value of this variable.

Go to the previous, next section.

Go to the previous, next section.

The Calendar and the Diary

Emacs provides the functions of a desk calendar, with a diary of planned or past events. To enter the calendar, type M-x calendar; this displays a three-month calendar centered on the current month, with point on the current date. With a numeric argument, as in C-u M-x calendar, it prompts you for the month and year to be the center of the three-month calendar. The calendar uses its own buffer, whose major mode is Calendar mode.

Mouse-2 in the calendar brings up a menu of operations on a particular date; C-Mouse-3 brings up a menu of commonly used calendar features that are independent of any particular date. To exit the calendar, type q. See section 'Calendar' in The Emacs Lisp Reference Manual, for customization information about the calendar and diary.

Movement in the Calendar

Calendar mode lets you move through the calendar in logical units of time such as days, weeks, months, and years. If you move outside the three months originally displayed, the calendar display "scrolls" automatically through time to make the selected date visible. Moving to a date lets you view its holidays or diary entries, convert it to other calendars; moving longer time periods is also useful simply to scroll the calendar.

Motion by Standard Lengths of Time

The commands for movement in the calendar buffer parallel the commands for movement in text. You can move forward and backward by days, weeks, months, and years.

C-f
: Move point one day forward (`calendar-forward-day`).

C-b
: Move point one day backward (`calendar-backward-day`).

C-n
: Move point one week forward (`calendar-forward-week`).

C-p
: Move point one week backward (`calendar-backward-week`).

M-}
: Move point one month forward (`calendar-forward-month`).

M-{
: Move point one month backward (`calendar-backward-month`).

C-x]

Move point one year forward (`calendar-forward-year`).

C-x [

Move point one year backward (`calendar-forward-year`).

The day and week commands are natural analogues of the usual Emacs commands for moving by characters and by lines. Just as C-n usually moves to the same column in the following line, in Calendar mode it moves to the same day in the following week. And C-p moves to the same day in the previous week.

The arrow keys are equivalent to C-f, C-b, C-n and C-p, just as they normally are in other modes.

The commands for motion by months and years work like those for weeks, but move a larger distance. The month commands M-} and M-{ move forward or backward by an entire month's time. The year commands C-x] and C-x [move forward or backward a whole year.

The easiest way to remember these commands is to consider months and years analogous to paragraphs and pages of text, respectively. But the commands themselves are not quite analogous. The ordinary Emacs paragraph commands move to the beginning or end of a paragraph, whereas these month and year commands move by an entire month or an entire year, which usually involves skipping across the end of a month or year.

All these commands accept a numeric argument as a repeat count. For convenience, the digit keys and the minus sign specify numeric arguments in Calendar mode even without the Meta modifier. For example, 100 C-f moves point 100 days forward from its present location.

Beginning or End of Week, Month or Year

A week (or month, or year) is not just a quantity of days; we think of weeks (months, years) as starting on particular dates. So Calendar mode provides commands to move to the beginning or end of a week, month or year:

C-a

Move point to start of week (`calendar-beginning-of-week`).

C-e

Move point to end of week (`calendar-end-of-week`).

M-a

Move point to start of month (`calendar-beginning-of-month`).

M-e

Move point to end of month (`calendar-end-of-month`).

M-<

Move point to start of year (`calendar-beginning-of-year`).

M->

Move point to end of year (`calendar-end-of-year`).

These commands also take numeric arguments as repeat counts, with the repeat count indicating how

many weeks, months, or years to move backward or forward.

By default, weeks begin on Sunday. To make them begin on Monday instead, set the variable `calendar-week-start-day` to 1.

Specified Dates

Calendar mode provides commands for moving to a particular date specified in various ways.

g d
: Move point to specified date (`calendar-goto-date`).

o
: Center calendar around specified month (`calendar-other-month`).

.
: Move point to today's date (`calendar-goto-today`).

g d (`calendar-goto-date`) prompts for a year, a month, and a day of the month, and then moves to that date. Because the calendar includes all dates from the beginning of the current era, you must type the year in its entirety; that is, type `1990', not `90'.

o (`calendar-other-month`) prompts for a month and year, then centers the three-month calendar around that month.

You can return to today's date with . (`calendar-goto-today`).

Scrolling in the Calendar

The calendar display scrolls automatically through time when you move out of the visible portion. You can also scroll it manually. Imagine that the calendar window contains a long strip of paper with the months on it. Scrolling it means moving the strip so that new months become visible in the window.

C-x <
: Scroll calendar one month forward (`scroll-calendar-left`).

C-x >
: Scroll calendar one month backward (`scroll-calendar-right`).

C-v

NEXT
: Scroll calendar three months forward (`scroll-calendar-left-three-months`).

M-v

PRIOR
: Scroll calendar three months backward (`scroll-calendar-right-three-months`).

The most basic calendar scroll commands scroll by one month at a time. This means that there are two months of overlap between the display before the command and the display after. C-x < scrolls the

calendar contents one month to the left; that is, it moves the display forward in time. C-x > scrolls the contents to the right, which moves backwards in time.

The commands C-v and M-v scroll the calendar by an entire "screenful"---three months--in analogy with the usual meaning of these commands. C-v makes later dates visible and M-v makes earlier dates visible. These commands take a numeric argument as a repeat count; in particular, since C-u multiplies the next command by four, typing C-u C-v scrolls the calendar forward by a year and typing C-u M-v scrolls the calendar backward by a year.

The function keys NEXT and PRIOR are equivalent to C-v and M-v, just as they are in other modes.

Counting Days

M-=
: Display the number of days in the current region (`calendar-count-days-region`).

To determine the number of days in the region, type M-= (`calendar-count-days-region`). The numbers of days printed is *inclusive*; that is, it includes the days specified by mark and point.

Miscellaneous Calendar Commands

p d
: Display day-in-year (`calendar-print-day-of-year`).

C-c C-l
: Regenerate the calendar window (`redraw-calendar`).

SPC
: Scroll the next window (`scroll-other-window`).

q
: Exit from calendar (`exit-calendar`).

To print the number of days elapsed since the start of the year, or the number of days remaining in the year, type the p d command (`calendar-print-day-of-year`). This displays both of those numbers in the echo area. The number of days elapsed includes the selected date. The number of days remaining does not include that date.

If the calendar window text gets corrupted, type C-c C-l (`redraw-calendar`) to redraw it. (This can only happen if you use non-Calendar-mode editing commands.)

In Calendar mode, you can use SPC (`scroll-other-window`) to scroll the other window. This is handy when you display a list of holidays or diary entries in another window.

To exit from the calendar, type q (`exit-calendar`). This buries all buffers related to the calendar, selecting other buffers. (If a frame contains a dedicated calendar window, exiting from the calendar iconifies that frame.)

TeX Calendar

The Calendar TeX commands produce a buffer of LaTeX code that prints as a calendar. Depending on the command you use, the printed calendar covers the day, week, month or year that point is in.

t m
: Generate a one-month calendar (`cal-tex-cursor-month`).

t M
: Generate a sideways-printing one-month calendar (`cal-tex-cursor-month-landscape`).

t d
: Generate a one-day calendar (`cal-tex-cursor-day`).

t w 1
: Generate a one-page calendar for one week (`cal-tex-cursor-week`).

t w 2
: Generate a two-page calendar for one week (`cal-tex-cursor-week2`).

t w 3
: Generate an ISO-style calendar for one week (`cal-tex-cursor-week-iso`).

t w 4
: Generate a calendar for one Monday-starting week (`cal-tex-cursor-week-monday`).

t f w
: Generate a Filofax-style two-weeks-at-a-glance calendar (`cal-tex-cursor-filofax-2week`).

t f W
: Generate a Filofax-style one-week-at-a-glance calendar (`cal-tex-cursor-filofax-week`).

t y
: Generate a calendar for one year (`cal-tex-cursor-year`).

t Y
: Generate a sideways-printing calendar for one year (`cal-tex-cursor-landscape-year`).

t f y
: Generate a Filofax-style calendar for one year (`cal-tex-cursor-filofax-year`).

Some of these commands print the calendar sideways (in "landscape mode"), so it can be wider than it is long. Some of them use Filofax paper size (3.75in x 6.75in). All of these commands accept a prefix argument which specifies how many days, weeks, months or years to print (starting always with the selected one).

If the variable `cal-tex-holidays` is non-`nil` (the default), then the printed calendars show the holidays in `calendar-holidays`. If the variable `cal-tex-diary` is non-`nil` (the default is `nil`), diary entries are included also (in weekly and monthly calendars only).

Holidays

The Emacs calendar knows about all major and many minor holidays, and can display them.

h
: Display holidays for the selected date (`calendar-cursor-holidays`).

Mouse-2 Holidays
: Display any holidays for the date you click on.

x
: Mark holidays in the calendar window (`mark-calendar-holidays`).

u
: Unmark calendar window (`calendar-unmark`).

a
: List all holidays for the displayed three months in another window (`list-calendar-holidays`).

M-x holidays
: List all holidays for three months around today's date in another window.

To see if any holidays fall on a given date, position point on that date in the calendar window and use the h command. Alternatively, click on that date with Mouse-2 and then choose Holidays from the menu that appears. Either way, this displays the holidays for that date, in the echo area if they fit there, otherwise in a separate window.

To view the distribution of holidays for all the dates shown in the calendar, use the x command. This displays the dates that are holidays in a different face (or places a `*' after these dates, if display with multiple faces is not available). The command applies both to the currently visible months and to other months that subsequently become visible by scrolling. To turn marking off and erase the current marks, type u, which also erases any diary marks (see section The Diary).

To get even more detailed information, use the a command, which displays a separate buffer containing a list of all holidays in the current three-month range. You can use SPC in the calendar window to scroll that list.

The command M-x holidays displays the list of holidays for the current month and the preceding and succeeding months; this works even if you don't have a calendar window. If you want the list of holidays centered around a different month, use C-u M-x holidays, which prompts for the month and year.

The holidays known to Emacs include American holidays and the major Christian, Jewish, and Islamic holidays; also the solstices and equinoxes.

The dates used by Emacs for holidays are based on *current practice*, not historical fact. Historically, for instance, the start of daylight savings time and even its existence have varied from year to year, but present American law mandates that daylight savings time begins on the first Sunday in April. In an American locale, Emacs always uses this definition, even though it is wrong for some prior years.

Times of Sunrise and Sunset

Special calendar commands can tell you, to within a minute or two, the times of sunrise and sunset for any date.

S
: Display times of sunrise and sunset for the selected date (`calendar-sunrise-sunset`).

Mouse-2 Sunrise/Sunset
: Display times of sunrise and sunset for the date you click on.

M-x sunrise-sunset
: Display times of sunrise and sunset for today's date.

C-u M-x sunrise-sunset
: Display times of sunrise and sunset for a specified date.

Within the calendar, to display the *local times* of sunrise and sunset in the echo area, move point to the date you want, and type S. Alternatively, click Mouse-2 on the date, then choose Sunrise/Sunset from the menu that appears. The command M-x sunrise-sunset is available outside the calendar to display this information for today's date or a specified date. To specify a date other than today, use C-u M-x sunrise-sunset, which prompts for the year, month, and day.

You can display the times of sunrise and sunset for any location and any date with C-u C-u M-x sunrise-sunset. This asks you for a longitude, latitude, number of minutes difference from Coordinated Universal Time, and date, and then tells you the times of sunrise and sunset for that location on that date.

Because the times of sunrise and sunset depend on the location on earth, you need to tell Emacs your latitude, longitude, and location name before using these commands. Here is an example of what to set:

```
(setq calendar-latitude 40.1)
(setq calendar-longitude -88.2)
(setq calendar-location-name "Urbana, IL")
```

Use one decimal place in the values of `calendar-latitude` and `calendar-longitude`.

Your time zone also affects the local time of sunrise and sunset. Emacs usually gets time zone information from the operating system, but if these values are not what you want (or if the operating system does not supply them), you must set them yourself. Here is an example:

```
(setq calendar-time-zone -360)
(setq calendar-standard-time-zone-name "CST")
(setq calendar-daylight-time-zone-name "CDT")
```

The value of `calendar-time-zone` is the number of minutes difference between your local standard time and Coordinated Universal Time (Greenwich time). The values of `calendar-standard-time-zone-name` and `calendar-daylight-time-zone-name` are the abbreviations used in your time zone. Emacs displays the times of sunrise and sunset *corrected for*

TOC

daylight savings time. See section Daylight Savings Time, for how daylight savings time is determin

As a user, you might find it convenient to set the calendar location variables for your usual physical location in your `.emacs' file. And when you install Emacs on a machine, you can create a `default.el' file which sets them properly for the typical location of most users of that machine. See section The Init File, `~/.emacs'.

Phases of the Moon

These calendar commands display the dates and times of the phases of the moon (new moon, first quarter, full moon, last quarter). This feature is useful for debugging problems that "depend on the phase of the moon."

M

Display the dates and times for all the quarters of the moon for the three-month period shown (`calendar-phases-of-moon`).

M-x phases-of-moon

Display dates and times of the quarters of the moon for three months around today's date.

Within the calendar, use the M command to display a separate buffer of the phases of the moon for the current three-month range. The dates and times listed are accurate to within a few minutes.

Outside the calendar, use the command M-x phases-of-moon to display the list of the phases of the moon for the current month and the preceding and succeeding months. For information about a different month, use C-u M-x phases-of-moon, which prompts for the month and year.

The dates and times given for the phases of the moon are given in local time (corrected for daylight savings, when appropriate); but if the variable `calendar-time-zone` is void, Coordinated Universal Time (the Greenwich time zone) is used. See section Daylight Savings Time.

Conversion To and From Other Calendars

The Emacs calendar displayed is *always* the Gregorian calendar, sometimes called the "new style" calendar, which is used in most of the world today. However, this calendar did not exist before the sixteenth century and was not widely used before the eighteenth century; it did not fully displace the Julian calendar and gain universal acceptance until the early twentieth century. The Emacs calendar can display any month since January, year 1 of the current era, but the calendar displayed is the Gregorian, even for a date at which the Gregorian calendar did not exist.

While Emacs cannot display other calendars, it can convert dates to and from several other calendars.

Supported Calendar Systems

The ISO commercial calendar is used largely in Europe.

The Julian calendar, named after Julius Caesar, was the one used in Europe throughout medieval times, and in many countries up until the nineteenth century.

Astronomers use a simple counting of days elapsed since noon, Monday, January 1, 4713 B.C. on the Julian calendar. The number of days elapsed is called the *Julian day number* or the *Astronomical day number*.

The Hebrew calendar is used by tradition in the Jewish religion. The Emacs calendar program uses the Hebrew calendar to determine the dates of Jewish holidays. Hebrew calendar dates begin and end at sunset.

The Islamic calendar is used in many predominantly Islamic countries. Emacs uses it to determine the dates of Islamic holidays. There is no universal agreement in the Islamic world about the calendar; Emacs uses a widely accepted version, but the precise dates of Islamic holidays often depend on proclamation by religious authorities, not on calculations. As a consequence, the actual dates of observance can vary slightly from the dates computed by Emacs. Islamic calendar dates begin and end at sunset.

The French Revolutionary calendar was created by the Jacobins after the 1789 revolution, to represent a more secular and nature-based view of the annual cycle, and to install a 10-day week in a rationalization measure similar to the metric system. The French government officially abandoned this calendar at the end of 1805.

The Maya of Central America used three separate, overlapping calendar systems, the *long count*, the *tzolkin*, and the *haab*. Emacs knows about all three of these calendars. Experts dispute the exact correlation between the Mayan calendar and our calendar; Emacs uses the Goodman-Martinez-Thompson correlation in its calculations.

The Copts use a calendar based on the ancient Egyptian solar calendar. Their calendar consists of twelve 30-day months followed by an extra five day period. Once every fourth year they add a leap day to this extra period to make it six days. The Ethiopic calendar is identical in structure, but has different year numbers and month names.

The Persians use a solar calendar based on a design of Omar Khayyam. Their calendar consists of twelve months of which the first six have 31 days, the next five have 30 days, and the last has 29 in ordinary years and 30 in leap years. Leap years occur in a complicated pattern every four or five years.

The Chinese calendar is a complicated system of lunar months arranged into solar years. The years go in cycles of sixty, each year containing either twelve months in an ordinary year or thirteen months in a leap year; each month has either 29 or 30 days. Years, ordinary months, and days are named by combining one of ten "celestial stems" with one of twelve "terrestrial branches" for a total of sixty names that are repeated in a cycle of sixty.

Converting To Other Calendars

The following commands describe the selected date (the date at point) in various other calendar systems.

Mouse-2 Other Calendars
: Display the date that you click on, expressed in various other calendars.

p c
: Display ISO commercial calendar equivalent for selected day (`calendar-print-iso-date`).

p j
: Display Julian date for selected day (`calendar-print-julian-date`).

p a
: Display astronomical (Julian) day number for selected day (`calendar-print-astro-day-number`).

p h
: Display Hebrew date for selected day (`calendar-print-hebrew-date`).

p i
: Display Islamic date for selected day (`calendar-print-islamic-date`).

p f
: Display French Revolutionary date for selected day (`calendar-print-french-date`).

p C
: Display Chinese date for selected day (`calendar-print-chinese-date`).

p k
: Display Coptic date for selected day (`calendar-print-coptic-date`).

p e
: Display Ethiopic date for selected day (`calendar-print-ethiopic-date`).

p p
: Display Persian date for selected day (`calendar-print-persian-date`).

p m
: Display Mayan date for selected day (`calendar-print-mayan-date`).

If you are using X, the easiest way to translate a date into other calendars is to click on it with Mouse-2, then choose Other Calendars from the menu that appears. This displays the equivalent forms of the date in all the calendars Emacs understands, in the form of a menu. (Choosing an alternative from this menu doesn't actually do anything--the menu is used only for display.)

Put point on the desired date of the Gregorian calendar, then type the appropriate keys. The p is a mnemonic for "print" since Emacs "prints" the equivalent date in the echo area.

Converting From Other Calendars

You can use the other supported calendars to specify a date to move to. This section describes the commands for doing this using calendars other than Mayan; for the Mayan calendar, see the following section.

g c
: Move to a date specified in the ISO commercial calendar (`calendar-goto-iso-date`).

g j
: Move to a date specified in the Julian calendar (`calendar-goto-julian-date`).

g a
: Move to a date specified in astronomical (Julian) day number (`calendar-goto-astro-day-number`).

g h
: Move to a date specified in the Hebrew calendar (`calendar-goto-hebrew-date`).

g i
: Move to a date specified in the Islamic calendar (`calendar-goto-islamic-date`).

g f
: Move to a date specified in the French Revolutionary calendar (`calendar-goto-french-date`).

g C
: Move to a date specified in the Chinese calendar (`calendar-goto-chinese-date`).

g p
: Move to a date specified in the Persian calendar (`calendar-goto-persian-date`).

g k
: Move to a date specified in the Coptic calendar (`calendar-goto-coptic-date`).

g e
: Move to a date specified in the Ethiopic calendar (`calendar-goto-ethiopic-date`).

These commands ask you for a date on the other calendar, move point to the Gregorian calendar date equivalent to that date, and display the other calendar's date in the echo area. Emacs uses strict completion (see section Completion) whenever it asks you to type a month name, so you don't have to worry about the spelling of Hebrew, Islamic, or French names.

One common question concerning the Hebrew calendar is the computation of the anniversary of a date of death, called a "yahrzeit." The Emacs calendar includes a facility for such calculations. If you are in the calendar, the command M-x list-yahrzeit-dates asks you for a range of years and then displays a list of the yahrzeit dates for those years for the date given by point. If you are not in the calendar, this command first asks you for the date of death and the range of years, and then displays the list of yahrzeit dates.

Converting from the Mayan Calendar

Here are the commands to select dates based on the Mayan calendar:

g m l

Move to a date specified by the long count calendar (`calendar-goto-mayan-long-count-date`).

g m n t

Move to the next occurrence of a place in the tzolkin calendar (`calendar-next-tzolkin-date`).

g m p t

Move to the previous occurrence of a place in the tzolkin calendar (`calendar-previous-tzolkin-date`).

g m n h

Move to the next occurrence of a place in the haab calendar (`calendar-next-haab-date`).

g m p h

Move to the previous occurrence of a place in the haab calendar (`calendar-previous-haab-date`).

g m n c

Move to the next occurrence of a place in the calendar round (`calendar-next-calendar-round-date`).

g m p c

Move to the previous occurrence of a place in the calendar round (`calendar-previous-calendar-round-date`).

To understand these commands, you need to understand the Mayan calendars. The long count is a counting of days with these units:

```
1 kin = 1 day   1 uinal = 20 kin   1 tun = 18 uinal
1 katun = 20 tun   1 baktun = 20 katun
```

Thus, the long count date 12.16.11.16.6 means 12 baktun, 16 katun, 11 tun, 16 uinal, and 6 kin. The Emacs calendar can handle Mayan long count dates as early as 7.17.18.13.1, but no earlier. When you use the g m l command, type the Mayan long count date with the baktun, katun, tun, uinal, and kin separated by periods.

The Mayan tzolkin calendar is a cycle of 260 days formed by a pair of independent cycles of 13 and 20 days. Since this cycle repeats endlessly, Emacs provides commands to move backward and forward to the previous or next point in the cycle. Type g m p t to go to the previous tzolkin date; Emacs asks you for a tzolkin date and moves point to the previous occurrence of that date. Similarly, type g m n t to go to the next occurrence of a tzolkin date.

The Mayan haab calendar is a cycle of 365 days arranged as 18 months of 20 days each, followed a 5-day monthless period. Like the tzolkin cycle, this cycle repeats endlessly, and there are commands to

move backward and forward to the previous or next point in the cycle. Type g m p h to go to the previous haab date; Emacs asks you for a haab date and moves point to the previous occurrence of that date. Similarly, type g m n h to go to the next occurrence of a haab date.

The Maya also used the combination of the tzolkin date and the haab date. This combination is a cycle of about 52 years called a *calendar round*. If you type g m p c, Emacs asks you for both a haab and a tzolkin date and then moves point to the previous occurrence of that combination. Use g m n c to move point to the next occurrence of a combination. These commands signal an error if the haab/tzolkin date combination you have typed is impossible.

Emacs uses strict completion (see section Strict Completion) whenever it asks you to type a Mayan name, so you don't have to worry about spelling.

The Diary

The Emacs diary keeps track of appointments or other events on a daily basis, in conjunction with the calendar. To use the diary feature, you must first create a diary file containing a list of events and their dates. Then Emacs can automatically pick out and display the events for today, for the immediate future, or for any specified date.

By default, Emacs uses `` `~/diary' `` as the diary file. This is the same file that the `calendar` utility uses. A sample `` `~/diary' `` file is:

```
12/22/1988  Twentieth wedding anniversary!!
&1/1.       Happy New Year!
10/22       Ruth's birthday.
* 21, *:    Payday
Tuesday--weekly meeting with grad students at 10am
         Supowit, Shen, Bitner, and Kapoor to attend.
1/13/89     Friday the thirteenth!!
&thu 4pm    squash game with Lloyd.
mar 16      Dad's birthday
April 15, 1989 Income tax due.
&* 15       time cards due.
```

This example uses extra spaces to align the event descriptions of most of the entries. Such formatting is purely a matter of taste.

Although you probably will start by creating a diary manually, Emacs provides a number of commands to let you view, add, and change diary entries.

Commands Displaying Diary Entries

Once you have created a `` `~/diary' `` file, you can use the calendar to view it. You can also view today's events outside of Calendar mode.

d

Display all diary entries for the selected date (`view-diary-entries`).

Mouse-2 Diary
: Display all diary entries for the date you click on.

s
: Display the entire diary file (`show-all-diary-entries`).

m
: Mark all visible dates that have diary entries (`mark-diary-entries`).

u
: Unmark the calendar window (`calendar-unmark`).

M-x print-diary-entries
: Print hard copy of the diary display as it appears.

M-x diary
: Display all diary entries for today's date.

Displaying the diary entries with d shows in a separate window the diary entries for the selected date in the calendar. The mode line of the new window shows the date of the diary entries and any holidays that fall on that date. If you specify a numeric argument with d, it shows all the diary entries for that many successive days. Thus, 2 d displays all the entries for the selected date and for the following day.

Another way to display the diary entries for a date is to click Mouse-2 on the date, and then choose Diary from the menu that appears.

To get a broader view of which days are mentioned in the diary, use the m command. This displays the dates that have diary entries fall in a different face (or places a `+' after these dates, if display with multiple faces is not available). The command applies both to the currently visible months and to other months that subsequently become visible by scrolling. To turn marking off and erase the current marks, type u, which also turns off holiday marks (see section Holidays).

To see the full diary file, rather than just some of the entries, use the s command.

Display of selected diary entries uses the selective display feature to hide entries that don't apply. This is the same feature that Outline mode uses to show part of an outline (see section Outline Mode).

The diary buffer as you see it is an illusion, so simply printing the buffer does not print what you see on your screen. There is a special command to print hard copy of the diary buffer *as it appears*; this command is M-x print-diary-entries. It sends the data directly to the printer. You can customize it like `lpr-region` (see section Hardcopy Output).

The command M-x diary displays the diary entries for the current date, independently of the calendar display, and optionally for the next few days as well; the variable `number-of-diary-entries` specifies how many days to include. See section 'Calendar/Diary Options' in The Emacs Lisp Reference Manual.

If you put `(diary)` in your `.emacs' file, this automatically displays a window with the day's diary entries, when you enter Emacs. The mode line of the displayed window shows the date and any holidays

TOC

that fall on that date.

The Diary File

Your diary file is a file that records events associated with particular dates. The name of the diary file is specified by the variable `diary-file`; `` `~/diary' `` is the default. The `calendar` utility program supports a subset of the format allowed by the Emacs diary facilities, so you can use that utility to view the diary file, with reasonable results aside from the entries it cannot understand.

Each entry in the diary file describes one event and consists of one or more lines. An entry always begins with a date specification at the left margin. The rest of the entry is simply text to describe the event. If the entry has more than one line, then the lines after the first must begin with whitespace to indicate they continue a previous entry. Lines that do not begin with valid dates and do not continue a preceding entry are ignored.

You can inhibit the marking of certain diary entries in the calendar window; to do this, insert an ampersand (`&') at the beginning of the entry, before the date. This has no effect on display of the entry in the diary window; it affects only marks on dates in the calendar window. Nonmarking entries are especially useful for generic entries that would otherwise mark many different dates.

If the first line of a diary entry consists only of the date or day name with no following blanks or punctuation, then the diary window display doesn't include that line; only the continuation lines appear. For example, this entry:

```
02/11/1989
      Bill B. visits Princeton today
      2pm Cognitive Studies Committee meeting
      2:30-5:30 Liz at Lawrenceville
      4:00pm Dentist appt
      7:30pm Dinner at George's
      8:00-10:00pm concert
```

appears in the diary window without the date line at the beginning. This style of entry looks neater when you display just a single day's entries, but can cause confusion if you ask for more than one day's entries.

You can edit the diary entries as they appear in the window, but it is important to remember that the buffer displayed contains the *entire* diary file, with portions of it concealed from view. This means, for instance, that the C-f (`forward-char`) command can put point at what appears to be the end of the line, but what is in reality the middle of some concealed line.

Be careful when editing the diary entries! Inserting additional lines or adding/deleting characters in the middle of a visible line cannot cause problems, but editing at the end of a line may not do what you expect. Deleting a line may delete other invisible entries that follow it. Before editing the diary, it is best to display the entire file with s (`show-all-diary-entries`).

Date Formats

Here are some sample diary entries, illustrating different ways of formatting a date. The examples all show dates in American order (month, day, year), but Calendar mode supports European order (day, month, year) as an option.

```
4/20/93  Switch-over to new tabulation system
apr. 25  Start tabulating annual results
4/30  Results for April are due
*/25  Monthly cycle finishes
Friday  Don't leave without backing up files
```

The first entry appears only once, on April 20, 1993. The second and third appear every year on the specified dates, and the fourth uses a wildcard (asterisk) for the month, so it appears on the 25th of every month. The final entry appears every week on Friday.

You can use just numbers to express a date, as in `month/day' or `month/day/year'. This must be followed by a nondigit. In the date itself, month and day are numbers of one or two digits. The optional year is also a number, and may be abbreviated to the last two digits; that is, you can use `11/12/1989' or `11/12/89'.

Dates can also have the form `monthname day' or `monthname day, year', where the month's name can be spelled in full or abbreviated to three characters (with or without a period). Case is not significant.

A date may be generic; that is, partially unspecified. Then the entry applies to all dates that match the specification. If the date does not contain a year, it is generic and applies to any year. Alternatively, month, day, or year can be a `*'; this matches any month, day, or year, respectively. Thus, a diary entry `3/*/*' matches any day in March of any year; so does `march *'.

If you prefer the European style of writing dates--in which the day comes before the month--type M-x european-calendar while in the calendar, or set the variable `european-calendar-style` to `t` *before* using any calendar or diary command. This mode interprets all dates in the diary in the European manner, and also uses European style for displaying diary dates. (Note that there is no comma after the monthname in the European style.) To go back to the (default) American style of writing dates, type M-x american-calendar.

You can use the name of a day of the week as a generic date which applies to any date falling on that day of the week. You can abbreviate the day of the week to three letters (with or without a period) or spell it in full; case is not significant.

Commands to Add to the Diary

While in the calendar, there are several commands to create diary entries:

i d

Add a diary entry for the selected date (`insert-diary-entry`).

i w

Add a diary entry for the selected day of the week (`insert-weekly-diary-entry`).

i m

Add a diary entry for the selected day of the month (`insert-monthly-diary-entry`).

i y

Add a diary entry for the selected day of the year (`insert-yearly-diary-entry`).

You can make a diary entry for a specific date by selecting that date in the calendar window and typing the i d command. This command displays the end of your diary file in another window and inserts the date; you can then type the rest of the diary entry.

If you want to make a diary entry that applies to a specific day of the week, select that day of the week (any occurrence will do) and type i w. This inserts the day-of-week as a generic date; you can then type the rest of the diary entry. You can make a monthly diary entry in the same fashion. Select the day of the month, use the i m command, and type rest of the entry. Similarly, you can insert a yearly diary entry with the i y command.

All of the above commands make marking diary entries by default. To make a nonmarking diary entry, give a numeric argument to the command. For example, C-u i w makes a nonmarking weekly diary entry.

When you modify the diary file, be sure to save the file before exiting Emacs.

Special Diary Entries

In addition to entries based on calendar dates, the diary file can contain sexp entries for regular events such as anniversaries. These entries are based on Lisp expressions (sexps) that Emacs evaluates as it scans the diary file. Instead of a date, a sexp entry contains `%%' followed by a Lisp expression which must begin and end with parentheses. The Lisp expression determines which dates the entry applies to.

Calendar mode provides commands to insert certain commonly used sexp entries:

i a

Add an anniversary diary entry for the selected date (`insert-anniversary-diary-entry`).

i b

Add a block diary entry for the current region (`insert-block-diary-entry`).

i c

Add a cyclic diary entry starting at the date (`insert-cyclic-diary-entry`).

If you want to make a diary entry that applies to the anniversary of a specific date, move point to that date and use the i a command. This displays the end of your diary file in another window and inserts the anniversary description; you can then type the rest of the diary entry. The entry looks like this:

```
%%(diary-anniversary 10 31 1948) Arthur's birthday
```

This entry applies to October 31 in any year after 1948; `10 31 1948' specifies the date. (If you are using the European calendar style, the month and day are interchanged.) The reason this expression requires a beginning year is that advanced diary functions can use it to calculate the number of elapsed years.

A block diary entry applies to a specified range of consecutive dates. Here is a block diary entry that applies to all dates from June 24, 1990 through July 10, 1990:

```
%%(diary-block 6 24 1990 7 10 1990) Vacation
```

The `6 24 1990' indicates the starting date and the `7 10 1990' indicates the stopping date. (Again, if you are using the European calendar style, the month and day are interchanged.)

To insert a block entry, place point and the mark on the two dates that begin and end the range, and type i b. This command displays the end of your diary file in another window and inserts the block description; you can then type the diary entry.

Cyclic diary entries repeat after a fixed interval of days. To create one, select the starting date and use the i c command. The command prompts for the length of interval, then inserts the entry, which looks like this:

```
%%(diary-cyclic 50 3 1 1990) Renew medication
```

This entry applies to March 1, 1990 and every 50th day following; `3 1 1990' specifies the starting date. (If you are using the European calendar style, the month and day are interchanged.)

All three of these commands make marking diary entries. To insert a nonmarking entry, give a numeric argument to the command. For example, C-u i a makes a nonmarking anniversary diary entry.

Marking sexp diary entries in the calendar is *extremely* time-consuming, since every date visible in the calendar window must be individually checked. So it's a good idea to make sexp diary entries nonmarking (with `&') when possible.

Another sophisticated kind of sexp entry, a floating diary entry, specifies a regularly-occurring event by offsets specified in days, weeks, and months. It is comparable to a crontab entry interpreted by the `cron` utility. Here is a nonmarking, floating diary entry that applies to the last Thursday in November:

```
&%%(diary-float 11 4 -1) American Thanksgiving
```

The 11 specifies November (the eleventh month), the 4 specifies Thursday (the fourth day of the week, where Sunday is numbered zero), and the -1 specifies "last" (1 would mean "first", 2 would mean "second", -2 would mean "second-to-last", and so on). The month can be a single month or a list of months. Thus you could change the 11 above to `'(1 2 3)' and have the entry apply to the last Thursday of January, February, and March. If the month is `t`, the entry applies to all months of the year.

Most generally, sexp diary entries can perform arbitrary computations to determine when they apply. See section 'Sexp Diary Entries' in The Emacs Lisp Reference Manual.

Appointments

If you have a diary entry for an appointment, and that diary entry begins with a recognizable time of day, Emacs can warn you, several minutes beforehand, that that appointment is pending. Emacs alerts you to

the appointment by displaying a message in the mode line.

To enable appointment notification, you must enable the time display feature of Emacs, M-x display-time (see section The Mode Line). You must also add the function `appt-make-list` to the `diary-hook`, like this:

```
(add-hook 'diary-hook 'appt-make-list)
```

With these preparations done, when you display the diary (either with the d command in the calendar window or with the M-x diary command), it sets up an appointment list of all the diary entries found with recognizable times of day, and reminds you just before each of them.

For example, suppose the diary file contains these lines:

```
Monday
  9:30am Coffee break
 12:00pm Lunch
```

Then on Mondays, after you have displayed the diary, you will be reminded at 9:20am about your coffee break and at 11:50am about lunch.

You can write times in am/pm style (with `12:00am' standing for midnight and `12:00pm' standing for noon), or 24-hour European/military style. You need not be consistent; your diary file can have a mixture of the two styles.

Emacs updates the appointments list automatically just after midnight. This also displays the next day's diary entries in the diary buffer, unless you set `appt-display-diary` to `nil`.

You can also use the appointment notification facility like an alarm clock. The command M-x appt-add adds entries to the appointment list without affecting your diary file. You delete entries from the appointment list with M-x appt-delete.

You can turn off the appointment notification feature at any time by setting `appt-issue-message` to `nil`.

Daylight Savings Time

Emacs understands the difference between standard time and daylight savings time--the times given for sunrise, sunset, solstices, equinoxes, and the phases of the moon take that into account. The rules for daylight savings time vary from place to place and have also varied historically from year to year. To do the job properly, Emacs needs to know which rules to use.

Some operating systems keep track of the rules that apply to the place where you are; on these systems, Emacs gets the information it needs from the system automatically. If some or all of this information is missing, Emacs fills in the gaps with the rules currently used in Cambridge, Massachusetts. If the resulting rules are not what you want, you can tell Emacs the rules to use by setting certain variables.

These values should be Lisp expressions that refer to the variable `year`, and evaluate to the Gregorian

date on which daylight savings time starts or (respectively) ends, in the form of a list `(month day year)`. The values should be `nil` if your area does not use daylight savings time.

Emacs uses these expressions to determine the starting date of daylight savings time for the holiday list and for correcting times of day in the solar and lunar calculations.

The values for Cambridge, Massachusetts are as follows:

```
(calendar-nth-named-day 1 0 4 year)
(calendar-nth-named-day -1 0 10 year)
```

That is, the first 0th day (Sunday) of the fourth month (April) in the year specified by `year`, and the last Sunday of the tenth month (October) of that year. If daylight savings time were changed to start on October 1, you would set `calendar-daylight-savings-starts` to this:

```
(list 10 1 year)
```

If there is no daylight savings time at your location, or if you want all times in standard time, set `calendar-daylight-savings-starts` and `calendar-daylight-savings-ends` to `nil`.

The variable `calendar-daylight-time-offset` specifies the difference between daylight savings time and standard time, measured in minutes. The value for Cambridge, Massachusetts is 60.

The two variables `calendar-daylight-savings-starts-time` and `calendar-daylight-savings-ends-time` specify the number of minutes after midnight local time when the transition to and from daylight savings time should occur. For Cambridge, Massachusetts both variables' values are 120.

Go to the previous, next section.

Go to the previous, next section.

Miscellaneous Commands

This chapter contains several brief topics that do not fit anywhere else: reading netnews, running shell commands and shell subprocesses, using a single shared Emacs for utilities that expect to run an editor as a subprocess, printing hardcopy, sorting text, narrowing display to part of the buffer, editing double-column files and binary files, saving an Emacs session for later resumption, emulating other editors, various diversions and amusements.

Gnus

Gnus is an Emacs package primarily designed for reading and posting Usenet news. It can also be used to read and respond to messages from a number of other sources--mail, remote directories, digests, and so on.

Here we introduce Gnus and describe several basic features. For full details on Gnus, type M-x info and then select the Gnus manual.

To start Gnus, type M-x gnus RET.

Gnus Buffers

As opposed to most normal Emacs packages, Gnus uses a number of different buffers to display information and to receive commands. The three buffers users spend most of their time in are the group buffer, the summary buffer and the article buffer.

The group buffer contains a list of groups. This is the first buffer Gnus displays when it starts up. It normally displays only the groups to which you subscribe and that contain unread articles. Use this buffer to select a specific group.

The summary buffer lists one line for each article in a single group. By default, the author, the subject and the line number are displayed for each article, but this is customizable, like most aspects of Gnus display. The summary buffer is created when you select a group in the group buffer, and is killed when you exit the group. Use this buffer to select an article.

The article buffer displays the article. In normal Gnus usage, you don't select this buffer--all useful article-oriented commands work in the summary buffer. But you can select the article buffer, and execute all Gnus commands from that buffer, if you want to.

When Gnus Starts Up

At startup, Gnus reads your `.newsrc' news initialization file and attempts to communicate with the local news server, which is a repository of news articles. The news server need not be the same computer you are logged in on.

If you start Gnus and connect to the server, but do not see any newsgroups listed in the group buffer, type L or A k to get a listing of all the groups. Then type u to toggle subscription to groups.

The first time you start Gnus, Gnus subscribes you to a few selected groups. All other groups start out as killed groups for you; you can list them with A k. All new groups that subsequently come to exist at the news server become zombie groups for you; type A z to list them. You can subscribe to a group shown in these lists using the u command.

When you quit Gnus with q, it automatically records in your `.newsrc' and `.newsrc.eld' initialization files the subscribed or unsubscribed status of all groups. You should normally not edit these files manually, but you may if you know how.

Summary of Gnus Commands

Reading news is a two step process:

1. Choose a group in the group buffer.
2. Select articles from the summary buffer. Each article selected is displayed in the article buffer in a large window, below the summary buffer in its small window.

Each Gnus buffer has its own special commands; however, the meanings of any given key in the various Gnus buffers are usually analogous, even if not identical. Here are commands for the group and summary buffers:

q

In the group buffer, update your `.newsrc' initialization file and quit Gnus.

In the summary buffer, exit the current group and return to the group buffer. Thus, typing q twice quits Gnus.

L

In the group buffer, list all the groups available on your news server (except those you have killed). This may be a long list!

l

In the group buffer, list only the groups to which you subscribe and which contain unread articles.

u

In the group buffer, unsubscribe from (or subscribe to) the group listed in the line that point is on. When you quit Gnus by typing q, Gnus lists in your `.newsrc' file which groups you have subscribed to. The next time you start Gnus, you won't see this group, because Gnus normally displays only subscribed-to groups.

C-k

In the group buffer, "kill" the current line's group--don't even list it in `.newsrc' from now on. This affects future Gnus sessions as well as the present session.

When you quit Gnus by typing q, Gnus writes information in the file `.newsrc' describing all newsgroups except those you have "killed."

SPC

In the group buffer, select the group on the line under the cursor and display the first unread ar in that group.

In the summary buffer,

Select the article on the line under the cursor if none is selected.

Scroll the text of the selected article (if there is one).

Select the next unread article if at the end of the current article.

Thus, you can move through all the articles by repeatedly typing SPC.

DEL

In the group buffer, move point to the previous group containing unread articles.

In the summary buffer, scroll the text of the article backwards.

n

Move point to the next unread group, or select the next unread article.

p

Move point to the previous unread group, or select the previous unread article.

C-n

C-p

Move point to the next or previous item, even if it is marked as read. This does not select the article or group on that line.

s

In the summary buffer, do an incremental search of the current text in the article buffer, just as if you switched to the article buffer and typed C-s.

M-s regexp RET

In the summary buffer, search forward for articles containing a match for regexp.

Running Shell Commands from Emacs

Emacs has commands for passing single command lines to inferior shell processes; it can also run a shell interactively with input and output to an Emacs buffer named `*shell*'.

M-! cmd RET

Run the shell command line cmd and display the output (`shell-command`).

M-| cmd RET

Run the shell command line cmd with region contents as input; optionally replace the region with the output (`shell-command-on-region`).

M-x shell

Run a subshell with input and output through an Emacs buffer. You can then give commands interactively.

Single Shell Commands

M-! (`shell-command`) reads a line of text using the minibuffer and executes it as a shell command in a subshell made just for that command. Standard input for the command comes from the null device. If the shell command produces any output, the output goes into an Emacs buffer named `*Shell Command Output*', which is displayed in another window but not selected. A numeric argument, as in M-1 M-!, directs this command to insert any output into the current buffer. In that case, point is left before the output and the mark is set after the output.

If the shell command line ends in `&', it runs asynchronously.

M-| (`shell-command-on-region`) is like M-! but passes the contents of the region as the standard input to the shell command, instead of no input. If a numeric argument is used, meaning insert the output in the current buffer, then the old region is deleted first and the output replaces it as the contents of the region.

Both M-! and M-| use `shell-file-name` to specify the shell to use. This variable is initialized based on your `SHELL` environment variable when Emacs is started. If the file name does not specify a directory, the directories in the list `exec-path` are searched; this list is initialized based on the environment variable `PATH` when Emacs is started. Your `` `.emacs' `` file can override either or both of these default initializations.

Both M-! and M-| wait for the shell command to complete. To stop waiting, type C-g to quit; that terminates the shell command with the signal `SIGINT`---the same signal that C-c normally generates in the shell. Emacs waits until the command actually terminates. If the shell command doesn't stop (because it ignores the `SIGINT` signal), type C-g again; this sends the command a `SIGKILL` signal which is impossible to ignore.

Interactive Inferior Shell

To run a subshell interactively, putting its typescript in an Emacs buffer, use M-x shell. This creates (or reuses) a buffer named `*shell*' and runs a subshell with input coming from and output going to that buffer. That is to say, any "terminal output" from the subshell goes into the buffer, advancing point, and any "terminal input" for the subshell comes from text in the buffer. To give input to the subshell, go to the end of the buffer and type the input, terminated by RET.

Emacs does not wait for the subshell to do anything. You can switch windows or buffers and edit them while the shell is waiting, or while it is running a command. Output from the subshell waits until Emacs has time to process it; this happens whenever Emacs is waiting for keyboard input or for time to elapse.

To make multiple subshells, rename the buffer `*shell*' to something different using M-x rename-uniquely. Then type M-x shell again to create a new buffer `*shell*' with its own subshell. If you rename this buffer as well, you can create a third one, and so on. All the subshells run independently and in parallel.

The file name used to load the subshell is the value of the variable `explicit-shell-file-name`, if that is non-`nil`. Otherwise, the environment variable `ESHELL` is used, or the environment variable `SHELL` if there is no `ESHELL`. If the file name specified is relative, the directories in the list

TOC

`exec-path` are searched; this list is initialized based on the environment variable `PATH` when Ema started. Your `.emacs' file can override either or both of these default initializations.

As soon as the subshell is started, it is sent as input the contents of the file `~/.emacs_shellname', if that file exists, where shellname is the name of the file that the shell was loaded from. For example, if you use bash, the file sent to it is `~/.emacs_bash'.

`cd`, `pushd` and `popd` commands given to the inferior shell are watched by Emacs so it can keep the `*shell*' buffer's default directory the same as the shell's working directory. These commands are recognized syntactically by examining lines of input that are sent. If you use aliases for these commands, you can tell Emacs to recognize them also. For example, if the value of the variable `shell-pushd-regexp` matches the beginning of a shell command line, that line is regarded as a `pushd` command. Change this variable when you add aliases for `pushd'. Likewise, `shell-popd-regexp` and `shell-cd-regexp` are used to recognize commands with the meaning of `popd' and `cd'. These commands are recognized only at the beginning of a shell command line.

If Emacs gets an error while trying to handle what it believes is a `cd', `pushd' or `popd' command, it runs the hook `shell-set-directory-error-hook` (see section Hooks).

If Emacs does not properly track changes in the current directory of the subshell, use the command M-x dirs to ask the shell what its current directory is. This command works for shells that support the most common command syntax; it may not work for unusual shells.

Shell Mode

Shell buffers use Shell mode, which defines several special keys attached to the C-c prefix. They are chosen to resemble the usual editing and job control characters present in shells that are not under Emacs, except that you must type C-c first. Here is a complete list of the special key bindings of Shell mode:

RET

At end of buffer send line as input; otherwise, copy current line to end of buffer and send it (`comint-send-input`). When a line is copied, any text at the beginning of the line that matches the variable `shell-prompt-pattern` is left out; this variable's value should be a regexp string that matches the prompts that your shell uses.

TAB

Complete the command name or file name before point in the shell buffer (`comint-dynamic-complete`). TAB also completes history references (see section Shell History References) and environment variable names.

The variable `shell-completion-fignore` specifies a list of file name extensions to ignore in Shell mode completion. The default setting ignores file names ending in `~', `#' or `%'. Other related Comint modes use the variable `comint-completion-fignore` instead.

M-?

Display temporarily a list of the possible completions of the file name before point in the shell buffer (`comint-dynamic-list-filename-completions`).

C-d

Either delete a character or send EOF (`comint-delchar-or-maybe-eof`). Typed at the end of the shell buffer, C-d sends EOF to the subshell. Typed at any other position in the buffer, C-d deletes a character as usual.

C-c C-a

Move to the beginning of the line, but after the prompt if any (`comint-bol`).

C-c C-u

Kill all text pending at end of buffer to be sent as input (`comint-kill-input`).

C-c C-w

Kill a word before point (`backward-kill-word`).

C-c C-c

Interrupt the shell or its current subjob if any (`comint-interrupt-subjob`).

C-c C-z

Stop the shell or its current subjob if any (`comint-stop-subjob`).

C-c C-\

Send quit signal to the shell or its current subjob if any (`comint-quit-subjob`).

C-c C-o

Kill the last batch of output from a shell command (`comint-kill-output`). This is useful if a shell command spews out lots of output that just gets in the way.

C-c C-r

C-M-l

Scroll to display the beginning of the last batch of output at the top of the window; also move the cursor there (`comint-show-output`).

C-c C-e

Scroll to put the end of the buffer at the bottom of the window (`comint-show-maximum-output`).

C-c C-f

Move forward across one shell command, but not beyond the current line (`shell-forward-command`). The variable `shell-command-regexp` specifies how to recognize the end of a command.

C-c C-b

Move backward across one shell command, but not beyond the current line (`shell-backward-command`).

C-c C-l

Display the buffer's history of shell commands in another window (`comint-dynamic-list-input-ring`).

M-x dirs

Ask the shell what its current directory is, so that Emacs can agree with the shell.

M-x send-invisible RET text RET

Send text as input to the shell, after reading it without echoing. This is useful when a shell command runs a program that asks for a password.

Alternatively, you can arrange for Emacs to notice password prompts and turn off echoing for them, as follows:

```
(add-hook 'comint-output-filter-functions
          'comint-watch-for-password-prompt)
```

M-x comint-continue-subjob

Continue the shell process. This is useful if you accidentally suspend the shell process.(3)

M-x comint-strip-ctrl-m

Discard all control-m characters from the current group of shell output. The most convenient way to use this command is to make it run automatically when you get output from the subshell. To do that, evaluate this Lisp expression:

```
(add-hook 'comint-output-filter-functions
          'comint-strip-ctrl-m)
```

M-x comint-truncate-buffer

This command truncates the shell buffer to a certain maximum number of lines, specified by the variable `comint-buffer-maximum-size`. Here's how to do this automatically each time you get output from the subshell:

```
(add-hook 'comint-output-filter-functions
          'comint-truncate-buffer)
```

Shell mode also customizes the paragraph commands so that only shell prompts start new paragraphs. Thus, a paragraph consists of an input command plus the output that follows it in the buffer.

Shell mode is a derivative of Comint mode, a general purpose mode for communicating with interactive subprocesses. Most of the features of Shell mode actually come from Comint mode, as you can see from the command names listed above. The special features of Shell mode in particular include the choice of regular expression for detecting prompts, the directory tracking feature, and a few user commands.

Other Emacs features that use variants of Comint mode include GUD (see section Running Debuggers Under Emacs) and M-x run-lisp (see section Running an External Lisp).

You can use M-x comint-run to execute any program of your choice in a subprocess using unmodified Comint mode--without the specializations of Shell mode.

Shell Command History

Shell buffers support three ways of repeating earlier commands. You can use the same keys used in the minibuffer; these work much as they do in the minibuffer, inserting text from prior commands while point remains always at the end of the buffer. You can move through the buffer to previous inputs in their original place, then resubmit them or copy them to the end. Or you can use a `!'-style history reference.

Shell History Ring

M-p
: Fetch the next earlier old shell command.

M-n
: Fetch the next later old shell command.

M-r regexp RET

M-s regexp RET
: Search backwards or forwards for old shell commands that match regexp.

Shell buffers provide a history of previously entered shell commands. To reuse shell commands from the history, use the editing commands M-p, M-n, M-r and M-s. These work just like the minibuffer history commands except that they operate on the text at the end of the shell buffer, where you would normally insert text to send to the shell.

M-p fetches an earlier shell command to the end of the shell buffer. Successive use of M-p fetches successively earlier shell commands, each replacing any text that was already present as potential shell input. M-n does likewise except that it finds successively more recent shell commands from the buffer.

The history search commands M-r and M-s read a regular expression and search through the history for a matching command. Aside from the choice of which command to fetch, they work just like M-p and M-r. If you enter an empty regexp, these commands reuse the same regexp used last time.

When you find the previous input you want, you can resubmit it by typing RET, or you can edit it first and then resubmit it if you wish.

These commands get the text of previous shell commands from a special history list, not from the shell buffer itself. Thus, editing the shell buffer, or even killing large parts of it, does not affect the history that these commands access.

Some shells store their command histories in files so that you can refer to previous commands from previous shell sessions. Emacs reads the command history file for your chosen shell, to initialize its own command history. The file name is `~/.bash_history' for bash, `~/.sh_history' for ksh, and `~/.history' for other shells.

Shell History Copying

C-c C-p
: Move point to the previous prompt (`comint-previous-prompt`).

C-c C-n
: Move point to the following prompt (`comint-next-prompt`).

C-c RET
: Copy the input command which point is in, inserting the copy at the end of the buffer (`comint-copy-old-input`). This is useful if you move point back to a previous command.

After you copy the command, you can submit the copy as input with RET. If you wish, you can edit the copy before resubmitting it.

Moving to a previous input and then copying it with C-c RET produces the same results--the same buffer contents--that you would get by using M-p enough times to fetch that previous input from the history list. However, C-c RET copies the text from the buffer, which can be different from what is in the history list if you edit the input text in the buffer after it has been sent.

Shell History References

Various shells including csh and bash support history references that begin with `!' and `^'. Shell mode can understand these constructs and perform the history substitution for you. If you insert a history reference and type TAB, this searches the input history for a matching command, performs substitution if necessary, and places the result in the buffer in place of the history reference. For example, you can fetch the most recent command beginning with `mv' with ! m v TAB. You can edit the command if you wish, and then resubmit the command to the shell by typing RET.

History references take effect only following a shell prompt. The variable `shell-prompt-pattern` specifies how to recognize a shell prompt. Comint modes in general use the variable `comint-prompt-regexp` to specify how to find a prompt; Shell mode uses `shell-prompt-pattern` to set up the local value of `comint-prompt-regexp`.

Shell mode can optionally expand history references in the buffer when you send them to the shell. To request this, set the variable `comint-input-autoexpand` to `input`.

You can make SPC perform history expansion by binding SPC to the command `comint-magic-space`.

Shell Mode Options

If the variable `comint-scroll-to-bottom-on-input` is non-`nil`, insertion and yank commands scroll the selected window to the bottom before inserting.

If `comint-scroll-show-maximum-output` is non-`nil`, then scrolling due to arrival of output tries to place the last line of text at the bottom line of the window, so as to show as much useful text as possible. (This mimics the scrolling behavior of many terminals.) The default is `nil`.

By setting `comint-scroll-to-bottom-on-output`, you can opt for having point jump to the end of the buffer whenever output arrives--no matter where in the buffer point was before. If the value is `this`, point jumps in the selected window. If the value is `all`, point jumps in each window that shows the comint buffer. If the value is `other`, point jumps in all nonselected windows that show the current buffer. The default value is `nil`, which means point does not jump to the end.

The variable `comint-input-ignoredups` controls whether successive identical inputs are stored in the input history. A non-`nil` value means to omit an input that is the same as the previous input. The default is `nil`, which means to store each input even if it is equal to the previous input.

Three variables customize file name completion. The variable `comint-completion-addsuffix`

controls whether completion inserts a space or a slash to indicate a fully completed file or directory r (non-`nil` means do insert a space or slash). `comint-completion-recexact`, if non-`nil`, dire TAB to choose the shortest possible completion if the usual Emacs completion algorithm cannot add even a single character. `comint-completion-autolist`, if non-`nil`, says to list all the possible completions whenever completion is not exact.

The command `comint-dynamic-complete-variable` does variable name completion using the environment variables as set within Emacs. The variables controlling file name completion apply to variable name completion too. This command is normally available through the menu bar.

Command completion normally considers only executable files. If you set `shell-command-execonly` to `nil`, it considers nonexecutable files as well.

You can configure the behavior of `pushd'. Variables control whether `pushd' behaves like `cd' if no argument is given (`shell-pushd-tohome`), pop rather than rotate with a numeric argument (`shell-pushd-dextract`), and only add directories to the directory stack if they are not already on it (`shell-pushd-dunique`). The values you choose should match the underlying shell, of course.

Remote Host Shell

Emacs provides two commands for logging in to another computer and communicating with it through an Emacs buffer.

M-x telnet RET hostname RET

Set up a Telnet connection to the computer named hostname.

M-x rlogin RET hostname RET

Set up an Rlogin connection to the computer named hostname.

Use M-x telnet to set up a Telnet connection to another computer. (Telnet is the standard Internet protocol for remote login.) It reads the host name of the other computer as an argument with the minibuffer. Once the connection is established, talking to the other computer works like talking to a subshell: you can edit input with the usual Emacs commands, and send it a line at a time by typing RET. The output is inserted in the Telnet buffer interspersed with the input.

Use M-x rlogin to set up an Rlogin connection. Rlogin is another remote login communication protocol, essentially much like the Telnet protocol but incompatible with it, and supported only by certain systems. Rlogin's advantages are that you can arrange not to have to give your user name and password when communicating between two machines you frequently use, and that you can make an 8-bit-clean connection. (To do that in Emacs, set `rlogin-explicit-args` to `("-8")` before you run Rlogin.)

M-x rlogin sets up the default file directory of the Emacs buffer to access the remote host via FTP (see section File Names), and it tracks the shell commands that change the current directory just like Shell mode.

There are two ways of doing directory tracking in an Rlogin buffer--either with remote directory names `` `/host:dir/' `` or with local names (that works if the "remote" machine shares file systems with your machine of origin). You can use the command `rlogin-directory-tracking-mode` to switch modes. No argument means use remote directory names, a positive argument means use local names, and

a negative argument means turn off directory tracking.

Using Emacs as a Server

Various programs such as `mail` can invoke your choice of editor to edit a particular piece of text, such as a message that you are sending. By convention, most of these programs use the environment variable `EDITOR` to specify which editor to run. If you set `EDITOR` to `emacs', they invoke Emacs--but in an inconvenient fashion, by starting a new, separate Emacs process. This is inconvenient because it takes time and because the new Emacs process doesn't share the buffers in the existing Emacs process.

You can arrange to use your existing Emacs process as the editor for programs like `mail` by using the Emacs client and Emacs server programs. Here is how.

First, the preparation. Within Emacs, call the function `server-start`. (Your `` `.emacs' `` file can do this automatically if you add the expression `(server-start)` to it.) Then, outside Emacs, set the `EDITOR` environment variable to `emacsclient'. (Note that some programs use a different environment variable; for example, to make TeX use `emacsclient', you should set the `TEXEDIT` environment variable to `emacsclient +%d %s'.)

Then, whenever any program invokes your specified `EDITOR` program, the effect is to send a message to your principal Emacs telling it to visit a file. (That's what the program `emacsclient` does.) Emacs displays the buffer immediately and you can immediately begin editing it.

When you've finished editing that buffer, type C-x # (`server-edit`). This saves the file and sends a message back to the `emacsclient` program telling it to exit. The programs that use `EDITOR` wait for the "editor" (actually, `emacsclient`) to exit. C-x # also checks for other pending external requests to edit various files, and selects the next such file.

You can switch to a server buffer manually if you wish; you don't have to arrive at it with C-x #. But C-x # is the only way to say that you are "finished" with one.

If you set the variable `server-window` to a window or a frame, C-x # displays the server buffer in that window or in that frame.

While `mail` or another application is waiting for `emacsclient` to finish, `emacsclient` does not read terminal input. So the terminal that `mail` was using is effectively blocked for the duration. In order to edit with your principal Emacs, you need to be able to use it without using that terminal. There are two ways to do this:

- Using a window system, run `mail` and the principal Emacs in two separate windows. While `mail` is waiting for `emacsclient`, the window where it was running is blocked, but you can use Emacs by switching windows.
- Use Shell mode in Emacs to run the other program such as `mail`; then, `emacsclient` blocks only the subshell under Emacs, and you can still use Emacs to edit the file.

Some programs write temporary files for you to edit. After you edit the temporary file, the program reads it back and deletes it. If the Emacs server is later asked to edit the same file name, it should assume this has nothing to do with the previous occasion for that file name. The server accomplishes this by killing

the temporary file's buffer when you finish with the file. Use the variable `server-temp-file-regexp` to specify which files are temporary in this sense; its value should be a regular expression that matches file names that are temporary.

Hardcopy Output

The Emacs commands for making hardcopy let you print either an entire buffer or just part of one, either with or without page headers. See also the hardcopy commands of Dired (see section Miscellaneous File Operations) and the diary (see section Commands Displaying Diary Entries).

M-x print-buffer

Print hardcopy of current buffer with page headings containing the file name and page number.

M-x lpr-buffer

Print hardcopy of current buffer without page headings.

M-x print-region

Like `print-buffer` but print only the current region.

M-x lpr-region

Like `lpr-buffer` but print only the current region.

The hardcopy commands (aside from the Postscript commands) pass extra switches to the `lpr` program based on the value of the variable `lpr-switches`. Its value should be a list of strings, each string an option starting with `-'. For example, to use a printer named `nearme', set `lpr-switches` like this:

```
(setq lpr-switches '("-Pnearme"))
```

The variable `lpr-command` specifies the name of the printer program to run; the default value depends on your operating system type. On most systems, the default is `"lpr"`. The variable `lpr-headers-switches` similarly specifies the extra switches to use to make page headers. The variable `lpr-add-switches` controls whether to supply `-T' and `-J' options (suitable for `lpr`) to the printer program: `nil` means don't add them. `lpr-add-switches` should be `nil` if your printer program is not compatible with `lpr`.

Postscript Hardcopy

These commands convert buffer contents to Postscript, either printing it or leaving it in another Emacs buffer.

M-x ps-print-buffer

Print hardcopy of the current buffer in Postscript form.

M-x ps-print-region

Print hardcopy of the current region in Postscript form.

M-x ps-print-buffer-with-faces

Print hardcopy of the current buffer in Postscript form, showing the faces used in the text by

means of Postscript features.

M-x ps-print-region-with-faces

Print hardcopy of the current region in Postscript form, showing the faces used in the text.

M-x ps-spool-buffer

Generate Postscript for the current buffer text.

M-x ps-spool-region

Generate Postscript for the current region.

M-x ps-spool-buffer-with-faces

Generate Postscript for the current buffer, showing the faces used.

M-x ps-spool-region-with-faces

Generate Postscript for the current region, showing the faces used.

The Postscript commands, `ps-print-buffer` and `ps-print-region`, print buffer contents in Postscript form. One command prints the entire buffer; the other, just the region. The corresponding `-with-faces' commands, `ps-print-buffer-with-faces` and `ps-print-region-with-faces`, use Postscript features to show the faces (fonts and colors) in the text properties of the text being printed.

If you are using a color display, you can print a buffer of program code with color highlighting by turning on Font-Lock mode in that buffer, and using `ps-print-buffer-with-faces`.

All four of the commands above use the variables `ps-lpr-command` and `ps-lpr-switches` to specify how to print the output. `ps-lpr-command` specifies the command name to run, and `ps-lpr-switches` specifies command line options to use. If you don't set these variables yourself, they take their initial values from `lpr-command` and `lpr-switches`.

The variable `ps-print-header` controls whether these commands add header lines to each page--set it to `nil` to turn headers off. You can turn off color processing by setting `ps-print-color-p` to `nil`. Many other customization variables for these commands are defined and described in the Lisp file `ps-print.el'.

The commands whose names have `spool' instead of `print' generate the Postscript output in an Emacs buffer instead of sending it to the printer.

Sorting Text

Emacs provides several commands for sorting text in the buffer. All operate on the contents of the region (the text between point and the mark). They divide the text of the region into many sort records, identify a sort key for each record, and then reorder the records into the order determined by the sort keys. The records are ordered so that their keys are in alphabetical order, or, for numeric sorting, in numeric order. In alphabetic sorting, all upper case letters `A' through `Z' come before lower case `a', in accord with the ASCII character sequence.

The various sort commands differ in how they divide the text into sort records and in which part of each

record is used as the sort key. Most of the commands make each line a separate sort record, but some commands use paragraphs or pages as sort records. Most of the sort commands use each entire sort record as its own sort key, but some use only a portion of the record as the sort key.

M-x sort-lines

Divide the region into lines, and sort by comparing the entire text of a line. A numeric argument means sort into descending order.

M-x sort-paragraphs

Divide the region into paragraphs, and sort by comparing the entire text of a paragraph (except for leading blank lines). A numeric argument means sort into descending order.

M-x sort-pages

Divide the region into pages, and sort by comparing the entire text of a page (except for leading blank lines). A numeric argument means sort into descending order.

M-x sort-fields

Divide the region into lines, and sort by comparing the contents of one field in each line. Fields are defined as separated by whitespace, so the first run of consecutive non-whitespace characters in a line constitutes field 1, the second such run constitutes field 2, etc.

Specify which field to sort by with a numeric argument: 1 to sort by field 1, etc. A negative argument means count fields from the right instead of from the left; thus, minus 1 means sort by the last field. If several lines have identical contents in the field being sorted, they keep same relative order that they had in the original buffer.

A negative argument means count fields from the right (from the end of the line).

M-x sort-numeric-fields

Like M-x sort-fields except the specified field is converted to an integer for each line, and the numbers are compared. `10' comes before `2' when considered as text, but after it when considered as a number.

M-x sort-columns

Like M-x sort-fields except that the text within each line used for comparison comes from a fixed range of columns. See below for an explanation.

M-x reverse-region

Reverse the order of the lines in the region. This is useful for sorting into descending order by fields or columns, since those sort commands do not have a feature for doing that.

For example, if the buffer contains this:

```
On systems where clash detection (locking of files being edited) is
implemented, Emacs also checks the first time you modify a buffer
whether the file has changed on disk since it was last visited or
saved.  If it has, you are asked to confirm that you want to change
the buffer.
```

applying M-x sort-lines to the entire buffer produces this:

```
On systems where clash detection (locking of files being edited) is
implemented, Emacs also checks the first time you modify a buffer
saved.  If it has, you are asked to confirm that you want to change
the buffer.
whether the file has changed on disk since it was last visited or
```

where the upper case `O' sorts before all lower case letters. If you use C-u 2 M-x sort-fields instead, you get this:

```
implemented, Emacs also checks the first time you modify a buffer
saved.  If it has, you are asked to confirm that you want to change
the buffer.
On systems where clash detection (locking of files being edited) is
whether the file has changed on disk since it was last visited or
```

where the sort keys were `Emacs', `If', `buffer', `systems' and `the'.

M-x sort-columns requires more explanation. You specify the columns by putting point at one of the columns and the mark at the other column. Because this means you cannot put point or the mark at the beginning of the first line to sort, this command uses an unusual definition of `region': all of the line point is in is considered part of the region, and so is all of the line the mark is in, as well as all the lines in between.

For example, to sort a table by information found in columns 10 to 15, you could put the mark on column 10 in the first line of the table, and point on column 15 in the last line of the table, and then run `sort-columns`. Equivalently, you could run it with the mark on column 15 in the first line and point on column 10 in the last line.

This can be thought of as sorting the rectangle specified by point and the mark, except that the text on each line to the left or right of the rectangle moves along with the text inside the rectangle. See section Rectangles.

Many of the sort commands ignore case differences when comparing, if `sort-fold-case` is non-`nil`.

Narrowing

Narrowing means focusing in on some portion of the buffer, making the rest temporarily inaccessible. The portion which you can still get to is called the accessible portion. Canceling the narrowing, which makes the entire buffer once again accessible, is called widening. The amount of narrowing in effect in a buffer at any time is called the buffer's restriction.

Narrowing can make it easier to concentrate on a single subroutine or paragraph by eliminating clutter. It can also be used to restrict the range of operation of a replace command or repeating keyboard macro.

C-x n n

Narrow down to between point and mark (`narrow-to-region`).

C-x n w

Widen to make the entire buffer accessible again (`widen`).

C-x n p

Narrow down to the current page (`narrow-to-page`).

When you have narrowed down to a part of the buffer, that part appears to be all there is. You can't see the rest, you can't move into it (motion commands won't go outside the accessible part), you can't change it in any way. However, it is not gone, and if you save the file all the inaccessible text will be saved. The word `Narrow' appears in the mode line whenever narrowing is in effect.

The primary narrowing command is C-x n n (`narrow-to-region`). It sets the current buffer's restrictions so that the text in the current region remains accessible but all text before the region or after the region is inaccessible. Point and mark do not change.

Alternatively, use C-x n p (`narrow-to-page`) to narrow down to the current page. See section Pages, for the definition of a page.

The way to cancel narrowing is to widen with C-x n w (`widen`). This makes all text in the buffer accessible again.

You can get information on what part of the buffer you are narrowed down to using the C-x = command. See section Cursor Position Information.

Because narrowing can easily confuse users who do not understand it, `narrow-to-region` is normally a disabled command. Attempting to use this command asks for confirmation and gives you the option of enabling it; if you enable the command, confirmation will no longer be required for it. See section Disabling Commands.

Two-Column Editing

Two-column mode lets you conveniently edit two side-by-side columns of text. It uses two side-by-side windows, each showing its own buffer.

There are three ways to enter two-column mode:

f2 2 or C-x 6 2

Enter two-column mode with the current buffer on the left, and on the right, a buffer whose name is based on the current buffer's name (`2C-two-columns`). If the right-hand buffer doesn't already exist, it starts out empty; the current buffer's contents are not changed.

This command is appropriate when the current buffer is empty or contains just one column and you want to add another column.

f2 s or C-x 6 s

Split the current buffer, which contains two-column text, into two buffers, and display them side by side (`2C-split`). The current buffer becomes the left-hand buffer, but the text in the

right-hand column is moved into the right-hand buffer. The current column specifies the split point. Splitting starts with the current line and continues to the end of the buffer.

This command is appropriate when you have a buffer that already contains two-column text, and you wish to separate the columns temporarily.

f2 b buffer RET

C-x 6 b buffer RET

Enter two-column mode using the current buffer as the left-hand buffer, and using buffer buffer as the right-hand buffer (`2C-associate-buffer`).

f2 s or C-x 6 s looks for a column separator which is a string that appears on each line between the two columns. You can specify the width of the separator with a numeric argument to f2 s; that many characters, before point, constitute the separator string. By default, the width is 1, so the column separator is the character before point.

When a line has the separator at the proper place, f2 s puts the text after the separator into the right-hand buffer, and deletes the separator. Lines that don't have the column separator at the proper place remain unsplit; they stay in the left-hand buffer, and the right-hand buffer gets an empty line to correspond. (This is the way to write a line which "spans both columns while in two-column mode": write it in the left-hand buffer, and put an empty line in the right-hand buffer.)

The command C-x 6 RET or f2 RET (`2C-newline`) inserts a newline in each of the two buffers at corresponding positions. This is the easiest way to add a new line to the two-column text while editing it in split buffers.

When you have edited both buffers as you wish, merge them with f2 1 or C-x 6 1 (`2C-merge`). This copies the text from the right-hand buffer as a second column in the other buffer. To go back to two-column editing, use f2 s.

Use f2 d or C-x 6 d to disassociate the two buffers, leaving each as it stands (`2C-dissociate`). If the other buffer, the one not current when you type f2 d, is empty, f2 d kills it.

Editing Binary Files

There is a special major mode for editing binary files: Hexl mode. To use it, use M-x hexl-find-file instead of C-x C-f to visit the file. This command converts the file's contents to hexadecimal and lets you edit the translation. When you save the file, it is converted automatically back to binary.

You can also use M-x hexl-mode to translate an existing buffer into hex. This is useful if you visit a file normally and then discover it is a binary file.

Ordinary text characters overwrite in Hexl mode. This is to reduce the risk of accidentally spoiling the alignment of data in the file. There are special commands for insertion. Here is a list of the commands of Hexl mode:

C-M-d

Insert a byte with a code typed in decimal.

C-M-o
: Insert a byte with a code typed in octal.

C-M-x
: Insert a byte with a code typed in hex.

C-x [
: Move to the beginning of a 1k-byte "page".

C-x]
: Move to the end of a 1k-byte "page".

M-g
: Move to an address specified in hex.

M-j
: Move to an address specified in decimal.

C-c C-c
: Leave Hexl mode, going back to the major mode this buffer had before you invoked `hexl-mode`.

Saving Emacs Sessions

You can use the Desktop library to save the state of Emacs from one session to another. Saving the state means that Emacs starts up with the same set of buffers, major modes, buffer positions, and so on that the previous Emacs session had.

To use Desktop, you should first add these lines at the end of your `` `.emacs' `` file:

```
(load "desktop")
(desktop-load-default)
(desktop-read)
```

The first time you save the state of the Emacs session, you must do it manually, with the command M-x desktop-save. Once you have done that, exiting Emacs will save the state again--not only the present Emacs session, but also subsequent sessions. You can also save the state at any time, without exiting Emacs, by typing M-x desktop-save again.

In order for Emacs to recover the state from a previous session, you must start it with the same current directory as you used when you started the previous session.

The variable `desktop-files-not-to-save` controls which files are excluded from state saving. Its value is a regular expression that matches the files to exclude. By default, remote (ftp-accessed) files are excluded; this is because visiting them again in the subsequent session would be slow. If you want to include these files in state saving, set `desktop-files-not-to-save` to `"^$"`.

Recursive Editing Levels

A recursive edit is a situation in which you are using Emacs commands to perform arbitrary editing while in the middle of another Emacs command. For example, when you type C-r inside of a `query-replace`, you enter a recursive edit in which you can change the current buffer. On exiting from the recursive edit, you go back to the `query-replace`.

Exiting the recursive edit means returning to the unfinished command, which continues execution. The command to exit is C-M-c (`exit-recursive-edit`).

You can also abort the recursive edit. This is like exiting, but also quits the unfinished command immediately. Use the command C-] (`abort-recursive-edit`) to do this. See section Quitting and Aborting.

The mode line shows you when you are in a recursive edit by displaying square brackets around the parentheses that always surround the major and minor mode names. Every window's mode line shows this, in the same way, since being in a recursive edit is true of Emacs as a whole rather than any particular window or buffer.

It is possible to be in recursive edits within recursive edits. For example, after typing C-r in a `query-replace`, you may type a command that enters the debugger. This begins a recursive editing level for the debugger, within the recursive editing level for C-r. Mode lines display a pair of square brackets for each recursive editing level currently in progress.

Exiting the inner recursive edit (such as, with the debugger c command) resumes the command running in the next level up. When that command finishes, you can then use C-M-c to exit another recursive editing level, and so on. Exiting applies to the innermost level only. Aborting also gets out of only one level of recursive edit; it returns immediately to the command level of the previous recursive edit. If you wish, you can then abort the next recursive editing level.

Alternatively, the command M-x top-level aborts all levels of recursive edits, returning immediately to the top level command reader.

The text being edited inside the recursive edit need not be the same text that you were editing at top level. It depends on what the recursive edit is for. If the command that invokes the recursive edit selects a different buffer first, that is the buffer you will edit recursively. In any case, you can switch buffers within the recursive edit in the normal manner (as long as the buffer-switching keys have not been rebound). You could probably do all the rest of your editing inside the recursive edit, visiting files and all. But this could have surprising effects (such as stack overflow) from time to time. So remember to exit or abort the recursive edit when you no longer need it.

In general, we try to minimize the use of recursive editing levels in GNU Emacs. This is because they constrain you to "go back" in a particular order--from the innermost level toward the top level. When possible, we present different activities in separate buffers so that you can switch between them as you please. Some commands switch to a new major mode which provides a command to switch back. These approaches give you more flexibility to go back to unfinished tasks in the order you choose.

Emulation

GNU Emacs can be programmed to emulate (more or less) most other editors. Standard facilities can emulate these:

EDT (DEC VMS editor)

Turn on EDT emulation with M-x edt-emulation-on. M-x edt-emulation-off restores normal Emacs command bindings.

Most of the EDT emulation commands are keypad keys, and most standard Emacs key bindings are still available. The EDT emulation rebindings are done in the global keymap, so there is no problem switching buffers or major modes while in EDT emulation.

vi (Berkeley editor)

Viper is the newest emulator for vi. It implements several levels of emulation; level 1 is closest to vi itself, while level 5 departs somewhat from strict emulation to take advantage of the capabilities of Emacs. To invoke Viper, type M-x viper-mode; it will guide you the rest of the way and ask for the emulation level.

vi (another emulator)

M-x vi-mode enters a major mode that replaces the previously established major mode. All of the vi commands that, in real vi, enter "input" mode are programmed instead to return to the previous major mode. Thus, ordinary Emacs serves as vi's "input" mode.

Because vi emulation works through major modes, it does not work to switch buffers during emulation. Return to normal Emacs first.

If you plan to use vi emulation much, you probably want to bind a key to the `vi-mode` command.

vi (alternate emulator)

M-x vip-mode invokes another vi emulator, said to resemble real vi more thoroughly than M-x vi-mode. "Input" mode in this emulator is changed from ordinary Emacs so you can use ESC to go back to emulated vi command mode. To get from emulated vi command mode back to ordinary Emacs, type C-z.

This emulation does not work through major modes, and it is possible to switch buffers in various ways within the emulator. It is not so necessary to assign a key to the command `vip-mode` as it is with `vi-mode` because terminating insert mode does not use it.

For full information, see the long comment at the beginning of the source file, which is `` `lisp/vip.el' `` in the Emacs distribution.

Dissociated Press

M-x dissociated-press is a command for scrambling a file of text either word by word or character by character. Starting from a buffer of straight English, it produces extremely amusing output. The input comes from the current Emacs buffer. Dissociated Press writes its output in a buffer named `*Dissociation*', and redisplays that buffer after every couple of lines (approximately) so you can read

the output as it comes out.

Dissociated Press asks every so often whether to continue generating output. Answer n to stop it. You can also stop at any time by typing C-g. The dissociation output remains in the `*Dissociation*' buffer for you to copy elsewhere if you wish.

Dissociated Press operates by jumping at random from one point in the buffer to another. In order to produce plausible output rather than gibberish, it insists on a certain amount of overlap between the end of one run of consecutive words or characters and the start of the next. That is, if it has just printed out `president' and then decides to jump to a different point in the file, it might spot the `ent' in `pentagon' and continue from there, producing `presidentagon'.(4) Long sample texts produce the best results.

A positive argument to M-x dissociated-press tells it to operate character by character, and specifies the number of overlap characters. A negative argument tells it to operate word by word and specifies the number of overlap words. In this mode, whole words are treated as the elements to be permuted, rather than characters. No argument is equivalent to an argument of two. For your againformation, the output goes only into the buffer `*Dissociation*'. The buffer you start with is not changed.

Dissociated Press produces nearly the same results as a Markov chain based on a frequency table constructed from the sample text. It is, however, an independent, ignoriginal invention. Dissociated Press techniquitously copies several consecutive characters from the sample between random choices, whereas a Markov chain would choose randomly for each word or character. This makes for more plausible sounding results, and runs faster.

It is a mustatement that too much use of Dissociated Press can be a developediment to your real work. Sometimes to the point of outragedy. And keep dissociwords out of your documentation, if you want it to be well userenced and properbose. Have fun. Your buggestions are welcome.

Other Amusements

If you are a little bit bored, you can try M-x hanoi. If you are considerably bored, give it a numeric argument. If you are very very bored, try an argument of 9. Sit back and watch.

If you want a little more personal involvement, try M-x gomoku, which plays the game Go Moku with you.

M-x blackbox and M-x mpuz are two kinds of puzzles. `blackbox` challenges you to determine the location of objects inside a box by tomography. `mpuz` displays a multiplication puzzle with letters standing for digits in a code that you must guess--to guess a value, type a letter and then the digit you think it stands for.

M-x dunnet runs an adventure-style exploration game, which is a bigger sort of puzzle.

When you are frustrated, try the famous Eliza program. Just do M-x doctor. End each input by typing RET twice.

When you are feeling strange, type M-x yow.

Go to the previous, next section.

Go to the previous, next section.

Customization

This chapter talks about various topics relevant to adapting the behavior of Emacs in minor ways. See The Emacs Lisp Reference Manual for how to make more far-reaching changes.

All kinds of customization affect only the particular Emacs session that you do them in. They are completely lost when you kill the Emacs session, and have no effect on other Emacs sessions you may run at the same time or later. The only way an Emacs session can affect anything outside of it is by writing a file; in particular, the only way to make a customization `permanent' is to put something in your `.emacs' file or other appropriate file to do the customization in each session. See section The Init File, `~/.emacs'.

Minor Modes

Minor modes are optional features which you can turn on or off. For example, Auto Fill mode is a minor mode in which SPC breaks lines between words as you type. All the minor modes are independent of each other and of the selected major mode. Most minor modes say in the mode line when they are on; for example, `Fill' in the mode line means that Auto Fill mode is on.

Append `-mode` to the name of a minor mode to get the name of a command function that turns the mode on or off. Thus, the command to enable or disable Auto Fill mode is called M-x auto-fill-mode. These commands are usually invoked with M-x, but you can bind keys to them if you wish. With no argument, the function turns the mode on if it was off and off if it was on. This is known as toggling. A positive argument always turns the mode on, and an explicit zero argument or a negative argument always turns it off.

Enabling or disabling some minor modes applies only to the current buffer; each buffer is independent of the other buffers. Therefore, you can enable the mode in particular buffers and disable it in others. The per-buffer minor modes include Auto Fill mode, Auto Save mode, Font-Lock mode, ISO Accents mode, Outline minor mode, Overwrite mode, and Binary Overwrite mode.

Auto Fill mode allows you to enter filled text without breaking lines explicitly. Emacs inserts newlines as necessary to prevent lines from becoming too long. See section Filling Text.

Auto Save mode causes the contents of a buffer to be saved periodically to reduce the amount of work you can lose in case of a system crash. See section Auto-Saving: Protection Against Disasters.

Enriched mode enables editing and saving of formatted text. See section Editing Formatted Text.

Font-Lock mode automatically highlights certain textual units found in programs, such as comments, strings, and function names being defined. This requires a window system that can display multiple fonts. See section Using Multiple Typefaces.

ISO Accents mode makes the characters ``', `'', `'"', `^', `/' and `~' combine with the following letter, to produce an accented letter in the ISO Latin-1 character set. See section European Character Set Display.

Outline minor mode provides the same facilities as the major mode called Outline mode; but since it is a minor mode instead, you can combine it with any major mode. See section Outline Mode.

Overwrite mode causes ordinary printing characters to replace existing text instead of shoving it to the right. For example, if point is in front of the `B' in `FOOBAR', then in Overwrite mode typing a G changes it to `FOOGAR', instead of producing it `FOOGBAR' as usual. Binary Overwrite mode is a variant of Overwrite mode for editing binary files; it treats newlines and tabs like other characters, so that they overwrite other characters and can be overwritten by them.

The following minor modes normally apply to all buffers at once. Since each is enabled or disabled by the value of a variable, you *can* set them differently for particular buffers, by explicitly making the corresponding variables local in those buffers. See section Local Variables.

Abbrev mode allows you to define abbreviations that automatically expand as you type them. For example, `amd' might expand to `abbrev mode'. See section Abbrevs, for full information.

Icomplete mode displays an indication of available completions when you are in the minibuffer and completion is active. See section Completion Options.

Line Number mode enables continuous display in the mode line of the line number of point. See section The Mode Line.

Resize-Minibuffer mode makes the minibuffer expand as necessary to hold the text that you put in it. See section Editing in the Minibuffer.

Scroll Bar mode gives each window a scroll bar (see section Scroll Bars). Menu Bar mode gives each frame a menu bar (see section Menu Bars). Both of these modes are enabled by default when you use the X Window System.

In Transient Mark mode, every change in the buffer contents "deactivates" the mark, so that commands that operate on the region will get an error. This means you must either set the mark, or explicitly "reactivate" it, before each command that uses the region. The advantage of Transient Mark mode is that Emacs can display the region highlighted (currently only when using X). See section Setting the Mark.

For most minor modes, the command name is also the name of a variable which directly controls the mode. The mode is enabled whenever this variable's value is non-`nil`, and the minor mode command works by setting the variable. For example, the command `outline-minor-mode` works by setting the value of `outline-minor-mode` as a variable; it is this variable that directly turns Outline minor mode on and off. To check whether a given minor mode works this way, use C-h v to ask for documentation on the variable name.

These minor mode variables provide a good way for Lisp programs to turn minor modes on and off; they are also useful in a file's local variables list. But please think twice before setting minor modes with a local variables list, because most minor modes are matter of user preference--other users editing the same file might not want the same minor modes you prefer.

Variables

A variable is a Lisp symbol which has a value. The symbol's name is also called the name of the variable. A variable name can contain any characters that can appear in a file, but conventionally variable names consist of words separated by hyphens. A variable can have a documentation string which describes what kind of value it should have and how the value will be used.

Lisp allows any variable to have any kind of value, but most variables that Emacs uses require a value of a certain type. Often the value should always be a string, or should always be a number. Sometimes we say that a certain feature is turned on if a variable is "non-`nil`," meaning that if the variable's value is `nil`, the feature is off, but the feature is on for *any* other value. The conventional value to use to turn on the feature--since you have to pick one particular value when you set the variable--is `t`.

Emacs uses many Lisp variables for internal record keeping, as any Lisp program must, but the most interesting variables for you are the ones that exist for the sake of customization. Emacs does not (usually) change the values of these variables; instead, you set the values, and thereby alter and control the behavior of certain Emacs commands. These variables are called user options. Most user options are documented in this manual, and appear in the Variable Index (see section Variable Index).

One example of a variable which is a user option is `fill-column`, which specifies the position of the right margin (as a number of characters from the left margin) to be used by the fill commands (see section Filling Text).

Examining and Setting Variables

C-h v var RET

Display the value and documentation of variable var (`describe-variable`).

M-x set-variable RET var RET value RET

Change the value of variable var to value.

To examine the value of a single variable, use C-h v (`describe-variable`), which reads a variable name using the minibuffer, with completion. It displays both the value and the documentation of the variable. For example,

```
C-h v fill-column RET
```

displays something like this:

```
fill-column's value is 75

Documentation:
*Column beyond which automatic line-wrapping should happen.
Automatically becomes buffer-local when set in any fashion.
```

The star at the beginning of the documentation indicates that this variable is a user option. C-h v is not

restricted to user options; it allows any variable name.

The most convenient way to set a specific user option is with M-x set-variable. This reads the variable name with the minibuffer (with completion), and then reads a Lisp expression for the new value using the minibuffer a second time. For example,

```
M-x set-variable RET fill-column RET 75 RET
```

sets `fill-column` to 75.

M-x set-variable is limited to user option variables. You can set any variable with a Lisp expression using the function `setq`. Here's how to use it to set `fill-column`:

```
(setq fill-column 75)
```

Setting variables, like all means of customizing Emacs except where otherwise stated, affects only the current Emacs session.

Editing Variable Values

These two functions make it easy to display all the Emacs user option variables, and to change some of them if you wish.

M-x list-options

: Display a buffer listing names, values and documentation of all options.

M-x edit-options

: Change user option values by editing a list of user option variables.

M-x list-options displays a list of all Emacs option variables, in an Emacs buffer named `*List Options*'. Each user option is shown with its documentation and its current value. Here is what a portion of it might look like:

```
;; exec-path:
("." "/usr/local/bin" "/usr/ucb" "/bin" "/usr/bin" "/u2/emacs/etc")
*List of directories to search programs to run in subprocesses.
Each element is a string (directory name)
or nil (try the default directory).
;;
;; fill-column:
75
*Column beyond which automatic line-wrapping should happen.
Automatically becomes buffer-local when set in any fashion.
;;
```

M-x edit-options goes one step further and immediately selects the `*List Options*' buffer; this buffer uses the major mode Options mode, which provides commands that allow you to point at a user option variable and change its value:

s

Set the variable point is in or near to a new value read using the minibuffer.

x

Toggle the variable point is in or near: if the value was `nil`, it becomes `t`; otherwise it becomes `nil`.

1

Set the variable point is in or near to `t`.

0

Set the variable point is in or near to `nil`.

n

p

Move to the next or previous user option.

Any changes take effect immediately, and last until you exit from Emacs.

Hooks

A hook is a variable where you can store a function or functions to be called on a particular occasion by an existing program. Emacs provides a number of hooks for the sake of customization.

Most of the hooks in Emacs are normal hooks. These variables contain lists of functions to be called with no arguments. The reason most hooks are normal hooks is so that you can use them in a uniform way. Every variable in Emacs whose name ends in `-hook' is a normal hook.

Most major modes run hooks as the last step of initialization. This makes it easy for a user to customize the behavior of the mode, by overriding the local variable assignments already made by the mode. But hooks may also be used in other contexts. For example, the hook `suspend-hook` runs just before Emacs suspends itself (see section Exiting Emacs).

The recommended way to add a hook function to a normal hook is by calling `add-hook`. You can use any valid Lisp function as the hook function. For example, here's how to set up a hook to turn on Auto Fill mode when entering Text mode and other modes based on Text mode:

```
(add-hook 'text-mode-hook 'turn-on-auto-fill)
```

The next example shows how to use a hook to customize the indentation of C code. (People often have strong personal preferences for one format compared to another.) Here the hook function is an anonymous lambda expression.

```
(setq my-c-style
  '((c-comment-only-line-offset . 4)
    (c-cleanup-list . (scope-operator
                       empty-defun-braces
                       defun-close-semi))
```

```
    (c-offsets-alist . ((arglist-close . c-lineup-arglist)
                        (substatement-open . 0))))

(add-hook 'c-mode-common-hook
  (function (lambda ()
    (c-add-style "my-style" my-c-style t))))
```

It is best to design your hook functions so that the order in which they are executed does not matter. Any dependence on the order is "asking for trouble." However, the order is predictable: the most recently added hook functions are executed first.

Local Variables

M-x make-local-variable RET var RET

Make variable var have a local value in the current buffer.

M-x kill-local-variable RET var RET

Make variable var use its global value in the current buffer.

M-x make-variable-buffer-local RET var RET

Mark variable var so that setting it will make it local to the buffer that is current at that time.

Almost any variable can be made local to a specific Emacs buffer. This means that its value in that buffer is independent of its value in other buffers. A few variables are always local in every buffer. Every other Emacs variable has a global value which is in effect in all buffers that have not made the variable local.

M-x make-local-variable reads the name of a variable and makes it local to the current buffer. Further changes in this buffer will not affect others, and further changes in the global value will not affect this buffer.

M-x make-variable-buffer-local reads the name of a variable and changes the future behavior of the variable so that it will become local automatically when it is set. More precisely, once a variable has been marked in this way, the usual ways of setting the variable automatically do `make-local-variable` first. We call such variables per-buffer variables.

Major modes (see section Major Modes) always make variables local to the buffer before setting the variables. This is why changing major modes in one buffer has no effect on other buffers. Minor modes also work by setting variables--normally, each minor mode has one controlling variable which is non-`nil` when the mode is enabled (see section Minor Modes). For most minor modes, the controlling variable is per buffer.

Emacs contains a number of variables that are always per-buffer. These include `abbrev-mode`, `auto-fill-function`, `case-fold-search`, `comment-column`, `ctl-arrow`, `fill-column`, `fill-prefix`, `indent-tabs-mode`, `left-margin`, `mode-line-format`, `overwrite-mode`, `selective-display-ellipses`, `selective-display`, `tab-width`, and `truncate-lines`. Some other variables are always local in every buffer, but they are used for internal purposes.

A few variables cannot be local to a buffer because they are always local to each display instead (See section Multiple Displays). If you try to make one of these variables buffer-local, you'll get an error message.

M-x kill-local-variable reads the name of a variable and makes it cease to be local to the current buffer. The global value of the variable henceforth is in effect in this buffer. Setting the major mode kills all the local variables of the buffer except for a few variables specially marked as permanent locals.

To set the global value of a variable, regardless of whether the variable has a local value in the current buffer, you can use the Lisp construct `setq-default`. This construct is used just like `setq`, but it sets variables' global values instead of their local values (if any). When the current buffer does have a local value, the new global value may not be visible until you switch to another buffer. Here is an example:

```
(setq-default fill-column 75)
```

`setq-default` is the only way to set the global value of a variable that has been marked with `make-variable-buffer-local`.

Lisp programs can use `default-value` to look at a variable's default value. This function takes a symbol as argument and returns its default value. The argument is evaluated; usually you must quote it explicitly. For example, here's how to obtain the default value of `fill-column`:

```
(default-value 'fill-column)
```

Local Variables in Files

A file can specify local variable values for use when you edit the file with Emacs. Visiting the file checks for local variables specifications; it automatically makes these variables local to the buffer, and sets them to the values specified in the file.

There are two ways to specify local variable values: in the first line, or with a local variables list. Here's how to specify them in the first line:

```
-*- mode: modename; var: value; ... -*-
```

You can specify any number of variables/value pairs in this way, each pair with a colon and semicolon as shown above. `mode: modename;` specifies the major mode; this should come first in the line. The values are not evaluated; they are used literally. Here is an example that specifies Lisp mode and sets two variables with numeric values:

```
;; -*-mode: Lisp; fill-column: 75; comment-column: 50; -*-
```

A local variables list goes near the end of the file, in the last page. (It is often best to put it on a page by itself.) The local variables list starts with a line containing the string `Local Variables:', and ends with a line containing the string `End:'. In between come the variable names and values, one set per line, as `variable: value'. The values are not evaluated; they are used literally. If a file has both a local variables list and a `-*-' line, Emacs processes *everything* in the `-*-' line first, and *everything* in the local variables

list afterward.

Here is an example of a local variables list:

```
;;; Local Variables: ***
;;; mode:lisp ***
;;; comment-column:0 ***
;;; comment-start: ";;; "  ***
;;; comment-end:"***" ***
;;; End: ***
```

As you see, each line starts with the prefix `;;; ' and each line ends with the suffix ` ***'. Emacs recognizes these as the prefix and suffix based on the first line of the list, by finding them surrounding the magic string `Local Variables:'; then it automatically discards them from the other lines of the list.

The usual reason for using a prefix and/or suffix is to embed the local variables list in a comment, so it won't confuse other programs that the file is intended as input for. The example above is for a language where comment lines start with `;;; ' and end with `***'; the local values for `comment-start` and `comment-end` customize the rest of Emacs for this unusual syntax. Don't use a prefix (or a suffix) if you don't need one.

Two "variable names" have special meanings in a local variables list: a value for the variable `mode` really sets the major mode, and a value for the variable `eval` is simply evaluated as an expression and the value is ignored. `mode` and `eval` are not real variables; setting variables named `mode` and `eval` in any other context has no special meaning. If `mode` is used to set a major mode, it should be the first "variable" in the list.

You can use the `mode` "variable" to set minor modes as well as major modes; in fact, you can use it more than once, first to set the major mode and then to set minor modes which are specific to particular buffers. But most minor modes should not be specified in the file in any fashion, because they represent user preferences. For example, you should not try to specify Auto Fill mode with file local variables, because whether to use Auto Fill mode for editing a particular kind of text is a matter of personal taste, not an aspect of the format of the text.

The start of the local variables list must be no more than 3000 characters from the end of the file, and must be in the last page if the file is divided into pages. Otherwise, Emacs will not notice it is there. The purpose of this rule is so that a stray `Local Variables:' not in the last page does not confuse Emacs, and so that visiting a long file that is all one page and has no local variables list need not take the time to search the whole file.

You may be tempted to try to turn on Auto Fill mode with a local variable list. That is a mistake. The choice of Auto Fill mode or not is a matter of individual taste, not a matter of the contents of particular files. If you want to use Auto Fill, set up major mode hooks with your `.emacs' file to turn it on (when appropriate) for you alone (see section The Init File, `~/.emacs'). Don't try to use a local variable list that would impose your taste on everyone.

The variable `enable-local-variables` controls whether to process local variables lists, and thus gives you a chance to override them. Its default value is `t`, which means do process local variables lists.

If you set the value to `nil`, Emacs simply ignores local variables lists. Any other value says to query about each local variables list, showing you the local variables list to consider.

The `eval` "variable", and certain actual variables, create a special risk; when you visit someone else's file, local variable specifications for these could affect your Emacs in arbitrary ways. Therefore, the option `enable-local-eval` controls whether Emacs processes `eval` variables, as well variables with names that end in `-hook', `-hooks', `-function' or `-functions', and certain other variables. The three possibilities for the option's value are `t`, `nil`, and anything else, just as for `enable-local-variables`. The default is `maybe`, which is neither `t` nor `nil`, so normally Emacs does ask for confirmation about file settings for these variables.

Use the command `normal-mode` to reset the local variables and major mode of a buffer according to the file name and contents, including the local variables list if any. See section How Major Modes are Chosen.

Keyboard Macros

A keyboard macro is a command defined by the user to stand for another sequence of keys. For example, if you discover that you are about to type C-n C-d forty times, you can speed your work by defining a keyboard macro to do C-n C-d and calling it with a repeat count of forty.

C-x (
: Start defining a keyboard macro (`start-kbd-macro`).

C-x)
: End the definition of a keyboard macro (`end-kbd-macro`).

C-x e
: Execute the most recent keyboard macro (`call-last-kbd-macro`).

C-u C-x (
: Re-execute last keyboard macro, then add more keys to its definition.

C-x q
: When this point is reached during macro execution, ask for confirmation (`kbd-macro-query`).

M-x name-last-kbd-macro
: Give a command name (for the duration of the session) to the most recently defined keyboard macro.

M-x insert-kbd-macro
: Insert in the buffer a keyboard macro's definition, as Lisp code.

C-x C-k
: Edit a previously defined keyboard macro (`edit-kbd-macro`).

M-x apply-macro-to-region-lines
: Run the last keyboard macro on each complete line in the region.

Keyboard macros differ from ordinary Emacs commands in that they are written in the Emacs command

language rather than in Lisp. This makes it easier for the novice to write them, and makes them more convenient as temporary hacks. However, the Emacs command language is not powerful enough as a programming language to be useful for writing anything intelligent or general. For such things, Lisp must be used.

You define a keyboard macro while executing the commands which are the definition. Put differently, as you define a keyboard macro, the definition is being executed for the first time. This way, you can see what the effects of your commands are, so that you don't have to figure them out in your head. When you are finished, the keyboard macro is defined and also has been, in effect, executed once. You can then do the whole thing over again by invoking the macro.

Basic Use

To start defining a keyboard macro, type the C-x (command (`start-kbd-macro`). From then on, your keys continue to be executed, but also become part of the definition of the macro. `Def' appears in the mode line to remind you of what is going on. When you are finished, the C-x ) command (`end-kbd-macro`) terminates the definition (without becoming part of it!). For example,

```
C-x ( M-f foo C-x )
```

defines a macro to move forward a word and then insert `foo'.

The macro thus defined can be invoked again with the C-x e command (`call-last-kbd-macro`), which may be given a repeat count as a numeric argument to execute the macro many times. C-x) can also be given a repeat count as an argument, in which case it repeats the macro that many times right after defining it, but defining the macro counts as the first repetition (since it is executed as you define it). Therefore, giving C-x) an argument of 4 executes the macro immediately 3 additional times. An argument of zero to C-x e or C-x) means repeat the macro indefinitely (until it gets an error or you type C-g).

If you wish to repeat an operation at regularly spaced places in the text, define a macro and include as part of the macro the commands to move to the next place you want to use it. For example, if you want to change each line, you should position point at the start of a line, and define a macro to change that line and leave point at the start of the next line. Then repeating the macro will operate on successive lines.

After you have terminated the definition of a keyboard macro, you can add to the end of its definition by typing C-u C-x (. This is equivalent to plain C-x (followed by retyping the whole definition so far. As a consequence it re-executes the macro as previously defined.

You can use function keys in a keyboard macro, just like keyboard keys. You can even use mouse events, but be careful about that: when the macro replays the mouse event, it uses the original mouse position of that event, the position that the mouse had while you were defining the macro. The effect of this may be hard to predict. (Using the current mouse position would be even less predictable.)

One thing that doesn't always work well in a keyboard macro is the command C-M-c (`exit-recursive-edit`). When this command exits a recursive edit that started within the macro, it works as you'd expect. But if it exits a recursive edit that started before you invoked the keyboard macro, it also necessarily exits the keyboard macro as part of the process.

You can edit a keyboard macro already defined by typing C-x C-k (`edit-kbd-macro`). Follow th with the keyboard input that you would use to invoke the macro---C-x e or M-x name or some other key sequence. This formats the macro definition in a buffer and enters a specialized major mode for editing it. Type C-h m once in that buffer to display details of how to edit the macro. When you are finished editing, type C-c C-c.

The command M-x apply-macro-to-region-lines repeats the last defined keyboard macro on each complete line within the current region. It does this line by line, by moving point to the beginning of the line and then executing the macro.

Naming and Saving Keyboard Macros

If you wish to save a keyboard macro for longer than until you define the next one, you must give it a name using M-x name-last-kbd-macro. This reads a name as an argument using the minibuffer and defines that name to execute the macro. The macro name is a Lisp symbol, and defining it in this way makes it a valid command name for calling with M-x or for binding a key to with `global-set-key` (see section Keymaps). If you specify a name that has a prior definition other than another keyboard macro, an error message is printed and nothing is changed.

Once a macro has a command name, you can save its definition in a file. Then it can be used in another editing session. First, visit the file you want to save the definition in. Then use this command:

```
M-x insert-kbd-macro RET macroname RET
```

This inserts some Lisp code that, when executed later, will define the same macro with the same definition it has now. (You need not understand Lisp code to do this, because `insert-kbd-macro` writes the Lisp code for you.) Then save the file. You can load the file later with `load-file` (see section Libraries of Lisp Code for Emacs). If the file you save in is your init file `` `~/.emacs' `` (see section The Init File, `` `~/.emacs' ``) then the macro will be defined each time you run Emacs.

If you give `insert-kbd-macro` a numeric argument, it makes additional Lisp code to record the keys (if any) that you have bound to the keyboard macro, so that the macro will be reassigned the same keys when you load the file.

Executing Macros with Variations

Using C-x q (`kbd-macro-query`), you can get an effect similar to that of `query-replace`, where the macro asks you each time around whether to make a change. While defining the macro, type C-x q at the point where you want the query to occur. During macro definition, the C-x q does nothing, but when you run the macro later, C-x q asks you interactively whether to continue.

The valid responses when C-x q asks are SPC (or y), DEL (or n), RET (or q), C-l and C-r. The answers are the same as in `query-replace`, though not all of the `query-replace` options are meaningful.

These responses include SPC to continue, and DEL to skip the remainder of this repetition of the macro and start right away with the next repetition. RET means to skip the remainder of this repetition and

cancel further repetitions. C-l redraws the screen and asks you again for a character to say what to do.

C-r enters a recursive editing level, in which you can perform editing which is not part of the macro. When you exit the recursive edit using C-M-c, you are asked again how to continue with the keyboard macro. If you type a SPC at this time, the rest of the macro definition is executed. It is up to you to leave point and the text in a state such that the rest of the macro will do what you want.

C-u C-x q, which is C-x q with a numeric argument, performs a completely different function. It enters a recursive edit reading input from the keyboard, both when you type it during the definition of the macro, and when it is executed from the macro. During definition, the editing you do inside the recursive edit does not become part of the macro. During macro execution, the recursive edit gives you a chance to do some particularized editing on each repetition. See section Recursive Editing Levels.

Customizing Key Bindings

This section describes key bindings which map keys to commands, and the keymaps which record key bindings. It also explains how to customize key bindings.

Recall that a command is a Lisp function whose definition provides for interactive use. Like every Lisp function, a command has a function name which usually consists of lower case letters and hyphens.

Keymaps

The bindings between key sequences and command functions are recorded in data structures called keymaps. Emacs has many of these, each used on particular occasions.

Recall that a key sequence (key, for short) is a sequence of input events that have a meaning as a unit. Input events include characters, function keys and mouse buttons--all the inputs that you can send to the computer with your terminal. A key sequence gets its meaning from its binding, which says what command it runs. The function of keymaps is to record these bindings.

The global keymap is the most important keymap because it is always in effect. The global keymap defines keys for Fundamental mode; most of these definitions are common to most or all major modes. Each major or minor mode can have its own keymap which overrides the global definitions of some keys.

For example, a self-inserting character such as g is self-inserting because the global keymap binds it to the command `self-insert-command`. The standard Emacs editing characters such as C-a also get their standard meanings from the global keymap. Commands to rebind keys, such as M-x global-set-key, actually work by storing the new binding in the proper place in the global map. See section Changing Key Bindings Interactively.

Meta characters work differently; Emacs translates each Meta character into a pair of characters starting with ESC. When you type the character M-a in a key sequence, Emacs replaces it with ESC a. A meta key comes in as a single input event, but becomes two events for purposes of key bindings. The reason for this is historical, and we might change it someday.

Most modern keyboards have function keys as well as character keys. Function keys send input events just as character keys do, and keymaps can have bindings for them.

On many terminals, typing a function key actually sends the computer a sequence of characters; the precise details of the sequence depends on which function key and on the model of terminal you are using. (Often the sequence starts with ESC [.) If Emacs understands your terminal type properly, it recognizes the character sequences forming function keys wherever they occur in a key sequence (not just at the beginning). Thus, for most purposes, you can pretend the function keys reach Emacs directly and ignore their encoding as character sequences.

Mouse buttons also produce input events. These events come with other data--the window and position where you pressed or released the button, and a time stamp. But only the choice of button matters for key bindings; the other data matters only if a command looks at it. (Commands designed for mouse invocation usually do look at the other data.)

A keymap records definitions for single events. Interpreting a key sequence of multiple events involves a chain of keymaps. The first keymap gives a definition for the first event; this definition is another keymap, which is used to look up the second event in the sequence, and so on.

Key sequences can mix function keys and characters. For example, C-x SELECT makes sense. If you make SELECT a prefix key, then SELECT C-n makes sense. You can even mix mouse events with keyboard events, but we recommend against it, because such sequences are inconvenient to type in.

As a user, you can redefine any key; but it might be best to stick to key sequences that consist of C-c followed by a letter. These keys are "reserved for users,", so they won't conflict with any properly designed Emacs extension. If you redefine some other key, your definition may be overridden by certain extensions or major modes which redefine the same key.

Prefix Keymaps

A prefix key such as C-x or ESC has its own keymap, which holds the definition for the event that immediately follows that prefix.

The definition of a prefix key is usually the keymap to use for looking up the following event. The definition can also be a Lisp symbol whose function definition is the following keymap; the effect is the same, but it provides a command name for the prefix key that can be used as a description of what the prefix key is for. Thus, the binding of C-x is the symbol `Ctl-X-Prefix`, whose function definition is the keymap for C-x commands. The definitions of C-c, C-x, C-h and ESC as prefix keys appear in the global map, so these prefix keys are always available.

Aside from ordinary prefix keys, there is a fictitious "prefix key" which represents the menu bar; see section 'Menu Bar' in The Emacs Lisp Reference Manual, for special information about menu bar key bindings. Mouse button events that invoke pop-up menus are also prefix keys; see section 'Menu Keymaps' in The Emacs Lisp Reference Manual, for more details.

Some prefix keymaps are stored in variables with names:

- `ctl-x-map` is the variable name for the map used for characters that follow C-x.
- `help-map` is for characters that follow C-h.

- `esc-map` is for characters that follow ESC. Thus, all Meta characters are actually defined by this map.
- `ctl-x-4-map` is for characters that follow C-x 4.
- `mode-specific-map` is for characters that follow C-c.

Local Keymaps

So far we have explained the ins and outs of the global map. Major modes customize Emacs by providing their own key bindings in local keymaps. For example, C mode overrides TAB to make it indent the current line for C code. Portions of text in the buffer can specify their own keymaps to substitute for the keymap of the buffer's major mode.

Minor modes can also have local keymaps. Whenever a minor mode is in effect, the definitions in its keymap override both the major mode's local keymap and the global keymap.

The local keymaps for Lisp mode and several other major modes always exist even when not in use. These are kept in variables named `lisp-mode-map` and so on. For major modes less often used, the local keymap is normally constructed only when the mode is used for the first time in a session. This is to save space. If you wish to change one of these keymaps, you must use the major mode's mode hook---see below.

All minor mode keymaps are created in advance. There is no way to defer their creation until the first time the minor mode is enabled.

A local keymap can locally redefine a key as a prefix key by defining it as a prefix keymap. If the key is also defined globally as a prefix, then its local and global definitions (both keymaps) effectively combine: both of them are used to look up the event that follows the prefix key. Thus, if the mode's local keymap defines C-c as another keymap, and that keymap defines C-z as a command, this provides a local meaning for C-c C-z. This does not affect other sequences that start with C-c; if those sequences don't have their own local bindings, their global bindings remain in effect.

Another way to think of this is that Emacs handles a multi-event key sequence by looking in several keymaps, one by one, for a binding of the whole key sequence. First it checks the minor mode keymaps for minor modes that are enabled, then it checks the major mode's keymap, and then it checks the global keymap. This is not precisely how key lookup works, but it's good enough for understanding ordinary circumstances.

To change the local bindings of a major mode, you must change the mode's local keymap. Normally you must wait until the first time the mode is used, because most major modes don't create their keymaps until then. If you want to specify something in your `` `~/.emacs' `` file to change a major mode's bindings, you must use the mode's mode hook to delay the change until the mode is first used.

For example, the command `texinfo-mode` to select Texinfo mode runs the hook `texinfo-mode-hook`. Here's how you can use the hook to add local bindings (not very useful, we admit) for C-c n and C-c p in Texinfo mode:

```
(add-hook 'texinfo-mode-hook
```

```
'(lambda ()
   (define-key texinfo-mode-map
               "\C-cp"
               'backward-paragraph)
   (define-key texinfo-mode-map
               "\C-cn"
               'forward-paragraph)
   ))
```

See section Hooks.

Minibuffer Keymaps

The minibuffer has its own set of local keymaps; they contain various completion and exit commands.

- `minibuffer-local-map` is used for ordinary input (no completion).
- `minibuffer-local-ns-map` is similar, except that SPC exits just like RET. This is used mainly for Mocklisp compatibility.
- `minibuffer-local-completion-map` is for permissive completion.
- `minibuffer-local-must-match-map` is for strict completion and for cautious completion.

Changing Key Bindings Interactively

The way to redefine an Emacs key is to change its entry in a keymap. You can change the global keymap, in which case the change is effective in all major modes (except those that have their own overriding local definitions for the same key). Or you can change the current buffer's local map, which affects all buffers using the same major mode.

M-x global-set-key RET key cmd RET
: Define key globally to run cmd.

M-x local-set-key RET key cmd RET
: Define key locally (in the major mode now in effect) to run cmd.

M-x global-unset-key RET key
: Make key undefined in the global map.

M-x local-unset-key RET key
: Make key undefined locally (in the major mode now in effect).

For example, suppose you like to execute commands in a subshell within an Emacs buffer, instead of suspending Emacs and executing commands in your login shell. Normally, C-z is bound to the function `suspend-emacs` (when not using the X Window System), but you can change C-z to invoke an interactive subshell within Emacs, by binding it to `shell` as follows:

```
M-x global-set-key RET C-z shell RET
```

`global-set-key` reads the command name after the key. After you press the key, a message like this

appears so that you can confirm that you are binding the key you want:

```
Set key C-z to command:
```

You can redefine function keys and mouse events in the same way; just type the function key or click the mouse when it's time to specify the key to rebind.

You can rebind a key that contains more than one event in the same way. Emacs keeps reading the key to rebind until it is a complete key (that is, not a prefix key). Thus, if you type C-f for key, that's the end; the minibuffer is entered immediately to read cmd. But if you type C-x, another character is read; if that is 4, another character is read, and so on. For example,

```
M-x global-set-key RET C-x 4 $ spell-other-window RET
```

redefines C-x 4 $ to run the (fictitious) command `spell-other-window`.

The two-character keys consisting of C-c followed by a letter are reserved for user customizations. Lisp programs are not supposed to define these keys, so the bindings you make for them will be available in all major modes and will never get in the way of anything.

You can remove the global definition of a key with `global-unset-key`. This makes the key undefined; if you type it, Emacs will just beep. Similarly, `local-unset-key` makes a key undefined in the current major mode keymap, which makes the global definition (or lack of one) come back into effect in that major mode.

If you have redefined (or undefined) a key and you subsequently wish to retract the change, undefining the key will not do the job--you need to redefine the key with its standard definition. To find the name of the standard definition of a key, go to a Fundamental mode buffer and use C-h c. The documentation of keys in this manual also lists their command names.

If you want to prevent yourself from invoking a command by mistake, it is better to disable the command than to undefine the key. A disabled command is less work to invoke when you really want to. See section Disabling Commands.

Rebinding Keys in Your Init File

If you have a set of key bindings that you like to use all the time, you can specify them in your `` `.emacs' `` file by using their Lisp syntax.

The simplest method for doing this works for ASCII characters and Meta-modified ASCII characters only. This method uses a string to represent the key sequence you want to rebind. For example, here's how to bind C-z to `shell`:

```
(global-set-key "\C-z" 'shell)
```

This example uses a string constant containing one character, C-z. The single-quote before the command name, `shell`, marks it as a constant symbol rather than a variable. If you omit the quote, Emacs would try to evaluate `shell` immediately as a variable. This probably causes an error; it certainly isn't what

you want.

Here is another example that binds a key sequence two characters long:

```
(global-set-key "\C-xl" 'make-symbolic-link)
```

When the key sequence includes function keys or mouse button events, or non-ASCII characters such as `C-=` or `H-a`, you must use the more general method of rebinding, which uses a vector to specify the key sequence.

The way to write a vector in Emacs Lisp is with square brackets around the vector elements. Use spaces to separate the elements. If an element is a symbol, simply write the symbol's name--no other delimiters or punctuation are needed. If a vector element is a character, write it as a Lisp character constant: `?' followed by the character as it would appear in a string.

Here are examples of using vectors to rebind C-= (a control character outside of ASCII), H-a (a Hyper character; ASCII doesn't have Hyper at all); f7 (a function key), and C-Mouse-1 (a keyboard-modified mouse button):

```
(global-set-key [?\C-=] 'make-symbolic-link)
(global-set-key [?\H-a] 'make-symbolic-link)
(global-set-key [f7] 'make-symbolic-link)
(global-set-key [C-mouse-1] 'make-symbolic-link)
```

You can use a vector for the simple cases too. Here's how to rewrite the first two examples, above, to use vectors:

```
(global-set-key [?\C-z] 'shell)

(global-set-key [?\C-x ?l] 'make-symbolic-link)
```

Rebinding Function Keys

Key sequences can contain function keys as well as ordinary characters. Just as Lisp characters (actually integers) represent keyboard characters, Lisp symbols represent function keys. If the function key has a word as its label, then that word is also the name of the corresponding Lisp symbol. Here are the conventional Lisp names for common function keys:

`left`, `up`, `right`, `down`

: Cursor arrow keys.

`begin`, `end`, `home`, `next`, `prior`

: Other cursor repositioning keys.

`select`, `print`, `execute`, `backtab`

`insert`, `undo`, `redo`, `clearline`

`insertline`, `deleteline`, `insertchar`, `deletechar`,

Miscellaneous function keys.

`f1`, `f2`, ... `f35`

Numbered function keys (across the top of the keyboard).

`kp-add`, `kp-subtract`, `kp-multiply`, `kp-divide`

`kp-backtab`, `kp-space`, `kp-tab`, `kp-enter`

`kp-separator`, `kp-decimal`, `kp-equal`

Keypad keys (to the right of the regular keyboard), with names or punctuation.

`kp-0`, `kp-1`, ... `kp-9`

Keypad keys with digits.

`kp-f1`, `kp-f2`, `kp-f3`, `kp-f4`

Keypad PF keys.

These names are conventional, but some systems (especially when using X windows) may use different names. To make certain what symbol is used for a given function key on your terminal, type C-h c followed by that key.

A key sequence which contains function key symbols (or anything but ASCII characters) must be a vector rather than a string. The vector syntax uses spaces between the elements, and square brackets around the whole vector. Thus, to bind function key `f1' to the command `rmail`, write the following:

```
(global-set-key [f1] 'rmail)
```

To bind the right-arrow key to the command `forward-char`, you can use this expression:

```
(global-set-key [right] 'forward-char)
```

This uses the Lisp syntax for a vector containing the symbol `right`. (This binding is present in Emacs by default.)

See section Rebinding Keys in Your Init File, for more information about using vectors for rebinding.

You can mix function keys and characters in a key sequence. This example binds C-x NEXT to the command `forward-page`.

```
(global-set-key [?\C-x next] 'forward-page)
```

where `?\C-x` is the Lisp character constant for the character C-x. The vector element `next` is a symbol and therefore does not take a question mark.

You can use the modifier keys CTRL, META, HYPER, SUPER, ALT and SHIFT with function keys. To represent these modifiers, add the strings `C-', `M-', `H-', `s-', `A-' and `S-' at the front of the symbol name. Thus, here is how to make Hyper-Meta-RIGHT move forward a word:

```
(global-set-key [H-M-right] 'forward-word)
```

Named ASCII Control Characters

TAB, RET, BS, LFD, ESC and DEL started out as names for certain ASCII control characters, used so often that they have special keys of their own. Later, users found it convenient to distinguish in Emacs between these keys and the "same" control characters typed with the CTRL key.

Emacs 19 distinguishes these two kinds of input, when used with the X Window System. It treats the "special" keys as function keys named `tab`, `return`, `backspace`, `linefeed`, `escape`, and `delete`. These function keys translate automatically into the corresponding ASCII characters *if* they have no bindings of their own. As a result, neither users nor Lisp programs need to pay attention to the distinction unless they care to.

If you do not want to distinguish between (for example) TAB and C-i, make just one binding, for the ASCII character TAB (octal code 011). If you do want to distinguish, make one binding for this ASCII character, and another for the "function key" `tab`.

With an ordinary ASCII terminal, there is no way to distinguish between TAB and C-i (and likewise for other such pairs), because the terminal sends the same character in both cases.

Rebinding Mouse Buttons

Emacs uses Lisp symbols to designate mouse buttons, too. The ordinary mouse events in Emacs are click events; these happen when you press a button and release it without moving the mouse. You can also get drag events, when you move the mouse while holding the button down. Drag events happen when you finally let go of the button.

The symbols for basic click events are `mouse-1` for the leftmost button, `mouse-2` for the next, and so on. Here is how you can redefine the second mouse button to split the current window:

```
(global-set-key [mouse-2] 'split-window-vertically)
```

The symbols for drag events are similar, but have the prefix `drag-' before the word `mouse'. For example, dragging the first button generates a `drag-mouse-1` event.

You can also define bindings for events that occur when a mouse button is pressed down. These events start with `down-' instead of `drag-'. Such events are generated only if they have key bindings. When you get a button-down event, a corresponding click or drag event will always follow.

If you wish, you can distinguish single, double, and triple clicks. A double click means clicking a mouse button twice in approximately the same place. The first click generates an ordinary click event. The second click, if it comes soon enough, generates a double-click event instead. The event type for a double click event starts with `double-': for example, `double-mouse-3`.

This means that you can give a special meaning to the second click at the same place, but it must act on the assumption that the ordinary single click definition has run when the first click was received.

This constrains what you can do with double clicks, but user interface designers say that this constraint ought to be followed in any case. A double click should do something similar to the single click, only

"more so". The command for the double-click event should perform the extra work for the double cli

If a double-click event has no binding, it changes to the corresponding single-click event. Thus, if you don't define a particular double click specially, it executes the single-click command twice.

Emacs also supports triple-click events whose names start with `triple-'. Emacs does not distinguish quadruple clicks as event types; clicks beyond the third generate additional triple-click events. However, the full number of clicks is recorded in the event list, so you can distinguish if you really want to. We don't recommend distinct meanings for more than three clicks, but sometimes it is useful for subsequent clicks to cycle through the same set of three meanings, so that four clicks are equivalent to one click, five are equivalent to two, and six are equivalent to three.

Emacs also records multiple presses in drag and button-down events. For example, when you press a button twice, then move the mouse while holding the button, Emacs gets a `double-drag-' event. And at the moment when you press it down for the second time, Emacs gets a `double-down-' event (which is ignored, like all button-down events, if it has no binding).

The variable `double-click-time` specifies how long may elapse between clicks that are recognized as a pair. Its value is measured in milliseconds. If the value is `nil`, double clicks are not detected at all. If the value is `t`, then there is no time limit.

The symbols for mouse events also indicate the status of the modifier keys, with the usual prefixes `C-', `M-', `H-', `s-', `A-' and `S-'. These always precede `double-' or `triple-', which always precede `drag-' or `down-'.

A frame includes areas that don't show text from the buffer, such as the mode line and the scroll bar. You can tell whether a mouse button comes from a special area of the screen by means of dummy "prefix keys." For example, if you click the mouse in the mode line, you get the prefix key `mode-line` before the ordinary mouse-button symbol. Thus, here is how to define the command for clicking the first button in a mode line to run `scroll-up`:

```
(global-set-key [mode-line mouse-1] 'scroll-up)
```

Here is the complete list of these dummy prefix keys and their meanings:

`mode-line`
: The mouse was in the mode line of a window.

`vertical-line`
: The mouse was in the vertical line separating side-by-side windows. (If you use scroll bars, they appear in place of these vertical lines.)

`vertical-scroll-bar`
: The mouse was in a vertical scroll bar. (This is the only kind of scroll bar Emacs currently supports.)

You can put more than one mouse button in a key sequence, but it isn't usual to do so.

Disabling Commands

Disabling a command marks the command as requiring confirmation before it can be executed. The purpose of disabling a command is to prevent beginning users from executing it by accident and being confused.

An attempt to invoke a disabled command interactively in Emacs displays a window containing the command's name, its documentation, and some instructions on what to do immediately; then Emacs asks for input saying whether to execute the command as requested, enable it and execute it, or cancel. If you decide to enable the command, you are asked whether to do this permanently or just for the current session. Enabling permanently works by automatically editing your `.emacs' file.

The direct mechanism for disabling a command is to put a non-`nil` `disabled` property on the Lisp symbol for the command. Here is the Lisp program to do this:

```
(put 'delete-region 'disabled t)
```

If the value of the `disabled` property is a string, that string is included in the message printed when the command is used:

```
(put 'delete-region 'disabled
     "It's better to use `kill-region' instead.\n")
```

You can make a command disabled either by editing the `.emacs' file directly or with the command M-x disable-command, which edits the `.emacs' file for you. Likewise, M-x enable-command edits `.emacs' to enable a command permanently. See section The Init File, `~/.emacs'.

Whether a command is disabled is independent of what key is used to invoke it; disabling also applies if the command is invoked using M-x. Disabling a command has no effect on calling it as a function from Lisp programs.

Keyboard Translations

Some keyboards do not make it convenient to send all the special characters that Emacs uses. The most common problem case is the DEL character. Some keyboards provide no convenient way to type this very important character--usually because they were designed to expect the character C-h to be used for deletion. On these keyboard, if you press the key normally used for deletion, Emacs handles the C-h as a prefix character and offers you a list of help options, which is not what you want.

You can work around this problem within Emacs by setting up keyboard translations to turn C-h into DEL and DEL into C-h, as follows:

```
;; Translate C-h to DEL.
(keyboard-translate ?\C-h ?\C-?)

;; Translate DEL to C-h.
```

```
(keyboard-translate ?\C-? ?\C-h)
```

Keyboard translations are not the same as key bindings in keymaps (see section Keymaps). Emacs contains numerous keymaps that apply in different situations, but there is only one set of keyboard translations, and it applies to every character that Emacs reads from the terminal. Keyboard translations take place at the lowest level of input processing; the keys that are looked up in keymaps contain the characters that result from keyboard translation.

Under X, the keyboard key named DELETE is a function key and is distinct from the ASCII character named DEL. See section Named ASCII Control Characters. Keyboard translations affect only ASCII character input, not function keys; thus, the above example used under X does not affect the DELETE key. However, the translation above isn't necessary under X, because Emacs can also distinguish between the BACKSPACE key and C-h; and it normally treats BACKSPACE as DEL.

For full information about how to use keyboard translations, see section 'Translating Input' in The Emacs Lisp Reference Manual.

The Syntax Table

All the Emacs commands which parse words or balance parentheses are controlled by the syntax table. The syntax table says which characters are opening delimiters, which are parts of words, which are string quotes, and so on. Each major mode has its own syntax table (though sometimes related major modes use the same one) which it installs in each buffer that uses that major mode. The syntax table installed in the current buffer is the one that all commands use, so we call it "the" syntax table. A syntax table is a Lisp object, a vector of length 256 whose elements are numbers.

To display a description of the contents of the current syntax table, type C-h s (`describe-syntax`). The description of each character includes both the string you would have to give to `modify-syntax-entry` to set up that character's current syntax, and some English to explain that string if necessary.

For full information on the syntax table, see section 'Syntax Tables' in The Emacs Lisp Reference Manual.

The Init File, `~/.emacs'

When Emacs is started, it normally loads a Lisp program from the file `.emacs' in your home directory. We call this file your init file because it specifies how to initialize Emacs for you. You can use the command line switches `-q' and `-u' to tell Emacs whether to load an init file, and which one (see section Entering and Exiting Emacs).

There can also be a default init file, which is the library named `default.el', found via the standard search path for libraries. The Emacs distribution contains no such library; your site may create one for local customizations. If this library exists, it is loaded whenever you start Emacs (except when you specify `-q'). But your init file, if any, is loaded first; if it sets `inhibit-default-init` non-`nil`, then `default' is not loaded.

Your site may also have a site startup file; this is named `site-start.el', if it exists. Emacs lo this library before it loads your init file. To inhibit loading of this library, use the option `-no-site-file'.

If you have a large amount of code in your `.emacs' file, you should move it into another file such as `~/something.el', byte-compile it, and make your `.emacs' file load it with `(load "~/something")'. See section 'Byte Compilation' in the Emacs Lisp Reference Manual, for more information about compiling Emacs Lisp programs.

Init File Syntax

The `.emacs' file contains one or more Lisp function call expressions. Each of these consists of a function name followed by arguments, all surrounded by parentheses. For example, `(setq fill-column 60)` calls the function `setq` to set the variable `fill-column` (see section Filling Text) to 60.

The second argument to `setq` is an expression for the new value of the variable. This can be a constant, a variable, or a function call expression. In `.emacs', constants are used most of the time. They can be:

Numbers:

Numbers are written in decimal, with an optional initial minus sign.

Strings:

Lisp string syntax is the same as C string syntax with a few extra features. Use a double-quote character to begin and end a string constant.

In a string, you can include newlines and special characters literally. But often it is cleaner to use backslash sequences for them: `\n' for newline, `\b' for backspace, `\r' for carriage return, `\t' for tab, `\f' for formfeed (control-L), `\e' for escape, `\\' for a backslash, `\"' for a double-quote, or `\ooo' for the character whose octal code is ooo. Backslash and double-quote are the only characters for which backslash sequences are mandatory.

`\C-' can be used as a prefix for a control character, as in `\C-s' for ASCII control-S, and `\M-' can be used as a prefix for a Meta character, as in `\M-a' for Meta-A or `\M-\C-a' for Control-Meta-A.

Characters:

Lisp character constant syntax consists of a `?' followed by either a character or an escape sequence starting with `\'. Examples: `?x`, `?\n`, `?\"`, `?\)`. Note that strings and characters are not interchangeable in Lisp; some contexts require one and some contexts require the other.

True:

`t` stands for `true'.

False:

`nil` stands for `false'.

Other Lisp objects:

Write a single-quote (') followed by the Lisp object you want.

Init File Examples

Here are some examples of doing certain commonly desired things with Lisp expressions:

- Make TAB in C mode just insert a tab if point is in the middle of a line.

  ```
  (setq c-tab-always-indent nil)
  ```

  Here we have a variable whose value is normally `t` for `true' and the alternative is `nil` for `false'.

- Make searches case sensitive by default (in all buffers that do not override this).

  ```
  (setq-default case-fold-search nil)
  ```

  This sets the default value, which is effective in all buffers that do not have local values for the variable. Setting `case-fold-search` with `setq` affects only the current buffer's local value, which is not what you probably want to do in an init file.

- Specify your own email address, if Emacs can't figure it out correctly.

  ```
  (setq user-mail-address "coon@yoyodyne.com")
  ```

  Various Emacs packages that need your own email address use the value of `user-mail-address`.

- Make Text mode the default mode for new buffers.

  ```
  (setq default-major-mode 'text-mode)
  ```

  Note that `text-mode` is used because it is the command for entering Text mode. The single-quote before it makes the symbol a constant; otherwise, `text-mode` would be treated as a variable name.

- Turn on Auto Fill mode automatically in Text mode and related modes.

  ```
  (add-hook 'text-mode-hook
    '(lambda () (auto-fill-mode 1)))
  ```

  This shows how to add a hook function to a normal hook variable (see section Hooks). The function we supply is a list starting with `lambda`, with a single-quote in front of it to make it a list constant rather than an expression.

  It's beyond the scope of this manual to explain Lisp functions, but for this example it is enough to know that the effect is to execute `(auto-fill-mode 1)` when Text mode is entered. You can replace that with any other expression that you like, or with several expressions in a row.

  Emacs comes with a function named `turn-on-auto-fill` whose definition is `(lambda () (auto-fill-mode 1))`. Thus, a simpler way to write the above example is as follows:

  ```
  (add-hook 'text-mode-hook 'turn-on-auto-fill)
  ```

- Load the installed Lisp library named `foo' (actually a file `foo.elc' or `foo.el' in a standard Emacs directory).

  ```
  (load "foo")
  ```

  When the argument to `load` is a relative file name, not starting with `/' or `~', `load` searches the directories in `load-path` (see section Libraries of Lisp Code for Emacs).

- Load the compiled Lisp file `foo.elc' from your home directory.

  ```
  (load "~/foo.elc")
  ```

  Here an absolute file name is used, so no searching is done.

- Rebind the key C-x l to run the function `make-symbolic-link`.

  ```
  (global-set-key "\C-xl" 'make-symbolic-link)
  ```

  or

  ```
  (define-key global-map "\C-xl" 'make-symbolic-link)
  ```

  Note once again the single-quote used to refer to the symbol `make-symbolic-link` instead of its value as a variable.

- Do the same thing for Lisp mode only.

  ```
  (define-key lisp-mode-map "\C-xl" 'make-symbolic-link)
  ```

- Redefine all keys which now run `next-line` in Fundamental mode so that they run `forward-line` instead.

  ```
  (substitute-key-definition 'next-line 'forward-line
                             global-map)
  ```

- Make C-x C-v undefined.

  ```
  (global-unset-key "\C-x\C-v")
  ```

  One reason to undefine a key is so that you can make it a prefix. Simply defining C-x C-v anything will make C-x C-v a prefix, but C-x C-v must first be freed of its usual non-prefix definition.

- Make `$' have the syntax of punctuation in Text mode. Note the use of a character constant for `$'.

  ```
  (modify-syntax-entry ?\$ "." text-mode-syntax-table)
  ```

- Enable the use of the command `eval-expression` without confirmation.

  ```
  (put 'eval-expression 'disabled nil)
  ```

Terminal-specific Initialization

Each terminal type can have a Lisp library to be loaded into Emacs when it is run on that type of terminal. For a terminal type named termtype, the library is called `term/termtype' and it is found by searching the directories `load-path` as usual and trying the suffixes `.elc' and `.el'. Normally it appears in the subdirectory `term' of the directory where most Emacs libraries are kept.

The usual purpose of the terminal-specific library is to map the escape sequences used by the terminal's function keys onto more meaningful names, using `function-key-map`. See the file `term/lk201.el' for an example of how this is done. Many function keys are mapped automatically according to the information in the Termcap data base; the terminal-specific library needs to map only the function keys that Termcap does not specify.

When the terminal type contains a hyphen, only the part of the name before the first hyphen is significant in choosing the library name. Thus, terminal types `aaa-48' and `aaa-30-rv' both use the library `term/aaa'. The code in the library can use `(getenv "TERM")` to find the full terminal type name.

The library's name is constructed by concatenating the value of the variable `term-file-prefix` and the terminal type. Your `.emacs' file can prevent the loading of the terminal-specific library by setting `term-file-prefix` to `nil`.

Emacs runs the hook `term-setup-hook` at the end of initialization, after both your `.emacs' file and any terminal-specific library have been read in. Add hook functions to this hook if you wish to override part of any of the terminal-specific libraries and to define initializations for terminals that do not have a library. See section Hooks.

How Emacs Finds Your Init File

Normally Emacs uses the environment variable HOME to find `.emacs'; that's what `~' means in a file name. But if you have done `su`, Emacs tries to find your own `.emacs', not that of the user you are currently pretending to be. The idea is that you should get your own editor customizations even if you are running as the super user.

More precisely, Emacs first determines which user's init file to use. It gets the user name from the environment variables LOGNAME and USER; if neither of those exists, it uses effective user-ID. If that user name matches the real user-ID, then Emacs uses HOME; otherwise, it looks up the home directory corresponding to that user name in the system's data base of users.

Go to the previous, next section.

Go to the previous, next section.

Dealing with Common Problems

If you type an Emacs command you did not intend, the results are often mysterious. This chapter tells what you can do to cancel your mistake or recover from a mysterious situation. Emacs bugs and system crashes are also considered.

Quitting and Aborting

C-g
: Quit. Cancel running or partially typed command.

C-]
: Abort innermost recursive editing level and cancel the command which invoked it (`abort-recursive-edit`).

ESC ESC ESC
: Either quit or abort, whichever makes sense (`keyboard-escape-quit`).

M-x top-level
: Abort all recursive editing levels that are currently executing.

C-x u
: Cancel a previously made change in the buffer contents (`undo`).

There are two ways of canceling commands which are not finished executing: quitting with C-g, and aborting with C-] or M-x top-level. Quitting cancels a partially typed command or one which is already running. Aborting exits a recursive editing level and cancels the command that invoked the recursive edit. (See section Recursive Editing Levels.)

Quitting with C-g is used for getting rid of a partially typed command, or a numeric argument that you don't want. It also stops a running command in the middle in a relatively safe way, so you can use it if you accidentally give a command which takes a long time. In particular, it is safe to quit out of killing; either your text will *all* still be in the buffer, or it will *all* be in the kill ring (or maybe both). Quitting an incremental search does special things documented under searching; in general, it may take two successive C-g characters to get out of a search (see section Incremental Search).

C-g works by setting the variable `quit-flag` to `t` the instant C-g is typed; Emacs Lisp checks this variable frequently and quits if it is non-`nil`. C-g is only actually executed as a command if you type it while Emacs is waiting for input.

If you quit with C-g a second time before the first C-g is recognized, you activate the "emergency escape" feature and return to the shell. See section Emergency Escape.

There may be times when you cannot quit. When Emacs is waiting for the operating system to do

something, quitting is impossible unless special pains are taken for the particular system call within Emacs where the waiting occurs. We have done this for the system calls that users are likely to want to quit from, but it's possible you will find another. In one very common case--waiting for file input or output using NFS--Emacs itself knows how to quit, but most NFS implementations simply do not allow user programs to stop waiting for NFS when the NFS server is hung.

Aborting with C-] (`abort-recursive-edit`) is used to get out of a recursive editing level and cancel the command which invoked it. Quitting with C-g does not do this, and could not do this, because it is used to cancel a partially typed command *within* the recursive editing level. Both operations are useful. For example, if you are in a recursive edit and type C-u 8 to enter a numeric argument, you can cancel that argument with C-g and remain in the recursive edit.

The command ESC ESC ESC (`keyboard-escape-quit`) can either quit or abort. This key was defined because ESC is used to "get out" in many PC programs. It can cancel a prefix argument, clear a selected region, or get out of a Query Replace, like C-g. It can get out of the minibuffer or a recursive edit, like C-]. It can also get out of splitting the frame into multiple windows, like C-x 1. One thing it cannot do, however, is stop a command that is running. That's because it executes as an ordinary command, and Emacs doesn't notice it until it is ready for a command.

The command M-x top-level is equivalent to "enough" C-] commands to get you out of all the levels of recursive edits that you are in. C-] gets you out one level at a time, but M-x top-level goes out all levels at once. Both C-] and M-x top-level are like all other commands, and unlike C-g, in that they take effect only when Emacs is ready for a command. C-] is an ordinary key and has its meaning only because of its binding in the keymap. See section Recursive Editing Levels.

C-x u (`undo`) is not strictly speaking a way of canceling a command, but you can think of it as canceling a command that already finished executing. See section Undoing Changes.

Dealing with Emacs Trouble

This section describes various conditions in which Emacs fails to work normally, and how to recognize them and correct them.

If DEL Fails to Delete

If you find that DEL enters Help like Control-h instead of deleting a character, your terminal is sending the wrong code for DEL. You can work around this problem by changing the keyboard translation table (see section Keyboard Translations).

Recursive Editing Levels

Recursive editing levels are important and useful features of Emacs, but they can seem like malfunctions to the user who does not understand them.

If the mode line has square brackets `[...]' around the parentheses that contain the names of the major and minor modes, you have entered a recursive editing level. If you did not do this on purpose, or if you don't

understand what that means, you should just get out of the recursive editing level. To do so, type M-C top-level. This is called getting back to top level. See section Recursive Editing Levels.

Garbage on the Screen

If the data on the screen looks wrong, the first thing to do is see whether the text is really wrong. Type C-l, to redisplay the entire screen. If the screen appears correct after this, the problem was entirely in the previous screen update. (Otherwise, see section Garbage in the Text.)

Display updating problems often result from an incorrect termcap entry for the terminal you are using. The file `etc/TERMS' in the Emacs distribution gives the fixes for known problems of this sort. `INSTALL' contains general advice for these problems in one of its sections. Very likely there is simply insufficient padding for certain display operations. To investigate the possibility that you have this sort of problem, try Emacs on another terminal made by a different manufacturer. If problems happen frequently on one kind of terminal but not another kind, it is likely to be a bad termcap entry, though it could also be due to a bug in Emacs that appears for terminals that have or that lack specific features.

Garbage in the Text

If C-l shows that the text is wrong, try undoing the changes to it using C-x u until it gets back to a state you consider correct. Also try C-h l to find out what command you typed to produce the observed results.

If a large portion of text appears to be missing at the beginning or end of the buffer, check for the word `Narrow' in the mode line. If it appears, the text you don't see is probably still present, but temporarily off-limits. To make it accessible again, type C-x n w. See section Narrowing.

Spontaneous Entry to Incremental Search

If Emacs spontaneously displays `I-search:' at the bottom of the screen, it means that the terminal is sending C-s and C-q according to the poorly designed xon/xoff "flow control" protocol.

If this happens to you, your best recourse is to put the terminal in a mode where it will not use flow control, or give it so much padding that it will never send a C-s. (One way to increase the amount of padding is to set the variable `baud-rate` to a larger value. Its value is the terminal output speed, measured in the conventional units of baud.)

If you don't succeed in turning off flow control, the next best thing is to tell Emacs to cope with it. To do this, call the function `enable-flow-control`.

Typically there are particular terminal types with which you must use flow control. You can conveniently ask for flow control on those terminal types only, using `enable-flow-control-on`. For example, if you find you must use flow control on VT-100 and H19 terminals, put the following in your `.emacs' file:

```
(enable-flow-control-on "vt100" "h19")
```

When flow control is enabled, you must type C-\ to get the effect of a C-s, and type C-^ to get the effect of a C-q. (These aliases work by means of keyboard translations; see section Keyboard Translations.)

Running out of Memory

If you get the error message `Virtual memory exceeded', save your modified buffers with C-x s. This method of saving them has the smallest need for additional memory. Emacs keeps a reserve of memory which it makes available when this error happens; that should be enough to enable C-x s to complete its work.

Once you have saved your modified buffers, you can exit this Emacs job and start another, or you can use M-x kill-some-buffers to free space in the current Emacs job. If you kill buffers containing a substantial amount of text, you can safely go on editing. Emacs refills its memory reserve automatically when it sees sufficient free space available, in case you run out of memory another time.

Do not use M-x buffer-menu to save or kill buffers when you run out of memory, because the buffer menu needs a fair amount memory itself, and the reserve supply may not be enough.

Recovery After a Crash

If Emacs or the computer crashes, you can recover the files you were editing at the time of the crash from their auto-save files. To do this, start Emacs again and type the command M-x recover-session.

This command initially displays a buffer which lists interrupted session files, each with its date. You must choose which session to recover from. Typically the one you want is the most recent one. Move point to the one you choose, and type C-c C-c.

Then `recover-session` asks about each of the files that you were editing during that session; it asks whether to recover that file. If you answer y for a file, it shows the dates of that file and its auto-save file, then asks once again whether to recover that file. For the second question, you must confirm with yes. If you do, Emacs visits the file but gets the text from the auto-save file.

When `recover-session` is done, the files you've chosen to recover are present in Emacs buffers. You should then save them. Only this--saving them--updates the files themselves.

Emergency Escape

Because at times there have been bugs causing Emacs to loop without checking `quit-flag`, a special feature causes Emacs to be suspended immediately if you type a second C-g while the flag is already set, so you can always get out of GNU Emacs. Normally Emacs recognizes and clears `quit-flag` (and quits!) quickly enough to prevent this from happening.

When you resume Emacs after a suspension caused by multiple C-g, it asks two questions before going back to what it had been doing:

```
Auto-save? (y or n)
Abort (and dump core)? (y or n)
```

Answer each one with y or n followed by RET.

Saying y to `Auto-save?' causes immediate auto-saving of all modified buffers in which auto-saving is enabled.

Saying y to `Abort (and dump core)?' causes an illegal instruction to be executed, dumping core. This is to enable a wizard to figure out why Emacs was failing to quit in the first place. Execution does not continue after a core dump. If you answer n, execution does continue. With luck, GNU Emacs will ultimately check `quit-flag` and quit normally. If not, and you type another C-g, it is suspended again.

If Emacs is not really hung, just slow, you may invoke the double C-g feature without really meaning to. Then just resume and answer n to both questions, and you will arrive at your former state. Presumably the quit you requested will happen soon.

The double-C-g feature is turned off when Emacs is running under the X Window System, since you can use the window manager to kill Emacs or to create another window and run another program.

Help for Total Frustration

If using Emacs (or something else) becomes terribly frustrating and none of the techniques described above solve the problem, Emacs can still help you.

First, if the Emacs you are using is not responding to commands, type C-g C-g to get out of it and then start a new one.

Second, type M-x doctor RET.

The doctor will help you feel better. Each time you say something to the doctor, you must end it by typing RET RET. This lets the doctor know you are finished.

Reporting Bugs

Sometimes you will encounter a bug in Emacs. Although we cannot promise we can or will fix the bug, and we might not even agree that it is a bug, we want to hear about problems you encounter. Often we agree they are bugs and want to fix them.

To make it possible for us to fix a bug, you must report it. In order to do so effectively, you must know when and how to do it.

When Is There a Bug

If Emacs executes an illegal instruction, or dies with an operating system error message that indicates a problem in the program (as opposed to something like "disk full"), then it is certainly a bug.

If Emacs updates the display in a way that does not correspond to what is in the buffer, then it is certainly a bug. If a command seems to do the wrong thing but the problem corrects itself if you type C-l, it is a case of incorrect display updating.

Taking forever to complete a command can be a bug, but you must make certain that it was really Emacs's fault. Some commands simply take a long time. Type C-g and then C-h l to see whether the input Emacs received was what you intended to type; if the input was such that you *know* it should have been processed quickly, report a bug. If you don't know whether the command should take a long time, find out by looking in the manual or by asking for assistance.

If a command you are familiar with causes an Emacs error message in a case where its usual definition ought to be reasonable, it is probably a bug.

If a command does the wrong thing, that is a bug. But be sure you know for certain what it ought to have done. If you aren't familiar with the command, or don't know for certain how the command is supposed to work, then it might actually be working right. Rather than jumping to conclusions, show the problem to someone who knows for certain.

Finally, a command's intended definition may not be best for editing with. This is a very important sort of problem, but it is also a matter of judgment. Also, it is easy to come to such a conclusion out of ignorance of some of the existing features. It is probably best not to complain about such a problem until you have checked the documentation in the usual ways, feel confident that you understand it, and know for certain that what you want is not available. If you are not sure what the command is supposed to do after a careful reading of the manual, check the index and glossary for any terms that may be unclear.

If after careful rereading of the manual you still do not understand what the command should do, that indicates a bug in the manual, which you should report. The manual's job is to make everything clear to people who are not Emacs experts--including you. It is just as important to report documentation bugs as program bugs.

If the on-line documentation string of a function or variable disagrees with the manual, one of them must be wrong; that is a bug.

Understanding Bug Reporting

When you decide that there is a bug, it is important to report it and to report it in a way which is useful. What is most useful is an exact description of what commands you type, starting with the shell command to run Emacs, until the problem happens.

The most important principle in reporting a bug is to report *facts*, not hypotheses or categorizations. It is always easier to report the facts, but people seem to prefer to strain to posit explanations and report them instead. If the explanations are based on guesses about how Emacs is implemented, they will be useless; we will have to try to figure out what the facts must have been to lead to such speculations. Sometimes this is impossible. But in any case, it is unnecessary work for us.

For example, suppose that you type C-x C-f /glorp/baz.ugh RET, visiting a file which (you know) happens to be rather large, and Emacs prints out `I feel pretty today'. The best way to report the bug is with a sentence like the preceding one, because it gives all the facts and nothing but the facts.

Do not assume that the problem is due to the size of the file and say, "When I visit a large file, Emacs prints out `I feel pretty today'." This is what we mean by "guessing explanations". The problem is just as likely to be due to the fact that there is a `z' in the file name. If this is so, then when we got your report,

we would try out the problem with some "large file", probably with no `z' in its name, and not find anything wrong. There is no way in the world that we could guess that we should try visiting a file with `z' in its name.

Alternatively, the problem might be due to the fact that the file starts with exactly 25 spaces. For this reason, you should make sure that you inform us of the exact contents of any file that is needed to reproduce the bug. What if the problem only occurs when you have typed the C-x C-a command previously? This is why we ask you to give the exact sequence of characters you typed since starting the Emacs session.

You should not even say "visit a file" instead of C-x C-f unless you *know* that it makes no difference which visiting command is used. Similarly, rather than saying "if I have three characters on the line," say "after I type RET A B C RET C-p," if that is the way you entered the text.

Checklist for Bug Reports

The best way to send a bug report is to mail it electronically to the Emacs maintainers at `bug-gnu-emacs@prep.ai.mit.edu'. (If you want to suggest a change as an improvement, use the same address.)

If you'd like to read the bug reports, you can find them on the newsgroup `gnu.emacs.bug'; keep in mind, however, that as a spectator you should not criticize anything about what you see there. The purpose of bug reports is to give information to the Emacs maintainers. Spectators are welcome only as long as they do not interfere with this. In particular, some bug reports contain large amounts of data; spectators should not complain about this.

Please do not post bug reports using netnews; mail is more reliable than netnews about reporting your correct address, which we may need in order to ask you for more information.

If you can't send electronic mail, then mail the bug report on paper or machine-readable media to this address:

```
GNU Emacs Bugs
Free Software Foundation
59 Temple Place, Suite 330
Boston, MA 02111-1307 USA
```

We do not promise to fix the bug; but if the bug is serious, or ugly, or easy to fix, chances are we will want to.

A convenient way to send a bug report for Emacs is to use the command M-x report-emacs-bug. This sets up a mail buffer (see section Sending Mail) and automatically inserts *some* of the essential information. However, it cannot supply all the necessary information; you should still read and follow the guidelines below, so you can enter the other crucial information by hand before you send the message.

To enable maintainers to investigate a bug, your report should include all these things:

- The version number of Emacs. Without this, we won't know whether there is any point in looking

for the bug in the current version of GNU Emacs.

You can get the version number by typing M-x emacs-version RET. If that command does not work, you probably have something other than GNU Emacs, so you will have to report the bug somewhere else.

- The type of machine you are using, and the operating system name and version number. M-x emacs-version RET provides this information too. Copy its output from the `*Messages*' buffer, so that you get it all and get it accurately.
- The operands given to the `configure` command when Emacs was installed.
- A complete list of any modifications you have made to the Emacs source. (We may not have time to investigate the bug unless it happens in an unmodified Emacs. But if you've made modifications and you don't tell us, you are sending us on a wild goose chase.)

  Be precise about these changes. A description in English is not enough--send a context diff for them.

  Adding files of your own, or porting to another machine, is a modification of the source.
- Details of any other deviations from the standard procedure for installing GNU Emacs.
- The complete text of any files needed to reproduce the bug.

  If you can tell us a way to cause the problem without visiting any files, please do so. This makes it much easier to debug. If you do need files, make sure you arrange for us to see their exact contents. For example, it can often matter whether there are spaces at the ends of lines, or a newline after the last line in the buffer (nothing ought to care whether the last line is terminated, but try telling the bugs that).
- The precise commands we need to type to reproduce the bug.

  The easy way to record the input to Emacs precisely is to write a dribble file. To start the file, execute the Lisp expression

  ```
  (open-dribble-file "~/dribble")
  ```

  using M-: or from the `*scratch*' buffer just after starting Emacs. From then on, Emacs copies all your input to the specified dribble file until the Emacs process is killed.
- For possible display bugs, the terminal type (the value of environment variable `TERM`), the complete termcap entry for the terminal from `/etc/termcap' (since that file is not identical on all machines), and the output that Emacs actually sent to the terminal.

  The way to collect the terminal output is to execute the Lisp expression

  ```
  (open-termscript "~/termscript")
  ```

  using M-: or from the `*scratch*' buffer just after starting Emacs. From then on, Emacs copies all terminal output to the specified termscript file as well, until the Emacs process is killed. If the problem happens when Emacs starts up, put this expression into your `.emacs' file so that the termscript file will be open when Emacs displays the screen for the first time.

Be warned: it is often difficult, and sometimes impossible, to fix a terminal-dependent bug wit access to a terminal of the type that stimulates the bug.

- A description of what behavior you observe that you believe is incorrect. For example, "The Emacs process gets a fatal signal," or, "The resulting text is as follows, which I think is wrong."

  Of course, if the bug is that Emacs gets a fatal signal, then one can't miss it. But if the bug is incorrect text, the maintainer might fail to notice what is wrong. Why leave it to chance?

  Even if the problem you experience is a fatal signal, you should still say so explicitly. Suppose something strange is going on, such as, your copy of the source is out of sync, or you have encountered a bug in the C library on your system. (This has happened!) Your copy might crash and the copy here might not. If you *said* to expect a crash, then when Emacs here fails to crash, we would know that the bug was not happening. If you don't say to expect a crash, then we would not know whether the bug was happening--we would not be able to draw any conclusion from our observations.
- If the manifestation of the bug is an Emacs error message, it is important to report the precise text of the error message, and a backtrace showing how the Lisp program in Emacs arrived at the error.

  To get the error message text accurately, copy it from the `*Messages*' buffer into the bug report. Copy all of it, not just part.

  To make a backtrace for the error, evaluate the Lisp expression `(setq debug-on-error t)` before the error happens (that is to say, you must execute that expression and then make the bug happen). This causes the error to run the Lisp debugger, which shows you a backtrace. Copy the text of the debugger's backtrace into the bug report.

  This use of the debugger is possible only if you know how to make the bug happen again. If you can't make it happen again, at least copy the whole error message.
- Check whether any programs you have loaded into the Lisp world, including your `.emacs' file, set any variables that may affect the functioning of Emacs. Also, see whether the problem happens in a freshly started Emacs without loading your `.emacs' file (start Emacs with the `-q` switch to prevent loading the init file.) If the problem does *not* occur then, you must report the precise contents of any programs that you must load into the Lisp world in order to cause the problem to occur.
- If the problem does depend on an init file or other Lisp programs that are not part of the standard Emacs system, then you should make sure it is not a bug in those programs by complaining to their maintainers first. After they verify that they are using Emacs in a way that is supposed to work, they should report the bug.
- If you wish to mention something in the GNU Emacs source, show the line of code with a few lines of context. Don't just give a line number.

  The line numbers in the development sources don't match those in your sources. It would take extra work for the maintainers to determine what code is in your version at a given line number, and we could not be certain.
- Additional information from a C debugger such as GDB might enable someone to find a problem on a machine which he does not have available. If you don't know how to use GDB, please read

the GDB manual--it is not very long, and using GDB is easy. You can find the GDB distribution, including the GDB manual in online form, in most of the same places you can find the Emacs distribution.

However, you need to think when you collect the additional information if you want it to show what causes the bug.

For example, many people send just a backtrace, but that is not very useful by itself. A simple backtrace with arguments often conveys little about what is happening inside GNU Emacs, because most of the arguments listed in the backtrace are pointers to Lisp objects. The numeric values of these pointers have no significance whatever; all that matters is the contents of the objects they point to (and most of the contents are themselves pointers).

To provide useful information, you need to show the values of Lisp objects in Lisp notation. Do this for each variable which is a Lisp object, in several stack frames near the bottom of the stack. Look at the source to see which variables are Lisp objects, because the debugger thinks of them as integers.

To show a variable's value in Lisp syntax, first print its value, then use the user-defined GDB command `pr` to print the Lisp object in Lisp syntax. (If you must use another debugger, call the function `debug_print` with the object as an argument.) The `pr` command is defined by the file `` `.gdbinit' `` in the `` `src' `` subdirectory, and it works only if you are debugging a running process (not with a core dump).

To make Lisp errors stop Emacs and return to GDB, put a breakpoint at `Fsignal`.

To find out which Lisp functions are running, using GDB, move up the stack, and each time you get to a frame for the function `Ffuncall`, type these GDB commands:

```
p *args
pr
```

To print the first argument that the function received, use these commands:

```
p args[1]
pr
```

You can print the other arguments likewise. The argument `nargs` of `Ffuncall` says how many arguments `Ffuncall` received; these include the Lisp function itself and the arguments for that function.

- If the symptom of the bug is that Emacs fails to respond, don't assume Emacs is "hung"---it may instead be in an infinite loop. To find out which, make the problem happen under GDB and stop Emacs once it is not responding. (If Emacs is using X Windows directly, you can stop Emacs by typing C-c at the GDB job.) Then try stepping with `step'. If Emacs is hung, the `step' command won't return. If it is looping, `step' will return.

  If this shows Emacs is hung in a system call, stop it again and examine the arguments of the call. In your bug report, state exactly where in the source the system call is, and what the arguments are.

If Emacs is in an infinite loop, please determine where the loop starts and ends. The easiest way to do this is to use the GDB command `finish'. Each time you use it, Emacs resumes execution until it exits one stack frame. Keep typing `finish' until it doesn't return--that means the infinite loop is in the stack frame which you just tried to finish.

Stop Emacs again, and use `finish' repeatedly again until you get *back to* that frame. Then use `next' to step through that frame. By stepping, you will see where the loop starts and ends. Also please examine the data being used in the loop and try to determine why the loop does not exit when it should. Include all of this information in your bug report.

Here are some things that are not necessary in a bug report:

- A description of the envelope of the bug--this is not necessary for a reproducible bug.

  Often people who encounter a bug spend a lot of time investigating which changes to the input file will make the bug go away and which changes will not affect it.

  This is often time consuming and not very useful, because the way we will find the bug is by running a single example under the debugger with breakpoints, not by pure deduction from a series of examples. You might as well save time by not searching for additional examples.

  Of course, if you can find a simpler example to report *instead* of the original one, that is a convenience. Errors in the output will be easier to spot, running under the debugger will take less time, etc.

  However, simplification is not vital; if you can't do this or don't have time to try, please report the bug with your original test case.

- A system call trace of Emacs execution.

  System call traces are very useful for certain special kinds of debugging, but in most cases they give little useful information. It is therefore strange that many people seem to think that *the* way to report information about a crash is to send a system call trace.

  In most programs, a backtrace is normally far, far more informative than a system call trace. Even in Emacs, a simple backtrace is generally more informative, though to give full information you should supplement the backtrace by displaying variable values and printing them as Lisp objects with `pr` (see above).

- A patch for the bug.

  A patch for the bug is useful if it is a good one. But don't omit the other information that a bug report needs, such as the test case, on the assumption that a patch is sufficient. We might see problems with your patch and decide to fix the problem another way, or we might not understand it at all. And if we can't understand what bug you are trying to fix, or why your patch should be an improvement, we mustn't install it.

- A guess about what the bug is or what it depends on.

  Such guesses are usually wrong. Even experts can't guess right about such things without first using the debugger to find the facts.

Sending Patches for GNU Emacs

If you would like to write bug fixes or improvements for GNU Emacs, that is very helpful. When you send your changes, please follow these guidelines to make it easy for the maintainers to use them. If you don't follow these guidelines, your information might still be useful, but using it will take extra work. Maintaining GNU Emacs is a lot of work in the best of circumstances, and we can't keep up unless you do your best to help.

- Send an explanation with your changes of what problem they fix or what improvement they bring about. For a bug fix, just include a copy of the bug report, and explain why the change fixes the bug.

  (Referring to a bug report is not as good as including it, because then we will have to look it up, and we have probably already deleted it if we've already fixed the bug.)
- Always include a proper bug report for the problem you think you have fixed. We need to convince ourselves that the change is right before installing it. Even if it is correct, we might have trouble understanding it if we don't have a way to reproduce the problem.
- Include all the comments that are appropriate to help people reading the source in the future understand why this change was needed.
- Don't mix together changes made for different reasons. Send them *individually*.

  If you make two changes for separate reasons, then we might not want to install them both. We might want to install just one. If you send them all jumbled together in a single set of diffs, we have to do extra work to disentangle them--to figure out which parts of the change serve which purpose. If we don't have time for this, we might have to ignore your changes entirely.

  If you send each change as soon as you have written it, with its own explanation, then two changes never get tangled up, and we can consider each one properly without any extra work to disentangle them.
- Send each change as soon as that change is finished. Sometimes people think they are helping us by accumulating many changes to send them all together. As explained above, this is absolutely the worst thing you could do.

  Since you should send each change separately, you might as well send it right away. That gives us the option of installing it immediately if it is important.
- Use `diff -c' to make your diffs. Diffs without context are hard to install reliably. More than that, they are hard to study; we must always study a patch to decide whether we want to install it. Unidiff format is better than contextless diffs, but not as easy to read as `-c' format.

  If you have GNU diff, use `diff -c -F'^[_a-zA-Z0-9$]+ *(" when making diffs of C code. This shows the name of the function that each change occurs in.
- Write the change log entries for your changes. This is both to save us the extra work of writing them, and to help explain your changes so we can understand them.

  The purpose of the change log is to show people where to find what was changed. So you need to be specific about what functions you changed; in large functions, it's often helpful to indicate where within the function the change was.

On the other hand, once you have shown people where to find the change, you need not explain its purpose in the change log. Thus, if you add a new function, all you need to say about it is that it is new. If you feel that the purpose needs explaining, it probably does--but put the explanation in comments in the code. It will be more useful there.

Please read the `ChangeLog' files in the `src' and `lisp' directories to see what sorts of information to put in, and to learn the style that we use. If you would like your name to appear in the header line, showing who made the change, send us the header line. See section Change Logs.

- When you write the fix, keep in mind that we can't install a change that would break other systems. Please think about what effect your change will have if compiled on another type of system.

  Sometimes people send fixes that *might* be an improvement in general--but it is hard to be sure of this. It's hard to install such changes because we have to study them very carefully. Of course, a good explanation of the reasoning by which you concluded the change was correct can help convince us.

  The safest changes are changes to the configuration files for a particular machine. These are safe because they can't create new bugs on other machines.

  Please help us keep up with the workload by designing the patch in a form that is clearly safe to install.

Contributing to Emacs Development

If you would like to help pretest Emacs releases to assure they work well, or if you would like to work on improving Emacs, please contact the maintainers at `bug-gnu-emacs@prep.ai.mit.edu`. A pretester should be prepared to investigate bugs as well as report them. If you'd like to work on improving Emacs, please ask for suggested projects or suggest your own ideas.

If you have already written an improvement, please tell us about it. If you have not yet started work, it is useful to contact `bug-gnu-emacs@prep.ai.mit.edu` before you start; it might be possible to suggest ways to make your extension fit in better with the rest of Emacs.

How To Get Help with GNU Emacs

If you need help installing, using or changing GNU Emacs, there are two ways to find it:

- Send a message to the mailing list `help-gnu-emacs@prep.ai.mit.edu`, or post your request on newsgroup `gnu.emacs.help`. (This mailing list and newsgroup interconnect, so it does not matter which one you use.)
- Look in the service directory for someone who might help you for a fee. The service directory is found in the file named `etc/SERVICE' in the Emacs distribution.

Go to the previous, next section.

Go to the previous, next section.

Command Line Arguments

GNU Emacs supports command line arguments to request various actions when invoking Emacs. These are for compatibility with other editors and for sophisticated activities. We don't recommend using them for ordinary editing.

Arguments starting with `-' are options. Other arguments specify files to visit. Emacs visits the specified files while it starts up. The last file name on your command line becomes the current buffer; the other files are also present in other buffers.

You can use options to specify various other things, such as the size and position of the X window Emacs uses, its colors, and so on. A few options support advanced usage, such as running Lisp functions on files in batch mode. The sections of this chapter describe the available options, arranged according to their purpose.

There are two ways of writing options: the short forms that start with a single `-', and the long forms that start with `--'. For example, `-d' is a short form and `--display' is the corresponding long form.

The long forms with `--' are easier to remember, but longer to type. However, you don't have to spell out the whole option name; any unambiguous abbreviation is enough. When a long option takes an argument, you can use either a space or an equal sign to separate the option name and the argument. Thus, you can write either `--display sugar-bombs:0.0' or `--display=sugar-bombs:0.0'. We recommend an equal sign because it makes the relationship clearer, and the tables below always show an equal sign.

Most options specify how to initialize Emacs, or set parameters for the Emacs session. We call them initial options. A few options specify things to do: for example, load libraries, call functions, or exit Emacs. These are called action options. These and file names together are called action arguments. Emacs processes all the action arguments in the order they are written.

Action Arguments

Here is a table of the action arguments and options:

`file'

Visit file using `find-file`. See section Visiting Files.

`+linenum file'

Visit file using `find-file`, then go to line number linenum in it.

`-l file'

`--load=file'

Load a file file of Lisp code with the function `load`. See section Libraries of Lisp Code for Emacs.

`-f function'

`--funcall=function'

Call Lisp function function with no arguments.

`--eval expression'

Evaluate Lisp expression expression.

`--insert=file'

Insert the contents of file into the current buffer. This is like what M-x insert-file does. See section Miscellaneous File Operations.

`--kill'

Exit from Emacs without asking for confirmation.

The init file can access the values of the action arguments as the elements of a list in the variable `command-line-args`. The init file can override the normal processing of the action arguments, or define new ones, by reading and setting this variable.

Initial Options

The initial options specify parameter for the Emacs session. This section describes the more general initial options; some other options specifically related to X Windows appear in the following sections.

Some initial options affect the loading of init files. The normal actions of Emacs are to first load `` `site-start.el' `` if it exists, then your own init file `` `~/.emacs' `` if it exists, and finally `` `default.el' `` if it exists; certain options prevent loading of some of these files or substitute other files for them.

`-t device'

`--terminal=device'

Use device as the device for terminal input and output.

`-d display'

`--display=display'

Use the X Window System and use the display named display to open the initial Emacs frame.

`-nw'

`--no-windows'

Don't communicate directly with X, disregarding the `DISPLAY` environment variable even if it is set.

`-batch'

`--batch'

Run Emacs in batch mode, which means that the text being edited is not displayed and the standard terminal interrupt characters such as C-z and C-c continue to have their normal effect. Emacs in batch mode outputs to `stderr` only what would normally be printed in the echo area under program control.

Batch mode is used for running programs written in Emacs Lisp from shell scripts, makefiles, and so on. Normally the `-l' option or `-f' option will be used as well, to invoke a Lisp program to do the batch processing.

`-batch' implies `-q' (do not load an init file). It also causes Emacs to kill itself after all command options have been processed. In addition, auto-saving is not done except in buffers for which it has been explicitly requested.

`-q'

`--no-init-file'

Do not load your Emacs init file `~/.emacs', or `default.el' either.

`--no-site-file'

Do not load `site-start.el'. The options `-q', `-u' and `-batch' have no effect on the loading of this file--this is the only option that blocks it.

`-u user'

`--user=user'

Load user's Emacs init file `~user/.emacs' instead of your own.

`--debug-init'

Enable the Emacs Lisp debugger for errors in the init file.

Command Argument Example

Here is an example of using Emacs with arguments and options. It assumes you have a Lisp program file called `hack-c.el' which, when loaded, performs some useful operation on current buffer, expected to be a C program.

```
emacs -batch foo.c -l hack-c -f save-buffer >& log
```

This says to visit `foo.c', load `hack-c.el' (which makes changes in the visited file), save `foo.c' (note that `save-buffer' is the function that C-x C-s is bound to), and then exit back to the shell (because of `-batch'). `-batch' also guarantees there will be no problem redirecting output to `log', because Emacs will not assume that it has a display terminal to work with.

Resuming Emacs with Arguments

You can specify action arguments for Emacs when you resume it after a suspension. To prepare for this, put the following code in your `.emacs' file (see section Hooks):

```
(add-hook 'suspend-hook 'resume-suspend-hook)
(add-hook 'suspend-resume-hook 'resume-process-args)
```

As further preparation, you must execute the shell script `emacs.csh' (if you use csh as your shell) or `emacs.bash' (if you use bash as your shell). These scripts define an alias named `edit', which will resume Emacs giving it new command line arguments such as files to visit.

Only action arguments work properly when you resume Emacs. Initial arguments are not recognized--it's too late to execute them anyway.

Note that resuming Emacs (with or without arguments) must be done from within the shell that is the parent of the Emacs job. This is why `edit' is an alias rather than a program or a shell script. It is not possible to implement a resumption command that could be run from other subjobs of the shell; no way to define a command that could be made the value of `EDITOR', for example. Therefore, this feature does not take the

place of the Emacs Server feature (see section Using Emacs as a Server).

The aliases use the Emacs Server feature if you appear to have a server Emacs running. However, they cannot determine this with complete accuracy. They may think that a server is still running when in actuality you have killed that Emacs, because the file `/tmp/.esrv...' still exists. If this happens, find that file and delete it.

Environment Variables

This appendix describes how Emacs uses environment variables. An environment variable is a string passed from the operating system to Emacs, and the collection of environment variables is known as the environment. Environment variable names are case sensitive and it is conventional to use upper case letters only.

Because environment variables come from the operating system there is no general way to set them; it depends on the operating system and especially the shell that you are using. For example, here's how to set the environment variable ORGANIZATION to `not very much' using bash:

```
export ORGANIZATION="not very much"
```

and here's how to do it in csh or tcsh:

```
setenv ORGANIZATION "not very much"
```

When Emacs is set-up to use the X windowing system, it inherits the use of a large number of environment variables from the X library. See the X documentation for more information.

General Variables

AUTHORCOPY
: The name of a file used to archive news articles posted with the GNUS package.

CDPATH
: Used by the cd command.

DOMAINNAME
: The name of the internet domain that the machine running Emacs is located in. Used by the GNUS package.

EMACSDATA
: Used to initialize the variable data-directory used to locate the architecture-independent files that come with Emacs. Setting this variable overrides the setting in `paths.h' when Emacs was built.

EMACSLOADPATH
: A colon-separated list of directories from which to load Emacs Lisp files. Setting this variable overrides the setting in `paths.h' when Emacs was built.

EMACSLOCKDIR

TOC

The directory that Emacs places lock files--files used to protect users from editing the same files simultaneously. Setting this variable overrides the setting in `paths.h' when Emacs was built.

EMACSPATH

The location of Emacs-specific binaries. Setting this variable overrides the setting in `paths.h' when Emacs was built.

ESHELL

Used for shell-mode to override the SHELL environment variable.

HISTFILE

The name of the file that shell commands are saved in between logins. This variable defaults to `~/.history' if you use (t)csh as shell, to `~/.bash_history' if you use bash, to `~/.sh_history' if you use ksh, and to `~/.history' otherwise.

HOME

The location of the user's files in the directory tree; used for expansion of file names starting with a tilde (`~'). On MS-DOS, it defaults to the directory from which Emacs was started, with `/bin' removed from the end if it was present.

HOSTNAME

The name of the machine that Emacs is running on.

INCPATH

A colon-separated list of directories. Used by the `complete' package to search for files.

INFOPATH

A colon separated list of directories holding info files. Setting this variable overrides the setting in `paths.el' when Emacs was built.

LOGNAME

The user's login name. See also USER.

MAIL

The name of the user's system mail box.

MAILRC

Name of file containing mail aliases. This defaults to `~/.mailrc'.

MH

Name of setup file for the mh system. This defaults to `~/.mh_profile'.

NAME

The real-world name of the user.

NNTPSERVER

The name of the news server. Used by the mh and GNUS packages.

ORGANIZATION

The name of the organization to which you belong. Used for setting the `Organization:' header in your posts from the GNUS package.

PATH

A colon-separated list of directories in which executables reside. (On MS-DOS, it is semicolon-separated instead.) This variable is used to set the Emacs Lisp variable `exec-path' which

you should consider to use instead.

`PWD`

If set, this should be the default directory when Emacs was started.

`REPLYTO`

If set, this specifies an initial value for the variable `mail-default-reply-to`. See section Mail Header Fields.

`SAVEDIR`

The name of a directory in which news articles are saved by default. Used by the GNUS package.

`SHELL`

The name of an interpreter used to parse and execute programs run from inside Emacs.

`TERM`

The name of the terminal that Emacs is running on. The variable must be set unless Emacs is run in batch mode. On MS-DOS, it defaults to `internal', which specifies a built-in terminal emulation that handles the machine's own display.

`TERMCAP`

The name of the termcap library file describing how to program the terminal specified by the `TERM` variable. This defaults to `` `/etc/termcap' ``.

`TMPDIR`

Used by the Emerge package as a prefix for temporary files.

`TZ`

This specifies the current time zone and possibly also daylight savings information. On MS-DOS, the default is based on country code; see the file `` `msdos.c' `` for details.

`USER`

The user's login name. See also `LOGNAME`. On MS-DOS, this defaults to `root'.

`VERSION_CONTROL`

Used to initialize the `version-control` variable (see section Single or Numbered Backups).

Misc Variables

These variables are used only on particular configurations:

`COMSPEC`

On MS-DOS, the name of the command interpreter to use. This is used to make a default value for the `SHELL` environment variable.

`NAME`

On MS-DOS, this variable defaults to the value of the `USER` variable.

`TEMP`

`TMP`

On MS-DOS, these specify the name of the directory for storing temporary files in.

`EMACSTEST`

On MS-DOS, this specifies a file to use to log the operation of the internal terminal emulator. This feature is useful for submitting bug reports.

`EMACSCOLORS`

Used on MS-DOS systems to set screen colors early, so that the screen won't momentarily flash the default colors when Emacs starts up. The value of this variable should be two-character encoding of the foreground (the first character) and the background (the second character) colors of the default face. Each character should be the hexadecimal code for the desired color on a standard PC text-mode display.

Only the low three bits of the background color are actually used, because the PC display supports only eight background colors.

`WINDOW_GFX`

Used when initializing the Sun windows system.

Specifying the Display Name

The environment variable `DISPLAY` tells all X clients, including Emacs, where to display their windows. Its value is set up by default in ordinary circumstances, when you start an X server and run jobs locally. Occasionally you may need to specify the display yourself; for example, if you do a remote login and want to run a client program remotely, displaying on your local screen.

With Emacs, the main reason people change the default display is to let them log into another system, run Emacs on that system, but have the window displayed at their local terminal. You might need to use login to another system because the files you want to edit are there, or because the Emacs executable file you want to run is there.

The syntax of the `DISPLAY` environment variable is `host:display.screen', where host is the host name of the X Window System server machine, display is an arbitrarily-assigned number that distinguishes your server (X terminal) from other servers on the same machine, and screen is a rarely-used field that allows an X server to control multiple terminal screens. The period and the screen field are optional. If included, screen is usually zero.

For example, if your host is named `glasperle' and your server is the first (or perhaps the only) server listed in the configuration, your `DISPLAY` is `glasperle:0.0'.

You can specify the display name explicitly when you run Emacs, either by changing the `DISPLAY` variable, or with the option `-d display' or `--display=display'. Here is an example:

```
emacs --display=glasperle:0 &
```

You can inhibit the direct use of X with the `-nw' option. This is also an initial option. It tells Emacs to display using ordinary ASCII on its controlling terminal.

Sometimes, security arrangements prevent a program on a remote system from displaying on your local system. In this case, trying to run Emacs produces messages like this:

```
Xlib:  connection to "glasperle:0.0" refused by server
```

You might be able to overcome this problem by using the `xhost` command on the local system to give permission for access from your remote machine.

Font Specification Options

By default, Emacs displays text in the font named `9x15', which makes each character nine pixels wide and fifteen pixels high. You can specify a different font on your command line through the option `-fn name'.

`-fn name'

Use font name as the default font.

`--font=name'

`--font' is an alias for `-fn'.

Under X, each font has a long name which consists of eleven words or numbers, separated by dashes. Some fonts also have shorter nicknames---`9x15' is such a nickname. You can use either kind of name. You can use wild card patterns for the font name; then Emacs lets X choose one of the fonts that match the pattern. Here is an example, which happens to specify the font whose nickname is `6x13':

```
emacs -fn "-misc-fixed-medium-r-semicondensed--13-*-*-*-c-60-iso8859-1" &
```

You can also specify the font in your `.Xdefaults' file:

```
emacs.font: -misc-fixed-medium-r-semicondensed--13-*-*-*-c-60-iso8859-1
```

A long font name has the following form:

```
-maker-family-weight-slant-widthtype-style...
...-pixels-height-horiz-vert-spacing-width-charset
```

family

This is the name of the font family--for example, `courier'.

weight

This is normally `bold', `medium' or `light'. Other words may appear here in some font names.

slant

This is `r' (roman), `i' (italic), `o' (oblique), `ri' (reverse italic), or `ot' (other).

widthtype

This is normally `condensed', `extended', `semicondensed' or `normal'. Other words may appear here in some font names.

style

This is an optional additional style name. Usually it is empty--most long font names have two hyphens in a row at this point.

pixels

This is the font height, in pixels.

height

This is the font height on the screen, measured in printer's points (approximately 1/72 of an inch), times ten. For a given vertical resolution, height and pixels are proportional; therefore, it is comm specify just one of them and use `*' for the other.

horiz

This is the horizontal resolution, in pixels per inch, of the screen for which the font is intended.

vert

This is the vertical resolution, in dots per inch, of the screen for which the font is intended. Normally the resolution of the fonts on your system is the right value for your screen; therefore, you normally specify `*' for this and horiz.

spacing

This is `m' (monospace), `p' (proportional) or `c' (character cell). Emacs can use `m' and `c' fonts.

width

This is the average character width, in pixels, times ten.

charset

This is the character set that the font depicts. Normally you should use `iso8859-1'.

Use only fixed width fonts--that is, fonts in which all characters have the same width; Emacs cannot yet handle display properly for variable width fonts. Any font with `m' or `c' in the spacing field of the long name is a fixed width font. Here's how to use the `xlsfonts` program to list all the fixed width fonts available on your system:

```
xlsfonts -fn '*x*'
xlsfonts -fn '*-*-*-*-*-*-*-*-*-*-m*'
xlsfonts -fn '*-*-*-*-*-*-*-*-*-*-c*'
```

To see what a particular font looks like, use the `xfd` command. For example:

```
xfd -fn 6x13
```

displays the entire font `6x13'.

While running Emacs, you can set the font of the current frame (see section Setting Frame Parameters) or for a specific kind of text (see section Using Multiple Typefaces).

Window Color Options

On a color display, you can specify which color to use for various parts of the Emacs display. To find out what colors are available on your system, look at the `/usr/lib/X11/rgb.txt' file. If you do not specify colors, the default for the background is white and the default for all other colors is black. On a monochrome display, the foreground is black, the background is white, and the border is gray if the display supports that.

Here is a list of the options for specifying colors:

`-fg color'

`--foreground-color=color'

Specify the foreground color.

`-bg color'

`--background-color=color'

Specify the background color.

`-bd color'

`--border-color=color'

Specify the color of the border of the X window.

`-cr color'

`--cursor-color=color'

Specify the color of the Emacs cursor which indicates where point is.

`-ms color'

`--mouse-color=color'

Specify the color for the mouse cursor when the mouse is in the Emacs window.

`-r'

`--reverse-video'

Reverse video--swap the foreground and background colors.

For example, to use a coral mouse cursor and a slate blue text cursor, enter:

```
emacs -ms coral -cr 'slate blue' &
```

You can reverse the foreground and background colors through the `-r' option or with the X resource `reverseVideo'.

Options for Window Geometry

The `-geometry' option controls the size and position of the initial Emacs frame. Here is the format for specifying the window geometry:

`-g widthxheight{+-}xoffset{+-}yoffset'

Specify window size width and height (measured in character columns and lines), and positions xoffset and yoffset (measured in pixels).

`--geometry=widthxheight{+-}xoffset{+-}yoffset'

This is another way of writing the same thing.

`{+-}` means either a plus sign or a minus sign. A plus sign before xoffset means it is the distance from the left side of the screen; a minus sign means it counts from the right side. A plus sign before yoffset means it is the distance from the top of the screen, and a minus sign there indicates the distance from the bottom. The values xoffset and yoffset may themselves be positive or negative, but that doesn't change their meaning, only their direction.

Emacs uses the same units as `xterm` does to interpret the geometry. The width and height are measured in characters, so a large font creates a larger frame than a small font. The xoffset and yoffset are measured in

pixels.

Since the mode line and the echo area occupy the last 2 lines of the frame, the height of the initial text window is 2 less than the height specified in your geometry. In non-X-toolkit versions of Emacs, the menu bar also takes one line of the specified number.

You do not have to specify all of the fields in the geometry specification.

If you omit both xoffset and yoffset, the window manager decides where to put the Emacs frame, possibly by letting you place it with the mouse. For example, `164x55' specifies a window 164 columns wide, enough for two ordinary width windows side by side, and 55 lines tall.

The default width for Emacs is 80 characters and the default height is 40 lines. You can omit either the width or the height or both. If you start the geometry with an integer, Emacs interprets it as the width. If you start with an `x' followed by an integer, Emacs interprets it as the height. Thus, `81' specifies just the width; `x45' specifies just the height.

If you start with `+' or `-', that introduces an offset, which means both sizes are omitted. Thus, `-3' specifies the xoffset only. (If you give just one offset, it is always xoffset.) `+3-3' specifies both the xoffset and the yoffset, placing the frame near the bottom left of the screen.

You can specify a default for any or all of the fields in `.Xdefaults' file, and then override selected fields with a `--geometry' option.

Internal and External Borders

An Emacs frame has an internal border and an external border. The internal border is an extra strip of the background color around all four edges of the frame. Emacs itself adds the internal border. The external border is added by the window manager outside the internal border; it may contain various boxes you can click on to move or iconify the window.

`-ib width'

`--internal-border=width'

Specify width as the width of the internal border.

`-bw width'

`--border-width=width'

Specify width as the width of the main border.

When you specify the size of the frame, that does not count the borders. The frame's position is measured from the outside edge of the external border.

Use the `-ib n' option to specify an internal border n pixels wide. The default is 1. Use `-bw n' to specify the width of the external border (though the window manager may not pay attention to what you specify). The default width of the external border is 2.

TOC

Frame Titles

An Emacs frame may or may not have a specified title. The frame title, if specified, appears in window decorations and icons as the name of the frame. If an Emacs frame has no specified title, the default title is the name of the executable program (if there is only one frame) or the selected window's buffer name (if there is more than one frame).

You can specify a title for the initial Emacs frame with a command line option:

`-title title'

`--title=title'

`-T title'

Specify title as the title for the initial Emacs frame.

The `--name' option (see section X Resources) also specifies the title for the initial Emacs frame.

Icons

Most window managers allow the user to "iconify" a frame, removing it from sight, and leaving a small, distinctive "icon" window in its place. Clicking on the icon window makes the frame itself appear again. If you have many clients running at once, you can avoid cluttering up the screen by iconifying most of the clients.

`-i'

`--icon-type'

Use a picture of a gnu as the Emacs icon.

`-iconic'

`--iconic'

Start Emacs in iconified state.

The `-i' or `--icon-type' option tells Emacs to use an icon window containing a picture of the GNU gnu. If omitted, Emacs lets the window manager choose what sort of icon to use--usually just a small rectangle containing the frame's title.

The `-iconic' option tells Emacs to begin running as an icon, rather than opening a frame right away. In this situation, the icon window provides only indication that Emacs has started; the usual text frame doesn't appear until you deiconify it.

X Resources

Programs running under the X Window System organize their user options under a hierarchy of classes and resources. You can specify default values for these options in your X resources file, usually named `~/.Xdefaults'.

Each line in the file specifies a value for one option or for a collection of related options, for one program or for several programs (optionally even for all programs).

Programs define named resources with particular meanings. They also define how to group resources into named classes. For instance, in Emacs, the `internalBorder' resource controls the width of the internal border, and the `borderWidth' resource controls the width of the external border. Both of these resources are part of the `BorderWidth' class. Case distinctions are significant in these names.

In `~/.Xdefaults', you can specify a value for a single resource on one line, like this:

```
emacs.borderWidth: 2
```

Or you can use a class name to specify the same value for all resources in that class. Here's an example:

```
emacs.BorderWidth: 2
```

If you specify a value for a class, it becomes the default for all resources in that class. You can specify values for individual resources as well; these override the class value, for those particular resources. Thus, this example specifies 2 as the default width for all borders, but overrides this value with 4 for the external border:

```
emacs.Borderwidth: 2
emacs.borderwidth: 4
```

The order in which the lines appear in the file does not matter. Also, command-line options always override the X resources file.

The string `emacs' in the examples above is also a resource name. It actually represents the name of the executable file that you invoke to run Emacs. If Emacs is installed under a different name, it looks for resources under that name instead of `emacs'.

`-name name'

`--name=name'

> Use name as the resource name (and the title) for the initial Emacs frame. This option does not affect subsequent frames, but Lisp programs can specify frame names when they create frames.
>
> If you don't specify this option, the default is to use the Emacs executable's name as the resource name.

`-xrm resource-values'

`--xrm=resource-values'

> Specify X resource values for this Emacs job (see below).

For consistency, `-name' also specifies the name to use for other resource values that do not belong to any particular frame.

The resources that name Emacs invocations also belong to a class; its name is `Emacs'. If you write `Emacs' instead of `emacs', the resource applies to all frames in all Emacs jobs, regardless of frame titles and regardless of the name of the executable file. Here is an example:

```
Emacs.BorderWidth: 2
Emacs.borderWidth: 4
```

You can specify a string of additional resource values for Emacs to use with the command line option `-xrm resources'. The text resources should have the same format that you would use inside a file of X resources. To include multiple resource specifications in data, put a newline between them, just as you would in a file. You can also use `#include "filename"' to include a file full of resource specifications. Resource values specified with `-xrm' take precedence over all other resource specifications.

The following table lists the resource names that designate options for Emacs, each with the class that it belongs to:

`background` (class `Background`)

Background color name.

`bitmapIcon` (class `BitmapIcon`)

Use a bitmap icon (a picture of a gnu) if `on', let the window manager choose an icon if `off'.

`borderColor` (class `BorderColor`)

Color name for the external border.

`borderWidth` (class `BorderWidth`)

Width in pixels of the external border.

`cursorColor` (class `Foreground`)

Color name for text cursor (point).

`font` (class `Font`)

Font name for text.

`foreground` (class `Foreground`)

Color name for text.

`geometry` (class `Geometry`)

Window size and position. Be careful not to specify this resource as `emacs*geometry', because that may affect individual menus as well as the Emacs frame itself.

If this resource specifies a position, that position applies only to the initial Emacs frame (or, in the case of a resource for a specific frame name, only that frame). However, the size if specified here applies to all frames.

`iconName` (class `Title`)

Name to display in the icon.

`internalBorder` (class `BorderWidth`)

Width in pixels of the internal border.

`menuBar` (class `MenuBar`)

Give frames menu bars if `on'; don't have menu bars if `off'.

`paneFont` (class `Font`)

Font name for menu pane titles, in non-toolkit versions of Emacs.

`pointerColor` (class `Foreground`)

Color of the mouse cursor.

`reverseVideo` (class `ReverseVideo`)

Switch foreground and background default colors if `on', use colors as specified if `off'.

`verticalScrollBars` (class `ScrollBars`)

Give frames scroll bars if `on'; don't have scroll bars if `off'.

`selectionFont` (class `Font`)

Font name for pop-up menu items, in non-toolkit versions of Emacs. (For toolkit versions, see section Lucid Menu X Resources, also see section Motif Menu X Resources.)

`title` (class `Title`)

Name to display in the title bar of the initial Emacs frame.

Here are resources for controlling the appearance of particular faces (see section Using Multiple Typefaces):

`face.attributeFont`

Font for face face.

`face.attributeForeground`

Foreground color for face face.

`face.attributeBackground`

Background color for face face.

`face.attributeUnderline`

Underline flag for face face. Use `on' or `true' for yes.

Lucid Menu X Resources

If the Emacs installed at your site was built to use the X toolkit with the Lucid menu widgets, then the menu bar is a separate widget and has its own resources. The resource names contain `pane.menubar' (following, as always, the name of the Emacs invocation or `Emacs' which stands for all Emacs invocations). Specify them like this:

```
Emacs.pane.menubar.resource:  value
```

For example, to specify the font `8x16' for the menu bar items, write this:

```
Emacs.pane.menubar.font:  8x16
```

Resources for *non-menubar* toolkit popup menus have `menu*', in like fashion. For example, to specify the font `8x16' for the popup menu items, write this:

```
Emacs.menu*.font:       8x16
```

For dialog boxes, use `dialog' instead of `menu':

```
Emacs.dialog*.font:     8x16
```

Experience shows that on some systems you may need to add `shell.' before the `pane.menubar' or `menu*'. On some other systems, you must not add `shell.'.

Here is a list of the specific resources for menu bars and popup menus:

TOC

`font`
: Font for menu item text.

`foreground`
: Color of the foreground.

`background`
: Color of the background.

`buttonForeground`
: In the menu bar, the color of the foreground for a selected item.

`horizontalSpacing`
: Horizontal spacing in pixels between items. Default is 3.

`verticalSpacing`
: Vertical spacing in pixels between items. Default is 1.

`arrowSpacing`
: Horizontal spacing between the arrow (which indicates a submenu) and the associated text. Default is 10.

`shadowThickness`
: Thickness of shadow line around the widget.

Motif Menu X Resources

If the Emacs installed at your site was built to use the X toolkit with the Motif widgets, then the menu bar is a separate widget and has its own resources. The resource names contain `pane.menubar' (following, as always, the name of the Emacs invocation or `Emacs' which stands for all Emacs invocations). Specify them like this:

```
Emacs.pane.menubar.subwidget.resource:  value
```

Each individual string in the menu bar is a subwidget; the subwidget's name is the same as the menu item string. For example, the word `Files' in the menu bar is part of a subwidget named `emacs.pane.menubar.Files'. Most likely, you want to specify the same resources for the whole menu bar. To do this, use `*' instead of a specific subwidget name. For example, to specify the font `8x16' for the menu bar items, write this:

```
Emacs.pane.menubar.*.fontList:  8x16
```

This also specifies the resource value for submenus.

Each item in a submenu in the menu bar also has its own name for X resources; for example, the `Files' submenu has an item named `Save Buffer'. A resource specification for a submenu item looks like this:

```
Emacs.pane.menubar.popup_*.menu.item.resource: value
```

For example, here's how to specify the font for the `Save Buffer' item:

```
Emacs.pane.menubar.popup_*.Files.Save Buffer.fontList: 8x16
```

For an item in a second-level submenu, such as `Check Message' under `Spell' under `Edit', the resource fits this template:

```
Emacs.pane.menubar.popup_*.popup_*.menu.resource: value
```

For example,

```
Emacs.pane.menubar.popup_*.popup_*.Spell.Check Message: value
```

It's impossible to specify a resource for all the menu bar items without also specifying it for the submenus as well. So if you want the submenu items to look different from the menu bar itself, you must ask for that in two steps. First, specify the resource for all of them; then, override the value for submenus alone. Here is an example:

```
Emacs.pane.menubar.*.fontList:  8x16
Emacs.pane.menubar.popup_*.fontList: 8x16
```

For toolkit popup menus, use `menu*' instead of `pane.menubar'. For example, to specify the font `8x16' for the popup menu items, write this:

```
Emacs.menu*.fontList:  8x16
```

Here is a list of the specific resources for menu bars and popup menus:

`armColor`
: The color to show in an armed button.

`fontList`
: The font to use.

`marginBottom`

`marginHeight`

`marginLeft`

`marginRight`

`marginTop`

`marginWidth`
: Amount of space to leave around the item, within the border.

`borderWidth`
: The width of border around the menu item, on all sides.

`shadowThickness`
: The width of the border shadow.

`bottomShadowColor`
: The color for the border shadow, on the bottom and the right.

`topShadowColor`

The color for the border shadow, on the bottom and the right.

Go to the previous, next section.

Emacs 19.28 and 19.29 Antinews

For those users who live backwards in time, here is information about downgrading to Emacs version 19.28 or 19.29. We hope you will enjoy the greater simplicity that results from the absence of certain Emacs 19.34 features.

- This version doesn't support Windows NT, or the DEC Alpha.
- In Emacs 19.28, or even 19.29, the features for controlling indentation in C are much simpler. There is a separate variable for each aspect of indentation which you can control. Here is a list of them:

  `c-indent-level`
  : Level of indentation of C statements with respect to containing block.

  `c-label-offset`
  : Offset of C label lines and case statements relative to usual indentation.

  `c-continued-brace-offset`
  : Extra indentation for substatements that start with open-braces. This is in addition to `c-continued-statement-offset`.

  `c-continued-statement-offset`
  : Extra indentation for lines not starting new statements.

  `c-brace-offset`
  : Extra indentation for braces, compared with other text in same context.

  `c-brace-imaginary-offset`
  : Imagined indentation of a C open brace that actually follows a statement.

  `c-argdecl-indent`
  : Indentation level of declarations of C function arguments.
- There is no support for editing formatted text. The text formatter TeX does a much better job of formatting than any formatted text editor; we recommend you learn to use it.
- C-Mouse-2 now runs the menu for setting the default font.
- F1 is no longer an alias for the Help key; you must actually type C-h if you want help.
- Integers and buffer sizes are limited to 24 bits on most machines. But as memory gets more expensive, you won't want to edit such large files any more.
- There are no indirect buffers, so you can only display one view of an outline. Meanwhile, the prefix key for Outline minor mode is now C-c C-o.
- When you are in Transient Mark mode, incremental search always deactivates the mark.
- Dynamic abbrev completion has been eliminated in 19.28, and some of the other dynamic abbrev customization features are also gone.
- In Dired, Occur mode, Compilation mode, and other such modes, you must use C-c C-c to select

the item point is on. RET won't do it.

- M-x buffer-menu now displays the menu buffer in another window.
- The VC (version control) package no longer supports CVS or selecting branches other than the principal branch.
- There is no `recover-session` command; if Emacs crashes, you simply have to remember which files you were editing before the crash, and use `recover-file` on the individual files.
- In Emacs Lisp mode, C-M-x now lets `defvar` operate as it usually does--setting the value of the variable only if it has no value yet. Use ESC ESC to evaluate a Lisp expression, instead of M-:.
- GNU-standard long option names are not supported. (Real hackers prefer the shorter single-dash names, to save typing.) All the initial options must come before all the action options, and whatever initial options you use must appear in this order: `-t', `-d', `-nw', `-batch', `-q' or `-no-init-file', `-no-site-file', `-u' or `-user', `-debug-init'.
- Many special-case kludges for MS-DOS have been removed. This means that many features don't work on MS-DOS; however, the code of Emacs is much simpler.

  For instance, you cannot print from within Emacs, Dired doesn't support shell wildcards in filenames, some Lisp packages won't work because their standard filenames are invalid on MS-DOS, `display-time` doesn't work, Font Lock mode won't work unless you create some faces by hand first, and `call-process` cannot redirect `stderr`.

  As an additional bonus, you get random characters inserted into the buffer without a warning (unless you're clever enough to discover that setting `visible-bell` makes this problem to go away).

  In a word, it's a great relief for those who still need proof that MS-DOG isn't a real operating system.

Go to the previous, next section.

Go to the previous, next section.

MS-DOS Issues

This section briefly describes the peculiarities of using Emacs under the MS-DOS "operating system" (also known as "MS-DOG"). If you build Emacs for MS-DOS, the binary will also run on Windows 3, Windows NT, Windows 95, or OS-2 as a DOS application; the information in this chapter applies for all of those systems, if you use an Emacs that was built for MS-DOS.

Note that it is possible to build Emacs specifically for Windows NT or Windows 95. If you do that, most of this chapter does not apply; instead, you get behavior much closer to what is documented in the rest of the manual, including support for long file names, multiple frames, scroll bars, mouse menus, and subprocesses. However, the section on text files and binary files does still apply. There are also two sections at the end of this chapter which apply specifically for Windows NT and 95.

Keyboard and Mouse on MS-DOS

The PC keyboard maps use the left Alt key as the META key. You have two choices for emulating the SUPER and HYPER keys: either the right CONTROL key or the right ALT key by setting the variables `dos-hyper-key` and `dos-super-key` to 1 or 2 respectively.

The variable `dos-keypad-mode` is a flag variable which controls what key codes are returned by keys in the numeric keypad. There is no dedicated LFD key; use C-j instead. You can also define the kp-enter key to act as LFD, by putting the following line into your `` `_emacs' `` file:

```
;; Make the Enter key from the Numeric keypad act as LFD.
(define-key function-key-map [kp-enter] [?\C-j])
```

The key which is called DEL in Emacs (because that's how it is designated on most workstations) is known as BS (backspace) on a PC. That is why the PC-specific terminal initialization remaps the BS key to act as DEL; the DEL key is remapped to act as C-d for the same reasons.

Emacs on MS-DOS supports a mouse (on the default terminal only). The mouse commands work as documented, including those that use menus and the menu bar (see section Menu Bars). Scroll bars don't work in MS-DOS Emacs. PC mice usually have only two buttons; these act as Mouse-1 and Mouse-2, but if you press both of them together, that has the effect of Mouse-3.

The variable `dos-display-scancodes`, when non-`nil`, directs Emacs to display the ASCII value and the keyboard scan code of each keystroke; this feature serves as a complement to the `view-lossage` command, for debugging.

Display on MS-DOS

Display on MS-DOS cannot use multiple fonts, but it does support multiple faces, each of which can specify a foreground and a background color. Therefore, you can get the full functionality of Emacs packages which use fonts (such as `font-lock`, Enriched Text mode, and others) by defining the relevant faces to use different colors. Use the `list-colors-display` and `list-faces-display` commands (see section Modifying Faces) to see what colors and faces are available and what they look like.

Multiple frames (see section Frames and X Windows) are supported on MS-DOS, but they all overlap, so you only see a single frame at any given moment. That single visible frame occupies the entire screen. When you run Emacs under Windows version 3, you can make the visible frame smaller than the full screen, but Emacs still cannot display more than a single frame at a time.

The `mode4350` command switches the display to 43 or 50 lines, depending on your hardware; the `mode25` command switches to the default 80x25 screen size.

By default, Emacs only knows how to set screen sizes of 80 columns by 25 or 43/50 rows. However, if your video adapter has special video modes that will switch the display to other sizes, you can have Emacs support those too. When you ask Emacs to switch the frame to n rows by m cols dimensions, it checks if there is a variable called `screen-dimensions-nxm`, and if so, uses its value (which must be an integer) as the video mode to switch to. (Emacs switches to that video mode by calling the BIOS `Set Video Mode` function with the value of `screen-dimensions-nxm` in the `AL` register.) For example, suppose your adapter will switch to 66x80 dimensions when put into video mode 85. Then you can make Emacs support this screen size by putting the following into your `` `_emacs' `` file:

```
(setq screen-dimensions-66x80 85)
```

Since Emacs on MS-DOS can only set the frame size to specific supported dimensions, it cannot honor every possible frame resizing request. When an unsupported size is requested, Emacs chooses the next larger supported size beyond the specified size. For example, if you ask for 36x80 frame, you will get 50x80 instead.

The variables `screen-dimensions-nxm` are used only when they exactly match the specified size; the search for the next larger supported size ignores them. In the above example, even if your VGA supports 44x80 dimensions and you define a variable `screen-dimensions-44x80` with a suitable value, you will still get 50x80 screen when you ask for a 36x80 frame. If you want to get the 44x80 size in this case, you can do it by setting the variable named `screen-dimensions-36x80` with the same video mode value as `screen-dimensions-44x80`.

Changing frame dimensions on MS-DOS has the effect of changing all the other frames to the new dimensions.

File Names on MS-DOS

MS-DOS normally uses a backslash, `\', to separate name units within a file name, instead of the slash used on other systems. Emacs on MS-DOS permits use of either slash or backslash, and also knows about drive letters in file names.

On MS-DOS, file names are case-insensitive and limited to eight characters, plus optionally a period and three more characters. Emacs knows enough about these limitations to handle file names that were meant for other operating systems. For instance, leading dots `.' in file names are invalid in MS-DOS, so Emacs transparently converts them to underscores `_'; thus your default init file (see section The Init File, `~/.emacs') is called `_emacs' on MS-DOS. Excess characters before or after the period are generally ignored by MS-DOS itself, so if you, e.g., visit a file `LongFileName.EvenLongerExtension', you will silently get `longfile.eve'; but Emacs will still display the long file name on the mode line. Other than that, it's up to you to specify file names which are valid under MS-DOS; the transparent conversion as described above only works on file names built into Emacs.

The above restrictions on the file names on MS-DOS make it almost impossible to construct the name of a backup file (see section Single or Numbered Backups) without losing some of the original file name characters. For example, the name of a backup file for `docs.txt' is `docs.tx~' even if single backup is used.

If you run Emacs as a DOS application under Windows 95 or NT, you can turn on support for long file names. If you do that, Emacs doesn't truncate file names or convert them to lower case; instead, it uses the file names that you specify, verbatim. To enable long file name support, set the environment variable `LFN` to `y' before starting Emacs.

MS-DOS has no notion of home directory, so Emacs on MS-DOS pretends that the directory where it is installed is the value of `HOME` environment variable. That is, if your Emacs binary, `emacs.exe', is in the directory `c:/utils/emacs/bin', then Emacs acts as if `HOME` were set to `c:/utils/emacs'. In particular, that is where Emacs looks for the init file `_emacs'. With this in mind, you can use `~' in file names as an alias for the home directory, as you would in Unix. You can also set `HOME` variable in the environment before starting Emacs; its value will then override the above default behavior.

Text Files and Binary Files

Emacs on MS-DOS distinguishes between text and binary files. This distinction is not part of MS-DOS; it is made by Emacs only. Emacs treats files of human-readable text (including program source code) as text files, and treats executable programs, compressed archives, etc., as binary files. Emacs uses the file name to decide whether to treat a file as text or binary: the variable `file-name-buffer-file-type-alist` defines the file name patterns which denote binary files.

Emacs reads and writes binary files verbatim. Text files use a two character sequence to end a line: carriage-return (control-m) followed by newline (control-j). When you visit a text file, Emacs strips off these control-m characters; when you write a text file to disk, Emacs puts them back in. Thus, the text

appears within Emacs with just a newline character at the end of each line.

You can tell whether Emacs considers the visited file as text or binary based on the mode line (see section The Mode Line). Text files have a `T:' marker prefixed to the major mode name; binary files have a `B:' prefix.

One consequence of this special format-conversion of text files is that character positions as reported by Emacs (see section Cursor Position Information) do not agree with the file size information known to the operating system.

Printing and MS-DOS

Printing commands, such as `lpr-buffer` (see section Hardcopy Output) and `ps-print-buffer` (see section Postscript Hardcopy) can work in MS-DOS by sending the output to one of the printer ports, if a Unix-style `lpr` program is unavailable. A few DOS-specific variables control how this works.

If you want to use your local printer, printing on it in the usual DOS manner, then set the Lisp variable `dos-printer` to the name of the printer port--for example. `"PRN"`, the usual local printer port (that's the default), or `"LPT2"` or `"COM1"` for a serial printer. You can also set `dos-printer` to a file name, in which case "printed" output is actually appended to that file. If you set `dos-printer` to `"NUL"`, printed output is silently discarded.

If you set `dos-printer` to a file name, it's best to use an absolute file name. Emacs changes the working directory according to the default directory of the current buffer, so if the file name in `dos-printer` is relative, you will end up with several such files, each one in the directory of the buffer from which the printing was done.

The commands `print-buffer` and `print-region` call the `pr` program, or use special switches to the `lpr` program, to produce headers on each printed page. MS-DOS doesn't normally have these programs, so by default, the variable `lpr-headers-switches` is set so that the requests to print page headers are silently ignored. Thus, `print-buffer` and `print-region` produce the same output as `lpr-buffer` and `lpr-region`, respectively. If you do have a suitable `pr` program (e.g., from GNU Textutils), set `lpr-headers-switches` to `nil`; Emacs will then call `pr` to produce the page headers, and print the resulting output as specified by `dos-printer`.

Finally, if you do have an `lpr` work-alike, you can set `print-region-function` to `nil`. Then Emacs uses `lpr` for printing, as on other systems. (If the name of the program isn't `lpr`, set the `lpr-command` variable to specify where to find it.)

A separate variable, `dos-ps-printer`, defines how PostScript files should be printed. If its value is a string, it is used as the name of the device (or file) to which PostScript output is sent, just as `dos-printer` is used for non-PostScript printing. (These are two distinct variables in case you have two printers attached to two different ports, and only one of them is a PostScript printer.) If the value of `dos-ps-printer` is not a string, then the variables `ps-lpr-command` and `ps-lpr-switches` (see section Postscript Hardcopy) control how to print PostScript files. Thus, if you have a non-PostScript printer, you can set these variables to the name and the switches appropriate for a PostScript interpreter program (e.g., Ghostscript).

For example, to use Ghostscript for printing on an Epson printer connected to `LPT2' port, put this c
your `.emacs' file:

```
(setq dos-ps-printer t)  ; Anything but a string.
(setq ps-lpr-command "c:/gs/gs386")
(setq ps-lpr-switches '("-q" "-dNOPAUSE"
                        "-sDEVICE=epson"
                        "-r240x72"
                        "-sOutputFile=LPT2"
                        "-Ic:/gs"
                        "-"))
```

(This assumes that Ghostscript is installed in the `"c:/gs"' directory.)

Subprocesses on MS-DOS

Because MS-DOS is a single-process "operating system", asynchronous subprocesses are not available. In particular, Shell mode and its variants do not work. Most Emacs features that use asynchronous subprocesses also don't work on MS-DOS, including spelling correction and GUD. When in doubt, try and see; commands that don't work print an error message saying that asynchronous processes aren't supported.

Compilation under Emacs with M-x compile and grep with M-x grep do work, by running the inferior processes synchronously. This means you cannot do any more editing until the compilation or the grep process finishes.

Printing commands, such as `lpr-buffer` (see section Hardcopy Output) and `ps-print-buffer` (see section Postscript Hardcopy), work in MS-DOS by sending the output to one of the printer ports. See section Printing and MS-DOS.

When you run a subprocess synchronously on MS-DOS, make sure the program terminates and does not try to read keyboard input. If the program does not terminate on its own, you will be unable to terminate it, because MS-DOS provides no general way to terminate a process.

Accessing files on other machines is not supported on MS-DOS. Other network-oriented commands such as sending mail, Web browsing, remote login, etc., don't work either, unless network access is built into MS-DOS with some network redirector.

Dired on MS-DOS uses the `ls-lisp` package where other platforms use the system `ls` command. Therefore, Dired on MS-DOS supports only some of the possible options you can mention in the `dired-listing-switches` variable. The options that work are `-A', `-a', `-c', `-i', `-r', `-S', `-s', `-t', and `-u'.

Subprocesses on Windows 95 and Windows NT

Subprocesses, both synchronous and asynchronous, work fine on both Windows 95 and Windows NT as long as you run only 32-bit Windows applications. However, when you run a DOS application in a subprocess, you may encounter problems or be unable to run the application at all; and if you run two DOS applications at the same time in two subprocesses, you may have to reboot your system.

Since the standard command interpreter (and most command line utilities) on Windows 95 are DOS applications, these problems are significant when using that system. But there's nothing we can do about them; only Microsoft can fix them.

If you run just one DOS application subprocess, the subprocess should work as expected as long as it is "well-behaved" and does not perform direct screen access or other unusual actions. If you have a CPU monitor application, your machine will appear to be 100% busy even when the DOS application is idle, but this is only an artefact of the way CPU monitors measure processor load.

You must terminate the DOS application before you start any other DOS application in a different subprocess. Emacs is unable to interrupt or terminate a DOS subprocess. The only way you can terminate such a subprocess is by giving it a command that tells its program to exit.

If you attempt to run two DOS applications at the same time in separate subprocesses, the second one that is started will be suspended until the first one finishes, even if either or both of them are asynchronous.

If you can go to the first subprocess, and tell it to exit, the second subprocess should continue normally. However, if the second subprocess is synchronous, Emacs itself will be hung until the first subprocess finishes. If it will not finish without user input, then you have no choice but to reboot if you are running on Windows 95. If you are running on Windows NT, you can use a process viewer application to kill the appropriate instance of ntvdm instead (this will terminate both DOS subprocesses).

If you have to reboot Windows 95 in this situation, do not use the `Shutdown` command on the `Start` menu; that usually hangs the system. Instead, type CTL-ALT-DEL and then choose `Shutdown`. That usually works, although it may take a few minutes to do its job.

Using the System Menu on Windows

Emacs normally turns off the Windows feature that tapping the ALT key invokes the Windows menu. The reason is that the ALT also serves as META in Emacs. When using Emacs, users often press the META key temporarily and then change their minds; if this has the effect of bringing up the Windows menu, it alters the meaning of subsequent commands. Many users find this frustrating.

You can reenable Windows's default handling of tapping the ALT key by setting `win32-pass-alt-to-system` to a non-`nil` value.

The GNU Manifesto

The GNU Manifesto which appears below was written by Richard Stallman at the beginning of the GNU project, to ask for participation and support. For the first few years, it was updated in minor ways to account for developments, but now it seems best to leave it unchanged as most people have seen it.

Since that time, we have learned about certain common misunderstandings that different wording could help avoid. Footnotes added in 1993 help clarify these points.

For up-to-date information about the available GNU software, please see the latest issue of the GNU's Bulletin. The list is much too long to include here.

What's GNU? Gnu's Not Unix!

GNU, which stands for Gnu's Not Unix, is the name for the complete Unix-compatible software system which I am writing so that I can give it away free to everyone who can use it.(5) Several other volunteers are helping me. Contributions of time, money, programs and equipment are greatly needed.

So far we have an Emacs text editor with Lisp for writing editor commands, a source level debugger, a yacc-compatible parser generator, a linker, and around 35 utilities. A shell (command interpreter) is nearly completed. A new portable optimizing C compiler has compiled itself and may be released this year. An initial kernel exists but many more features are needed to emulate Unix. When the kernel and compiler are finished, it will be possible to distribute a GNU system suitable for program development. We will use TeX as our text formatter, but an nroff is being worked on. We will use the free, portable X window system as well. After this we will add a portable Common Lisp, an Empire game, a spreadsheet, and hundreds of other things, plus on-line documentation. We hope to supply, eventually, everything useful that normally comes with a Unix system, and more.

GNU will be able to run Unix programs, but will not be identical to Unix. We will make all improvements that are convenient, based on our experience with other operating systems. In particular, we plan to have longer file names, file version numbers, a crashproof file system, file name completion perhaps, terminal-independent display support, and perhaps eventually a Lisp-based window system through which several Lisp programs and ordinary Unix programs can share a screen. Both C and Lisp will be available as system programming languages. We will try to support UUCP, MIT Chaosnet, and Internet protocols for communication.

GNU is aimed initially at machines in the 68000/16000 class with virtual memory, because they are the easiest machines to make it run on. The extra effort to make it run on smaller machines will be left to someone who wants to use it on them.

To avoid horrible confusion, please pronounce the `G' in the word `GNU' when it is the name of this project.

Why I Must Write GNU

I consider that the golden rule requires that if I like a program I must share it with other people who like it. Software sellers want to divide the users and conquer them, making each user agree not to share with others. I refuse to break solidarity with other users in this way. I cannot in good conscience sign a nondisclosure agreement or a software license agreement. For years I worked within the Artificial Intelligence Lab to resist such tendencies and other inhospitalities, but eventually they had gone too far: I could not remain in an institution where such things are done for me against my will.

So that I can continue to use computers without dishonor, I have decided to put together a sufficient body of free software so that I will be able to get along without any software that is not free. I have resigned from the AI lab to deny MIT any legal excuse to prevent me from giving GNU away.

Why GNU Will Be Compatible with Unix

Unix is not my ideal system, but it is not too bad. The essential features of Unix seem to be good ones, and I think I can fill in what Unix lacks without spoiling them. And a system compatible with Unix would be convenient for many other people to adopt.

How GNU Will Be Available

GNU is not in the public domain. Everyone will be permitted to modify and redistribute GNU, but no distributor will be allowed to restrict its further redistribution. That is to say, proprietary modifications will not be allowed. I want to make sure that all versions of GNU remain free.

Why Many Other Programmers Want to Help

I have found many other programmers who are excited about GNU and want to help.

Many programmers are unhappy about the commercialization of system software. It may enable them to make more money, but it requires them to feel in conflict with other programmers in general rather than feel as comrades. The fundamental act of friendship among programmers is the sharing of programs; marketing arrangements now typically used essentially forbid programmers to treat others as friends. The purchaser of software must choose between friendship and obeying the law. Naturally, many decide that friendship is more important. But those who believe in law often do not feel at ease with either choice. They become cynical and think that programming is just a way of making money.

By working on and using GNU rather than proprietary programs, we can be hospitable to everyone and obey the law. In addition, GNU serves as an example to inspire and a banner to rally others to join us in sharing. This can give us a feeling of harmony which is impossible if we use software that is not free. For about half the programmers I talk to, this is an important happiness that money cannot replace.

How You Can Contribute

I am asking computer manufacturers for donations of machines and money. I'm asking individuals for donations of programs and work.

One consequence you can expect if you donate machines is that GNU will run on them at an early date. The machines should be complete, ready to use systems, approved for use in a residential area, and not in need of sophisticated cooling or power.

I have found very many programmers eager to contribute part-time work for GNU. For most projects, such part-time distributed work would be very hard to coordinate; the independently-written parts would not work together. But for the particular task of replacing Unix, this problem is absent. A complete Unix system contains hundreds of utility programs, each of which is documented separately. Most interface specifications are fixed by Unix compatibility. If each contributor can write a compatible replacement for a single Unix utility, and make it work properly in place of the original on a Unix system, then these utilities will work right when put together. Even allowing for Murphy to create a few unexpected problems, assembling these components will be a feasible task. (The kernel will require closer communication and will be worked on by a small, tight group.)

If I get donations of money, I may be able to hire a few people full or part time. The salary won't be high by programmers' standards, but I'm looking for people for whom building community spirit is as important as making money. I view this as a way of enabling dedicated people to devote their full energies to working on GNU by sparing them the need to make a living in another way.

Why All Computer Users Will Benefit

Once GNU is written, everyone will be able to obtain good system software free, just like air.(6)

This means much more than just saving everyone the price of a Unix license. It means that much wasteful duplication of system programming effort will be avoided. This effort can go instead into advancing the state of the art.

Complete system sources will be available to everyone. As a result, a user who needs changes in the system will always be free to make them himself, or hire any available programmer or company to make them for him. Users will no longer be at the mercy of one programmer or company which owns the sources and is in sole position to make changes.

Schools will be able to provide a much more educational environment by encouraging all students to study and improve the system code. Harvard's computer lab used to have the policy that no program could be installed on the system if its sources were not on public display, and upheld it by actually refusing to install certain programs. I was very much inspired by this.

Finally, the overhead of considering who owns the system software and what one is or is not entitled to do with it will be lifted.

Arrangements to make people pay for using a program, including licensing of copies, always incur a tremendous cost to society through the cumbersome mechanisms necessary to figure out how much (that

is, which programs) a person must pay for. And only a police state can force everyone to obey them. Consider a space station where air must be manufactured at great cost: charging each breather per li air may be fair, but wearing the metered gas mask all day and all night is intolerable even if everyone can afford to pay the air bill. And the TV cameras everywhere to see if you ever take the mask off are outrageous. It's better to support the air plant with a head tax and chuck the masks.

Copying all or parts of a program is as natural to a programmer as breathing, and as productive. It ought to be as free.

Some Easily Rebutted Objections to GNU's Goals

> "Nobody will use it if it is free, because that means they can't rely on any support."
>
> "You have to charge for the program to pay for providing the support."

If people would rather pay for GNU plus service than get GNU free without service, a company to provide just service to people who have obtained GNU free ought to be profitable.(7)

We must distinguish between support in the form of real programming work and mere handholding. The former is something one cannot rely on from a software vendor. If your problem is not shared by enough people, the vendor will tell you to get lost.

If your business needs to be able to rely on support, the only way is to have all the necessary sources and tools. Then you can hire any available person to fix your problem; you are not at the mercy of any individual. With Unix, the price of sources puts this out of consideration for most businesses. With GNU this will be easy. It is still possible for there to be no available competent person, but this problem cannot be blamed on distribution arrangements. GNU does not eliminate all the world's problems, only some of them.

Meanwhile, the users who know nothing about computers need handholding: doing things for them which they could easily do themselves but don't know how.

Such services could be provided by companies that sell just hand-holding and repair service. If it is true that users would rather spend money and get a product with service, they will also be willing to buy the service having got the product free. The service companies will compete in quality and price; users will not be tied to any particular one. Meanwhile, those of us who don't need the service should be able to use the program without paying for the service.

> "You cannot reach many people without advertising, and you must charge for the program to support that."
>
> "It's no use advertising a program people can get free."

There are various forms of free or very cheap publicity that can be used to inform numbers of computer users about something like GNU. But it may be true that one can reach more microcomputer users with advertising. If this is really so, a business which advertises the service of copying and mailing GNU for a fee ought to be successful enough to pay for its advertising and more. This way, only the users who benefit from the advertising pay for it.

On the other hand, if many people get GNU from their friends, and such companies don't succeed, th will show that advertising was not really necessary to spread GNU. Why is it that free market advoca don't want to let the free market decide this?(8)

"My company needs a proprietary operating system to get a competitive edge."

GNU will remove operating system software from the realm of competition. You will not be able to get an edge in this area, but neither will your competitors be able to get an edge over you. You and they will compete in other areas, while benefiting mutually in this one. If your business is selling an operating system, you will not like GNU, but that's tough on you. If your business is something else, GNU can save you from being pushed into the expensive business of selling operating systems.

I would like to see GNU development supported by gifts from many manufacturers and users, reducing the cost to each.(9)

"Don't programmers deserve a reward for their creativity?"

If anything deserves a reward, it is social contribution. Creativity can be a social contribution, but only in so far as society is free to use the results. If programmers deserve to be rewarded for creating innovative programs, by the same token they deserve to be punished if they restrict the use of these programs.

"Shouldn't a programmer be able to ask for a reward for his creativity?"

There is nothing wrong with wanting pay for work, or seeking to maximize one's income, as long as one does not use means that are destructive. But the means customary in the field of software today are based on destruction.

Extracting money from users of a program by restricting their use of it is destructive because the restrictions reduce the amount and the ways that the program can be used. This reduces the amount of wealth that humanity derives from the program. When there is a deliberate choice to restrict, the harmful consequences are deliberate destruction.

The reason a good citizen does not use such destructive means to become wealthier is that, if everyone did so, we would all become poorer from the mutual destructiveness. This is Kantian ethics; or, the Golden Rule. Since I do not like the consequences that result if everyone hoards information, I am required to consider it wrong for one to do so. Specifically, the desire to be rewarded for one's creativity does not justify depriving the world in general of all or part of that creativity.

"Won't programmers starve?"

I could answer that nobody is forced to be a programmer. Most of us cannot manage to get any money for standing on the street and making faces. But we are not, as a result, condemned to spend our lives standing on the street making faces, and starving. We do something else.

But that is the wrong answer because it accepts the questioner's implicit assumption: that without ownership of software, programmers cannot possibly be paid a cent. Supposedly it is all or nothing.

The real reason programmers will not starve is that it will still be possible for them to get paid for programming; just not paid as much as now.

Restricting copying is not the only basis for business in software. It is the most common basis because it brings in the most money. If it were prohibited, or rejected by the customer, software business would

move to other bases of organization which are now used less often. There are always numerous ways to organize any kind of business.

Probably programming will not be as lucrative on the new basis as it is now. But that is not an argument against the change. It is not considered an injustice that sales clerks make the salaries that they now do. If programmers made the same, that would not be an injustice either. (In practice they would still make considerably more than that.)

"Don't people have a right to control how their creativity is used?"

"Control over the use of one's ideas" really constitutes control over other people's lives; and it is usually used to make their lives more difficult.

People who have studied the issue of intellectual property rights carefully (such as lawyers) say that there is no intrinsic right to intellectual property. The kinds of supposed intellectual property rights that the government recognizes were created by specific acts of legislation for specific purposes.

For example, the patent system was established to encourage inventors to disclose the details of their inventions. Its purpose was to help society rather than to help inventors. At the time, the life span of 17 years for a patent was short compared with the rate of advance of the state of the art. Since patents are an issue only among manufacturers, for whom the cost and effort of a license agreement are small compared with setting up production, the patents often do not do much harm. They do not obstruct most individuals who use patented products.

The idea of copyright did not exist in ancient times, when authors frequently copied other authors at length in works of non-fiction. This practice was useful, and is the only way many authors' works have survived even in part. The copyright system was created expressly for the purpose of encouraging authorship. In the domain for which it was invented--books, which could be copied economically only on a printing press--it did little harm, and did not obstruct most of the individuals who read the books.

All intellectual property rights are just licenses granted by society because it was thought, rightly or wrongly, that society as a whole would benefit by granting them. But in any particular situation, we have to ask: are we really better off granting such license? What kind of act are we licensing a person to do?

The case of programs today is very different from that of books a hundred years ago. The fact that the easiest way to copy a program is from one neighbor to another, the fact that a program has both source code and object code which are distinct, and the fact that a program is used rather than read and enjoyed, combine to create a situation in which a person who enforces a copyright is harming society as a whole both materially and spiritually; in which a person should not do so regardless of whether the law enables him to.

"Competition makes things get done better."

The paradigm of competition is a race: by rewarding the winner, we encourage everyone to run faster. When capitalism really works this way, it does a good job; but its defenders are wrong in assuming it always works this way. If the runners forget why the reward is offered and become intent on winning, no matter how, they may find other strategies--such as, attacking other runners. If the runners get into a fist fight, they will all finish late.

Proprietary and secret software is the moral equivalent of runners in a fist fight. Sad to say, the only

referee we've got does not seem to object to fights; he just regulates them ("For every ten yards you r
you can fire one shot"). He really ought to break them up, and penalize runners for even trying to fig

> "Won't everyone stop programming without a monetary incentive?"

Actually, many people will program with absolutely no monetary incentive. Programming has an irresistible fascination for some people, usually the people who are best at it. There is no shortage of professional musicians who keep at it even though they have no hope of making a living that way.

But really this question, though commonly asked, is not appropriate to the situation. Pay for programmers will not disappear, only become less. So the right question is, will anyone program with a reduced monetary incentive? My experience shows that they will.

For more than ten years, many of the world's best programmers worked at the Artificial Intelligence Lab for far less money than they could have had anywhere else. They got many kinds of non-monetary rewards: fame and appreciation, for example. And creativity is also fun, a reward in itself.

Then most of them left when offered a chance to do the same interesting work for a lot of money.

What the facts show is that people will program for reasons other than riches; but if given a chance to make a lot of money as well, they will come to expect and demand it. Low-paying organizations do poorly in competition with high-paying ones, but they do not have to do badly if the high-paying ones are banned.

> "We need the programmers desperately. If they demand that we stop helping our neighbors, we have to obey."

You're never so desperate that you have to obey this sort of demand. Remember: millions for defense, but not a cent for tribute!

> "Programmers need to make a living somehow."

In the short run, this is true. However, there are plenty of ways that programmers could make a living without selling the right to use a program. This way is customary now because it brings programmers and businessmen the most money, not because it is the only way to make a living. It is easy to find other ways if you want to find them. Here are a number of examples.

A manufacturer introducing a new computer will pay for the porting of operating systems onto the new hardware.

The sale of teaching, hand-holding and maintenance services could also employ programmers.

People with new ideas could distribute programs as freeware, asking for donations from satisfied users, or selling hand-holding services. I have met people who are already working this way successfully.

Users with related needs can form users' groups, and pay dues. A group would contract with programming companies to write programs that the group's members would like to use.

All sorts of development can be funded with a Software Tax:

> Suppose everyone who buys a computer has to pay x percent of the price as a software tax. The government gives this to an agency like the NSF to spend on software development.

But if the computer buyer makes a donation to software development himself, he can take a credit against the tax. He can donate to the project of his own choosing--often, chosen because he hopes to use the results when it is done. He can take a credit for any amount of donation up to the total tax he had to pay.

The total tax rate could be decided by a vote of the payers of the tax, weighted according to the amount they will be taxed on.

The consequences:

- The computer-using community supports software development.
- This community decides what level of support is needed.
- Users who care which projects their share is spent on can choose this for themselves.

In the long run, making programs free is a step toward the post-scarcity world, where nobody will have to work very hard just to make a living. People will be free to devote themselves to activities that are fun, such as programming, after spending the necessary ten hours a week on required tasks such as legislation, family counseling, robot repair and asteroid prospecting. There will be no need to be able to make a living from programming.

We have already greatly reduced the amount of work that the whole society must do for its actual productivity, but only a little of this has translated itself into leisure for workers because much nonproductive activity is required to accompany productive activity. The main causes of this are bureaucracy and isometric struggles against competition. Free software will greatly reduce these drains in the area of software production. We must do this, in order for technical gains in productivity to translate into less work for us.

Go to the previous, next section.

Go to the previous, next section.

Glossary

Abbrev

An abbrev is a text string which expands into a different text string when present in the buffer. For example, you might define a few letters as an abbrev for a long phrase that you want to insert frequently. See section Abbrevs.

Aborting

Aborting means getting out of a recursive edit (q.v.). The commands C-] and M-x top-level are used for this. See section Quitting and Aborting.

Alt

Alt is the name of a modifier bit which a keyboard input character may have. To make a character Alt, type it while holding down the ALT key. Such characters are given names that start with Alt- (usually written A- for short). (Note that many terminals have a key labeled ALT which is really a META key.) See section Kinds of User Input.

Auto Fill Mode

Auto Fill mode is a minor mode in which text that you insert is automatically broken into lines of fixed width. See section Filling Text.

Auto Saving

Auto saving is the practice of saving the contents of an Emacs buffer in a specially-named file, so that the information will not be lost if the buffer is lost due to a system error or user error. See section Auto-Saving: Protection Against Disasters.

Backup File

A backup file records the contents that a file had before the current editing session. Emacs makes backup files automatically to help you track down or cancel changes you later regret making. See section Backup Files.

Balance Parentheses

Emacs can balance parentheses manually or automatically. Manual balancing is done by the commands to move over balanced expressions (see section Lists and Sexps). Automatic balancing is done by blinking or highlighting the parenthesis that matches one just inserted (see section Automatic Display Of Matching Parentheses).

Bind

To bind a key sequence means to give it a binding (q.v.). See section Changing Key Bindings Interactively.

Binding

A key sequence gets its meaning in Emacs by having a binding, which is a command (q.v.), a Lisp function that is run when the user types that sequence. See section Keys and Commands.

Customization often involves rebinding a character to a different command function. The bind of all key sequences are recorded in the keymaps (q.v.). See section Keymaps.

Blank Lines

Blank lines are lines that contain only whitespace. Emacs has several commands for operating on the blank lines in the buffer.

Buffer

The buffer is the basic editing unit; one buffer corresponds to one text being edited. You can have several buffers, but at any time you are editing only one, the `selected' buffer, though several can be visible when you are using multiple windows (q.v.). Most buffers are visiting (q.v.) some file. See section Using Multiple Buffers.

Buffer Selection History

Emacs keeps a buffer selection history which records how recently each Emacs buffer has been selected. This is used for choosing a buffer to select. See section Using Multiple Buffers.

Button Down Event

A button down event is the kind of input event generated right away when you press a mouse button. See section Rebinding Mouse Buttons.

C-

C- in the name of a character is an abbreviation for Control. See section Kinds of User Input.

C-M-

C-M- in the name of a character is an abbreviation for Control-Meta. See section Kinds of User Input.

Case Conversion

Case conversion means changing text from upper case to lower case or vice versa. See section Case Conversion Commands, for the commands for case conversion.

Character

Characters form the contents of an Emacs buffer; see section Character Set for Text. Also, key sequences (q.v.) are usually made up of characters (though they may include other input events as well). See section Kinds of User Input.

Click Event

A click event is the kind of input event generated when you press a mouse button and release it without moving the mouse. See section Rebinding Mouse Buttons.

Command

A command is a Lisp function specially defined to be able to serve as a key binding in Emacs. When you type a key sequence (q.v.), its binding (q.v.) is looked up in the relevant keymaps (q.v.) to find the command to run. See section Keys and Commands.

Command Name

A command name is the name of a Lisp symbol which is a command (see section Keys and Commands). You can invoke any command by its name using M-x (see section Running

Commands by Name).

Comment

A comment is text in a program which is intended only for humans reading the program, and which is marked specially so that it will be ignored when the program is loaded or compiled. Emacs offers special commands for creating, aligning and killing comments. See section Manipulating Comments.

Compilation

Compilation is the process of creating an executable program from source code. Emacs has commands for compiling files of Emacs Lisp code (see section 'Byte Compilation' in the Emacs Lisp Reference Manual) and programs in C and other languages (see section Running Compilations under Emacs).

Complete Key

A complete key is a key sequence which fully specifies one action to be performed by Emacs. For example, X and C-f and C-x m are complete keys. Complete keys derive their meanings from being bound (q.v.) to commands (q.v.). Thus, X is conventionally bound to a command to insert `X' in the buffer; C-x m is conventionally bound to a command to begin composing a mail message. See section Keys.

Completion

Completion is what Emacs does when it automatically fills out an abbreviation for a name into the entire name. Completion is done for minibuffer (q.v.) arguments when the set of possible valid inputs is known; for example, on command names, buffer names, and file names. Completion occurs when TAB, SPC or RET is typed. See section Completion.

Continuation Line

When a line of text is longer than the width of the window, it takes up more than one screen line when displayed. We say that the text line is continued, and all screen lines used for it after the first are called continuation lines. See section Basic Editing Commands.

Control Character

ASCII characters with octal codes 0 through 037, and also code 0177, do not have graphic images assigned to them. These are the Control characters. To type a Control character, hold down the CTRL key and type the corresponding non-Control character. RET, TAB, ESC, LFD and DEL are all control characters. See section Kinds of User Input.

When you are using the X Window System, every non-control character has a corresponding control character variant.

Copyleft

A copyleft is a notice giving the public legal permission to redistribute a program or other work of art. Copylefts are used by left-wing programmers to give people equal rights, just as copyrights are used by right-wing programmers to gain power over other people.

The particular form of copyleft used by the GNU project is called the GNU General Public License. See section GNU GENERAL PUBLIC LICENSE.

Current Buffer

The current buffer in Emacs is the Emacs buffer on which most editing commands operate. You can select any Emacs buffer as the current one. See section Using Multiple Buffers.

Current Line

The line point is on (see section Point).

Current Paragraph

The paragraph that point is in. If point is between paragraphs, the current paragraph is the one that follows point. See section Paragraphs.

Current Defun

The defun (q.v.) that point is in. If point is between defuns, the current defun is the one that follows point. See section Defuns.

Cursor

The cursor is the rectangle on the screen which indicates the position called point (q.v.) at which insertion and deletion takes place. The cursor is on or under the character that follows point. Often people speak of `the cursor' when, strictly speaking, they mean `point'. See section Basic Editing Commands.

Customization

Customization is making minor changes in the way Emacs works. It is often done by setting variables (see section Variables) or by rebinding key sequences (see section Keymaps).

Default Argument

The default for an argument is the value that will be assumed if you do not specify one. When the minibuffer is used to read an argument, the default argument is used if you just type RET. See section The Minibuffer.

Default Directory

When you specify a file name that does not start with `/' or `~', it is interpreted relative to the current buffer's default directory. See section Minibuffers for File Names.

Defun

A defun is a list at the top level of parenthesis or bracket structure in a program. It is so named because most such lists in Lisp programs are calls to the Lisp function `defun`. See section Defuns.

DEL

DEL is a character that runs the command to delete one character of text. See section Basic Editing Commands.

Deletion

Deletion means erasing text without copying it into the kill ring (q.v.). The alternative is killing (q.v.). See section Deletion and Killing.

Deletion of Files

Deleting a file means erasing it from the file system. See section Miscellaneous File Operations.

Deletion of Messages

Deleting a message means flagging it to be eliminated from your mail file. Until you expunge (q.v.) the Rmail file, you can still undelete the messages you have deleted. See section Deleting Messages.

Deletion of Windows

Deleting a window means eliminating it from the screen. Other windows expand to use up the space. The deleted window can never come back, but no actual text is thereby lost. See section Multiple Windows.

Directory

File directories are named collections in the file system, within which you can place individual files or subdirectories. See section File Directories.

Dired

Dired is the Emacs facility that displays the contents of a file directory and allows you to "edit the directory", performing operations on the files in the directory. See section Dired, the Directory Editor.

Disabled Command

A disabled command is one that you may not run without special confirmation. The usual reason for disabling a command is that it is confusing for beginning users. See section Disabling Commands.

Down Event

Short for `button down event'.

Drag Event

A drag event is the kind of input event generated when you press a mouse button, move the mouse, and then release the button. See section Rebinding Mouse Buttons.

Dribble File

A file into which Emacs writes all the characters that the user types on the keyboard. Dribble files are used to make a record for debugging Emacs bugs. Emacs does not make a dribble file unless you tell it to. See section Reporting Bugs.

Echo Area

The echo area is the bottom line of the screen, used for echoing the arguments to commands, for asking questions, and printing brief messages (including error messages). The messages are stored in the buffer `*Messages*' so you can review them later. See section The Echo Area.

Echoing

Echoing is acknowledging the receipt of commands by displaying them (in the echo area). Emacs never echoes single-character key sequences; longer key sequences echo only if you pause while typing them.

Error

An error occurs when an Emacs command cannot execute in the current circumstances. When an error occurs, execution of the command stops (unless the command has been programmed to do

otherwise) and Emacs reports the error by printing an error message (q.v.). Type-ahead is discarded. Then Emacs is ready to read another editing command.

Error Message

An error message is a single line of output displayed by Emacs when the user asks for something impossible to do (such as, killing text forward when point is at the end of the buffer). They appear in the echo area, accompanied by a beep.

ESC

ESC is a character used as a prefix for typing Meta characters on keyboards lacking a META key. Unlike the META key (which, like the SHIFT key, is held down while another character is typed), the ESC key is pressed once and applies to the next character typed.

Expunging

Expunging an Rmail file or Dired buffer means really discarding the messages or files you have previously flagged for deletion.

File Name

A file name is a name that refers to a file. File names may be relative or absolute; the meaning of a relative file name depends on the current directory, but an absolute file name refers to the same file regardless of which directory is current. On GNU and Unix systems, an absolute file name starts with a slash (the root directory) or with `~/' or `~user/' (a home directory).

Some people use the term "pathname" for file names, but we do not; we use the word "path" only in the term "search path" (q.v.).

File Name Component

A file name component names a file directly within a particular directory. On GNU and Unix systems, a file name is a sequence of file name components, separated by slashes. For example, `foo/bar' is a file name containing two components, `foo' and `bar'; it refers to the file named `bar' in the directory named `foo' in the current directory.

Fill Prefix

The fill prefix is a string that should be expected at the beginning of each line when filling is done. It is not regarded as part of the text to be filled. See section Filling Text.

Filling

Filling text means shifting text between consecutive lines so that all the lines are approximately the same length. See section Filling Text.

Formatted Text

Formatted text is text that displays with formatting information while you edit. Formatting information includes fonts, colors, and specified margins. See section Editing Formatted Text.

Frame

A frame is a rectangular cluster of Emacs windows. Emacs starts out with one frame, but you can create more. You can subdivide each frame into Emacs windows (q.v.). When you are using X windows, all the frames can be visible at the same time. See section Frames and X Windows.

Function Key

A function key is a key on the keyboard that sends input but does not correspond to any chara
See section Rebinding Function Keys.

Global

Global means `independent of the current environment; in effect throughout Emacs'. It is the opposite of local (q.v.). Particular examples of the use of `global' appear below.

Global Abbrev

A global definition of an abbrev (q.v.) is effective in all major modes that do not have local (q.v.) definitions for the same abbrev. See section Abbrevs.

Global Keymap

The global keymap (q.v.) contains key bindings that are in effect except when overridden by local key bindings in a major mode's local keymap (q.v.). See section Keymaps.

Global Mark Ring

The global mark ring records the series of buffers you have recently set a mark in. In many cases you can use this to backtrack through buffers you have been editing in, or in which you have found tags. See section The Global Mark Ring.

Global Substitution

Global substitution means replacing each occurrence of one string by another string through a large amount of text. See section Replacement Commands.

Global Variable

The global value of a variable (q.v.) takes effect in all buffers that do not have their own local (q.v.) values for the variable. See section Variables.

Graphic Character

Graphic characters are those assigned pictorial images rather than just names. All the non-Meta (q.v.) characters except for the Control (q.v.) characters are graphic characters. These include letters, digits, punctuation, and spaces; they do not include RET or ESC. In Emacs, typing a graphic character inserts that character (in ordinary editing modes). See section Basic Editing Commands.

Highlighting

Highlighting text means displaying it with a different foreground and/or background color to make it stand out from the rest of the text in the buffer.

Hardcopy

Hardcopy means printed output. Emacs has commands for making printed listings of text in Emacs buffers. See section Hardcopy Output.

HELP

You can type HELP at any time to ask what options you have, or to ask what any command does. The character HELP is really C-h. See section Help.

Hyper

Hyper is the name of a modifier bit which a keyboard input character may have. To make a character Hyper, type it while holding down the HYPER key. Such characters are given names that

start with Hyper- (usually written H- for short). See section Kinds of User Input.

Inbox

An inbox is a file in which mail is delivered by the operating system. Rmail transfers mail from inboxes to Rmail files (q.v.) in which the mail is then stored permanently or until explicitly deleted. See section Rmail Files and Inboxes.

Indentation

Indentation means blank space at the beginning of a line. Most programming languages have conventions for using indentation to illuminate the structure of the program, and Emacs has special commands to adjust indentation. See section Indentation.

Indirect Buffer

An indirect buffer is a buffer that shares the text of another buffer, called its base buffer. See section Indirect Buffers.

Input Event

An input event represents, within Emacs, one action taken by the user on the terminal. Input events include typing characters, typing function keys, pressing or releasing mouse buttons, and switching between Emacs frames. See section Kinds of User Input.

Insertion

Insertion means copying text into the buffer, either from the keyboard or from some other place in Emacs.

Justification

Justification means adding extra spaces to lines of text to make them come exactly to a specified width. See section Filling Text.

Keyboard Macro

Keyboard macros are a way of defining new Emacs commands from sequences of existing ones, with no need to write a Lisp program. See section Keyboard Macros.

Key Sequence

A key sequence (key, for short) is a sequence of input events (q.v.) that are meaningful as a single unit. If the key sequence is enough to specify one action, it is a complete key (q.v.); if it is not enough, it is a prefix key (q.v.). See section Keys.

Keymap

The keymap is the data structure that records the bindings (q.v.) of key sequences to the commands that they run. For example, the global keymap binds the character C-n to the command function `next-line`. See section Keymaps.

Keyboard Translation Table

The keyboard translation table is an array that translates the character codes that come from the terminal into the character codes that make up key sequences. See section Keyboard Translations.

Kill Ring

The kill ring is where all text you have killed recently is saved. You can reinsert any of the killed text still in the ring; this is called yanking (q.v.). See section Yanking.

Killing

Killing means erasing text and saving it on the kill ring so it can be yanked (q.v.) later. Some other systems call this "cutting". Most Emacs commands to erase text do killing, as opposed to deletion (q.v.). See section Deletion and Killing.

Killing Jobs

Killing a job (such as, an invocation of Emacs) means making it cease to exist. Any data within it, if not saved in a file, is lost. See section Exiting Emacs.

List

A list is, approximately, a text string beginning with an open parenthesis and ending with the matching close parenthesis. In C mode and other non-Lisp modes, groupings surrounded by other kinds of matched delimiters appropriate to the language, such as braces, are also considered lists. Emacs has special commands for many operations on lists. See section Lists and Sexps.

Local

Local means `in effect only in a particular context'; the relevant kind of context is a particular function execution, a particular buffer, or a particular major mode. It is the opposite of `global' (q.v.). Specific uses of `local' in Emacs terminology appear below.

Local Abbrev

A local abbrev definition is effective only if a particular major mode is selected. In that major mode, it overrides any global definition for the same abbrev. See section Abbrevs.

Local Keymap

A local keymap is used in a particular major mode; the key bindings (q.v.) in the current local keymap override global bindings of the same key sequences. See section Keymaps.

Local Variable

A local value of a variable (q.v.) applies to only one buffer. See section Local Variables.

M-

M- in the name of a character is an abbreviation for META, one of the modifier keys that can accompany any character. See section Kinds of User Input.

M-C-

M-C- in the name of a character is an abbreviation for Control-Meta; it means the same thing as C-M-. If your terminal lacks a real META key, you type a Control-Meta character by typing ESC and then typing the corresponding Control character. See section Kinds of User Input.

M-x

M-x is the key sequence which is used to call an Emacs command by name. This is how you run commands that are not bound to key sequences. See section Running Commands by Name.

Mail

Mail means messages sent from one user to another through the computer system, to be read at the recipient's convenience. Emacs has commands for composing and sending mail, and for reading and editing the mail you have received. See section Sending Mail. See section Reading Mail with Rmail, for how to read mail.

Major Mode

The Emacs major modes are a mutually exclusive set of options, each of which configures Emacs for editing a certain sort of text. Ideally, each programming language has its own major mode. See section Major Modes.

Mark

The mark points to a position in the text. It specifies one end of the region (q.v.), point being the other end. Many commands operate on all the text from point to the mark. Each buffer has its own mark. See section The Mark and the Region.

Mark Ring

The mark ring is used to hold several recent previous locations of the mark, just in case you want to move back to them. Each buffer has its own mark ring; in addition, there is a single global mark ring (q.v.). See section The Mark Ring.

Menu Bar

The menu bar is the line at the top of an Emacs frame. It contains words you can click on with the mouse to bring up menus. The menu bar feature is supported only with X. See section Menu Bars.

Message

See `mail'.

Meta

Meta is the name of a modifier bit which a command character may have. It is present in a character if the character is typed with the META key held down. Such characters are given names that start with Meta- (usually written M- for short). For example, M-< is typed by holding down META and at the same time typing < (which itself is done, on most terminals, by holding down SHIFT and typing ,). See section Kinds of User Input.

Meta Character

A Meta character is one whose character code includes the Meta bit.

Minibuffer

The minibuffer is the window that appears when necessary inside the echo area (q.v.), used for reading arguments to commands. See section The Minibuffer.

Minibuffer History

The minibuffer history records the text you have specified in the past for minibuffer arguments, so you can conveniently use the same text again. See section Minibuffer History.

Minor Mode

A minor mode is an optional feature of Emacs which can be switched on or off independently of all other features. Each minor mode has a command to turn it on or off. See section Minor Modes.

Minor Mode Keymap

A keymap that belongs to a minor mode and is active when that mode is enabled. Minor mode keymaps take precedence over the buffer's local keymap, just as the local keymap takes precedence over the global keymap. See section Keymaps.

Mode Line

The mode line is the line at the bottom of each window (q.v.), giving status information on the buffer displayed in that window. See section The Mode Line.

Modified Buffer

A buffer (q.v.) is modified if its text has been changed since the last time the buffer was saved (or since when it was created, if it has never been saved). See section Saving Files.

Moving Text

Moving text means erasing it from one place and inserting it in another. The usual way to move text by killing (q.v.) and then yanking (q.v.). See section Deletion and Killing.

Named Mark

A named mark is a register (q.v.) in its role of recording a location in text so that you can move point to that location. See section Registers.

Narrowing

Narrowing means creating a restriction (q.v.) that limits editing in the current buffer to only a part of the text in the buffer. Text outside that part is inaccessible to the user until the boundaries are widened again, but it is still there, and saving the file saves it all. See section Narrowing.

Newline

Linefeed characters in the buffer terminate lines of text and are therefore also called newlines. See section Character Set for Text.

Numeric Argument

A numeric argument is a number, specified before a command, to change the effect of the command. Often the numeric argument serves as a repeat count. See section Numeric Arguments.

Overwrite Mode

Overwrite mode is a minor mode. When it is enabled, ordinary text characters replace the existing text after point rather than pushing it to the right. See section Minor Modes.

Page

A page is a unit of text, delimited by formfeed characters (ASCII control-L, code 014) coming at the beginning of a line. Some Emacs commands are provided for moving over and operating on pages. See section Pages.

Paragraph

Paragraphs are the medium-size unit of English text. There are special Emacs commands for moving over and operating on paragraphs. See section Paragraphs.

Parsing

We say that certain Emacs commands parse words or expressions in the text being edited. Really, all they know how to do is find the other end of a word or expression. See section The Syntax Table.

Point

Point is the place in the buffer at which insertion and deletion occur. Point is considered to be between two characters, not at one character. The terminal's cursor (q.v.) indicates the location of

point. See section Basic Editing Commands.

Prefix Argument

See `numeric argument'.

Prefix Key

A prefix key is a key sequence (q.v.) whose sole function is to introduce a set of longer key sequences. C-x is an example of prefix key; any two-character sequence starting with C-x is therefore a legitimate key sequence. See section Keys.

Primary Rmail File

Your primary Rmail file is the file named `RMAIL' in your home directory. That's where Rmail stores your incoming mail, unless you specify a different file name. See section Reading Mail with Rmail.

Primary Selection

The primary selection is one particular X selection (q.v.); it is the selection that most X applications use for transferring text to and from other applications.

The Emacs kill commands set the primary selection and the yank command uses the primary selection when appropriate. See section Deletion and Killing.

Prompt

A prompt is text printed to ask the user for input. Displaying a prompt is called prompting. Emacs prompts always appear in the echo area (q.v.). One kind of prompting happens when the minibuffer is used to read an argument (see section The Minibuffer); the echoing which happens when you pause in the middle of typing a multi-character key sequence is also a kind of prompting (see section The Echo Area).

Quitting

Quitting means canceling a partially typed command or a running command, using C-g. See section Quitting and Aborting.

Quoting

Quoting means depriving a character of its usual special significance. In Emacs this is usually done with C-q. What constitutes special significance depends on the context and on convention. For example, an "ordinary" character as an Emacs command inserts itself; so in this context, a special character is any character that does not normally insert itself (such as DEL, for example), and quoting it makes it insert itself as if it were not special. Not all contexts allow quoting. See section Basic Editing Commands.

Read-Only Buffer

A read-only buffer is one whose text you are not allowed to change. Normally Emacs makes buffers read-only when they contain text which has a special significance to Emacs; for example, Dired buffers. Visiting a file that is write protected also makes a read-only buffer. See section Using Multiple Buffers.

Rectangle

A rectangle consists of the text in a given range of columns on a given range of lines. Normally

you specify a rectangle by putting point at one corner and putting the mark at the opposite cor
See section Rectangles.

Recursive Editing Level

A recursive editing level is a state in which part of the execution of a command involves asking the user to edit some text. This text may or may not be the same as the text to which the command was applied. The mode line indicates recursive editing levels with square brackets (`[' and `]'). See section Recursive Editing Levels.

Redisplay

Redisplay is the process of correcting the image on the screen to correspond to changes that have been made in the text being edited. See section The Organization of the Screen.

Regexp

See `regular expression'.

Region

The region is the text between point (q.v.) and the mark (q.v.). Many commands operate on the text of the region. See section The Mark and the Region.

Registers

Registers are named slots in which text or buffer positions or rectangles can be saved for later use. See section Registers.

Regular Expression

A regular expression is a pattern that can match various text strings; for example, `l[0-9]+' matches `l' followed by one or more digits. See section Syntax of Regular Expressions.

Repeat Count

See `numeric argument'.

Replacement

See `global substitution'.

Restriction

A buffer's restriction is the amount of text, at the beginning or the end of the buffer, that is temporarily inaccessible. Giving a buffer a nonzero amount of restriction is called narrowing (q.v.). See section Narrowing.

RET

RET is a character that in Emacs runs the command to insert a newline into the text. It is also used to terminate most arguments read in the minibuffer (q.v.). See section Kinds of User Input.

Rmail File

An Rmail file is a file containing text in a special format used by Rmail for storing mail. See section Reading Mail with Rmail.

Saving

Saving a buffer means copying its text into the file that was visited (q.v.) in that buffer. This is the way text in files actually gets changed by your Emacs editing. See section Saving Files.

Scroll Bar

A scroll bar is a tall thin hollow box that appears at the side of a window. You can use mouse commands in the scroll bar to scroll the window. The scroll bar feature is supported only with X. See section Scroll Bars.

Scrolling

Scrolling means shifting the text in the Emacs window so as to see a different part of the buffer. See section Controlling the Display.

Searching

Searching means moving point to the next occurrence of a specified string or the next match for a specified regular expression. See section Searching and Replacement.

Search Path

A search path is a list of directory names, to be used for searching for files for certain purposes. For example, the variable `load-path` holds a search path for finding Lisp library files. See section Libraries of Lisp Code for Emacs.

Secondary Selection

The secondary selection is one particular X selection; some X applications can use it for transferring text to and from other applications. Emacs has special mouse commands for transferring text using the secondary selection. See section Secondary Selection.

Selecting

Selecting a buffer means making it the current (q.v.) buffer. See section Using Multiple Buffers.

Selection

The X window system allows an application program to specify named selections whose values are text. A program can also read the selections that other programs have set up. This is the principal way of transferring text between window applications. Emacs has commands to work with the primary (q.v.) selection and the secondary (q.v.) selection.

Self-Documentation

Self-documentation is the feature of Emacs which can tell you what any command does, or give you a list of all commands related to a topic you specify. You ask for self-documentation with the help character, C-h. See section Help.

Sentences

Emacs has commands for moving by or killing by sentences. See section Sentences.

Sexp

A sexp (short for `s-expression') is the basic syntactic unit of Lisp in its textual form: either a list, or Lisp atom. Many Emacs commands operate on sexps. The term `sexp' is generalized to languages other than Lisp, to mean a syntactically recognizable expression. See section Lists and Sexps.

Simultaneous Editing

Simultaneous editing means two users modifying the same file at once. Simultaneous editing if not detected can cause one user to lose his work. Emacs detects all cases of simultaneous editing and

warns one of the users to investigate. See section Protection against Simultaneous Editing.

String

A string is a kind of Lisp data object which contains a sequence of characters. Many Emacs variables are intended to have strings as values. The Lisp syntax for a string consists of the characters in the string with a `"' before and another `"' after. A `"' that is part of the string must be written as `\"' and a `\' that is part of the string must be written as `\\'. All other characters, including newline, can be included just by writing them inside the string; however, backslash sequences as in C, such as `\n' for newline or `\241' using an octal character code, are allowed as well.

String Substitution

See `global substitution'.

Syntax Table

The syntax table tells Emacs which characters are part of a word, which characters balance each other like parentheses, etc. See section The Syntax Table.

Super

Super is the name of a modifier bit which a keyboard input character may have. To make a character Super, type it while holding down the SUPER key. Such characters are given names that start with Super- (usually written s- for short). See section Kinds of User Input.

Tags Table

A tags table is a file that serves as an index to the function definitions in one or more other files. See section Tags Tables.

Termscript File

A termscript file contains a record of all characters sent by Emacs to the terminal. It is used for tracking down bugs in Emacs redisplay. Emacs does not make a termscript file unless you tell it to. See section Reporting Bugs.

Text

Two meanings (see section Commands for Human Languages):

> Data consisting of a sequence of characters, as opposed to binary numbers, images, graphics commands, executable programs, and the like. The contents of an Emacs buffer are always text in this sense.
>
> Data consisting of written human language, as opposed to programs, or following the stylistic conventions of human language.

Top Level

Top level is the normal state of Emacs, in which you are editing the text of the file you have visited. You are at top level whenever you are not in a recursive editing level (q.v.) or the minibuffer (q.v.), and not in the middle of a command. You can get back to top level by aborting (q.v.) and quitting (q.v.). See section Quitting and Aborting.

Transposition

Transposing two units of text means putting each one into the place formerly occupied by the other. There are Emacs commands to transpose two adjacent characters, words, sexps (q.v.) or

lines (see section Transposing Text).

Truncation

Truncating text lines in the display means leaving out any text on a line that does not fit within the right margin of the window displaying it. See also `continuation line'. See section Basic Editing Commands.

Undoing

Undoing means making your previous editing go in reverse, bringing back the text that existed earlier in the editing session. See section Undoing Changes.

User Option

A user option is a variable (q.v.) that exists so that you can customize Emacs by setting it to a new value. See section Variables.

Variable

A variable is an object in Lisp that can store an arbitrary value. Emacs uses some variables for internal purposes, and has others (known as `user options' (q.v.)) just so that you can set their values to control the behavior of Emacs. The variables used in Emacs that you are likely to be interested in are listed in the Variables Index in this manual. See section Variables, for information on variables.

Version Control

Version control systems keep track of multiple versions of a source file. They provide a more powerful alternative to keeping backup files (q.v.). See section Version Control.

Visiting

Visiting a file means loading its contents into a buffer (q.v.) where they can be edited. See section Visiting Files.

Whitespace

Whitespace is any run of consecutive formatting characters (space, tab, newline, and backspace).

Widening

Widening is removing any restriction (q.v.) on the current buffer; it is the opposite of narrowing (q.v.). See section Narrowing.

Window

Emacs divides a frame (q.v.) into one or more windows, each of which can display the contents of one buffer (q.v.) at any time. See section The Organization of the Screen, for basic information on how Emacs uses the screen. See section Multiple Windows, for commands to control the use of windows.

Word Abbrev

Synonymous with `abbrev'.

Word Search

Word search is searching for a sequence of words, considering the punctuation between them as insignificant. See section Word Search.

WYSIWYG

WYSIWYG stands for "What you see is what you get." Emacs generally provides WYSIWYG editing for files of characters; in Enriched mode (see section Editing Formatted Text), it provides WYSIWYG editing for files that include text formatting information.

Yanking

Yanking means reinserting text previously killed. It can be used to undo a mistaken kill, or for copying or moving text. Some other systems call this "pasting". See section Yanking.

GNU Emacs Manual

(1)

In some editors, search-and-replace operations are the only convenient way to make a single change in the text.

(2)

Some systems use Mouse-3 for a mode-specific menu. We took a survey of users, and found they preferred to keep Mouse-3 for selecting and killing regions. Hence the decision to use C-Mouse-3 for this menu.

(3)

You should not suspend the shell process. Suspending a subjob of the shell is a completely different matter--that is normal practice, but you must use the shell to continue the subjob; this command won't do it.

(4)

This dissociword actually appeared during the Vietnam War, when it was very appropriate.

(5)

The wording here was careless. The intention was that nobody would have to pay for *permission* to use the GNU system. But the words don't make this clear, and people often interpret them as saying that copies of GNU should always be distributed at little or no charge. That was never the intent; later on, the manifesto mentions the possibility of companies providing the service of distribution for a profit. Subsequently I have learned to distinguish carefully between "free" in the sense of freedom and "free" in the sense of price. Free software is software that users have the freedom to distribute and change. Some users may obtain copies at no charge, while others pay to obtain copies--and if the funds help support improving the software, so much the better. The important thing is that everyone who has a copy has the freedom to cooperate with others in using it.

(6)

This is another place I failed to distinguish carefully between the two different meanings of "free". The statement as it stands is not false--you can get copies of GNU software at no charge, from your friends or over the net. But it does suggest the wrong idea.

(7)

Several such companies now exist.

(8)

The Free Software Foundation raises most of its funds from a distribution service, although it is a charity rather than a company. If *no one* chooses to obtain copies by ordering from the FSF, it will be unable to do its work. But this does not mean that proprietary restrictions are justified to force every user to pay. If a small fraction of all the users order copies from the FSF, that is sufficient to keep the FSF afloat. So we ask users to choose to support us in this way. Have you done your part?

A group of computer companies recently pooled funds to support maintenance of the GNU C Compiler.

Expanded Plain TeX

March 1993

For version 2.3.

Karl Berry Steven Smith

Go to the next section.

@paragraphindent 2

Introduction

The Eplain macro package expands on and extends the definitions in plain TeX. This manual describes the definitions that you, as either an author or a macro writer, might like to use. It doesn't discuss the implementation; see comments in the source code for that.

Eplain is not intended to provide "generic typesetting capabilities, as do LaTeX (written by Leslie Lamport) or Texinfo (written by Richard Stallman and others). Instead, it provides definitions that are intended to be useful regardless of the high-level commands that you use when you actually prepare your manuscript.

For example, Eplain does not have a command `\section`, which would format section headings in an "appropriate" way, such as LaTeX's `\section`. The philosophy of Eplain is that some people will always need or want to go beyond the macro designer's idea of "appropriate". Such "canned" macros are fine--as long as you are willing to accept the resulting output. If you don't like the results, or if you are trying to match a different format, you are out of luck.

On the other hand, almost everyone would like capabilities such as cross-referencing by labels, so that you don't have to put actual page numbers in the manuscript. The author of Eplain is not aware of any generally available macro packages that (1) do not force their typographic style on an author, and yet (2) provide such capabilities.

Besides such generic macros as cross-referencing, Eplain contains another set of definitions: ones that change the conventions of plain TeX's output. For example, math displays in TeX are, by default, centered. If you want your displays to come out left-justified, you have to plow through The TeXbook to find some way to do it, and then adapt the code to your own needs. Eplain tries to take care of the messy details of such things, while still leaving the detailed appearance of the output up to you.

Finally, numerous definitions turned out to be useful as Eplain was developed. They are also documented

in this manual, on the chance that people writing other macros will be able to use them.

You can send bug reports or suggestions to `karl@cs.umb.edu`. The current version number of Eplain is defined as the macro `\fmtversion` at the end of the source file `` `eplain.tex' ``. When corresponding, please refer to it.

Go to the next section.

Go to the previous, next section.

Installation

The simplest way to install Eplain is simply to install the file `eplain.tex' in a directory where TeX will find it. What that directory is obviously depends on your operating system and TeX installation. I install `eplain.tex' in `/usr/local/lib/tex/macros/plain'.

If you want, you can also create a format (`.fmt') file for Eplain, which will eliminate the time spent reading the macro source file with \input. You do this by issuing a sequence of commands something like this:

```
initex
This is TeX, ...
**&plain eplain
(eplain.tex)
*\dump
... messages ...
```

You must make sure that `eplain.aux' exists *before* you run `initex'; otherwise, warning messages about undefined labels will never be issued.

You then have to install the resulting `eplain.fmt' in some system directory or set an environment variable to tell TeX how to find it. I install the format files in `/usr/local/lib/tex/formats'; the environment variable for the Web2C port of TeX to Unix is TEXFORMATS.

Some implementations of TeX (including Web2C) use the name by which TeX is invoked to determine what format to read. For them, you should make a link to the `virtex' program named `etex', and then install the format file with the name `etex.fmt'. This lets users invoke TeX as `etex' and get the format file read automatically.

For convenience, the file `etex.tex' in the distribution directory does \input eplain and then \dump, so that if you replace `eplain' with `etex' in the example above, the format file will end up with the right name.

The install target in the `Makefile' does all this properly for Unix systems and Web2C. You may have to change the pathnames.

Go to the previous, next section.

Go to the previous, next section.

Invoking Eplain

The simplest way to use Eplain is simply to put:

```
\input eplain
```

at the beginning of your input file. The macro file is small enough that reading it does not take an unbearably long time--at least on contemporary machines.

In addition, if a format (`.fmt') file has been created for Eplain (see the previous section), you can eliminate the time spent reading the macro source file. You do this by responding `&eplain` or `&etex` to TeX's `**' prompt. For example:

```
initex
This is TeX, ...
**&eplain myfile
```

Depending on the implementation of TeX which you are using, you might also be able to invoke TeX as `etex' and have the format file automatically read.

If you write something which you will be distributing to others, you won't know if the Eplain format will be loaded already. If it is, then doing `\input eplain` will waste time; if it isn't, then you must load it. To solve this, Eplain defines the control sequence `\eplain` to be the letter `t` (a convention borrowed from Lisp; it doesn't actually matter what the definition is, only that the definition exists). Therefore, you can do the following:

```
\ifx\eplain\undefined \input eplain \fi
```

where `\undefined` must never acquire a definition.

Eplain consists of several source files:

`xeplain.tex'
: most of the macros;

`arrow.tex'
: commutative diagram macros, see section Arrow theoretic diagrams (written by Steven Smith);

`btxmac.tex'
: bibliography-related macros, see section Citations;

`texnames.sty'
: abbreviations for various TeX-related names, see section Logos (edited by Nelson Beebe).

The file `eplain.tex' is all of these files merged together, with comments removed.

All of these files except `xeplain.tex' can be input individually, if all you want are the definit in that file.

Also, since the bibliography macros are fairly extensive, you might to not load them, while loading the rest of Eplain, to conserve memory in TeX. Therefore, you can control whether or not `eplain.tex' defines the bibliography-related stuff when you run TeX: if the control sequence \nobibtex is defined, then the definitions aren't made. You must set \nobibtex before `eplain.tex' is read, naturally. For example, you could start your input file like this:

```
\let\nobibtex = t
\input eplain
```

By default, \nobibtex is undefined, and so the bibliography definitions *are* made.

Sometimes you may want to be even more drastic than \nobibtex---not read or write an `aux' file at all, for any kind of cross-referencing. This happens if you define \noauxfile before reading `eplain.tex'. This also turns off all warnings about undefined labels.

Go to the previous, next section.

Go to the previous, next section.

User definitions

This chapter describes definitions that are meant to be used directly in a document. When appropriate, ways to change the default formatting are described in subsections.

Diagnostics

Plain TeX provides the `\tracingall` command, to turn on the maximum amount of tracing possible in TeX. The (usually voluminous) output from `\tracingall` goes both on the terminal and into the transcript file. It is sometimes easier to have the output go only to the transcript file, so you can peruse it at your leisure and not obscure other output to the terminal. So, Eplain provides the command `\loggingall`. (For some reason, this command is available in Metafont, but not in TeX.)

It is also sometimes useful to see the complete contents of boxes. `\tracingboxes` does this. (It doesn't affect whether or not the contents are shown on the terminal.)

You can turn off all tracing with `\tracingoff`.

You can also turn logging on and off globally, so you don't have to worry about whether or not you're inside a group at the time of command. These variants are named `\gloggingall` and `\gtracingall`.

Finally, if you write your own help messages (see `\newhelp` in The TeXbook), you want a convenient way to break lines in them. This is what TeX's `\newlinechar` parameter is for; however, plain TeX doesn't set `\newlinechar`. Therefore, Eplain defines it to be the character `^^J`.

For example, one of Eplain's own error messages is defined as follows:

```
\newhelp\envhelp{Perhaps you forgot to end the previous^^J%
   environment? I'm finishing off the current group,^^J%
   hoping that will fix it.}%
```

Rules

The default dimensions of rules are defined in chapter 21 of the The TeXbook. To sum up what is given there, the "thickness" of rules is 0.4pt by default. Eplain defines three parameters that let you change this dimension: `\hruledefaultheight`, `\hruledefaultdepth`, and `\vruledefaultwidth`. By default, they are defined as The TeXbook describes.

But it would be wrong to redefine `\hrule` and `\vrule`. For one thing, some macros in plain TeX depend on the default dimensions being used; for another, rules are used quite heavily, and the performance impact of making it a macro can be noticeable. Therefore, to take advantage of the default

rule parameters, you must use `\ehrule` and `\evrule`.

Citations

Bibliographies are part of almost every technical document. To handle them easily, you need two things: a program to do the tedious formatting, and a way to cite references by labels, rather than by numbers. The BibTeX program, written by Oren Patashnik, takes care of the first item; the citation commands in LaTeX, written to be used with BibTeX, take care of the second. Therefore, Eplain adopts the use of BibTeX, and virtually the same interface as LaTeX.

The general idea is that you put citation commands in the text of your document, and commands saying where the bibliography data is. When you run TeX, these commands produce output on the file with the same root name as your document (by default) and the extension `` `.aux' ``. BibTeX reads this file. You should put the bibliography data in a file or files with the extension `` `.bib' ``. BibTeX writes out a file with the same root name as your document and extension `` `.bbl' ``. Eplain reads this file the next time you run your document through TeX. (It takes multiple passes to get everything straight, because usually after seeing your bibliography typeset, you want to make changes in the `` `.bib' `` file, which means you have to run BibTeX again, which means you have to run TeX again...) An annotated example of the whole process is given below.

If your document has more than one bibliography--for example, if it is a collection of papers--you can tell Eplain to use a different root name for the `` `.bbl' `` file by defining the control sequence `\bblfilebasename`. The default definition is simply `\jobname`.

See the document BibTeXing (whose text is in the file `` `btxdoc.tex' ``, which should be in the Eplain distribution you got) for information on how to write your `.bib` files. Both the BibTeX and the Eplain distributions contain several examples, also.

The `\cite` command produces a citation in the text of your document. The exact printed form the citation will take is under your control; see section Formatting citations. `\cite` takes one required argument, a comma-separated list of cross-reference labels (see section Cross-references, for exactly what characters are allowed in such labels). Warning: spaces in this list are taken as part of the following label name, which is probably not what you expect. The `\cite` command also produces a command in the `.aux` file that tells BibTeX to retrieve the given reference(s) from the `.bib` file. `\cite` also takes one optional argument, which you specify within square brackets, as in LaTeX. This text is simply typeset after the citations. (See the example below.)

Another command, `\nocite`, puts the given reference(s) into the bibliography, but produces nothing in the text.

The `\bibliography` command is next. It serves two purposes: producing the typeset bibliography, and telling BibTeX the root names of the `.bib` files. Therefore, the argument to `\bibliography` is a comma separated list of the `.bib` files (without the `.bib'). Again, spaces in this list are significant.

You tell BibTeX the particular style in which you want your bibliography typeset with one more command: `\bibliographystyle`. The argument to this is a single filename style, which tells BibTeX to look for a file style`.bst`. See the document Designing BibTeX styles (whose text is in the

`btxhak.tex') for information on how to write your own styles.

Eplain automatically reads the citations from the `.aux` file when your job starts.

If you don't want to see the messages about undefined citations, you can say `\xrefwarningfalse` before making any citations. Eplain automatically does this if the `.aux` file does not exist. You can restore the default by saying `\xrefwarningtrue`.

Here is a TeX input file that illustrates the various commands.

```
\input eplain                    % Reads the .aux file.
Two citations to Knuthian works:
  \cite[note]{surreal,concrete-math}.
\beginsection{References.}\par   % Title for the bibliography.
\bibliography{knuth}             % Use knuth.bib for the labels.
\bibliographystyle{plain}        % Number the references.
\end                             % End of the document.
```

If we suppose that this file was named `citex.tex' and that the bibliography data is in `knuth.bib' (as the `\bibliography` command says), the following commands do what's required. (`$ ' represents the shell prompt.)

```
$ tex citex       (produces undefined citation messages)
$ bibtex citex    (read knuth.bib and citex.aux, write citex.bbl)
$ tex citex       (read citex.bbl, still have undefined citations)
$ tex citex       (one more time, to resolve the references)
```

The output looks something like (because we used the `plain` bibliography style):

> Two citations to Knuthian works: [2,1 note].
>
> **References**
>
> [1] Ronald L. Graham, Donald E. Knuth, and Oren Patashnik. *Concrete Mathematics*. Addison-Wesley, Reading, Massachusetts, 1989.
>
> [2] Donald E. Knuth. *Surreal Numbers*. Addison-Wesley, Reading, Massachusetts, 1974.

See the BibTeX documentation for information on how to write the bibliography databases, and the bibliography styles that are available. (If you want your references printed with names, as in [Knu74], instead of numbered, the bibliography style is `alpha`.)

Formatting citations

You may wish to change Eplain's formatting of citations; i.e., the result of your `\cite` commands. By default, the citation labels are printed one after another, separated by commas and enclosed in brackets, using the main text font. Some formats require other styles, such as superscripted labels. You can accomodate such formats by redefining the following macros.

`\printcitestart`

`\printcitefinish`

Eplain expands these macros at the begining and end of the list of citations for each `\cite` command. By default, they produce a `[' and `]', respectively.

`\printbetweencitations`

If a `\cite` command has multiple citations, as in `\cite{acp,texbook}`, Eplain expands this macro in between each pair of citations. By default, it produces a comma followed by a space.

`\printcitenote`

This macro takes one argument, which is the optional note to the `\cite` command. If the `\cite` command had no note, this macro isn't used. Otherwise, it should print the note. By default, the note is preceded with a comma and a space.

Here is an example, showing you could produce citations as superscripted labels, with the optional notes in parentheses.

```
\def\printcitestart{\unskip $^\bgroup}
\def\printbetweencitations{,}
\def\printcitefinish{\egroup$}
\def\printcitenote#1{\hbox{\sevenrm\space (#1)}}
```

Formatting bibliographies

You may wish to change Eplain's formatting of the bibliography, especially with respect to the fonts that are used. Therefore, Eplain provides the following control sequences:

`\biblabelwidth`

This control sequence represents a `\dimen` register, and its value is the width of the widest label in the bibliography. Although it is unlikely you will ever want to redefine it, you might want to use it if you redefine `\biblabelprint`, below.

`\biblabelprint`

This macro takes one argument, the label to print. By default, the label is put in a box of width `\biblabelwidth`, and is followed by an enspace. When you want to change the spacing around the labels, this is the right macro to redefine.

`\biblabelcontents`

This macro also takes one argument, the label to print. By default, the label is printed using the font `\bblrm` (below), and enclosed in brackets. When you want to change the appearance of the label, but not the spacing around it, this is the right macro to redefine.

`\bblrm`

The default font used for printing the bibliography.

`\bblem`

The font used for printing the titles and other "emphasized" material.

`\bblsc`

In some styles, authors' names are printed in a caps-and-small-caps font. In those cases, this font is used.

`\bblnewblock`

This is invoked between each of the parts of a bibliography entry. The default is to leave some extra space between the parts; you could redefine it to start each part on a new line (for example). A part is simply a main element of the entry; for example, the author is a part. (It was LaTeX that introduced the (misleading, as far as I am concerned) term `block' for this.)

`\biblabelextraspace`

Bibliography entries are typeset with a hanging indentation of `\biblabelwidth` plus this. The default is `.5em`, where the em width is taken from the `\bblrm` font. If you want to change this, you should do it inside `\bblhook`.

`\bblhook`

This is invoked before reading the `.bbl` file. By default, it does nothing. You could, for example, define it to set the bibliography fonts, or produce the heading for the references. Two spacing parameters must be changed inside `\bblhook`: `\parskip`, which produces extra space between the items; and `\biblabelextraspace`, which is described above.

If you are really desperate, you can also hand-edit the `.bbl` file that BibTeX produces to do anything you wish.

Displays

By default, TeX centers displayed material. (Displayed material is just whatever you put between $$'s--it's not necessarily mathematics.) Many layouts would be better served if the displayed material was left-justified. Therefore, Eplain provides the command `\leftdisplays`, which indents displayed material by `\parindent` plus `\leftskip`, plus `\leftdisplayindent`.

You can go back to centering displays with `\centereddisplays`. (It is usually poor typography to have both centered and left-justified displays in a single publication, though.)

`\leftdisplays` also changes the plain TeX commands that deal with alignments inside math displays, `\displaylines`, `\eqalignno`, and `\leqalignno`, to produce left-justified text. You can still override this formatting by inserting `\hfill` glue, as explained in The TeXbook.

TOC

Formatting displays

If you want some other kind of formatting, you can write a definition of your own, analogous to `\leftdisplays`. You need only make sure that `\leftdisplaysetup` is called at the beginning of every display (presumably by invoking it in TeX's `\everydisplay` parameter), and to define `\generaldisplay`.

`\leftdisplays` expands the old value of `\everydisplay` before calling `\leftdisplaysetup`, so that any changes you have made to it won't be lost. That old token list as available as the value of the token register `\previouseverydisplay`.

Time of day

TeX provides the day, month, and year as numeric quantities (unless your TeX implementation is woefully deficient). Eplain provides some control sequences to make them a little more friendly to humans.

`\monthname` produces the name of the current month, abbreviated to three letters.

`\fullmonthname` produces the name of the current month, unabbreviated (in English).

`\timestring` produces the current time, as in `1:14 p.m.'

`\timestamp` produces the current date and time, as in `23 Apr 64 1:14 p.m.'. (Except the spacing is slightly different.)

`\today` produces the current date, as in `23 April 1964'.

Lists

Many documents require lists of items, either numbered or simply enumerated. Plain TeX defines one macro to help with creating lists, `\item`, but that is insufficient in many cases. Therefore, Eplain provides two pairs of commands:

`\numberedlist ... \endnumberedlist`

`\orderedlist ... \endorderedlist`

> These commands (they are synonyms) produce a list with the items numbered sequentially, starting from one. A nested `\numberedlist` labels the items with lowercase letters, starting with `a'. Another nested `\numberedlist` labels the items with roman numerals. Yet more deeply nested numbered lists label items with `*'.

`\unorderedlist ... \endunorderedlist`

> This produces a list with the items labelled with small black boxes ("square bullets"). A nested `\unorderedlist` labels items with em-dashes. Doubly (and deeper) nested unordered lists label items with `*'s.

The two kinds of lists can be nested within each other, as well.

In both kinds of lists, you begin an item with `\li`. An item may continue for several paragraphs. Ea(item starts a paragraph.

You can give `\li` an optional argument, a cross-reference label. It's defined to be the "marker" for the current item. This is useful if the list items are numbered. You can produce the value of the label with `\xrefn`. See section Cross-references.

You can also say `\listcompact` right after `\numberedlist` or `\unorderedlist`. The items in the list will then not have any extra space between them (see section Formatting lists). You might want to do this if the items in this particular list are short.

Here is an example:

```
\numberedlist\listcompact
\li The first item.
\li The second item.

The second paragraph of the second item.
\endnumberedlist
```

Formatting lists

Several registers define the spacing associated with lists. It is likely that their default values won't suit your particular layout.

`\abovelistskipamount, \belowlistskipamount`

> The vertical glue inserted before and after every list, respectively.

`\interitemskipamount`

> The vertical glue inserted before each item except the first. `\listcompact` resets this to zero, as mentioned above.

`\listleftindent, \listrightindent`

> `\listrightindent` is the amount of space by which the list is indented on the right; i.e., it is added to `\rightskip`. `\listleftindent` is the amount of space, *relative to* `\parindent`, by which the list is indented on the left. Why treat the two parameters differently? Because (a) it is more useful to make the list indentation depend on the paragraph indentation; (b) footnotes aren't formatted right if `\parindent` is reset to zero.

The three vertical glues are inserted by macros, and preceded by penalties: `\abovelistskip` does `\vpenalty\abovelistpenalty` and then `\vskip\abovelistskip`. `\belowlistskip` and `\interitemskip` are analogous.

In addition, the macro `\listmarkerspace` is called to separate the item label from the item text. This is set to `\enspace` by default.

If you want to change the labels on the items, you can redefine these macros: `\numberedmarker` or `\unorderedmarker`. The following registers might be useful if you do:

`\numberedlistdepth, \unorderedlistdepth`

These keep track of the depth of nesting of the two kinds of lists.

`\itemnumber, \itemletter`

These keep track of the number of items that have been seen in the current numbered list. They are both integer registers. The difference is that `\itemnumber` starts at one, and `\itemletter` starts at 97, i.e., lowercase `a'.

You can also redefine the control sequences that are used internally, if you want to do something radically different: `\beginlist` is invoked to begin both kinds of lists; `\printitem` is invoked to print the label (and space following the label) for each item; and `\endlist` is invoked to end both kinds of lists.

Verbatim listing

It is sometimes useful to include a file verbatim in your document; for example, part of a computer program. The `\listing` command is given one argument, a filename, and produces the contents of that file in your document. `\listing` expands `\listingfont` to set the current font. The default value of `listingfont` is `\tt`.

You can take arbitrary actions before reading the file by defining `\setuplistinghook`. This is expanded just before the file is input.

If you want to have line numbers on the output, you can say `\let\setuplistinghook = \linenumberedlisting`. The line numbers are stored in the count register `\lineno` while the file is being read. You can redefine the macro `\printlistinglineno` to change how they are printed.

You can produce verbatim text in your document with `\verbatim`. End the text with `|endverbatim`. If you need a `|' in the text, double it. For example:

```
\verbatim ||\#%&!|endverbatim
```

produces `|\#%&!`.

Line breaks and spaces in the verbatim text are preserved.

Because `\verbatim` must change the category code of special characters, calling inside a macro definition of your own does not work properly. For example:

```
\def\mymacro{\verbatim &#%|endverbatim}% Doesn't work!
```

If you need to do this, you must change the category codes yourself before making the macro definition. Perhaps the `\uncatcodespecials` will help you (see section Category codes).

Contents

Producing a table of contents that is both useful and aesthetic is one of the most difficult design problems in any work. Naturally, Eplain does not pretend to solve the design problem. Collecting the raw data for a table of contents, however, is much the same across documents. Eplain uses an auxiliary file with extension `.toc` (and the same root name as your document) to save the information.

To write an entry for the table of contents, you say `\writetocentry{part}{text}`, where part is the type of part this entry is, e.g., `chapter', and text is the text of the title. `\writetocentry` puts an entry into the `.toc` file that looks like `\tocpartentry{text}{page number}`. The text is written unexpanded.

A related command, `\writenumberedtocentry`, takes one additional argument, and writes it unchanged. The first token is expanded at the point of the `\writenumberedtocentry`, but the rest of the argument is not expanded. The usual application is when the parts of the document are numbered. On the other hand, the one-level expansion allows you to use the argument for other things as well (author's names in a proceedings, say), and not have accents or other control sequences expanded. The downside is that if you *want* full expansion of the third argument, you don't get it--you must expand it yourself, before you call `\writenumberedtocentry`.

Here is a concrete example:

```
\writenumberedtocentry{chapter}{A $\sin$ wave}{\the\chapno}
\writetocentry{section}{A section title}
```

Supposing `\the\chapno` expanded to `3' and that the `\write`'s occurred on pages eight and nine, respectively, those lines would write the following to the `.toc` file:

```
\tocchapterentry{A $\sin$ wave}{3}{8}
\tocsectionentry{A section title}{9}
```

You read the `.toc` file with the command `\readtocfile`. Naturally, whatever `\toc ... entry` commands that were written to the file must be defined when `\readtocfile` is invoked. Eplain has simple definitions for `\tocchapterentry`, `\tocsectionentry`, and `\tocsubsectionentry` (unnumbered), but they aren't suitable for anything but preliminary proofs.

After reading the `.toc` file, `\readtocfile` opens the file for writing, thereby deleting the information from the previous run. You should therefore arrange that `\readtocfile` be called *before* the first call to a `\writetoc ...` macro. On the other hand, if you don't want to rewrite the `.toc` file, perhaps because you are only running TeX on part of your manuscript, you can set `\rewritetocfilefalse`.

By default, the `` `.toc' `` file has the root `\jobname`. If your document has more than one contents--for example, if it is a collection of papers--you can tell Eplain to use a different root name by defining the control sequence `\tocfilebasename`.

Cross-references

It is often useful to refer the reader to other parts of your document; but putting literal page, section, equation, or whatever numbers in the text is certainly a bad thing.

Eplain therefore provides commands for symbolic cross-references. It uses an auxiliary file with extension `.aux` (and the same root name as your document) to keep track of the information. Therefore, it takes two passes to get the cross-references right--one to write them out, and one to read them in. Eplain automatically reads the `.aux` file at the first reference; after reading it, Eplain reopens it for writing.

You can control whether or not Eplain warns you about undefined labels. See section Citations.

Labels in Eplain's cross-reference commands can use characters of category code eleven (letter), twelve (other), ten (space), three (math shift), four (alignment tab), seven (superscript), or eight (subscript). For example, `(a1 $&^_' is a valid label (assuming the category codes of plain TeX), but `%#\{' has no valid characters.

You can also do symbolic cross-references for bibliographic citations and list items. See section Citations, and section Lists.

Defining generic references

Eplain provides the command `\definexref` for general cross-references. It takes three arguments: the name of the label (see section above for valid label names), the value of the label (which can be anything), and the "class" of the reference--whether it's a section, or theorem, or what. For example:

```
\definexref{sec-intro}{3.1}{section}
```

Of course, the label value is usually generated by another macro using TeX count registers or some such.

`\definexref` doesn't actually define label; instead, it writes out the definition to the `.aux` file, where Eplain will read it on the next TeX run.

The class argument is used by the `\ref` and `\refs` commands. See the next section.

Using generic references

To retrieve the value of the label defined via `\definexref` (see the previous section), Eplain provides the following macros:

`\refn{label}`

`\xrefn{label}`

> `\refn` and `\xrefn` (they are synonyms) produce the bare definition of label. If label isn't defined, issue a warning, and produce label itself instead, in typewriter. (The warning isn't given if `\xrefwarningfalse`.)

`\ref{label}`

Given the class c for label (see the description of `\definexref` in the previous section), expand the control sequence `\c word` (if it's defined) followed by a tie. Then call `\refn` on label. (Example below.)

`\refs{label}`

Like `\ref`, but append the letter `s' to the `\...word`.

The purpose of the `\...word` macro is to produce the word `Section' or `Figure' or whatever that usually precedes the actual reference number.

Here is an example:

```
\def\sectionword{Section}
\definexref{sec-intro}{3.1}{section}
\definexref{sec-next}{3.2}{section}
See \refs{sec-intro} and \refn{sec-next} ...
```

This produces `See Sections 3.1 and 3.2 ...'

Page references

Eplain provides two commands for handling references to page numbers, one for definition and one for use.

`\xrdef{label}`

Define label to be the current page number. This produces no printed output, and ignores following spaces.

`\xref{label}`

Produce the text `p. page-number', which is the usual form for cross-references. The page-number is actually label's definition; if label isn't defined, the text of the label itself is printed.

Equation references

Instead of referring to pages, it's most useful if equation labels refer to equation numbers. Therefore, Eplain reserves a `\count` register, `\eqnumber`, for the current equation number, and increments it at each numbered equation.

Here are the commands to define equation labels and then refer to them:

`\eqdef{label}`

This defines label to be the current value of `\eqnumber`, and, if the current context is not inner, then produces a `\eqno` command. (The condition makes it possible to use `\eqdef` in an `\eqalignno` construction, for example.) The text of the equation number is produced using `\eqprint`. See section Formatting equation references.

`\eqdefn{label}`

This is like `\eqdef`, except it always omits the `\eqno` command. It can therefore be used in

places where `\eqdef` can't; for example, in a non-displayed equation. The text of the equation number is not produced, so you can also use it in the (admittedly unusual) circumstance where you want to define an equation label but not print that label.

`\eqref{label}`

This produces a formatted reference to label. If label is undefined (perhaps because it is a forward reference), it just produces the text of the label itself. Otherwise, it calls `\eqprint`.

`\eqrefn{label}`

This produces the cross-reference text for label. That is, it is like `\eqref`, except it doesn't call `\eqprint`.

Equation labels can contain the same characters that are valid in general cross-references.

Formatting equation references

Both defining an equation label and referring to it should usually produce output. This output is produced with the `\eqprint` macro, which takes one argument, the equation number being defined or referred to. By default, this just produces `(number)', where number is the equation number. To produce the equation number in a different font, or with different surrounding symbols, or whatever, you can redefine `\eqprint`. For example, the following definition would print all equation numbers in italics. (The extra braces define a group, to keep the font change from affecting surrounding text.)

```
\def\eqprint#1{{\it (#1)}}
```

In addition to changing the formatting of equation numbers, you might to add more structure to the equation number; for example, you might want to include the chapter number, to get equation numbers like `(1.2)'. To achieve this, you redefine `\eqconstruct`. For example:

```
\def\eqconstruct#1{\the\chapternumber.#1}
```

(If you are keeping the chapter number in a count register named `\chapternumber`, naturally.)

The reason why both `\eqconstruct` and `\eqprint` may not be immediately apparent, since they appear to perform similar functions. The difference is that `\eqconstruct` affects the text that cross-reference label is defined to be, while `\eqprint` affects only what is typeset on the page. The example just below might help.

Usually, you want equation labels to refer to equation numbers. But sometimes you might want a more complicated text. For example, you might have an equation `(1)', and then have a variation several pages later which you want to refer to as `(1*)'.

Therefore, Eplain allows you to give an optional argument (i.e., arbitrary text in square brackets) before the cross-reference label to \eqdef. Then, when you refer to the equation, that text is produced. Here's how to get the example just mentioned:

```
$$...\eqdef{a-eq}$$
...
```

```
$$...\eqdef[\eqrefn{a-eq}*]{a-eq-var}$$
In \eqref{a-eq-var}, we expand on \eqref{a-eq}, ...
```

We use `\eqrefn` in the cross-reference text, not `\eqref`, so that `\eqprint` is called only once.

Subequation references

Eplain also provides for one level of substructure for equations. That is, you might want to define a related group of equations with numbers like `2.1' and `2.2', and then be able to refer to the group as a whole: "... in the system of equations (2)...".

The commands to do this are `\eqsubdef` and `\eqsubdefn`. They take one label argument like their counterparts above, and generally behave in the same way. The difference is in how they construct the equation number: instead of using just `\eqnumber`, they also use another counter, `\subeqnumber`. This counter is advanced by one at every `\eqsubdef` or `\eqsubdefn`, and reset to zero at every `\eqdef` or `\eqdefn`.

You use `\eqref` to refer to subequations as well as main equations.

To put the two together to construct the text that the label will produce, they use a macro `\eqsubreftext`. This macros takes two arguments, the "main" equation number (which, because the equation label can be defined as arbitrary text, as described in the previous section, might be anything at all) and the "sub" equation number (which is always just a number). Eplain's default definition just puts a period between them:

```
  \def\eqsubreftext#1#2{#1.#2}%
```

You can redefine `\eqsubreftext` to print however you like. For example, this definition makes the labels print as `2a', `2b', and so on.

```
\newcount\subref
\def\eqsubreftext#1#2{%
  \subref = #2           % The space stops a <number>.
  \advance\subref by 96  % `a' is character code 97.
  #1\char\subref
}
```

Sadly, we must define a new count register, `\subref`, instead of using the scratch count register `\count255`, because `#1' might include other macro calls which use `\count255`.

Justification

Eplain defines three commands to conveniently justify multiple lines of text: `\flushright`, `\flushleft`, and `\center`.

They all work in the same way; let's take `\center` as the example. To start centering lines, you say `\center` inside a group; to stop, you end the group. Between the two commands, each end-of-line in

the input file also starts a new line in the output file.

The entire block of text is broken into paragraphs at blank lines, so all the TeX paragraph-shaping parameters apply in the usual way. This is convenient, but it implies something else that isn't so convenient: changes to any linespacing parameters, such as `\baselineskip`, will have *no effect* on the paragraph in which they are changed. TeX does not handle linespacing changes within a paragraph (because it doesn't know where the line breaks are until the end of the paragraph).

The space between paragraphs is by default one blank line's worth. You can adjust this space by assigning to `\blanklineskipamount`; this (vertical) glue is inserted after each blank line.

Here is an example:

```
{\center First line.

   Second line, with a blank line before.
}
```

This produces:

First line. Second line, with a blank line before.

You may wish to use the justification macros inside of your own macros. Just be sure to put them in a group. For example, here is how a title macro might be defined:

```
\def\title{\begingroup\titlefont\center}
\def\endtitle{\endgroup}
```

Tables

Eplain provides a single command, `\makecolumns`, to make generating one particular kind of table easier. More ambitious macro packages might be helpful to you for more difficult applications. The files `` `ruled.tex' `` and `` `TXSruled.tex' ``, available from `lifshitz.ph.utexas.edu' in `` `texis/tables' ``, is the only one I know of.

Many tables are homogenous, i.e., all the entries are semantically the same. The arrangement into columns is to save space on the page, not to encode different meanings. In this kind of the table, it is useful to have the column breaks chosen automatically, so that you can add or delete entries without worrying about the column breaks.

`\makecolumns` takes two arguments: the number of entries in the table, and the number of columns to break them into. As you can see from the example below, the first argument is delimited by a slash, and the second by a colon and a space (or end-of-line). The entries for the table then follow, one per line (not including the line with the `\makecolumns` command itself).

`\parindent` defines the space to the left of the table. `\hsize` defines the width of the table. So you can adjust the position of the table on the page by assignments to these parameters, probably inside a group.

You can also control the penalty at a page break before the `\makecolumns` by setting the parameter `\abovecolumnspenalty`. Usually, the table is preceded by some explanatory text. You wouldn't want a page break to occur after the text and before the table, so Eplain sets it to `10000`. But if the table produced by `\makecolumns` is standing on its own, `\abovecolumnspenalty` should be decreased.

If you happen to give `\makecolumns` a smaller number of entries than you really have, some text beyond the (intended) end of the table will be incorporated into the table, probably producing an error message, or at least some strange looking entries. And if you give `\makecolumns` a larger number of entries than you really have, some of the entries will be typeset as straight text, probably also looking somewhat out of place.

Here is an example:

```
% Arrange 6 entries into 2 columns:
\makecolumns 6/2: % This line doesn't have an entry.
one
two
three
four
five
six
Text after the table.
```

This produces `one', `two', and `three' in the first column, and `four', `five', and `six' in the second.

Margins

TeX's primitives describe the type area in terms of an offset from the upper left corner, and the width and height of the type. Some people prefer to think in terms of the margins at the top, bottom, left, and right of the page, and most composition systems other than TeX conceive of the page laid out in this way. Therefore, Eplain provides commands to directly assign and increment the margins.

`\topmargin = dimen`

`\bottommargin = dimen`

`\leftmargin = dimen`

`\rightmargin = dimen`

> These commands set the specified margin to the dimen given. The = and the spaces around it are optional. The control sequences here are not TeX registers, despite appearances; therefore, commands like `\showthe\topmargin` will not do what you expect.

`\advancetopmargin by dimen`

`\advancebottommargin by dimen`

`\advanceleftmargin by dimen`

`\advancerightmargin by dimen`

These commands change the specified margin by the dimen given.

Regardless of whether you use the assignment or the advance commands, Eplain always changes the type area in response, not the other margins. For example, when TeX starts, the left and right margins are both one inch. If you then say `\leftmargin = 2in`, the right margin will remain at one inch, and the width of the lines (i.e., `\hsize`) will decrease by one inch.

When you use any of these commands, Eplain computes the old value of the particular margin, by how much you want to change it, and then resets the values of TeX's primitive parameters to correspond. Unfortunately, Eplain cannot compute the right or bottom margin without help: you must tell it the full width and height of the final output page. It defines two new parameters for this:

`\paperheight`

The height of the output page; default is 11in.

`\paperwidth`

The width of the output page; default is 8.5in.

If your output page has different dimensions than this, you must reassign to these parameters, as in

```
\paperheight = 11in
\paperwidth = 17in
```

Double columns

Eplain provides for double column output: you just say `\doublecolumns`, and from that point on, the manuscript will be set in two columns. If you want to go back to one column, say `\singlecolumn`.

`\doublecolumns` inserts the value of the glue parameter `\abovedoublecolumnskip` before the double column text, and the value of the glue parameter `\belowdoublecolumnskip` after it. The default value for both of these parameters is `\bigskipamount`, i.e., one linespace.

The two columns are separated by the value of the dimen parameter `\gutter`. The column widths are therefore (`\hsize` - `\gutter`)/2. The default value for `\gutter` is two picas.

`\doublecolumns` takes into account only the insertion classes defined by plain TeX, namely, footnotes and `\topinsert`s. If you have defined additional insertion classes, you will need to change the macro `\@doublecolumnsplit`. Furthermore, the insertions do not respect the column widths; if you want them to, you have to change the way your output routine works. (Eplain uses whatever the current output routine is; it is not tied to `\plainoutput`.)

Footnotes

The most common reference mark for footnotes is a raised number, incremented on each footnote. The `\numberedfootnote` macro provides this. It takes one argument, the footnote text.

If your document uses only numbered footnotes, you could make typing `\numberedfootnote` more

convenient with a command such as:

```
\let\footnote = \numberedfootnote
```

After doing this, you can type your footnotes as `\footnote{footnote text}`, instead of as `\numberedfootnote{footnote text}`.

Eplain keeps the current footnote number in the count register `\footnotenumber`. So, to reset the footnote number to zero, as you might want to do at, for example, the beginning of a chapter, you could say `\footnotenumber=0`.

Plain TeX separates the footnote marker from the footnote text by an en space (it uses the `\textindent` macro). In Eplain, you can change this space by setting the dimension register `\footnotemarkseparation`. The default is still an en.

You can produce a space between footenotes by setting the glue register `\interfootnoteskip`. The default is zero.

You can also control footnote formatting in a more general way: Eplain expands the token register `\everyfootnote` before a footnote is typeset, but after the default values for all the parameters have been established. For example, if you want your footnotes to be printed in seven-point type, indented by one inch, you could say:

```
\everyfootnote = {\sevenrm \leftskip = 1in}
```

By default, an `\hrule` is typeset above each group of footnotes on a page. You can control the dimensions of this rule by setting the dimension registers `\footnoterulewidth` and `\footnoteruleheight`. The space between the rule and the first footnote on the page is determined by the dimension register `\belowfootnoterulespace`. If you don't want any rule at all, set `\footenoteruleheight=0pt`, and, most likely, `\belowfootnoterulespace=0pt`. The defaults for these parameters typeset the rule in the same way as plain TeX: the rule is 0.4 points high, 2 true inches wide, with 2.6 points below it.

The space above the rule and below the text on the page is controlled by the glue register `\skip\footins`. The default is a Plain `\bigskip`.

Fractions

Exercise 11.6 of The TeXbook describes a macro `\frac` for setting fractions, but `\frac` never made it into plain TeX. So Eplain includes it.

`\frac` typesets the numerator and denominator in `\scriptfont0`, slightly raised and lowered. The numerator and denominator are separated by a slash. The denominator must be enclosed in braces if it's more than one token long, but the numerator need not be. (This is a consequence of `\frac` taking delimited arguments; see page 203 of The TeXbook for an explanation of delimited macro arguments.)

For example, `\frac 23/{64}` turns `23/64' into .

Paths

When you typeset long pathnames, electronic mail addresses, or other such "computer" names, you would like TeX to break lines at punctuation characters within the name, rather than trying to find hyphenation points within the words. For example, it would be better to break the email address `letters@alpha.gnu.ai.mit.edu` at the `@' or a `.', rather than at the hyphenation points in `letters' and `alpha'.

If you use the `\path` macro to typeset the names, TeX will find these good breakpoints. The argument to `\path` is delimited by any other other than `\' which does not appear in the name itself. `|' is often a good choice, as in:

```
\path|letters@alpha.gnu.ai.mit.edu|
```

You can control the exact set of characters at which breakpoints will be allowed by calling `\discretionaries`. This takes the same sort of delimited argument; any character in the argument will henceforth be a valid breakpoint within `\path`. The default set is essentially all the punctuation characters:

```
\discretionaries |~!@$%^&*()_+`-=#{}[]:";'<>,.?\/|
```

If for some reason you absolutely must use `\` as the delimiter character for `\path`, you can set `\specialpathdelimiterstrue`. (Other delimiter characters can still be used.) TeX then processes the `\path` argument about four times more slowly.

Logos

Eplain redefines the `\TeX` macro of plain TeX to end with `\null`, so that the proper spacing is produced when `\TeX` is used at the end of a sentence. The other ...TeX macros listed here do this, also.

Eplain defines `\AMSTeX`, `\BibTeX` `\AMSLaTeX`, `\LAMSTeX`, `\LaTeX` `\MF`, and `\SLiTeX` to produce their respective logos. (Sorry, the logos are not shown here.) Some spelling variants of these are also supported.

Boxes

The solid rectangle that Eplain uses as a marker in unordered lists (see section Lists) is available by itself: just say `\blackbox`.

You can create black boxes of arbitrary size with `\hrule` or `\vrule`.

You can also get unfilled rectangles with `\makeblankbox`. This takes two explicit arguments: the height and depth of the rules that define the top and bottom of the rectangle. (The two arguments are added to get the width of the left and right borders, so that the thickness of the border is the same on all four sides.) It also uses, as implicit arguments, the dimensions of `\box0` to define the dimensions of the

rectangle it produces. (The contents of `\box0` are ignored.)

Here is an example. This small raised open box is suitable for putting next to numbers in, e.g., a table of contents.

```
\def\openbox{%
  \ht0 = 1.75pt \dp0 = 1.75pt \wd0 = 3.5pt
  \raise 2.75pt \makeblankbox{.2pt}{.2pt}
}
```

Finally, you can put a box around arbitrary text with `\boxit`. This takes one argument, which must itself be a (TeX) box, and puts a printed box around it, separated by `\boxitspace` white space (3 points by default) on all four sides. For example:

```
\boxit{\hbox{This text is boxed.}}
```

The reason that the argument must be a box is that when the text is more than one line long, TeX cannot figure out the line length for itself. Eplain does set `\parindent` to zero inside `\boxit`, since it is very unlikely you would want indentation there. (If you do, you can always reset it yourself.)

`\boxit` uses `\ehrule` and `\evrule` so that you can easily adjust the thicknesses of the box rules. See section Rules.

Arrow theoretic diagrams

This chapter describes definitions for producing commutative diagrams.

Steven Smith wrote this documentation (and the macros).

Slanted lines and vectors

The macros `\drawline` and `\drawvector` provide the capability found in LaTeX's picture mode to draw slanted lines and vectors of certain directions. Both of these macros take three arguments: two integer arguments to specify the direction of the line or vector, and one argument to specify its length. For example, `\drawvector(-4,1){60pt}' produces the vector which lies in the 2d quadrant, has a slope of minus 1/4, and a width of 60 pt.

Note that if an `\hbox` is placed around `\drawline` or `\drawvector`, then the width of the `\hbox` will be the positive dimension specified in the third argument, except when a vertical line or vector is specified, e.g., `\drawline(0,1){1in}`, which has zero width. If the specified direction lies in the 1st or 2d quadrant (e.g., `(1,1)` or `(-2,3)`), then the `\hbox` will have positive height and zero depth. Conversely, if the specified direction lies in the 3d or 4th quadrant (e.g., `(-1,-1)` or `(2,-3)`), then the `\hbox` will have positive depth and zero height.

There are a finite number of directions that can be specified. For `\drawline`, the absolute value of each integer defining the direction must be less than or equal to six, i.e., `(7,-1)` is incorrect, but `(6,-1)` is acceptable. For `\drawvector`, the absolute value of each integer must be less than or equal to four. Furthermore, the two integers cannot have common divisors; therefore, if a line with slope 2 is desired, say `(2,1)` instead of `(4,2)`. Also, specify `(1,0)` instead of, say, `(3,0)` for horizontal lines and likewise for vertical lines.

Finally, these macros depend upon the LaTeX font `line10`. If your site doesn't have this font, ask your system administrator to get it. Future enhancements will include macros to draw dotted lines and dotted vectors of various directions.

Commutative diagrams

The primitive commands `\drawline` and `\drawvector` can be used to typeset arrow theoretic diagrams. This section describes (1) macros to facilitate typesetting arrows and morphisms, and (2) macros to facilitate the construction of commutative diagrams. All macros described in this section must be used in math mode.

Arrows and morphisms

The macros `\mapright` and `\mapleft` produce right and left pointing arrows, respectively. Use superscript (^) to place a morphism above the arrow, e.g., `\mapright^\alpha'; use subscript (_) to place a morphism below the arrow, e.g., `\mapright_{\tilde l}'. Superscripts and subscripts may be used simulataneously, e.g., `\mapright^\pi_{\rm epimor.}'.

Similarly, the macros `\mapup` and `\mapdown` produce up and down pointing arrows, respectively. Use `\rt` to place a morphism to the right of the arrow, e.g., `\mapup\rt{\rm id}'; use `\lft` to place a morphism to the left of the arrow, e.g., `\mapup\lft\omega'. `\lft` and `\rt` may be used simultaneously, e.g., `\mapdown\lft\pi\rt{\rm monomor.}'.

Slanted arrows are produced by the macro `\arrow`, which takes a direction argument (e.g., `\arrow(3,-4)'). Use `\rt` and `\lft` to place morphisms to the right and left, respectively, of the arrow. A slanted line (no arrowhead) is produced with the macro `\sline`, whose syntax is identical to that of `\arrow`.

The length of these macros is predefined by the default TeX dimensions `\harrowlength`, for horizontal arrows (or lines), `\varrowlength`, for vertical arrows (or lines), and `\sarrowlength`, for slanted arrows (or lines). To change any of these dimensions, say, e.g., `\harrowlength=40pt'. As with all other TeX dimensions, the change may be as global or as local as you like. Furthermore, the placement of morphisms on the arrows is controlled by the dimensions `\hmorphposn`, `\vmorphposn`, and `\morphdist`. The first two dimensions control the horizontal and vertical position of the morphism from its default position; the latter dimension controls the distance of the morphism from the arrow. If you have more than one morphism per arrow (i.e., a ^/_ or `\lft`/`\rt` construction), use the parameters `\hmorphposnup`, `\hmorphposndn`, `\vmorphposnup`, `\vmorphposndn`, `\hmorphposnrt`, `\hmorphposnlft`, `\vmorphposnrt`, and `\vmorphposnlft`. The default values of all these dimensions are provided in the section on parameters that follows below.

There is a family of macros to produce horizontal lines, arrows, and adjoint arrows. The following macros produce horizontal maps and have the same syntax as `\mapright`:

```
\mapright
    $X\mapright Y$
\mapleft
    $X\mapleft Y$
\hline
    $X\hline Y$
\bimapright
    $X\bimapright Y$
\bimapleft
    $X\bimapleft Y$
\adjmapright
    $X\adjmapright Y$
\adjmapleft
    $X\adjmapleft Y$
\bihline
    $X\bihline Y$
```

There is also a family of macros to produce vertical lines, arrows, and adjoint arrows. The following macros produce vertical maps and have the same syntax as `\mapdown`:

`\mapdown`

(a down arrow)

`\mapup`
: (an up arrow)

`\vline`
: (vertical line)

`\bimapdown`
: (two down arrows)

`\bimapup`
: (two up arrows)

`\adjmapdown`
: (two adjoint arrows; down then up)

`\adjmapup`
: (two adjoint arrows; up then down)

`\bivline`
: (two vertical lines)

Finally, there is a family of macros to produce slanted lines, arrows, and adjoint arrows. The following macros produce slanted maps and have the same syntax as `\arrow`:

`\arrow`
: (a slanted arrow)

`\sline`
: (a slanted line)

`\biarrow`
: (two straight arrows)

`\adjarrow`
: (two adjoint arrows)

`\bisline`
: (two straight lines)

The width between double arrows is controlled by the parameter `\channelwidth`. There are also the parameters `\hchannel` and `\vchannel` which, if nonzero, override `\channelwidth` by controlling the horizontal and vertical shifting from the first arrow to the second.

There are no adornments on these arrows to distinguish inclusions from epimorphisms from monomorphisms. Many texts, such as Lang's book Algebra, use as a tasteful alternative the symbol `inc' (in roman) next to an arrow to denote inclusion.

Future enhancements will include a mechanism to draw curved arrows found in, e.g., the Snake Lemma, by employing a version of the `\path` macros of Appendix D of The TeXbook.

Construction of commutative diagrams

There are two approaches to the construction of commutative diagrams described here. The first approach, and the simplest, treats commutative diagrams like fancy matrices, as Knuth does in Exercise 18.46 of The

TeXbook. This case is covered by the macro `\commdiag`, which is an altered version of the Plain TeX macro `\matrix`. An example suffices to demonstrate this macro. The following commutative diagram (illustrating the covering homotopy property; Bott and Tu, Differential Forms in Algebraic Topology) is produced with the code

```
$$\commdiag{Y&\mapright^f&E\cr \mapdown&\arrow(3,2)\lft{f_t}&\mapdown\cr
Y\times I&\mapright^{\bar f_t}&X}$$
```

Of course, the parameters may be changed to produce a different effect. The following commutative diagram (illustrating the universal mapping property; Warner, Foundations of Differentiable Manifolds and Lie Groups) is produced with the code

```
$$\varrowlength=20pt
\commdiag{V\otimes W\cr \mapup\lft\phi&\arrow(3,-1)\rt{\tilde l}\cr
V\times W&\mapright^l&U\cr}$$
```

A diagram containing isosceles triangles is achieved by placing the apex of the triangle in the center column, as shown in the example (illustrating all constant minimal realizations of a linear system; Brockett, Finite Dimensional Linear Systems) which is produced with the code

```
$$\sarrowlength=.42\harrowlength
\commdiag{&R^m\cr &\arrow(-1,-1)\lft{\bf B}\quad \arrow(1,-1)\rt{\bf G}\cr
R^n&\mapright^{\bf P}&R^n\cr
\mapdown\lft{e^{{\bf A}t}}&&\mapdown\rt{e^{{\bf F}t}}\cr
R^n&\mapright^{\bf P}&R^n\cr
&\arrow(1,-1)\lft{\bf C}\quad \arrow(-1,-1)\rt{\bf H}\cr
&R^q\cr}$$
```

Other commutative diagram examples appear in the file `commdiags.tex`, which is distributed with this package.

In these examples the arrow lengths and line slopes were carefully chosen to blend with each other. In the first example, the default settings for the arrow lengths are used, but a direction for the arrow must be chosen. The ratio of the default horizontal and vertical arrow lengths is approximately the golden mean the arrow direction closest to this mean is `(3,2)`. In the second example, a slope of is desired and the default horizontal arrow length is 60 pt; therefore, choose a vertical arrow length of 20 pt. You may affect the interline glue settings of `\commdiag` by redefining the macro `\commdiagbaselines`. (cf. Exercise 18.46 of The TeXbook and the section on parameters below.)

The width, height, and depth of all morphisms are hidden so that the morphisms' size do not affect arrow positions. This can cause a large morphism at the top or bottom of a diagram to impinge upon the text surrounding the diagram. To overcome this problem, use TeX's `\noalign` primitive to insert a `\vskip` immediately above or below the offending line, e.g., `$$\commdiag{\noalign{\vskip6pt}X&\mapright^\int&Y\cr ...}'.

The macro `\commdiag` is too simple to be used for more complicated diagrams, which may have intersecting or overlapping arrows. A second approach, borrowed from Francis Borceux's Diagram macros for LaTeX, treats the commutative diagram like a grid of identically shaped boxes. To compose the commutative diagram, first draw an equally spaced grid, e.g., on a piece of scratch paper. Then draw each element (vertices and

arrows) of the commutative diagram on this grid, centered at each grid point. Finally, use the macro `\gridcommdiag` to implement your design as a TeX alignment. For example, the cubic diagram that appears in Francis Borceux's documentation can be implemented on a 7 by 7 grid, and is achieved with the code

```
$$\harrowlength=48pt \varrowlength=48pt \sarrowlength=20pt
\def\cross#1#2{\setbox0=\hbox{$#1$}%
  \hbox to\wd0{\hss\hbox{$#2$}\hss}\llap{\unhbox0}}
\gridcommdiag{&&B&&\mapright^b&&D\cr
&\arrow(1,1)\lft a&&&&\arrow(1,1)\lft d\cr
A&&\cross{\hmorphposn=12pt\mapright^c}{\vmorphposn=-12pt\mapdown\lft f}
&&C&&\mapdown\rt h\cr\cr
\mapdown\lft e&&F&&\cross{\hmorphposn=-12pt\mapright_j}
{\vmorphposn=12pt\mapdown\rt g}&&H\cr
&\arrow(1,1)\lft i&&&&\arrow(1,1)\rt l\cr
E&&\mapright_k&&G\cr}$$
```

The dimensions `\hgrid` and `\vgrid` control the horizontal and vertical spacing of the grid used by `\gridcommdiag`. The default setting for both of these dimensions is 15 pt. Note that in the example of the cube the arrow lengths must be adjusted so that the arrows overlap into neighboring boxes by the desired amount. Hence, the `\gridcommdiag` method, albeit more powerful, is less automatic than the simpler `\commdiag` method. Furthermore, the ad hoc macro `\cross` is introduced to allow the effect of overlapping arrows. Finally, note that the positions of four of the morphisms are adjusted by setting `\hmorphposn` and `\vmorphposn`.

One is not restricted to a square grid. For example, the proof of Zassenhaus's Butterfly Lemma can be illustrated by the diagram (appearing in Lang's book Algebra) This diagram may be implemented on a 9 by 12 grid with an aspect ratio of 1/2, and is set with the code

```
$$\hgrid=16pt \vgrid=8pt \sarrowlength=32pt
\def\cross#1#2{\setbox0=\hbox{$#1$}%
  \hbox to\wd0{\hss\hbox{$#2$}\hss}\llap{\unhbox0}}
\def\l#1{\llap{$#1$\hskip.5em}}
\def\r#1{\rlap{\hskip.5em$#1$}}
\gridcommdiag{&&U&&&&V\cr &&\bullet&&&&\bullet\cr
&&\sarrowlength=16pt\sline(0,1)&&&&\sarrowlength=16pt\sline(0,1)\cr
&&\l{u(U\cap V)}\bullet&&&&\bullet\r{(U\cap V)v}\cr
&&&\sline(2,-1)&&\sline(2,1)\cr
&&\cross{=}{\sline(0,1)}&&\bullet&&\cross{=}{\sline(0,1)}\cr\cr
&&\l{^{\textstyle u(U\cap v)}}\bullet&&\cross{=}{\sline(0,1)}&&
 \bullet\r{^{\textstyle(u\cap V)v}}\cr
&\sline(2,1)&&\sline(2,-1)&&\sline(2,1)&&\sline(2,-1)\cr
\l{u}\bullet&&&&\bullet&&&&\bullet\r{v}\cr
&\sline(2,-1)&&\sline(2,1)&&\sline(2,-1)&&\sline(2,1)\cr
&&\bullet&&&&\bullet\cr &&u\cap V&&&&U\cap v\cr}$$
```

Again, the construction of this diagram requires careful choices for the arrow lengths and is facilitated by the introduction of the ad hoc macros `\cross`, `\r`, and `\l`. Note also that superscripts were used to adjust the

position of the vertices Many diagrams may be typeset with the predefined macros that appear here; howe ingenuity is often required to handle special cases.

Commutative diagram parameters

The following is a list describing the parameters used in the commutative diagram macros. These dimensions may be changed globally or locally.

`\harrowlength`

(Default: 60 pt) The length of right or left arrows.

`\varrowlength`

(Default: 0.618`\harrowlength`) The length of up or down arrows.

`\sarrowlength`

(Default: 60 pt) The horizontal length of slanted arrows.

`\hmorphposn`

(Default: 0 pt) The horizontal position of the morphism with respect to its default position. There are also the dimensions `\hmorphposnup`, `\hmorphposndn`, `\hmorphposnrt`, and `\hmorphposnlft` for ^/_ or `\lft`/`\rt` constructions.

`\vmorphposn`

(Default: 0 pt) The vertical position of the morphism with respect to its default position. There are also the dimensions `\vmorphposnup`, `\vmorphposndn`, `\vmorphposnrt`, and `\vmorphposnlft` for ^/_ or `\lft`/`\rt` constructions.

`\morphdist`

(Default: 4 pt) The distance of morphisms from slanted lines or arrows.

`\channelwidth`

(Default: 3 pt) The distance between double lines or arrows.

`\hchannel, \vchannel`

(Defaults: 0 pt) Overrides `\channelwidth`. The horizontal and vertical shifts between double lines or arrows.

`\commdiagbaselines`

(Default: `\baselineskip=15pt \lineskip=3pt \lineskiplimit=3pt`) The parameters used by `\commdiag` for setting interline glue.

`\hgrid`

(Default: 15 pt) The horizontal spacing of the grid used by `\gridcommdiag`.

`\vgrid`

(Default: 15 pt) The vertical spacing of the grid used by `\gridcommdiag`.

Go to the previous, next section.

Programming definitions

The definitions in this section are only likely to be useful when you are writing nontrivial macros, not for controlling the appearance of your document.

Category codes

Plain TeX defines `\active` (as the number 13) for use in changing category codes. Although the author of The TeXbook has "intentionally kept the category codes numeric", two other categories are commonly used: letters (category code 11) and others (12). Therefore, Eplain defines `\letter` and `\other`.

Sometimes it is cleaner to make a character active without actually writing a `\catcode` command. The `\makeactive` command takes a character as an argument to make active (and ignores following spaces). For example, here are two commands which both make \ active:

```
\makeactive`\\   \makeactive92
```

Usually, when you give a definition to an active character, you have to do so inside a group where you temporarily make the character active, and then give it a global definition (cf. the definition of `\obeyspaces` in The TeXbook). This is inconvenient if you are writing a long macro, or if the character already has a global definition you do not wish to transcend. Eplain provides `\letreturn`, which defines the usual end-of-line character to be the argument. For example:

```
\def\mymacro{... \letreturn\myreturn ... }
\mymacro hello
there
```

The end-of-line between `hello' and `there' causes `\myreturn` to be expanded.

The TeXbook describes `\uncatcodespecials`, which makes all characters which are normally "special" into "other" characters, but the definition never made it into plain TeX. Eplain therefore defines it.

Finally, `\percentchar` expands into a literal `%' character. This is useful when you `\write` TeX output to a file, and want to avoid spurious spaces. For example, Eplain writes a `\percentchar` after the definition of cross-references. The macros `\lbracechar` and `\rbracechar` expand similarly.

Allocation macros

Plain TeX provides macros that allocate registers of each primitive type in TeX, to prevent different sets of macros from using the same register for two different things. The macros are all named starting with `new', e.g., `\newcount` allocates a new "count" (integer) register. Such allocations are usually needed

only at the top level of some macro definition file; therefore, plain TeX makes the allocation register `\outer`, to help find errors. (The error this helps to find is a missing right brace in some macro definition.)

Sometimes, however, it is useful to allocate a register as part of some macro. An outer control sequence cannot be used as part of a macro definition (or in a few other contexts: the parameter text of a definition, an argument to a definition, the preamble of an alignment, or in conditional text that is being skipped). Therefore, Eplain defines "inner" versions of all the allocation macros, named with the prefix `inner': `\innernewbox`, `\innernewcount`, `\innernewdimen`, `\innernewfam`, `\innernewhelp`, `\innernewif`, `\innernewinsert`, `\innernewlanguage`, `\innernewread`, `\innernewskip`, `\innernewtoks`, `\innernewwrite`.

You can also define non-outer versions of other macros in the same way that Eplain defines the above. The basic macro is called `\innerdef`:

```
\innerdef \innername {outername}
```

The first argument (\innername) to `\innerdef` is the control sequence that you want to define. Any previous definition of \innername is replaced. The second argument (outername) is the *characters* in the name of the outer control sequence. (You can't use the actual control sequence name, since it's outer!)

If the outer control sequence is named \cs, and you want to define `innercs` as the inner one, you can use `\innerinnerdef`, which is just an abbreviation for a call to `\innerdef`. For example, these two calls are equivalent:

```
\innerdef\innerproclaim{proclaim}
\innerinnerdef{proclaim}
```

Iteration

You can iterate through a comma-separated list of items with `\for`. Here is an example:

```
\for\name:=karl,kathy\do{%
   \message{\name}%
}%
```

This writes `karl' and `kathy' to the terminal. Spaces before or after the commas in the list, or after the `:=`, are *not* ignored.

`\for` expands the iterated values fully (with `\edef`), so this is equivalent to the above:

```
\def\namelist{karl,kathy}%
\for\name:=\namelist\do ...
```

Macro arguments

It is occasionally useful to redefine a macro that takes arguments to do nothing. Eplain defines `\gobble`, `\gobbletwo`, and `\gobblethree` to swallow one, two, and three arguments, respectively.

For example, if you want to produce a "short" table of contents--one that includes only chapters, say--the easiest thing to do is read the entire `.toc` file (see section Contents), and just ignore the commands that produce section or subsection entries. To be specific:

```
\let\tocchapterentry = \shorttocchapter
\let\tocsectionentry = \gobbletwo
\let\tocsubsectionentry = \gobbletwo
\readtocfile
```

(Of course, this assumes you only have chapters, sections, and subsections in your document.)

In addition, Eplain defines `\eattoken` to swallow the single following token, using `\let`. Thus, `\gobble` followed by `{...}' ignores the entire brace-enclosed text. `\eattoken` followed by the same ignores only the opening left brace.

Eplain defines a macro `\identity` which takes one argument and expands to that argument. This may be useful if you want to provide a function for the user to redefine, but don't need to do anything by default. (For example, the default definition of `\eqconstruct` (see section Formatting equation references) is `\identity`.)

You may also want to read an optional argument. The established convention is that optional arguments are put in square brackets, so that is the syntax Eplain recognizes. Eplain ignores space tokens before an optional argument, via `\futurenonspacelet`.

You test for an optional argument by using `\@getoptionalarg`. It takes one argument, a control sequence to expand after reading the argument, if present. If an optional argument is present, the control sequence `\@optionalarg` expands to it; otherwise, `\@optionalarg` is `\empty`. You must therefore have the category code of @ set to 11 (letter). Here is an example:

```
\catcode`@=\letter
\def\cmd{\@getoptionalarg\finishcmd}
\def\finishcmd{%
  \ifx\@optionalarg\empty
    % No optional argument present.
  \else
    % One was present.
  \fi
}
```

If an optional argument contains another optional argument, the inner one will need to be enclosed in braces, so TeX does not mistake the end of the first for the end of the second.

Converting to characters

Eplain defines `\xrlabel`. to produce control sequence names for cross-reference labels, et al. This macro expands to its argument with an `_' appended. (It does this because the usual use of `\xrlabel` is to generate a control sequence name, and conflicts between control sequence names would lead to obscure bugs.)

Because `\xrlabel` is fully expandable, to make a control sequence name out of the result you need only do

```
\csname \xrlabel{label}\endcsname
```

The `\csname` primitive makes a control sequence name out of any sequence of character tokens, regardless of category code. Labels can therefore include any characters except for `\', `{', `}', and `#', all of which are used in macro definitions themselves.

`\sanitize` takes a control sequence as an argument and converts the expansion of the control sequence into a list of character tokens. This is the behavior you want when writing information like chapter titles to an output file. For example, here is part of the definition of `\writenumberedtocentry`; `#2` is the title that the user has given.

```
...
\def\temp{#2}%
...
  \write\tocfile{%
    ...
    \sanitize\temp
    ...
  }%
```

Expansion

This section describes some miscellanous macros for expansion, etc.

\csn and \ece

`\csn`{name} simply abbreviates `\csname` name `\encsname`, thus saving some typing. The extra level of expansion does take some time, though, so I don't recommend it for an inner loop.

`\ece`{token}{name} abbreviates

```
\expandafter token \csname name \endcsname
```

For example,

```
\def\fontabbrevdef#1#2{\ece\def{@#1font}{#2}}
\fontabbrevdef{normal}{ptmr}
```

defines a control sequence `\@normalfont` to expand to `ptmr`.

\edefappend

`\edefappend` is a way of adding on to an existing definition. It takes two arguments: the first is the control sequence name, the second the new tokens to append to the definition. The second argument is fully expanded (in the `\edef` that redefines the control sequence).

For example:

```
\def\foo{abc}
\def\bar{xyz}
\edefappend\foo{\bar karl}
```

results in `\foo` being defined as `abcxyzkarl'.

Hooks

A hook is simply a name for a group of actions which is executed in certain places--presumably when it is most useful to allow customization or modification. TeX already provides many builtin hooks; for example, the `\every ...` token lists are all examples of hooks.

Eplain provides several macros for adding actions to hooks. They all take two arguments: the name of the hook and the new actions.

`hookaction name actions`

`hookappend name actions`

`hookprepend name actions`

Each of these adds actions to the hook name. (Any previously-defined actions are retained.) name is not a control sequence, but rather the characters of the name.

`hookactiononce name \cs`

`\hookactiononce` adds cs to name, like the macros above, but first it adds

```
\global\let \cs \relax
```

to the definition of \cs. (This implies \cs must be a true expandable macro, not a control sequence `\let` to a primitive or some other such thing.) Thus, \cs is expanded the next time the hook name is run, but it will disappear after that.

The `\global` is useful because `\hookactiononce` is most useful when the grouping structure of the TeX code could be anything. Neither this nor the other hook macros do global assignments to the hook variable itself, so TeX's usual grouping rules apply.

The companion macro to defining hook actions is `\hookrun`, for running them. This takes a single argument, the name of the hook. If no actions for the hook are defined, no error ensues.

Here is a skeleton of general `\begin` and `\end` macros that run hooks, and a couple of calls to define actions. The use of `\hookprepend` for the begin action and `\hookappend` for the end action ensures that the actions are executed in proper sequence with other actions (as long as the other actions use `\hookprepend` and `\hookappend` also).

```
\def\begin#1{ ... \hookrun{begin} ... }
\def\end#1{ ... \hookrun{end} ... }
\hookprepend{begin}\start_underline
\hookappend{end}\finish_underline
```

Properties

A property is a name/value pair associated with another symbol, traditionally called an atom. Both atom and property names are control sequence names.

Eplain provides two macros for dealing with property lists: `\setproperty` and `\getproperty`.

`\setproperty atom propname value`

> `\setproperty` defines the property property on the atom atom to be value. atom and propname can be anything acceptable to `\csname`. value can be anything.

`\getproperty atom propname`

> `\getproperty` expands to the value stored for propname on atom. If propname is undefined, it expands to nothing (i.e., `\empty`).

The idea of properties originated in Lisp (I believe). There, the implementation truly does associate properties with atoms. In TeX, where we have no builtin support for properties, the association is only conceptual.

The following example typesets `xyz'.

```
\setproperty{a}{pr}{xyz}
\getproperty{a}{pr}
```

\expandonce

`\expandonce` is defined as `\expandafter\noexpand`. Thus, `\expandonce token` expands token once, instead of to TeX primitives. This is most useful in an `\edef`.

For example, the following defines `\temp` to be `\foo`, not `abc'.

```
\def\foo{abc}
\def\bar{\foo}
\edef\temp{\expandonce\bar}
```

\ifundefined

`\ifundefined{cs} t \else f \fi` expands the t text if the control sequence `\cs` is undefined or has been `\let` to `\relax`, and the f text otherwise.

Since `\ifundefined` is not a primitive conditional, it cannot be used in places where TeX might skip tokens "at high speed", e.g., within another conditional---TeX can't match up the `\if`'s and `\fi`'s.

This macro was taken directly from The TeXbook, page 308.

\futurenonspacelet

The `\futurelet` primitive allows you to look at the next token from the input. Sometimes, though, you want to look ahead ignoring any spaces. This is what `\futurenonspacelet` does. It is otherwise the same as `\futurelet`: you give it two control sequences as arguments, and it assigns the next nonspace token to the first, and then expands the second. For example:

```
\futurenonspacelet\temp\finishup
\def\finishup{\ifx\temp ...}
```

Obeying spaces

`\obeywhitespace` makes both end-of-lines and space characters in the input be respected in the output. Unlike plain TeX's `\obeyspaces`, even spaces at the beginnings of lines turn into blank space.

By default, the size of the space that is produced by a space character is the natural space of the current font, i.e., what `\ ` produces.

Ordinarily, a blank line in the input produces as much blank vertical space as a line of text would occupy. You can adjust this by assigning to the parameter `\blanklineskipamount`: if you set this negative, the space produced by a blank line will be smaller; if positive, larger.

Tabs are not affected by this routine. In particular, if tabs occur at the beginning of a line, they will disappear. (If you are trying to make TeX do the "right thing" with tabs, don't. Use a utility program like *expand* instead.)

Writing out numbers

`\numbername` produces the written-out form of its argument, i.e., `zero' through `ten' for the numbers 0--10, and numerals for all others.

Mode-specific penalties

TeX's built-in `\penalty` command simply appends to the current list, no matter what kind of list it is. You might intend a particular penalty to always be a "vertical" penalty, however, i.e., appended to a vertical list. Therefore, Eplain provides `\vpenalty` and `\hpenalty` which first leave the other mode and then do `\penalty`.

More precisely, `\vpenalty` inserts `\par` if the current mode is horizontal, and `\hpenalty` inserts `\leavevmode` if the current mode is vertical. (Thus, `\vpenalty` cannot be used in math mode.)

Auxiliary files

It is common to write some information out to a file to be used on a subsequent run. But when it is time to read the file again, you only want to do so if the file actually exists. `\testfileexistence` is given an argument which is appended to `\jobname`, and sets the conditional `\iffileexists` appropriately.

For example:

```
\testfileexistence{toc}%
\iffileexists
   \input \jobname.toc
\fi
```

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free use or not licensed at all.

TOC

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.

2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

   You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

3. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:

   1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
   2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
   3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

   These requirements apply to the modified work as a whole. If identifiable sections of that work are not derived from the Program, and can be reasonably considered independent and separate works in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on

the Program, the distribution of the whole must be on the terms of this License, whose permission other licensees extend to the entire whole, and thus to each and every part regardless of who wrote

Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for noncommercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

    The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

    If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.

5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.
6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on

it.

7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

   If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

   It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

   This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.
9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.
11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

Appendix: How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and a brief idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or modify
it under the terms of the GNU General Public License as published by
the Free Software Foundation; either version 2 of the License, or
(at your option) any later version.

This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
```

```
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details type `show w'.
This is free software, and you are welcome to redistribute it
under certain conditions; type `show c' for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright interest in the program
`Gnomovision' (which makes passes at compilers) written by James Hacker.

signature of Ty Coon, 1 April 1989
Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License instead of this License.

Regain your programming freedom

Until a few years ago, programmers in the United States could write any program they wished. This freedom has now been taken away by two developments: software patents, which grant the patent holder an absolute monopoly on some programming technique, and user interface copyright, which forbid compatible implementations of an existing user interface.

In Europe, especially through the GATT treaty, things are rapidly approaching the same pass.

Software patents

The U.S. Patent and Trademark Office has granted numerous software patents on software techniques. Patents are an absolute monopoly--independent reinvention is precluded. This monopoly lasts for seventeen years, i.e., forever (with respect to computer science).

One patent relevant to TeX is patent 4,956,809, issued to the Mark Williams company on September 11, 1990, applied for in 1982, which covers (among other things)

> representing in a standardized order consisting of a standard binary structure file stored on auxiliary memory or transported on a communications means, said standardized order being different from a different order used on at least one of the different computers;
>
> Converting in each of the different computers binary data read from an auxiliary data storage or communications means from the standardized order to the natural order of the respective host computer after said binary data are read from said auxiliary data storage or communications means and before said binary data are used by the respective host computer; and
>
> Converting in each of the different computers binary data written into auxiliary data storage or communications means from the natural order of the respective host computer to the standardized order prior to said writing.

... in other words, storing data on disk in a machine-independent order, as the DVI, TFM, GF, and PK file formats specify. Even though TeX is "prior art" in this respect, the patent was granted (the patent examiners not being computer scientists, even less computer typographers). Since there is a strong presumption in the courts of a patent's validity once it has been granted, there is a good chance that users or implementors of TeX could be successfully sued on the issue.

As another example, the X window system, which was intended to be able to be used freely by everyone, is now being threatened by two patents: 4,197,590 on the use of exclusive-or to redraw cursors, held by Cadtrak, a litigation company (this has been upheld twice in court); and 4,555,775, held by AT&T, on the use of backing store to redraw windows quickly.

Here is one excerpt from a recent mailing by the League for Programming Freedom (see section What to

do?) which I feel sums up the situation rather well. It comes from an article in Think magazine, issue 1990. The comments after the quote were written by Richard Stallman.

> "You get value from patents in two ways," says Roger Smith, IBM Assistant General Counsel, intellectual property law. "Through fees, and through licensing negotiations that give IBM access to other patents.
>
> "The IBM patent portfolio gains us the freedom to do what we need to do through cross-licensing--it gives us access to the inventions of others that are the key to rapid innovation. Access is far more valuable to IBM than the fees it receives from its 9,000 active patents. There's no direct calculation of this value, but it's many times larger than the fee income, perhaps an order of magnitude larger."

This information should dispel the belief that the patent system will "protect" a small software developer from competition from IBM. IBM can always find patents in its collection which the small developer is infringing, and thus obtain a cross-license.

However, the patent system does cause trouble for the smaller companies which, like IBM, need access to patented techniques in order to do useful work in software. Unlike IBM, the smaller companies do not have 9,000 patents and cannot usually get a cross-license. No matter how hard they try, they cannot have enough patents to do this.

Only the elimination of patents from the software field can enable most software developers to continue with their work.

The value IBM gets from cross-licensing is a measure of the amount of harm that the patent system would do to IBM if IBM could not avoid it. IBM's estimate is that the trouble could easily be ten times the good one can expect from one's own patents--even for a company with 9,000 of them.

User interface copyright

(This section is copied from the GCC manual, by Richard Stallman.)

> *This section is a political message from the League for Programming Freedom to the users of Eplain. It is included here as an expression of support for the League on my part.*

Apple, Lotus and Xerox are trying to create a new form of legal monopoly: a copyright on a class of user interfaces. These monopolies would cause serious problems for users and developers of computer software and systems.

Until a few years ago, the law seemed clear: no one could restrict others from using a user interface; programmers were free to implement any interface they chose. Imitating interfaces, sometimes with changes, was standard practice in the computer field. The interfaces we know evolved gradually in this way; for example, the Macintosh user interface drew ideas from the Xerox interface, which in turn drew on work done at Stanford and SRI. 1-2-3 imitated VisiCalc, and dBase imitated a database program from JPL.

Most computer companies, and nearly all computer users, were happy with this state of affairs. The companies that are suing say it does not offer "enough incentive" to develop their products, but they must

have considered it "enough" when they made their decision to do so. It seems they are not satisfied w the opportunity to continue to compete in the marketplace--not even with a head start.

If Xerox, Lotus, and Apple are permitted to make law through the courts, the precedent will hobble the software industry:

- Gratuitous incompatibilities will burden users. Imagine if each car manufacturer had to arrange the pedals in a different order.
- Software will become and remain more expensive. Users will be "locked in" to proprietary interfaces, for which there is no real competition.
- Large companies have an unfair advantage wherever lawsuits become commonplace. Since they can easily afford to sue, they can intimidate small companies with threats even when they don't really have a case.
- User interface improvements will come slower, since incremental evolution through creative imitation will no longer be permitted.
- Even Apple, etc., will find it harder to make improvements if they can no longer adapt the good ideas that others introduce, for fear of weakening their own legal positions. Some users suggest that this stagnation may already have started.
- If you use GNU software, you might find it of some concern that user interface copyright will make it hard for the Free Software Foundation to develop programs compatible with the interfaces that you already know.

What to do?

(This section is copied from the GCC manual, by Richard Stallman.)

To protect our freedom from lawsuits like these, a group of programmers and users have formed a new grass-roots political organization, the League for Programming Freedom.

The purpose of the League is to oppose new monopolistic practices such as user-interface copyright and software patents; it calls for a return to the legal policies of the recent past, in which these practices were not allowed. The League is not concerned with free software as an issue, and not affiliated with the Free Software Foundation.

The League's membership rolls include John McCarthy, inventor of Lisp, Marvin Minsky, founder of the Artificial Intelligence lab, Guy L. Steele, Jr., author of well-known books on Lisp and C, as well as Richard Stallman, the developer of GNU CC. Please join and add your name to the list. Membership dues in the League are $42 per year for programmers, managers and professionals; $10.50 for students; $21 for others.

The League needs both activist members and members who only pay their dues.

To join, or for more information, phone (617) 492-0023 or write to:

```
League for Programming Freedom
1 Kendall Square #143
```

```
P.O. Box 9171
Cambridge, MA 02139
```

You can also send electronic mail to `league@prep.ai.mit.edu`.

Here are some suggestions from the League for things you can do to protect your freedom to write programs:

- Don't buy from Xerox, Lotus or Apple. Buy from their competitors or from the defendants they are suing.
- Don't develop software to work with the systems made by these companies.
- Port your existing software to competing systems, so that you encourage users to switch.
- Write letters to company presidents to let them know their conduct is unacceptable.
- Tell your friends and colleagues about this issue and how it threatens to ruin the computer industry.
- Above all, don't work for the look-and-feel plaintiffs, and don't accept contracts from them.
- Write to Congress to explain the importance of this issue.

```
House Subcommittee on Intellectual Property
2137 Rayburn Bldg
Washington, DC 20515

Senate Subcommittee on Patents, Trademarks and Copyrights
United States Senate
Washington, DC 20510
```

(These committees have received lots of mail already; let's give them even more.)

Express your opinion! You can make a difference.

Forms Mode User's Manual

Forms Mode User's Manual

Forms Mode User's Manual

Forms-Mode version 2.3

September 1993

Johan Vromans *jv@nl.net*

Forms mode is an Emacs major mode for working with simple textual data bases in a forms-oriented manner. In Forms mode, the information in these files is presented in an Emacs window in a user-defined format, one record at a time. The user can view records or modify their contents.

Forms mode is not a simple major mode, but requires two files to do its job: a control file and a data file. The data file holds the actual data to be presented. The control file describes how to present it.

Forms Example

Let's illustrate Forms mode with an example. Suppose you are looking at the `/etc/passwd' file, and the screen looks like this:

```
====== /etc/passwd ======

User : root   Uid: 0   Gid: 1

Name : Super User

Home : /

Shell: /bin/sh
```

As you can see, the familiar fields from the entry for the super user are all there, but instead of being colon-separated on one single line, they make up a forms.

The contents of the forms consists of the contents of the fields of the record (e.g. `root', `0', `1', `Super User') interspersed with normal text (e.g `User : ', `Uid: ').

If you modify the contents of the fields, Forms mode will analyze your changes and update the file appropriately. You cannot modify the interspersed explanatory text (unless you go to some trouble about it), because that is marked read-only (see section 'Text Properties' in The Emacs Lisp Reference Manual).

The Forms mode control file specifies the relationship between the format of `/etc/passwd' and what appears on the screen in Forms mode. See section Control File Format.

Entering and Exiting Forms Mode

M-x forms-find-file RET control-file RET

Visit a database using Forms mode. Specify the name of the **control file**, not the data file!

M-x forms-find-file-other-window RET control-file RET

Similar, but displays the file in another window.

The command `forms-find-file` evaluates the file control-file, and also visits it in Forms mode. What you see in its buffer is not the contents of this file, but rather a single record of the corresponding data file that is visited in its own buffer. So there are two buffers involved in Forms mode: the forms buffer that is initially used to visit the control file and that shows the records being browsed, and the data buffer that holds the data file being visited. The latter buffer is normally not visible.

Initially, the first record is displayed in the forms buffer. The mode line displays the major mode name `Forms', followed by the minor mode `View' if the data base is read-only. The number of the current record (n) and the total number of records in the file(t) are shown in the mode line as `n/t'. For example:

```
--%%-Emacs: passwd-demo          (Forms View 1/54)----All-------
```

If the buffer is not read-only, you may change the buffer to modify the fields in the record. When you move to a different record, the contents of the buffer are parsed using the specifications in `forms-format-list`, and the data file is updated. If the record has fields that aren't included in the display, they are not changed.

Entering Forms mode runs the normal hook `forms-mode-hooks` to perform user-defined customization.

To save any modified data, you can use C-x C-s (`save-buffer`). This does not save the forms buffer (which would be rather useless), but instead saves the buffer visiting the data file.

To terminate Forms mode, you can use C-x C-s (`save-buffer`) and then kill the forms buffer. However, the data buffer will still remain. If this is not desired, you have to kill this buffer too.

Forms Commands

The commands of Forms mode belong to the C-c prefix, with one exception: TAB, which moves to the next field. Forms mode uses different key maps for normal mode and read-only mode. In read-only Forms mode, you can access most of the commands without the C-c prefix, but you must type ordinary letters instead of control characters; for example, type n instead of C-c C-n.

C-c C-n

Show the next record (`forms-next-record`). With a prefix argument n, show the nth next record.

C-c C-p

Show the previous record (`forms-prev-record`). With a prefix argument n, show the nth previous record.

C-c C-l

Jump to a record by number (`forms-jump-record`). Specify the record number with a prefix argument.

C-c <

Jump to the first record (`forms-first-record`).

C-c >

Jump to the last record (`forms-last-record`). This command also recalculates the number of records in the data file.

TAB

C-c TAB

Jump to the next field in the current record (`forms-next-field`). With a numeric argument n, jump forward n fields. If this command would move past the last field, it wraps around to the first field.

C-c C-q

Toggles read-only mode (`forms-toggle-read-only`). In read-only Forms mode, you cannot edit the fields; most Forms mode commands can be accessed without the prefix C-c if you use the normal letter instead (for example, type n instead of C-c C-n). In edit mode, you can edit the fields and thus change the contents of the data base; you must begin Forms mode commands with `C-c`. Switching to edit mode is allowed only if you have write access to the data file.

C-c C-o

Create a new record and insert it before the current record (`forms-insert-record`). It starts out with empty (or default) contents for its fields; you can then edit the fields. With a prefix argument, the new record is created *after* the current one. See also `forms-modified-record-filter` in section Modifying The Forms Contents.

C-c C-k

Delete the current record (`forms-delete-record`). You are prompted for confirmation before the record is deleted unless a prefix argument has been provided.

C-c C-s regexp RET

Search for regexp in all records following this one (`forms-search`). If found, this record is shown. If you give an empty argument, the previous regexp is used again.

M-x forms-prev-field

Similar to `forms-next-field` but moves backwards.

In addition, commands such as C-x C-s (`save-buffer`) and M-x revert-buffer are useful in Forms mode just as in other modes.

The following function key definitions are set up in Forms mode (whether read-only or not):

next

forms-next-record

prior

forms-prev-record

begin

forms-first-record

end

forms-last-record

S-Tab

forms-prev-field

Data File Format

Files for use with Forms mode are very simple--each record (usually one line) forms the contents of one form. Each record consists of a number of fields, which are separated by the value of the string `forms-field-sep`, which is `"\t"` (a tab) by default.

Fields may contain text which shows up in the forms in multiple lines. These lines are separated in the field using a "pseudo-newline" character which is defined by the value of the string `forms-multi-line`. Its default value is `"\^k"`. If it is set to `nil`, multiple line fields are prohibited.

Control File Format

The Forms mode control file serves two purposes. First, it names the data file to use, and defines its format and properties. Second, the Emacs buffer it occupies is used by Forms mode to display the forms.

The contents of the control file are evaluated as a Lisp program. It should set the following Lisp variables to suitable values:

`forms-file`

This variable specifies the name of the data file. Example:

```
(setq forms-file "my/data-file")
```

`forms-format-list`

This variable describes the way the fields of the record are formatted on the screen. For details, see section The Format Description.

`forms-number-of-fields`

This variable holds the number of fields in each record of the data file. Example:

```
(setq forms-number-of-fields 10)
```

If the control file doesn't set all of these variables, Forms mode reports an error.

The control file can optionally set the following additional Forms mode variables. Most of them have default values that are good for most applications.

`forms-field-sep`

This variable may be used to designate the string which separates the fields in the records of the data file. If not set, it defaults to the string `"\t"` (a tab character). Example:

```
(setq forms-field-sep "\t")
```

`forms-read-only`

If the value is non-`nil`, the data file is treated read-only. (Forms mode also treats the data file as read-only if you don't have access to write it.) Example:

```
(set forms-read-only t)
```

`forms-multi-line`

This variable specifies the pseudo newline separator that allows multi-line fields. This separator goes between the "lines" within a field--thus, the field doesn't really contain multiple lines, but it appears that way when displayed in Forms mode. If the value is `nil`, multi-line text fields are prohibited. The pseudo newline must not be a character contained in `forms-field-sep`.

The default value is `"\^k"`, so the default pseudo newline is the character control-k. Example:

```
(setq forms-multi-line "\^k")
```

`forms-new-record-filter`

This variable holds a function to be called whenever a new record is created to supply default values for fields. If it is `nil`, no function is called. See section Modifying The Forms Contents, for details.

`forms-modified-record-filter`

This variable holds a function to be called whenever a record is modified, just before updating the Forms data file. If it is `nil`, no function is called. See section Modifying The Forms Contents, for details.

The Format Description

The variable `forms-format-list` specifies the format of the data in the data file, and how to convert the data for display in Forms mode. Its value must be a list of Forms mode formatting elements, each of which can be a string, a number, a Lisp list, or a Lisp symbol that evaluates to one of those. The formatting elements are processed in the order they appear in the list.

string

A string formatting element is inserted in the forms "as is," as text that the user cannot alter.

number

A number element selects a field of the record. The contents of this field are inserted in the display at this point. Field numbers count starting from 1 (one).

list

A formatting element that is a list specifies a function call. This function is called every time a record is displayed, and its result, which must be a string, is inserted in the display text. The function should do nothing but returning a string.

The function you call can access the fields of the record as a list in the variable `forms-fields`.

symbol

A symbol used as a formatting element should evaluate to a string, number, or list; the value is interpreted as a formatting element, as described above.

If a record does not contain the number of fields as specified in `forms-number-of-fields`, a warning message will be printed. Excess fields are ignored, missing fields are set to empty.

The control file which displays `` `/etc/passwd' `` file as demonstrated in the beginning of this manual might look as follows:

```
;; This demo visits `/etc/passwd'.

(setq forms-file "/etc/passwd")
(setq forms-number-of-fields 7)
(setq forms-read-only t)                ; to make sure
(setq forms-field-sep ":")
;; Don't allow multi-line fields.
(setq forms-multi-line nil)

(setq forms-format-list
      (list
       "====== /etc/passwd ======\n\n"
       "User : "    1
       "   Uid: "   3
       "   Gid: "   4
       "\n\n"
```

```
        "Name : "    5
        "\n\n"
        "Home : "    6
        "\n\n"
        "Shell: "    7
        "\n"))
```

When you construct the value of `forms-format-list`, you should usually either quote the whole value, like this,

```
(setq forms-format-list
      '(
        "====== " forms-file " ======\n\n"
        "User : "    1
        (make-string 20 ?-)
        ...
       ))
```

or quote the elements which are lists, like this:

```
(setq forms-format-list
       (list
        "====== " forms-file " ======\n\n"
        "User : "    1
        '(make-string 20 ?-)
        ...
       ))
```

Forms mode validates the contents of `forms-format-list` when you visit a database. If there are errors, processing is aborted with an error message which includes a descriptive text. See section Error Messages, for a detailed list of error messages.

Modifying The Forms Contents

If `forms-read-only` is `nil`, the user can modify the fields and records of the database.

All normal editing commands are available for editing the contents of the displayed record. You cannot delete or modify the fixed, explanatory text that comes from string formatting elements, but you can modify the actual field contents.

If the variable `forms-modified-record-filter` is non-`nil`, it is called as a function before the new data is written to the data file. The function receives one argument, a vector that contains the contents of the fields of the record.

The function can refer to fields with `aref` and modify them with `aset`. The first field has number 1 (one); thus, element 0 of the vector is not used. The function should return the same vector it was passed;

the (possibly modified) contents of the vector determine what is actually written in the file. Here is an example:

```
(defun my-modified-record-filter (record)
  ;; Modify second field.
  (aset record 2 (current-time-string))
  ;; Return the field vector.
  record)

(setq forms-modified-record-filter 'my-modified-record-filter)
```

If the variable `forms-new-record-filter` is non-`nil`, its value is a function to be called to fill in default values for the fields of a new record. The function is passed a vector of empty strings, one for each field; it should return the same vector, with the desired field values stored in it. Fields are numbered starting from 1 (one). Example:

```
(defun my-new-record-filter (fields)
  (aset fields 5 (login-name))
  (aset fields 1 (current-time-string))
  fields)

(setq forms-new-record-filter 'my-new-record-filter)
```

Miscellaneous

The global variable `forms-version` holds the version information of the Forms mode software.

It is very convenient to use symbolic names for the fields in a record. The function `forms-enumerate` provides an elegant means to define a series of variables whose values are consecutive integers. The function returns the highest number used, so it can be used to set `forms-number-of-fields` also. For example:

```
(setq forms-number-of-fields
      (forms-enumerate
       '(field1 field2 field3 ...)))
```

This sets `field1` to 1, `field2` to 2, and so on.

Care has been taken to keep the Forms mode variables buffer-local, so it is possible to visit multiple files in Forms mode simultaneously, even if they have different properties.

If you have visited the control file in normal fashion with `find-file` or a like command, you can switch to Forms mode with the command `M-x forms-mode`. If you put `-*- forms -*-' in the first line of the control file, then visiting it enables Forms mode automatically. But this makes it hard to edit the control file itself, so you'd better think twice before using this.

The default format for the data file, using `"\t"` to separate fields and `"\^k"` to separate lines within a field, matches the file format of some popular database programss, e.g. FileMaker. So `forms-mode` can decrease the need to use proprietary software.

Error Messages

This section describes all error messages which can be generated by forms mode. Error messages that result from parsing the control file all start with the text `Forms control file error'. Messages generated while analyzing the definition of `forms-format-list` start with `Forms format error'.

`Forms control file error: 'forms-file' has not been set`

The variable `forms-file` was not set by the control file.

`Forms control file error: 'forms-number-of-fields' has not been set`

The variable `forms-number-of-fields` was not set by the control file.

`Forms control file error: 'forms-number-of-fields' must be a number > 0`

The variable `forms-number-of-fields` did not contain a positive number.

`Forms control file error: 'forms-field-sep' is not a string`

`Forms control file error: 'forms-multi-line' must be nil or a one-character string`

The variable `forms-multi-line` was set to something other than `nil` or a single-character string.

`Forms control file error: 'forms-multi-line' is equal to 'forms-field-sep'`

The variable `forms-multi-line` may not be equal to `forms-field-sep` for this would make it impossible to distinguish fields and the lines in the fields.

`Forms control file error: 'forms-new-record-filter' is not a function`

`Forms control file error: 'forms-modified-record-filter' is not a function`

The variable has been set to something else than a function.

`Forms control file error: 'forms-format-list' has not been set`

`Forms control file error: 'forms-format-list' is not a list`

The variable `forms-format-list` was not set to a Lisp list by the control file.

`Forms format error: field number xx out of range 1..nn`

A field number was supplied in `forms-format-list` with a value of xx, which was not greater than zero and smaller than or equal to the number of fields in the forms, nn.

`Forms format error: not a function fun`

The first element of a list which is an element of `forms-format-list` was not a valid Lisp function.

`Forms format error: invalid element xx`

A list element was supplied in `forms-format-list` which was not a string, number or list.

`Warning: this record has xx fields instead of yy`

The number of fields in this record in the data file did not match `forms-number-of-fields`. Missing fields will be made empty.

`Multi-line fields in this record - update refused!`

The current record contains newline characters, hence can not be written back to the data file, for it would corrupt it. Probably you inserted a newline in a field, while `forms-multi-line` was `nil`.

`Record number xx out of range 1..yy`

A jump was made to non-existing record xx. yy denotes the number of records in the file.

`Stuck at record xx`

An internal error prevented a specific record from being retrieved.

`No write access to "file"`

An attempt was made to enable edit mode on a file that has been write protected.

`"regexp" not found`

The regexp could not be found in the data file, starting at the current record location.

`Warning: number of records changed to nn`

Forms mode's idea of the number of records has been adjusted to the number of records actually present in the data file.

`Problem saving buffers?`

An error occurred while saving the data file buffer. Most likely, Emacs did ask to confirm deleting the buffer because it had been modified, and you said `no'.

Long Example

The following example exploits most of the features of Forms mode. This example is included in the distribution as file `forms-d2.el'.

```
;; demo2 -- demo forms-mode     -*- emacs-lisp -*-

       "\n\n====== Remarks ======\n\n"
       arch-remarks
     ))

;; That's all, folks!
```

Credits

Forms mode was developed by Johan Vromans while working at Multihouse Research in the Netherlands.

Bug fixes and other useful suggestions were supplied by Richard Stallman (`rms@gnu.ai.mit.edu`), Harald Hanche-Olsen (`hanche@imf.unit.no`), `cwitty@portia.stanford.edu`, Jonathan I. Kamens, Per Cederqvist (`ceder@signum.se`), and Ignatios Souvatzis.

This documentation was slightly inspired by the documentation of "rolo mode" by Paul Davis at Schlumberger Cambridge Research (`davis%scrsu1%sdr.slb.com@relay.cs.net`).

None of this would have been possible without GNU Emacs of the Free Software Foundation. Thanks, Richard!

Flex, version 2.5

A fast scanner generator

Edition 2.5, March 1995

Vern Paxson

Flex, version 2.5

Name

flex - fast lexical analyzer generator

Synopsis

```
flex [-bcdfhilnpstvwBFILTV78+? -C[aefFmr] -ooutput -Pprefix -Sskeleton]
[--help --version] [filename ...]
```

Overview

This manual describes `flex`, a tool for generating programs that perform pattern-matching on text. The manual includes both tutorial and reference sections:

Description
: a brief overview of the tool

Some Simple Examples

Format Of The Input File

Patterns
: the extended regular expressions used by flex

How The Input Is Matched

Description

`flex` is a tool for generating scanners: programs which recognized lexical patterns in text. `flex` reads the given input files, or its standard input if no file names are given, for a description of a scanner to generate. The description is in the form of pairs of regular expressions and C code, called rules. `flex` generates as output a C source file, `` `lex.yy.c' ``, which defines a routine `yylex()'. This file is compiled and linked with the `-lfl' library to produce an executable. When the executable is run, it analyzes its input for occurrences of the regular expressions. Whenever it finds one, it executes the corresponding C code.

Some simple examples

First some simple examples to get the flavor of how one uses `flex`. The following `flex` input specifies a scanner which whenever it encounters the string "username" will replace it with the user's login name:

```
%%
username    printf( "%s", getlogin() );
```

By default, any text not matched by a `flex` scanner is copied to the output, so the net effect of this scanner is to copy its input file to its output with each occurrence of "username" expanded. In this input, there is just one rule. "username" is the pattern and the "printf" is the action. The "%%" marks the beginning of the rules.

Here's another simple example:

```
        int num_lines = 0, num_chars = 0;

%%
\n      ++num_lines; ++num_chars;
.       ++num_chars;

%%
main()
        {
        yylex();
        printf( "# of lines = %d, # of chars = %d\n",
                num_lines, num_chars );
        }
```

This scanner counts the number of characters and the number of lines in its input (it produces no output other than the final report on the counts). The first line declares two globals, "num_lines" and "num_chars", which are accessible both inside `yylex()' and in the `main()' routine declared after the second "%%". There are two rules, one which matches a newline ("\n") and increments both the line count and the character count, and one which matches any character other than a newline (indicated by the "." regular expression).

A somewhat more complicated example:

```
/* scanner for a toy Pascal-like language */

%{
/* need this for the call to atof() below */
#include <math.h>
%}

DIGIT    [0-9]
ID       [a-z][a-z0-9]*

%%

{DIGIT}+    {
            printf( "An integer: %s (%d)\n", yytext,
                    atoi( yytext ) );
            }

{DIGIT}+"."{DIGIT}*         {
            printf( "A float: %s (%g)\n", yytext,
                    atof( yytext ) );
            }

if|then|begin|end|procedure|function        {
            printf( "A keyword: %s\n", yytext );
            }

{ID}        printf( "An identifier: %s\n", yytext );

"+"|"-"|"*"|"/"   printf( "An operator: %s\n", yytext );

"{"[^}\n]*"}"     /* eat up one-line comments */

[ \t\n]+          /* eat up whitespace */

.           printf( "Unrecognized character: %s\n", yytext );

%%

main( argc, argv )
int argc;
char **argv;
    {
    ++argv, --argc;  /* skip over program name */
    if ( argc > 0 )
```

```
            yyin = fopen( argv[0], "r" );
    else
            yyin = stdin;

    yylex();
    }
```

This is the beginnings of a simple scanner for a language like Pascal. It identifies different types of tokens and reports on what it has seen.

The details of this example will be explained in the following sections.

Format of the input file

The `flex` input file consists of three sections, separated by a line with just `%%' in it:

```
definitions
%%
rules
%%
user code
```

The definitions section contains declarations of simple name definitions to simplify the scanner specification, and declarations of start conditions, which are explained in a later section. Name definitions have the form:

```
name definition
```

The "name" is a word beginning with a letter or an underscore ('_') followed by zero or more letters, digits, '_', or '-' (dash). The definition is taken to begin at the first non-white-space character following the name and continuing to the end of the line. The definition can subsequently be referred to using "{name}", which will expand to "(definition)". For example,

```
DIGIT    [0-9]
ID       [a-z][a-z0-9]*
```

defines "DIGIT" to be a regular expression which matches a single digit, and "ID" to be a regular expression which matches a letter followed by zero-or-more letters-or-digits. A subsequent reference to

```
{DIGIT}+"."{DIGIT}*
```

is identical to

```
([0-9])+"."([0-9])*
```

and matches one-or-more digits followed by a '.' followed by zero-or-more digits.

The rules section of the `flex` input contains a series of rules of the form:

```
pattern   action
```

where the pattern must be unindented and the action must begin on the same line.

See below for a further description of patterns and actions.

Finally, the user code section is simply copied to `` `lex.yy.c' `` verbatim. It is used for companion routines which call or are called by the scanner. The presence of this section is optional; if it is missing, the second `%%' in the input file may be skipped, too.

In the definitions and rules sections, any *indented* text or text enclosed in `%{' and `%}' is copied verbatim to the output (with the `%{}"s removed). The `%{}"s must appear unindented on lines by themselves.

In the rules section, any indented or %{} text appearing before the first rule may be used to declare variables which are local to the scanning routine and (after the declarations) code which is to be executed whenever the scanning routine is entered. Other indented or %{} text in the rule section is still copied to the output, but its meaning is not well-defined and it may well cause compile-time errors (this feature is present for `POSIX` compliance; see below for other such features).

In the definitions section (but not in the rules section), an unindented comment (i.e., a line beginning with "/*") is also copied verbatim to the output up to the next "*/".

Patterns

The patterns in the input are written using an extended set of regular expressions. These are:

`x'
: match the character `x'

`.'
: any character (byte) except newline

`[xyz]'
: a "character class"; in this case, the pattern matches either an `x', a `y', or a `z'

`[abj-oZ]'
: a "character class" with a range in it; matches an `a', a `b', any letter from `j' through `o', or a `Z'

`[^A-Z]'
: a "negated character class", i.e., any character but those in the class. In this case, any character EXCEPT an uppercase letter.

`[^A-Z\n]'
: any character EXCEPT an uppercase letter or a newline

`r*'
: zero or more r's, where r is any regular expression

`r+'
: one or more r's

`r?'
: zero or one r's (that is, "an optional r")

`r{2,5}'
: anywhere from two to five r's

`r{2,}'
: two or more r's

`r{4}'
: exactly 4 r's

`{name}'
: the expansion of the "name" definition (see above)

`"[xyz]\"foo"'
: the literal string: `[xyz]"foo'

`\x'
: if x is an `a', `b', `f', `n', `r', `t', or `v', then the ANSI-C interpretation of \x. Otherwise, a literal `x' (used to escape operators such as `*')

`\0'
: a NUL character (ASCII code 0)

`\123'
: the character with octal value 123

`\x2a'
: the character with hexadecimal value `2a`

`(r)'
: match an r; parentheses are used to override precedence (see below)

`rs'
: the regular expression r followed by the regular expression s; called "concatenation"

`r|s'
: either an r or an s

`r/s'
: an r but only if it is followed by an s. The text matched by s is included when determining whether this rule is the longest match, but is then returned to the input before the action is executed. So the action only sees the text matched by r. This type of pattern is called trailing context. (There are some combinations of `r/s' that `flex` cannot match correctly; see notes in the Deficiencies / Bugs section below regarding "dangerous trailing context".)

`^r'
: an r, but only at the beginning of a line (i.e., which just starting to scan, or right after a newline has been scanned).

`r$'

an r, but only at the end of a line (i.e., just before a newline). Equivalent to "r/\n".

Note that flex's notion of "newline" is exactly whatever the C compiler used to compile flex interprets '\n' as; in particular, on some DOS systems you must either filter out \r's in the input yourself, or explicitly use r/\r\n for "r$".

`<s>r'

an r, but only in start condition s (see below for discussion of start conditions) <s1,s2,s3>r same, but in any of start conditions s1, s2, or s3

`<*>r'

an r in any start condition, even an exclusive one.

`<<EOF>>'

an end-of-file <s1,s2><<EOF>> an end-of-file when in start condition s1 or s2

Note that inside of a character class, all regular expression operators lose their special meaning except escape ('\') and the character class operators, '-', ']', and, at the beginning of the class, '^'.

The regular expressions listed above are grouped according to precedence, from highest precedence at the top to lowest at the bottom. Those grouped together have equal precedence. For example,

```
foo|bar*
```

is the same as

```
(foo)|(ba(r*))
```

since the '*' operator has higher precedence than concatenation, and concatenation higher than alternation ('|'). This pattern therefore matches *either* the string "foo" *or* the string "ba" followed by zero-or-more r's. To match "foo" or zero-or-more "bar"'s, use:

```
foo|(bar)*
```

and to match zero-or-more "foo"'s-or-"bar"'s:

```
(foo|bar)*
```

In addition to characters and ranges of characters, character classes can also contain character class expressions. These are expressions enclosed inside `[': and `:'] delimiters (which themselves must appear between the '[' and ']' of the character class; other elements may occur inside the character class, too). The valid expressions are:

```
[:alnum:] [:alpha:] [:blank:]
[:cntrl:] [:digit:] [:graph:]
[:lower:] [:print:] [:punct:]
[:space:] [:upper:] [:xdigit:]
```

These expressions all designate a set of characters equivalent to the corresponding standard C `isXXX' function. For example, `[:alnum:]' designates those characters for which `isalnum()' returns true - i.e., alphabetic or numeric. Some systems don't provide `isblank()', so flex defines `[:blank:]' as a blank or a tab.

For example, the following character classes are all equivalent:

```
[[:alnum:]]
[[:alpha:][:digit:]
[[:alpha:]0-9]
[a-zA-Z0-9]
```

If your scanner is case-insensitive (the `-i' flag), then `[:upper:]' and `[:lower:]' are equivalent to `[:alpha:]'.

Some notes on patterns:

- A negated character class such as the example "[^A-Z]" above *will match a newline* unless "\n" (or an equivalent escape sequence) is one of the characters explicitly present in the negated character class (e.g., "[^A-Z\n]"). This is unlike how many other regular expression tools treat negated character classes, but unfortunately the inconsistency is historically entrenched. Matching newlines means that a pattern like [^"]* can match the entire input unless there's another quote in the input.
- A rule can have at most one instance of trailing context (the '/' operator or the '$' operator). The start condition, '^', and "<<EOF>>" patterns can only occur at the beginning of a pattern, and, as well as with '/' and '$', cannot be grouped inside parentheses. A '^' which does not occur at the beginning of a rule or a '$' which does not occur at the end of a rule loses its special properties and is treated as a normal character.

  The following are illegal:

  ```
  foo/bar$
  <sc1>foo<sc2>bar
  ```

  Note that the first of these, can be written "foo/bar\n".

  The following will result in '$' or '^' being treated as a normal character:

  ```
  foo|(bar$)
  foo|^bar
  ```

  If what's wanted is a "foo" or a bar-followed-by-a-newline, the following could be used (the special '|' action is explained below):

  ```
  foo      |
  bar$     /* action goes here */
  ```

  A similar trick will work for matching a foo or a bar-at-the-beginning-of-a-line.

How the input is matched

When the generated scanner is run, it analyzes its input looking for strings which match any of its patterns. If it finds more than one match, it takes the one matching the most text (for trailing context rules, this includes the length of the trailing part, even though it will then be returned to the input). If it finds two or more matches of the same length, the rule listed first in the `flex` input file is chosen.

Once the match is determined, the text corresponding to the match (called the token) is made available in the global character pointer `yytext`, and its length in the global integer `yyleng`. The action corresponding to the matched pattern is then executed (a more detailed description of actions follows), and then the remaining input is scanned for another match.

If no match is found, then the default rule is executed: the next character in the input is considered matched and copied to the standard output. Thus, the simplest legal `flex` input is:

```
%%
```

which generates a scanner that simply copies its input (one character at a time) to its output.

Note that `yytext` can be defined in two different ways: either as a character *pointer* or as a character *array*. You can control which definition `flex` uses by including one of the special directives `%pointer' or `%array' in the first (definitions) section of your flex input. The default is `%pointer', unless you use the `-l' lex compatibility option, in which case `yytext` will be an array. The advantage of using `%pointer' is substantially faster scanning and no buffer overflow when matching very large tokens (unless you run out of dynamic memory). The disadvantage is that you are restricted in how your actions can modify `yytext` (see the next section), and calls to the `unput()' function destroys the present contents of `yytext`, which can be a considerable porting headache when moving between different `lex` versions.

The advantage of `%array' is that you can then modify `yytext` to your heart's content, and calls to `unput()' do not destroy `yytext` (see below). Furthermore, existing `lex` programs sometimes access `yytext` externally using declarations of the form:

```
extern char yytext[];
```

This definition is erroneous when used with `%pointer', but correct for `%array'.

`%array' defines `yytext` to be an array of `YYLMAX` characters, which defaults to a fairly large value. You can change the size by simply #define'ing `YYLMAX` to a different value in the first section of your `flex` input. As mentioned above, with `%pointer' yytext grows dynamically to accommodate large tokens. While this means your `%pointer' scanner can accommodate very large tokens (such as matching entire blocks of comments), bear in mind that each time the scanner must resize `yytext` it also must rescan the entire token from the beginning, so matching such tokens can prove slow. `yytext` presently does *not* dynamically grow if a call to `unput()' results in too much text being pushed back; instead, a run-time error results.

Also note that you cannot use `%array' with C++ scanner classes (the `c++` option; see below).

Actions

Each pattern in a rule has a corresponding action, which can be any arbitrary C statement. The pattern ends at the first non-escaped whitespace character; the remainder of the line is its action. If the action is empty, then when the pattern is matched the input token is simply discarded. For example, here is the specification for a program which deletes all occurrences of "zap me" from its input:

```
%%
"zap me"
```

(It will copy all other characters in the input to the output since they will be matched by the default rule.)

Here is a program which compresses multiple blanks and tabs down to a single blank, and throws away whitespace found at the end of a line:

```
%%
[ \t]+        putchar( ' ' );
[ \t]+$       /* ignore this token */
```

If the action contains a '{', then the action spans till the balancing '}' is found, and the action may cross multiple lines. `flex` knows about C strings and comments and won't be fooled by braces found within them, but also allows actions to begin with `%{' and will consider the action to be all the text up to the next `%}' (regardless of ordinary braces inside the action).

An action consisting solely of a vertical bar ('|') means "same as the action for the next rule." See below for an illustration.

Actions can include arbitrary C code, including `return` statements to return a value to whatever routine called `yylex()'. Each time `yylex()' is called it continues processing tokens from where it last left off until it either reaches the end of the file or executes a return.

Actions are free to modify `yytext` except for lengthening it (adding characters to its end--these will overwrite later characters in the input stream). This however does not apply when using `%array' (see above); in that case, `yytext` may be freely modified in any way.

Actions are free to modify `yyleng` except they should not do so if the action also includes use of `yymore()' (see below).

There are a number of special directives which can be included within an action:

- `ECHO' copies yytext to the scanner's output.
- `BEGIN` followed by the name of a start condition places the scanner in the corresponding start condition (see below).
- `REJECT` directs the scanner to proceed on to the "second best" rule which matched the input (or a prefix of the input). The rule is chosen as described above in "How the Input is Matched", and `yytext` and `yyleng` set up appropriately. It may either be one which matched as much text as the originally chosen rule but came later in the `flex` input file, or one which matched less text. For example, the following will both count the words in the input and call the routine special()

whenever "frob" is seen:

```
        int word_count = 0;
%%

frob        special(); REJECT;
[^ \t\n]+   ++word_count;
```

Without the `REJECT`, any "frob"'s in the input would not be counted as words, since the scanner normally executes only one action per token. Multiple `REJECT's` are allowed, each one finding the next best choice to the currently active rule. For example, when the following scanner scans the token "abcd", it will write "abcdabcaba" to the output:

```
%%
a           |
ab          |
abc         |
abcd        ECHO; REJECT;
.|\n        /* eat up any unmatched character */
```

(The first three rules share the fourth's action since they use the special '|' action.) `REJECT` is a particularly expensive feature in terms of scanner performance; if it is used in *any* of the scanner's actions it will slow down *all* of the scanner's matching. Furthermore, `REJECT` cannot be used with the `-Cf' or `-CF' options (see below).

Note also that unlike the other special actions, `REJECT` is a *branch*; code immediately following it in the action will *not* be executed.

- `yymore()' tells the scanner that the next time it matches a rule, the corresponding token should be *appended* onto the current value of `yytext` rather than replacing it. For example, given the input "mega-kludge" the following will write "mega-mega-kludge" to the output:

  ```
  %%
  mega-    ECHO; yymore();
  kludge   ECHO;
  ```

  First "mega-" is matched and echoed to the output. Then "kludge" is matched, but the previous "mega-" is still hanging around at the beginning of `yytext` so the `ECHO' for the "kludge" rule will actually write "mega-kludge".

Two notes regarding use of `yymore()'. First, `yymore()' depends on the value of `yyleng` correctly reflecting the size of the current token, so you must not modify `yyleng` if you are using `yymore()'. Second, the presence of `yymore()' in the scanner's action entails a minor performance penalty in the scanner's matching speed.

- `yyless(n)' returns all but the first n characters of the current token back to the input stream, where they will be rescanned when the scanner looks for the next match. `yytext` and `yyleng` are adjusted appropriately (e.g., `yyleng` will now be equal to n). For example, on the input "foobar"

the following will write out "foobarbar":

```
%%
foobar    ECHO; yyless(3);
[a-z]+    ECHO;
```

An argument of 0 to `yyless` will cause the entire current input string to be scanned again. Unless you've changed how the scanner will subsequently process its input (using `BEGIN`, for example), this will result in an endless loop.

Note that `yyless` is a macro and can only be used in the flex input file, not from other source files.

- `unput(c)' puts the character `c` back onto the input stream. It will be the next character scanned. The following action will take the current token and cause it to be rescanned enclosed in parentheses.

```
{
int i;
/* Copy yytext because unput() trashes yytext */
char *yycopy = strdup( yytext );
unput( ')' );
for ( i = yyleng - 1; i >= 0; --i )
    unput( yycopy[i] );
unput( '(' );
free( yycopy );
}
```

Note that since each `unput()' puts the given character back at the *beginning* of the input stream, pushing back strings must be done back-to-front. An important potential problem when using `unput()' is that if you are using `%pointer' (the default), a call to `unput()' *destroys* the contents of `yytext`, starting with its rightmost character and devouring one character to the left with each call. If you need the value of yytext preserved after a call to `unput()' (as in the above example), you must either first copy it elsewhere, or build your scanner using `%array' instead (see How The Input Is Matched).

Finally, note that you cannot put back `EOF` to attempt to mark the input stream with an end-of-file.

- `input()' reads the next character from the input stream. For example, the following is one way to eat up C comments:

```
%%
"/*"        {
            register int c;

            for ( ; ; )
                {
                while ( (c = input()) != '*' &&
                        c != EOF )
```

```
            ;    /* eat up text of comment */

        if ( c == '*' )
            {
            while ( (c = input()) == '*' )
                ;
            if ( c == '/' )
                break;    /* found the end */
            }

        if ( c == EOF )
            {
            error( "EOF in comment" );
            break;
            }
        }
    }
```

(Note that if the scanner is compiled using `C++', then `input()' is instead referred to as `yyinput()', in order to avoid a name clash with the `C++' stream by the name of `input'.)

- YY_FLUSH_BUFFER flushes the scanner's internal buffer so that the next time the scanner attempts to match a token, it will first refill the buffer using `YY_INPUT' (see The Generated Scanner, below). This action is a special case of the more general `yy_flush_buffer()' function, described below in the section Multiple Input Buffers.
- `yyterminate()' can be used in lieu of a return statement in an action. It terminates the scanner and returns a 0 to the scanner's caller, indicating "all done". By default, `yyterminate()' is also called when an end-of-file is encountered. It is a macro and may be redefined.

The generated scanner

The output of `flex' is the file `lex.yy.c', which contains the scanning routine `yylex()', a number of tables used by it for matching tokens, and a number of auxiliary routines and macros. By default, `yylex()' is declared as follows:

```
int yylex()
    {
    ... various definitions and the actions in here ...
    }
```

(If your environment supports function prototypes, then it will be "int yylex(void)".) This definition may be changed by defining the "YY_DECL" macro. For example, you could use:

```
#define YY_DECL float lexscan( a, b ) float a, b;
```

to give the scanning routine the name `lexscan', returning a float, and taking two floats as arguments.

Note that if you give arguments to the scanning routine using a K&R-style/non-prototyped function declaration, you must terminate the definition with a semi-colon (`;').

Whenever `yylex()' is called, it scans tokens from the global input file `yyin` (which defaults to stdin). It continues until it either reaches an end-of-file (at which point it returns the value 0) or one of its actions executes a `return` statement.

If the scanner reaches an end-of-file, subsequent calls are undefined unless either `yyin` is pointed at a new input file (in which case scanning continues from that file), or `yyrestart()' is called. `yyrestart()' takes one argument, a `FILE *' pointer (which can be nil, if you've set up `YY_INPUT` to scan from a source other than `yyin`), and initializes `yyin` for scanning from that file. Essentially there is no difference between just assigning `yyin` to a new input file or using `yyrestart()' to do so; the latter is available for compatibility with previous versions of `flex`, and because it can be used to switch input files in the middle of scanning. It can also be used to throw away the current input buffer, by calling it with an argument of `yyin`; but better is to use `YY_FLUSH_BUFFER` (see above). Note that `yyrestart()' does *not* reset the start condition to `INITIAL` (see Start Conditions, below).

If `yylex()' stops scanning due to executing a `return` statement in one of the actions, the scanner may then be called again and it will resume scanning where it left off.

By default (and for purposes of efficiency), the scanner uses block-reads rather than simple `getc()' calls to read characters from `yyin`. The nature of how it gets its input can be controlled by defining the `YY_INPUT` macro. YY_INPUT's calling sequence is "YY_INPUT(buf,result,max_size)". Its action is to place up to max_size characters in the character array buf and return in the integer variable result either the number of characters read or the constant YY_NULL (0 on Unix systems) to indicate EOF. The default YY_INPUT reads from the global file-pointer "yyin".

A sample definition of YY_INPUT (in the definitions section of the input file):

```
%{
#define YY_INPUT(buf,result,max_size) \
    { \
    int c = getchar(); \
    result = (c == EOF) ? YY_NULL : (buf[0] = c, 1); \
    }
%}
```

This definition will change the input processing to occur one character at a time.

When the scanner receives an end-of-file indication from YY_INPUT, it then checks the `yywrap()' function. If `yywrap()' returns false (zero), then it is assumed that the function has gone ahead and set up `yyin` to point to another input file, and scanning continues. If it returns true (non-zero), then the scanner terminates, returning 0 to its caller. Note that in either case, the start condition remains unchanged; it does *not* revert to `INITIAL`.

If you do not supply your own version of `yywrap()', then you must either use `%option noyywrap' (in which case the scanner behaves as though `yywrap()' returned 1), or you must link with `-lfl' to obtain the default version of the routine, which always returns 1.

Three routines are available for scanning from in-memory buffers rather than files: `yy_scan_string()', `yy_scan_bytes()', and `yy_scan_buffer()'. See the discussion of them below in the section Multiple Input Buffers.

The scanner writes its `ECHO' output to the `yyout` global (default, stdout), which may be redefined by the user simply by assigning it to some other `FILE` pointer.

Start conditions

`flex` provides a mechanism for conditionally activating rules. Any rule whose pattern is prefixed with "<sc>" will only be active when the scanner is in the start condition named "sc". For example,

```
<STRING>[^"]*        { /* eat up the string body ... */
             ...
             }
```

will be active only when the scanner is in the "STRING" start condition, and

```
<INITIAL,STRING,QUOTE>\.        { /* handle an escape ... */
             ...
             }
```

will be active only when the current start condition is either "INITIAL", "STRING", or "QUOTE".

Start conditions are declared in the definitions (first) section of the input using unindented lines beginning with either `%s' or `%x' followed by a list of names. The former declares *inclusive* start conditions, the latter *exclusive* start conditions. A start condition is activated using the `BEGIN` action. Until the next `BEGIN` action is executed, rules with the given start condition will be active and rules with other start conditions will be inactive. If the start condition is *inclusive*, then rules with no start conditions at all will also be active. If it is *exclusive*, then *only* rules qualified with the start condition will be active. A set of rules contingent on the same exclusive start condition describe a scanner which is independent of any of the other rules in the `flex` input. Because of this, exclusive start conditions make it easy to specify "mini-scanners" which scan portions of the input that are syntactically different from the rest (e.g., comments).

If the distinction between inclusive and exclusive start conditions is still a little vague, here's a simple example illustrating the connection between the two. The set of rules:

```
%s example
%%

<example>foo   do_something();

bar            something_else();
```

is equivalent to

```
%x example
%%

<example>foo   do_something();

<INITIAL,example>bar    something_else();
```

Without the `<INITIAL,example>' qualifier, the `bar' pattern in the second example wouldn't be active (i.e., couldn't match) when in start condition `example'. If we just used `<example>' to qualify `bar', though, then it would only be active in `example' and not in `INITIAL', while in the first example it's active in both, because in the first example the `example' starting condition is an *inclusive* (`%s') start condition.

Also note that the special start-condition specifier `<*>' matches every start condition. Thus, the above example could also have been written;

```
%x example
%%

<example>foo   do_something();

<*>bar    something_else();
```

The default rule (to `ECHO' any unmatched character) remains active in start conditions. It is equivalent to:

```
<*>.|\\n     ECHO;
```

`BEGIN(0)' returns to the original state where only the rules with no start conditions are active. This state can also be referred to as the start-condition "INITIAL", so `BEGIN(INITIAL)' is equivalent to `BEGIN(0)'. (The parentheses around the start condition name are not required but are considered good style.)

`BEGIN` actions can also be given as indented code at the beginning of the rules section. For example, the following will cause the scanner to enter the "SPECIAL" start condition whenever `yylex()' is called and the global variable `enter_special` is true:

```
        int enter_special;

%x SPECIAL
%%
        if ( enter_special )
            BEGIN(SPECIAL);

<SPECIAL>blahblahblah
...more rules follow...
```

To illustrate the uses of start conditions, here is a scanner which provides two different interpretations of a string like "123.456". By default it will treat it as as three tokens, the integer "123", a dot ('.'), and the integer "456". But if the string is preceded earlier in the line by the string "expect-floats" it will treat it as a single token, the floating-point number 123.456:

```
%{
#include <math.h>
%}
%s expect

%%
expect-floats        BEGIN(expect);

<expect>[0-9]+"."[0-9]+      {
            printf( "found a float, = %f\n",
                    atof( yytext ) );
            }
<expect>\n           {
            /* that's the end of the line, so
             * we need another "expect-number"
             * before we'll recognize any more
             * numbers
             */
            BEGIN(INITIAL);
            }

[0-9]+       {

Version 2.5                 December 1994                          18

            printf( "found an integer, = %d\n",
                    atoi( yytext ) );
            }

"."          printf( "found a dot\n" );
```

Here is a scanner which recognizes (and discards) C comments while maintaining a count of the current input line.

```
%x comment
%%
        int line_num = 1;

"/*"         BEGIN(comment);
```

```
<comment>[^*\n]*        /* eat anything that's not a '*' */
<comment>"*"+[^*/\n]*   /* eat up '*'s not followed by '/'s */
<comment>\n             ++line_num;
<comment>"*"+"/"        BEGIN(INITIAL);
```

This scanner goes to a bit of trouble to match as much text as possible with each rule. In general, when attempting to write a high-speed scanner try to match as much possible in each rule, as it's a big win.

Note that start-conditions names are really integer values and can be stored as such. Thus, the above could be extended in the following fashion:

```
%x comment foo
%%
        int line_num = 1;
        int comment_caller;

"/*"         {
             comment_caller = INITIAL;
             BEGIN(comment);
             }

...

<foo>"/*"    {
             comment_caller = foo;
             BEGIN(comment);
             }

<comment>[^*\n]*        /* eat anything that's not a '*' */
<comment>"*"+[^*/\n]*   /* eat up '*'s not followed by '/'s */
<comment>\n             ++line_num;
<comment>"*"+"/"        BEGIN(comment_caller);
```

Furthermore, you can access the current start condition using the integer-valued `YY_START` macro. For example, the above assignments to `comment_caller` could instead be written

```
comment_caller = YY_START;
```

Flex provides `YYSTATE` as an alias for `YY_START` (since that is what's used by AT&T `lex`).

Note that start conditions do not have their own name-space; %s's and %x's declare names in the same fashion as #define's.

Finally, here's an example of how to match C-style quoted strings using exclusive start conditions, including expanded escape sequences (but not including checking for a string that's too long):

```
%x str
```

```
%%
        char string_buf[MAX_STR_CONST];
        char *string_buf_ptr;

\"      string_buf_ptr = string_buf; BEGIN(str);

<str>\"        { /* saw closing quote - all done */
        BEGIN(INITIAL);
        *string_buf_ptr = '\0';
        /* return string constant token type and
         * value to parser
         */
        }

<str>\n        {
        /* error - unterminated string constant */
        /* generate error message */
        }

<str>\\[0-7]{1,3} {
        /* octal escape sequence */
        int result;

        (void) sscanf( yytext + 1, "%o", &result );

        if ( result > 0xff )
                /* error, constant is out-of-bounds */

        *string_buf_ptr++ = result;
        }

<str>\\[0-9]+ {
        /* generate error - bad escape sequence; something
         * like '\48' or '\0777777'
         */
        }

<str>\\n  *string_buf_ptr++ = '\n';
<str>\\t  *string_buf_ptr++ = '\t';
<str>\\r  *string_buf_ptr++ = '\r';
<str>\\b  *string_buf_ptr++ = '\b';
<str>\\f  *string_buf_ptr++ = '\f';

<str>\\(.|\n)  *string_buf_ptr++ = yytext[1];
```

```
<str>[^\\\n\"]+        {
        char *yptr = yytext;

        while ( *yptr )
                *string_buf_ptr++ = *yptr++;
        }
```

Often, such as in some of the examples above, you wind up writing a whole bunch of rules all preceded by the same start condition(s). Flex makes this a little easier and cleaner by introducing a notion of start condition scope. A start condition scope is begun with:

```
<SCs>{
```

where SCs is a list of one or more start conditions. Inside the start condition scope, every rule automatically has the prefix `<SCs>' applied to it, until a `}' which matches the initial `{'. So, for example,

```
<ESC>{
    "\\n"   return '\n';
    "\\r"   return '\r';
    "\\f"   return '\f';
    "\\0"   return '\0';
}
```

is equivalent to:

```
<ESC>"\\n"  return '\n';
<ESC>"\\r"  return '\r';
<ESC>"\\f"  return '\f';
<ESC>"\\0"  return '\0';
```

Start condition scopes may be nested.

Three routines are available for manipulating stacks of start conditions:

`void yy_push_state(int new_state)'

pushes the current start condition onto the top of the start condition stack and switches to new_state as though you had used `BEGIN new_state' (recall that start condition names are also integers).

`void yy_pop_state()'

pops the top of the stack and switches to it via `BEGIN`.

`int yy_top_state()'

returns the top of the stack without altering the stack's contents.

The start condition stack grows dynamically and so has no built-in size limitation. If memory is exhausted, program execution aborts.

To use start condition stacks, your scanner must include a `%option stack' directive (see Options below).

Multiple input buffers

Some scanners (such as those which support "include" files) require reading from several input streams. As `flex` scanners do a large amount of buffering, one cannot control where the next input will be read from by simply writing a `YY_INPUT` which is sensitive to the scanning context. `YY_INPUT` is only called when the scanner reaches the end of its buffer, which may be a long time after scanning a statement such as an "include" which requires switching the input source.

To negotiate these sorts of problems, `flex` provides a mechanism for creating and switching between multiple input buffers. An input buffer is created by using:

```
YY_BUFFER_STATE yy_create_buffer( FILE *file, int size )
```

which takes a `FILE` pointer and a size and creates a buffer associated with the given file and large enough to hold size characters (when in doubt, use `YY_BUF_SIZE` for the size). It returns a `YY_BUFFER_STATE` handle, which may then be passed to other routines (see below). The `YY_BUFFER_STATE` type is a pointer to an opaque `struct yy_buffer_state` structure, so you may safely initialize YY_BUFFER_STATE variables to `((YY_BUFFER_STATE) 0)' if you wish, and also refer to the opaque structure in order to correctly declare input buffers in source files other than that of your scanner. Note that the `FILE` pointer in the call to `yy_create_buffer` is only used as the value of `yyin` seen by `YY_INPUT`; if you redefine `YY_INPUT` so it no longer uses `yyin`, then you can safely pass a nil `FILE` pointer to `yy_create_buffer`. You select a particular buffer to scan from using:

```
void yy_switch_to_buffer( YY_BUFFER_STATE new_buffer )
```

switches the scanner's input buffer so subsequent tokens will come from new_buffer. Note that `yy_switch_to_buffer()' may be used by `yywrap()' to set things up for continued scanning, instead of opening a new file and pointing `yyin` at it. Note also that switching input sources via either `yy_switch_to_buffer()' or `yywrap()' does *not* change the start condition.

```
void yy_delete_buffer( YY_BUFFER_STATE buffer )
```

is used to reclaim the storage associated with a buffer. You can also clear the current contents of a buffer using:

```
void yy_flush_buffer( YY_BUFFER_STATE buffer )
```

This function discards the buffer's contents, so the next time the scanner attempts to match a token from the buffer, it will first fill the buffer anew using `YY_INPUT`.

`yy_new_buffer()' is an alias for `yy_create_buffer()', provided for compatibility with the C++ use of `new` and `delete` for creating and destroying dynamic objects.

Finally, the `YY_CURRENT_BUFFER` macro returns a `YY_BUFFER_STATE` handle to the current buffer.

Here is an example of using these features for writing a scanner which expands include files (the

`<<EOF>>' feature is discussed below):

```
/* the "incl" state is used for picking up the name
 * of an include file
 */
%x incl

%{
#define MAX_INCLUDE_DEPTH 10
YY_BUFFER_STATE include_stack[MAX_INCLUDE_DEPTH];
int include_stack_ptr = 0;
%}

%%
include             BEGIN(incl);

[a-z]+              ECHO;
[^a-z\n]*\n?        ECHO;

<incl>[ \t]*      /* eat the whitespace */
<incl>[^ \t\n]+   { /* got the include file name */
        if ( include_stack_ptr >= MAX_INCLUDE_DEPTH )
            {
            fprintf( stderr, "Includes nested too deeply" );
            exit( 1 );
            }

        include_stack[include_stack_ptr++] =
            YY_CURRENT_BUFFER;

        yyin = fopen( yytext, "r" );

        if ( ! yyin )
            error( ... );

        yy_switch_to_buffer(
            yy_create_buffer( yyin, YY_BUF_SIZE ) );

        BEGIN(INITIAL);
        }

<<EOF>> {
        if ( --include_stack_ptr < 0 )
            {
            yyterminate();
            }
```

```
        else
            {
            yy_delete_buffer( YY_CURRENT_BUFFER );
            yy_switch_to_buffer(
                 include_stack[include_stack_ptr] );
            }
        }
```

Three routines are available for setting up input buffers for scanning in-memory strings instead of files. All of them create a new input buffer for scanning the string, and return a corresponding YY_BUFFER_STATE handle (which you should delete with `yy_delete_buffer()' when done with it). They also switch to the new buffer using `yy_switch_to_buffer()', so the next call to `yylex()' will start scanning the string.

`yy_scan_string(const char *str)'

scans a NUL-terminated string.

`yy_scan_bytes(const char *bytes, int len)'

scans `len` bytes (including possibly NUL's) starting at location bytes.

Note that both of these functions create and scan a *copy* of the string or bytes. (This may be desirable, since `yylex()' modifies the contents of the buffer it is scanning.) You can avoid the copy by using:

`yy_scan_buffer(char *base, yy_size_t size)'

which scans in place the buffer starting at base, consisting of size bytes, the last two bytes of which *must* be YY_END_OF_BUFFER_CHAR (ASCII NUL). These last two bytes are not scanned; thus, scanning consists of `base[0]' through `base[size-2]', inclusive.

If you fail to set up base in this manner (i.e., forget the final two YY_END_OF_BUFFER_CHAR bytes), then `yy_scan_buffer()' returns a nil pointer instead of creating a new input buffer.

The type `yy_size_t` is an integral type to which you can cast an integer expression reflecting the size of the buffer.

End-of-file rules

The special rule "<<EOF>>" indicates actions which are to be taken when an end-of-file is encountered and yywrap() returns non-zero (i.e., indicates no further files to process). The action must finish by doing one of four things:

- assigning `yyin` to a new input file (in previous versions of flex, after doing the assignment you had to call the special action YY_NEW_FILE; this is no longer necessary);
- executing a `return` statement;
- executing the special `yyterminate()' action;
- or, switching to a new buffer using `yy_switch_to_buffer()' as shown in the example above.

<<EOF>> rules may not be used with other patterns; they may only be qualified with a list of start

conditions. If an unqualified <<EOF>> rule is given, it applies to *all* start conditions which do not already have <<EOF>> actions. To specify an <<EOF>> rule for only the initial start condition, use

```
<INITIAL><<EOF>>
```

These rules are useful for catching things like unclosed comments. An example:

```
%x quote
%%

...other rules for dealing with quotes...

<quote><<EOF>>   {
         error( "unterminated quote" );
         yyterminate();
         }
<<EOF>>  {
         if ( *++filelist )
             yyin = fopen( *filelist, "r" );
         else
            yyterminate();
         }
```

Miscellaneous macros

The macro `YY_USER_ACTION` can be defined to provide an action which is always executed prior to the matched rule's action. For example, it could be #define'd to call a routine to convert yytext to lower-case. When `YY_USER_ACTION` is invoked, the variable `yy_act` gives the number of the matched rule (rules are numbered starting with 1). Suppose you want to profile how often each of your rules is matched. The following would do the trick:

```
#define YY_USER_ACTION ++ctr[yy_act]
```

where `ctr` is an array to hold the counts for the different rules. Note that the macro `YY_NUM_RULES` gives the total number of rules (including the default rule, even if you use `-s', so a correct declaration for `ctr` is:

```
int ctr[YY_NUM_RULES];
```

The macro `YY_USER_INIT` may be defined to provide an action which is always executed before the first scan (and before the scanner's internal initializations are done). For example, it could be used to call a routine to read in a data table or open a logging file.

The macro `yy_set_interactive(is_interactive)' can be used to control whether the current buffer is considered *interactive*. An interactive buffer is processed more slowly, but must be used when the scanner's input source is indeed interactive to avoid problems due to waiting to fill buffers (see the

discussion of the `-I' flag below). A non-zero value in the macro invocation marks the buffer as interactive, a zero value as non-interactive. Note that use of this macro overrides `%option always-interactive' or `%option never-interactive' (see Options below). `yy_set_interactive()' must be invoked prior to beginning to scan the buffer that is (or is not) to be considered interactive.

The macro `yy_set_bol(at_bol)' can be used to control whether the current buffer's scanning context for the next token match is done as though at the beginning of a line. A non-zero macro argument makes rules anchored with

The macro `YY_AT_BOL()' returns true if the next token scanned from the current buffer will have '^' rules active, false otherwise.

In the generated scanner, the actions are all gathered in one large switch statement and separated using YY_BREAK, which may be redefined. By default, it is simply a "break", to separate each rule's action from the following rule's. Redefining YY_BREAK allows, for example, C++ users to #define YY_BREAK to do nothing (while being very careful that every rule ends with a "break" or a "return"!) to avoid suffering from unreachable statement warnings where because a rule's action ends with "return", the YY_BREAK is inaccessible.

Values available to the user

This section summarizes the various values available to the user in the rule actions.

- `char *yytext' holds the text of the current token. It may be modified but not lengthened (you cannot append characters to the end).

  If the special directive `%array' appears in the first section of the scanner description, then `yytext` is instead declared `char yytext[YYLMAX]', where YYLMAX is a macro definition that you can redefine in the first section if you don't like the default value (generally 8KB). Using `%array' results in somewhat slower scanners, but the value of `yytext` becomes immune to calls to `input()' and `unput()', which potentially destroy its value when `yytext` is a character pointer. The opposite of `%array' is `%pointer', which is the default.

  You cannot use `%array' when generating C++ scanner classes (the `-+' flag).
- `int yyleng' holds the length of the current token.
- `FILE *yyin' is the file which by default `flex` reads from. It may be redefined but doing so only makes sense before scanning begins or after an EOF has been encountered. Changing it in the midst of scanning will have unexpected results since `flex` buffers its input; use `yyrestart()' instead. Once scanning terminates because an end-of-file has been seen, you can assign `yyin` at the new input file and then call the scanner again to continue scanning.
- `void yyrestart( FILE *new_file )' may be called to point `yyin` at the new input file. The switch-over to the new file is immediate (any previously buffered-up input is lost). Note that calling `yyrestart()' with `yyin` as an argument thus throws away the current input buffer and continues scanning the same input file.
- `FILE *yyout' is the file to which `ECHO' actions are done. It can be reassigned by the user.
- YY_CURRENT_BUFFER returns a YY_BUFFER_STATE handle to the current buffer.

- YY_START returns an integer value corresponding to the current start condition. You can subsequently use this value with BEGIN to return to that start condition.

Interfacing with yacc

One of the main uses of `flex` is as a companion to the `yacc` parser-generator. `yacc` parsers expect to call a routine named `yylex()' to find the next input token. The routine is supposed to return the type of the next token as well as putting any associated value in the global `yylval`. To use `flex` with `yacc`, one specifies the `-d' option to `yacc` to instruct it to generate the file `` `y.tab.h' `` containing definitions of all the `%tokens' appearing in the `yacc` input. This file is then included in the `flex` scanner. For example, if one of the tokens is "TOK_NUMBER", part of the scanner might look like:

```
%{
#include "y.tab.h"
%}

%%

[0-9]+        yylval = atoi( yytext ); return TOK_NUMBER;
```

Options

`flex` has the following options:

`-b'

Generate backing-up information to `` `lex.backup' ``. This is a list of scanner states which require backing up and the input characters on which they do so. By adding rules one can remove backing-up states. If *all* backing-up states are eliminated and `-Cf' or `-CF' is used, the generated scanner will run faster (see the `-p' flag). Only users who wish to squeeze every last cycle out of their scanners need worry about this option. (See the section on Performance Considerations below.)

`-c'

is a do-nothing, deprecated option included for POSIX compliance.

`-d'

makes the generated scanner run in debug mode. Whenever a pattern is recognized and the global `yy_flex_debug` is non-zero (which is the default), the scanner will write to `stderr` a line of the form:

```
--accepting rule at line 53 ("the matched text")
```

The line number refers to the location of the rule in the file defining the scanner (i.e., the file that was fed to flex). Messages are also generated when the scanner backs up, accepts the default rule, reaches the end of its input buffer (or encounters a NUL; at this point, the two look the same as far as the scanner's concerned), or reaches an end-of-file.

`-f'

specifies fast scanner. No table compression is done and stdio is bypassed. The result is large but fast. This option is equivalent to `-Cfr' (see below).

`-h'

generates a "help" summary of `flex's options to `stdout` and then exits. `-?' and `--help' are synonyms for `-h'.

`-i'

instructs `flex` to generate a *case-insensitive* scanner. The case of letters given in the `flex` input patterns will be ignored, and tokens in the input will be matched regardless of case. The matched text given in `yytext` will have the preserved case (i.e., it will not be folded).

`-l'

turns on maximum compatibility with the original AT&T `lex` implementation. Note that this does not mean *full* compatibility. Use of this option costs a considerable amount of performance, and it cannot be used with the `-+, -f, -F, -Cf', or `-CF' options. For details on the compatibilities it provides, see the section "Incompatibilities With Lex And POSIX" below. This option also results in the name `YY_FLEX_LEX_COMPAT` being #define'd in the generated scanner.

`-n'

is another do-nothing, deprecated option included only for POSIX compliance.

`-p'

generates a performance report to stderr. The report consists of comments regarding features of the `flex` input file which will cause a serious loss of performance in the resulting scanner. If you give the flag twice, you will also get comments regarding features that lead to minor performance losses.

Note that the use of `REJECT`, `%option yylineno' and variable trailing context (see the Deficiencies / Bugs section below) entails a substantial performance penalty; use of `yymore()', the `^' operator, and the `-I' flag entail minor performance penalties.

`-s'

causes the default rule (that unmatched scanner input is echoed to `stdout`) to be suppressed. If the scanner encounters input that does not match any of its rules, it aborts with an error. This option is useful for finding holes in a scanner's rule set.

`-t'

instructs `flex` to write the scanner it generates to standard output instead of `lex.yy.c'.

`-v'

specifies that `flex` should write to `stderr` a summary of statistics regarding the scanner it generates. Most of the statistics are meaningless to the casual `flex` user, but the first line identifies the version of `flex` (same as reported by `-V'), and the next line the flags used when generating the scanner, including those that are on by default.

`-w'

suppresses warning messages.

`-B'

instructs `flex` to generate a *batch* scanner, the opposite of *interactive* scanners generated by `-I'

(see below). In general, you use `-B' when you are *certain* that your scanner will never be used interactively, and you want to squeeze a *little* more performance out of it. If your goal is instead to squeeze out a *lot* more performance, you should be using the `-Cf' or `-CF' options (discussed below), which turn on `-B' automatically anyway.

`-F'

specifies that the fast scanner table representation should be used (and stdio bypassed). This representation is about as fast as the full table representation `(-f)', and for some sets of patterns will be considerably smaller (and for others, larger). In general, if the pattern set contains both "keywords" and a catch-all, "identifier" rule, such as in the set:

```
"case"    return TOK_CASE;
"switch"  return TOK_SWITCH;
...
"default" return TOK_DEFAULT;
[a-z]+    return TOK_ID;
```

then you're better off using the full table representation. If only the "identifier" rule is present and you then use a hash table or some such to detect the keywords, you're better off using `-F'.

This option is equivalent to `-CFr' (see below). It cannot be used with `-+'.

`-I'

instructs `flex` to generate an *interactive* scanner. An interactive scanner is one that only looks ahead to decide what token has been matched if it absolutely must. It turns out that always looking one extra character ahead, even if the scanner has already seen enough text to disambiguate the current token, is a bit faster than only looking ahead when necessary. But scanners that always look ahead give dreadful interactive performance; for example, when a user types a newline, it is not recognized as a newline token until they enter *another* token, which often means typing in another whole line.

`Flex` scanners default to *interactive* unless you use the `-Cf' or `-CF' table-compression options (see below). That's because if you're looking for high-performance you should be using one of these options, so if you didn't, `flex` assumes you'd rather trade off a bit of run-time performance for intuitive interactive behavior. Note also that you *cannot* use `-I' in conjunction with `-Cf' or `-CF'. Thus, this option is not really needed; it is on by default for all those cases in which it is allowed.

You can force a scanner to *not* be interactive by using `-B' (see above).

`-L'

instructs `flex` not to generate `#line' directives. Without this option, `flex` peppers the generated scanner with #line directives so error messages in the actions will be correctly located with respect to either the original `flex` input file (if the errors are due to code in the input file), or `` `lex.yy.c' `` (if the errors are `flex's` fault -- you should report these sorts of errors to the email address given below).

`-T'

makes `flex` run in `trace` mode. It will generate a lot of messages to `stderr` concerning the form of the input and the resultant non-deterministic and deterministic finite automata. This option

is mostly for use in maintaining `flex`.

`-V'

prints the version number to `stdout` and exits. `--version' is a synonym for `-V'.

`-7'

instructs `flex` to generate a 7-bit scanner, i.e., one which can only recognized 7-bit characters in its input. The advantage of using `-7' is that the scanner's tables can be up to half the size of those generated using the `-8' option (see below). The disadvantage is that such scanners often hang or crash if their input contains an 8-bit character.

Note, however, that unless you generate your scanner using the `-Cf' or `-CF' table compression options, use of `-7' will save only a small amount of table space, and make your scanner considerably less portable. `Flex's` default behavior is to generate an 8-bit scanner unless you use the `-Cf' or `-CF', in which case `flex` defaults to generating 7-bit scanners unless your site was always configured to generate 8-bit scanners (as will often be the case with non-USA sites). You can tell whether flex generated a 7-bit or an 8-bit scanner by inspecting the flag summary in the `-v' output as described above.

Note that if you use `-Cfe' or `-CFe' (those table compression options, but also using equivalence classes as discussed see below), flex still defaults to generating an 8-bit scanner, since usually with these compression options full 8-bit tables are not much more expensive than 7-bit tables.

`-8'

instructs `flex` to generate an 8-bit scanner, i.e., one which can recognize 8-bit characters. This flag is only needed for scanners generated using `-Cf' or `-CF', as otherwise flex defaults to generating an 8-bit scanner anyway.

See the discussion of `-7' above for flex's default behavior and the tradeoffs between 7-bit and 8-bit scanners.

`-+'

specifies that you want flex to generate a C++ scanner class. See the section on Generating C++ Scanners below for details.

`-C[aefFmr]'

controls the degree of table compression and, more generally, trade-offs between small scanners and fast scanners.

`-Ca' ("align") instructs flex to trade off larger tables in the generated scanner for faster performance because the elements of the tables are better aligned for memory access and computation. On some RISC architectures, fetching and manipulating long-words is more efficient than with smaller-sized units such as shortwords. This option can double the size of the tables used by your scanner.

`-Ce' directs `flex` to construct equivalence classes, i.e., sets of characters which have identical lexical properties (for example, if the only appearance of digits in the `flex` input is in the character class "[0-9]" then the digits '0', '1', ..., '9' will all be put in the same equivalence class). Equivalence classes usually give dramatic reductions in the final table/object file sizes (typically a factor of 2-5) and are pretty cheap performance-wise (one array look-up per character scanned).

`-Cf' specifies that the *full* scanner tables should be generated - `flex` should not compress the tables by taking advantages of similar transition functions for different states.

`-CF' specifies that the alternate fast scanner representation (described above under the `-F' flag) should be used. This option cannot be used with `-+'.

`-Cm' directs `flex` to construct meta-equivalence classes, which are sets of equivalence classes (or characters, if equivalence classes are not being used) that are commonly used together. Meta-equivalence classes are often a big win when using compressed tables, but they have a moderate performance impact (one or two "if" tests and one array look-up per character scanned).

`-Cr' causes the generated scanner to *bypass* use of the standard I/O library (stdio) for input. Instead of calling `fread()' or `getc()', the scanner will use the `read()' system call, resulting in a performance gain which varies from system to system, but in general is probably negligible unless you are also using `-Cf' or `-CF'. Using `-Cr' can cause strange behavior if, for example, you read from `yyin` using stdio prior to calling the scanner (because the scanner will miss whatever text your previous reads left in the stdio input buffer).

`-Cr' has no effect if you define `YY_INPUT` (see The Generated Scanner above).

A lone `-C' specifies that the scanner tables should be compressed but neither equivalence classes nor meta-equivalence classes should be used.

The options `-Cf' or `-CF' and `-Cm' do not make sense together - there is no opportunity for meta-equivalence classes if the table is not being compressed. Otherwise the options may be freely mixed, and are cumulative.

The default setting is `-Cem', which specifies that `flex` should generate equivalence classes and meta-equivalence classes. This setting provides the highest degree of table compression. You can trade off faster-executing scanners at the cost of larger tables with the following generally being true:

```
slowest & smallest
      -Cem
      -Cm
      -Ce
      -C
      -C{f,F}e
      -C{f,F}
      -C{f,F}a
fastest & largest
```

Note that scanners with the smallest tables are usually generated and compiled the quickest, so during development you will usually want to use the default, maximal compression.

`-Cfe' is often a good compromise between speed and size for production scanners.

`-ooutput'

directs flex to write the scanner to the file `out-' `put` instead of `` `lex.yy.c' ``. If you combine `-o'

with the `-t' option, then the scanner is written to `stdout' but its `#line' directives (see the `-L' option above) refer to the file `output'.

`-Pprefix'

changes the default `yy' prefix used by `flex' for all globally-visible variable and function names to instead be prefix. For example, `-Pfoo' changes the name of `yytext' to `footext'. It also changes the name of the default output file from `lex.yy.c' to `lex.foo.c'. Here are all of the names affected:

```
yy_create_buffer
yy_delete_buffer
yy_flex_debug
yy_init_buffer
yy_flush_buffer
yy_load_buffer_state
yy_switch_to_buffer
yyin
yyleng
yylex
yylineno
yyout
yyrestart
yytext
yywrap
```

(If you are using a C++ scanner, then only `yywrap' and `yyFlexLexer' are affected.) Within your scanner itself, you can still refer to the global variables and functions using either version of their name; but externally, they have the modified name.

This option lets you easily link together multiple `flex' programs into the same executable. Note, though, that using this option also renames `yywrap()', so you now *must* either provide your own (appropriately-named) version of the routine for your scanner, or use `%option noyywrap', as linking with `-lfl' no longer provides one for you by default.

`-Sskeleton_file'

overrides the default skeleton file from which `flex' constructs its scanners. You'll never need this option unless you are doing `flex' maintenance or development.

`flex' also provides a mechanism for controlling options within the scanner specification itself, rather than from the flex command-line. This is done by including `%option' directives in the first section of the scanner specification. You can specify multiple options with a single `%option' directive, and multiple directives in the first section of your flex input file. Most options are given simply as names, optionally preceded by the word "no" (with no intervening whitespace) to negate their meaning. A number are equivalent to flex flags or their negation:

```
7bit            -7 option
8bit            -8 option
```

```
align           -Ca option
backup          -b option
batch           -B option
c++             -+ option

caseful or
case-sensitive  opposite of -i (default)

case-insensitive or
caseless        -i option

debug           -d option
default         opposite of -s option
ecs             -Ce option
fast            -F option
full            -f option
interactive     -I option
lex-compat      -l option
meta-ecs        -Cm option
perf-report     -p option
read            -Cr option
stdout          -t option
verbose         -v option
warn            opposite of -w option
                (use "%option nowarn" for -w)

array           equivalent to "%array"
pointer         equivalent to "%pointer" (default)
```

Some `%option's' provide features otherwise not available:

`always-interactive'

instructs flex to generate a scanner which always considers its input "interactive". Normally, on each new input file the scanner calls `isatty()' in an attempt to determine whether the scanner's input source is interactive and thus should be read a character at a time. When this option is used, however, then no such call is made.

`main'

directs flex to provide a default `main()' program for the scanner, which simply calls `yylex()'. This option implies `noyywrap` (see below).

`never-interactive'

instructs flex to generate a scanner which never considers its input "interactive" (again, no call made to `isatty())'. This is the opposite of `always-' *interactive*.

`stack'

enables the use of start condition stacks (see Start Conditions above).

`stdinit'

if unset (i.e., `%option nostdinit') initializes `yyin` and `yyout` to nil `FILE` pointers, instead of `stdin` and `stdout`.

`yylineno'

directs `flex` to generate a scanner that maintains the number of the current line read from its input in the global variable `yylineno`. This option is implied by `%option lex-compat'.

`yywrap'

if unset (i.e., `%option noyywrap'), makes the scanner not call `yywrap()' upon an end-of-file, but simply assume that there are no more files to scan (until the user points `yyin` at a new file and calls `yylex()' again).

`flex` scans your rule actions to determine whether you use the `REJECT` or `yymore()' features. The `reject` and `yymore` options are available to override its decision as to whether you use the options, either by setting them (e.g., `%option reject') to indicate the feature is indeed used, or unsetting them to indicate it actually is not used (e.g., `%option noyymore').

Three options take string-delimited values, offset with '=':

```
%option outfile="ABC"
```

is equivalent to `-oABC', and

```
%option prefix="XYZ"
```

is equivalent to `-PXYZ'.

Finally,

```
%option yyclass="foo"
```

only applies when generating a C++ scanner (`-+' option). It informs `flex` that you have derived `foo' as a subclass of `yyFlexLexer` so `flex` will place your actions in the member function `foo::yylex()' instead of `yyFlexLexer::yylex()'. It also generates a `yyFlexLexer::yylex()' member function that emits a run-time error (by invoking `yyFlexLexer::LexerError()') if called. See Generating C++ Scanners, below, for additional information.

A number of options are available for lint purists who want to suppress the appearance of unneeded routines in the generated scanner. Each of the following, if unset, results in the corresponding routine not appearing in the generated scanner:

```
input, unput
yy_push_state, yy_pop_state, yy_top_state
yy_scan_buffer, yy_scan_bytes, yy_scan_string
```

(though `yy_push_state()' and friends won't appear anyway unless you use `%option stack').

Performance considerations

The main design goal of `flex` is that it generate high-performance scanners. It has been optimized for dealing well with large sets of rules. Aside from the effects on scanner speed of the table compression `-C' options outlined above, there are a number of options/actions which degrade performance. These are, from most expensive to least:

```
REJECT
%option yylineno
arbitrary trailing context

pattern sets that require backing up
%array
%option interactive
%option always-interactive

'^' beginning-of-line operator
yymore()
```

with the first three all being quite expensive and the last two being quite cheap. Note also that `unput()' is implemented as a routine call that potentially does quite a bit of work, while `yyless()' is a quite-cheap macro; so if just putting back some excess text you scanned, use `yyless()'.

`REJECT` should be avoided at all costs when performance is important. It is a particularly expensive option.

Getting rid of backing up is messy and often may be an enormous amount of work for a complicated scanner. In principal, one begins by using the `-b' flag to generate a `` `lex.backup' `` file. For example, on the input

```
%%
foo         return TOK_KEYWORD;
foobar      return TOK_KEYWORD;
```

the file looks like:

```
State #6 is non-accepting -
 associated rule line numbers:
       2       3
 out-transitions: [ o ]
 jam-transitions: EOF [ \001-n  p-\177 ]

State #8 is non-accepting -
 associated rule line numbers:
       3
 out-transitions: [ a ]
```

```
 jam-transitions: EOF [ \001-`  b-\177 ]

State #9 is non-accepting -
 associated rule line numbers:
       3
 out-transitions: [ r ]
 jam-transitions: EOF [ \001-q  s-\177 ]

Compressed tables always back up.
```

The first few lines tell us that there's a scanner state in which it can make a transition on an 'o' but not on any other character, and that in that state the currently scanned text does not match any rule. The state occurs when trying to match the rules found at lines 2 and 3 in the input file. If the scanner is in that state and then reads something other than an 'o', it will have to back up to find a rule which is matched. With a bit of head-scratching one can see that this must be the state it's in when it has seen "fo". When this has happened, if anything other than another 'o' is seen, the scanner will have to back up to simply match the 'f' (by the default rule).

The comment regarding State #8 indicates there's a problem when "foob" has been scanned. Indeed, on any character other than an 'a', the scanner will have to back up to accept "foo". Similarly, the comment for State #9 concerns when "fooba" has been scanned and an 'r' does not follow.

The final comment reminds us that there's no point going to all the trouble of removing backing up from the rules unless we're using `-Cf' or `-CF', since there's no performance gain doing so with compressed scanners.

The way to remove the backing up is to add "error" rules:

```
%%
foo         return TOK_KEYWORD;
foobar      return TOK_KEYWORD;

fooba       |
foob        |
fo          {
            /* false alarm, not really a keyword */
            return TOK_ID;
            }
```

Eliminating backing up among a list of keywords can also be done using a "catch-all" rule:

```
%%
foo         return TOK_KEYWORD;
foobar      return TOK_KEYWORD;

[a-z]+      return TOK_ID;
```

This is usually the best solution when appropriate.

Backing up messages tend to cascade. With a complicated set of rules it's not uncommon to get hundr of messages. If one can decipher them, though, it often only takes a dozen or so rules to eliminate the backing up (though it's easy to make a mistake and have an error rule accidentally match a valid token. A possible future `flex` feature will be to automatically add rules to eliminate backing up).

It's important to keep in mind that you gain the benefits of eliminating backing up only if you eliminate *every* instance of backing up. Leaving just one means you gain nothing.

Variable trailing context (where both the leading and trailing parts do not have a fixed length) entails almost the same performance loss as `REJECT` (i.e., substantial). So when possible a rule like:

```
%%
mouse|rat/(cat|dog)   run();
```

is better written:

```
%%
mouse/cat|dog         run();
rat/cat|dog           run();
```

or as

```
%%
mouse|rat/cat         run();
mouse|rat/dog         run();
```

Note that here the special '|' action does *not* provide any savings, and can even make things worse (see Deficiencies / Bugs below).

Another area where the user can increase a scanner's performance (and one that's easier to implement) arises from the fact that the longer the tokens matched, the faster the scanner will run. This is because with long tokens the processing of most input characters takes place in the (short) inner scanning loop, and does not often have to go through the additional work of setting up the scanning environment (e.g., `yytext`) for the action. Recall the scanner for C comments:

```
%x comment
%%
        int line_num = 1;

"/*"         BEGIN(comment);

<comment>[^*\n]*
<comment>"*"+[^*/\n]*
<comment>\n             ++line_num;
<comment>"*"+"/"        BEGIN(INITIAL);
```

This could be sped up by writing it as:

```
%x comment
%%
        int line_num = 1;

"/*"         BEGIN(comment);

<comment>[^*\n]*
<comment>[^*\n]*\n      ++line_num;
<comment>"*"+[^*/\n]*
<comment>"*"+[^*/\n]*\n ++line_num;
<comment>"*"+"/"        BEGIN(INITIAL);
```

Now instead of each newline requiring the processing of another action, recognizing the newlines is "distributed" over the other rules to keep the matched text as long as possible. Note that *adding* rules does *not* slow down the scanner! The speed of the scanner is independent of the number of rules or (modulo the considerations given at the beginning of this section) how complicated the rules are with regard to operators such as '*' and '|'.

A final example in speeding up a scanner: suppose you want to scan through a file containing identifiers and keywords, one per line and with no other extraneous characters, and recognize all the keywords. A natural first approach is:

```
%%
asm      |
auto     |
break    |
... etc ...
volatile |
while    /* it's a keyword */

.|\n     /* it's not a keyword */
```

To eliminate the back-tracking, introduce a catch-all rule:

```
%%
asm      |
auto     |
break    |
... etc ...
volatile |
while    /* it's a keyword */

[a-z]+   |
.|\n     /* it's not a keyword */
```

Now, if it's guaranteed that there's exactly one word per line, then we can reduce the total number of

matches by a half by merging in the recognition of newlines with that of the other tokens:

```
%%
asm\n    |
auto\n   |
break\n  |
... etc ...
volatile\n |
while\n  /* it's a keyword */

[a-z]+\n |
.|\n     /* it's not a keyword */
```

One has to be careful here, as we have now reintroduced backing up into the scanner. In particular, while *we* know that there will never be any characters in the input stream other than letters or newlines, `flex` can't figure this out, and it will plan for possibly needing to back up when it has scanned a token like "auto" and then the next character is something other than a newline or a letter. Previously it would then just match the "auto" rule and be done, but now it has no "auto" rule, only a "auto\n" rule. To eliminate the possibility of backing up, we could either duplicate all rules but without final newlines, or, since we never expect to encounter such an input and therefore don't how it's classified, we can introduce one more catch-all rule, this one which doesn't include a newline:

```
%%
asm\n    |
auto\n   |
break\n  |
... etc ...
volatile\n |
while\n  /* it's a keyword */

[a-z]+\n |
[a-z]+   |
.|\n     /* it's not a keyword */
```

Compiled with `-Cf', this is about as fast as one can get a `flex` scanner to go for this particular problem.

A final note: `flex` is slow when matching NUL's, particularly when a token contains multiple NUL's. It's best to write rules which match *short* amounts of text if it's anticipated that the text will often include NUL's.

Another final note regarding performance: as mentioned above in the section How the Input is Matched, dynamically resizing `yytext` to accommodate huge tokens is a slow process because it presently requires that the (huge) token be rescanned from the beginning. Thus if performance is vital, you should attempt to match "large" quantities of text but not "huge" quantities, where the cutoff between the two is at about 8K characters/token.

Generating C++ scanners

`flex` provides two different ways to generate scanners for use with C++. The first way is to simply compile a scanner generated by `flex` using a C++ compiler instead of a C compiler. You should not encounter any compilations errors (please report any you find to the email address given in the Author section below). You can then use C++ code in your rule actions instead of C code. Note that the default input source for your scanner remains `yyin`, and default echoing is still done to `yyout`. Both of these remain `FILE *' variables and not C++ `streams`.

You can also use `flex` to generate a C++ scanner class, using the `-+' option, (or, equivalently, `%option c++'), which is automatically specified if the name of the flex executable ends in a `+', such as `flex++`. When using this option, flex defaults to generating the scanner to the file `` `lex.yy.cc' `` instead of `` `lex.yy.c' ``. The generated scanner includes the header file `` `FlexLexer.h' ``, which defines the interface to two C++ classes.

The first class, `FlexLexer`, provides an abstract base class defining the general scanner class interface. It provides the following member functions:

`const char* YYText()'

> returns the text of the most recently matched token, the equivalent of `yytext`.

`int YYLeng()'

> returns the length of the most recently matched token, the equivalent of `yyleng`.

`int lineno() const'

> returns the current input line number (see `%option yylineno'), or 1 if `%option yylineno' was not used.

`void set_debug(int flag)'

> sets the debugging flag for the scanner, equivalent to assigning to `yy_flex_debug` (see the Options section above). Note that you must build the scanner using `%option debug' to include debugging information in it.

`int debug() const'

> returns the current setting of the debugging flag.

Also provided are member functions equivalent to `yy_switch_to_buffer(), yy_create_buffer()' (though the first argument is an `istream*' object pointer and not a `FILE*', `yy_flush_buffer()', `yy_delete_buffer()', and `yyrestart()' (again, the first argument is a `istream*' object pointer).

The second class defined in `` `FlexLexer.h' `` is `yyFlexLexer`, which is derived from `FlexLexer`. It defines the following additional member functions:

`yyFlexLexer(istream* arg_yyin = 0, ostream* arg_yyout = 0)'

> constructs a `yyFlexLexer` object using the given streams for input and output. If not specified, the streams default to `cin` and `cout`, respectively.

`virtual int yylex()'

> performs the same role is `yylex()' does for ordinary flex scanners: it scans the input stream, consuming tokens, until a rule's action returns a value. If you derive a subclass S from

`yyFlexLexer` and want to access the member functions and variables of S inside `yylex()', then you need to use `%option yyclass="S"' to inform `flex` that you will be using that subclass instead of `yyFlexLexer`. In this case, rather than generating `yyFlexLexer::yylex()', `flex` generates `S::yylex()' (and also generates a dummy `yyFlexLexer::yylex()' that calls `yyFlexLexer::LexerError()' if called).

`virtual void switch_streams(istream* new_in = 0, ostream* new_out = 0)'

reassigns `yyin` to `new_in` (if non-nil) and `yyout` to `new_out` (ditto), deleting the previous input buffer if `yyin` is reassigned.

`int yylex(istream* new_in = 0, ostream* new_out = 0)'

first switches the input streams via `switch_streams( new_in, new_out )' and then returns the value of `yylex()'.

In addition, `yyFlexLexer` defines the following protected virtual functions which you can redefine in derived classes to tailor the scanner:

`virtual int LexerInput(char* buf, int max_size)'

reads up to `max_size' characters into buf and returns the number of characters read. To indicate end-of-input, return 0 characters. Note that "interactive" scanners (see the `-B' and `-I' flags) define the macro `YY_INTERACTIVE`. If you redefine `LexerInput()` and need to take different actions depending on whether or not the scanner might be scanning an interactive input source, you can test for the presence of this name via `#ifdef'.

`virtual void LexerOutput(const char* buf, int size)'

writes out size characters from the buffer buf, which, while NUL-terminated, may also contain "internal" NUL's if the scanner's rules can match text with NUL's in them.

`virtual void LexerError(const char* msg)'

reports a fatal error message. The default version of this function writes the message to the stream `cerr` and exits.

Note that a `yyFlexLexer` object contains its *entire* scanning state. Thus you can use such objects to create reentrant scanners. You can instantiate multiple instances of the same `yyFlexLexer` class, and you can also combine multiple C++ scanner classes together in the same program using the `-P' option discussed above. Finally, note that the `%array' feature is not available to C++ scanner classes; you must use `%pointer' (the default).

Here is an example of a simple C++ scanner:

```
    // An example of using the flex C++ scanner class.

%{
int mylineno = 0;
%}

string  \"[^\n"]+\"

ws      [ \t]+
```

```
alpha   [A-Za-z]
dig     [0-9]
name    ({alpha}|{dig}|\$)({alpha}|{dig}|[_.\-/$])*
num1    [-+]?{dig}+\.?([eE][-+]?{dig}+)?
num2    [-+]?{dig}*\.{dig}+([eE][-+]?{dig}+)?
number  {num1}|{num2}

%%

{ws}    /* skip blanks and tabs */

"/*"    {
        int c;

        while((c = yyinput()) != 0)
            {
            if(c == '\n')
                ++mylineno;

            else if(c == '*')
                {
                if((c = yyinput()) == '/')
                    break;
                else
                    unput(c);
                }
            }
        }

{number}  cout << "number " << YYText() << '\n';

\n        mylineno++;

{name}    cout << "name " << YYText() << '\n';

{string}  cout << "string " << YYText() << '\n';

%%

Version 2.5                December 1994                        44

int main( int /* argc */, char** /* argv */ )
    {
    FlexLexer* lexer = new yyFlexLexer;
    while(lexer->yylex() != 0)
```

```
    ;
return 0;
}
```

If you want to create multiple (different) lexer classes, you use the `-P' flag (or the `prefix=' option) to rename each `yyFlexLexer` to some other `xxFlexLexer`. You then can include `<FlexLexer.h>' in your other sources once per lexer class, first renaming `yyFlexLexer` as follows:

```
#undef yyFlexLexer
#define yyFlexLexer xxFlexLexer
#include <FlexLexer.h>

#undef yyFlexLexer
#define yyFlexLexer zzFlexLexer
#include <FlexLexer.h>
```

if, for example, you used `%option prefix="xx"' for one of your scanners and `%option prefix="zz"' for the other.

IMPORTANT: the present form of the scanning class is *experimental* and may change considerably between major releases.

Incompatibilities with `lex` and POSIX

`flex` is a rewrite of the AT&T Unix `lex` tool (the two implementations do not share any code, though), with some extensions and incompatibilities, both of which are of concern to those who wish to write scanners acceptable to either implementation. Flex is fully compliant with the POSIX `lex` specification, except that when using `%pointer' (the default), a call to `unput()' destroys the contents of `yytext`, which is counter to the POSIX specification.

In this section we discuss all of the known areas of incompatibility between flex, AT&T lex, and the POSIX specification.

`flex's` `-l' option turns on maximum compatibility with the original AT&T `lex` implementation, at the cost of a major loss in the generated scanner's performance. We note below which incompatibilities can be overcome using the `-l' option.

`flex` is fully compatible with `lex` with the following exceptions:

- The undocumented `lex` scanner internal variable `yylineno` is not supported unless `-l' or `%option yylineno' is used. `yylineno` should be maintained on a per-buffer basis, rather than a per-scanner (single global variable) basis. `yylineno` is not part of the POSIX specification.
- The `input()' routine is not redefinable, though it may be called to read characters following whatever has been matched by a rule. If `input()' encounters an end-of-file the normal `yywrap()' processing is done. A "real" end-of-file is returned by `input()' as `EOF`.

  Input is instead controlled by defining the `YY_INPUT` macro.

The `flex` restriction that `input()' cannot be redefined is in accordance with the POSIX specification, which simply does not specify any way of controlling the scanner's input other th by making an initial assignment to `yyin`.

- The `unput()' routine is not redefinable. This restriction is in accordance with POSIX.
- `flex` scanners are not as reentrant as `lex` scanners. In particular, if you have an interactive scanner and an interrupt handler which long-jumps out of the scanner, and the scanner is subsequently called again, you may get the following message:

  ```
  fatal flex scanner internal error--end of buffer missed
  ```

  To reenter the scanner, first use

  ```
  yyrestart( yyin );
  ```

  Note that this call will throw away any buffered input; usually this isn't a problem with an interactive scanner.

  Also note that flex C++ scanner classes *are* reentrant, so if using C++ is an option for you, you should use them instead. See "Generating C++ Scanners" above for details.
- `output()' is not supported. Output from the `ECHO' macro is done to the file-pointer `yyout` (default `stdout`).

  `output()' is not part of the POSIX specification.
- `lex` does not support exclusive start conditions (%x), though they are in the POSIX specification.
- When definitions are expanded, `flex` encloses them in parentheses. With lex, the following:

  ```
  NAME    [A-Z][A-Z0-9]*
  %%
  foo{NAME}?      printf( "Found it\n" );
  %%
  ```

  will not match the string "foo" because when the macro is expanded the rule is equivalent to "foo[A-Z][A-Z0-9]*?" and the precedence is such that the '?' is associated with "[A-Z0-9]*". With `flex`, the rule will be expanded to "foo([A-Z][A-Z0-9]*)?" and so the string "foo" will match.

  Note that if the definition begins with `^' or ends with `$' then it is *not* expanded with parentheses, to allow these operators to appear in definitions without losing their special meanings. But the `<s>, /', and `<<EOF>>' operators cannot be used in a `flex` definition.

  Using `-l' results in the `lex` behavior of no parentheses around the definition.

  The POSIX specification is that the definition be enclosed in parentheses.
- Some implementations of `lex` allow a rule's action to begin on a separate line, if the rule's pattern has trailing whitespace:

  ```
  %%
  ```

```
foo|bar<space here>
  { foobar_action(); }
```

`flex` does not support this feature.

- The `lex` `%r' (generate a Ratfor scanner) option is not supported. It is not part of the POSIX specification.
- After a call to `unput()', `yytext` is undefined until the next token is matched, unless the scanner was built using `%array'. This is not the case with `lex` or the POSIX specification. The `-l' option does away with this incompatibility.
- The precedence of the `{}' (numeric range) operator is different. `lex` interprets "abc{1,3}" as "match one, two, or three occurrences of 'abc'", whereas `flex` interprets it as "match 'ab' followed by one, two, or three occurrences of 'c'". The latter is in agreement with the POSIX specification.
- The precedence of the `^' operator is different. `lex` interprets "^foo|bar" as "match either 'foo' at the beginning of a line, or 'bar' anywhere", whereas `flex` interprets it as "match either 'foo' or 'bar' if they come at the beginning of a line". The latter is in agreement with the POSIX specification.
- The special table-size declarations such as `%a' supported by `lex` are not required by `flex` scanners; `flex` ignores them.
- The name FLEX_SCANNER is #define'd so scanners may be written for use with either `flex` or `lex`. Scanners also include `YY_FLEX_MAJOR_VERSION` and `YY_FLEX_MINOR_VERSION` indicating which version of `flex` generated the scanner (for example, for the 2.5 release, these defines would be 2 and 5 respectively).

The following `flex` features are not included in `lex` or the POSIX specification:

```
C++ scanners
%option
start condition scopes
start condition stacks
interactive/non-interactive scanners
yy_scan_string() and friends
yyterminate()
yy_set_interactive()
yy_set_bol()
YY_AT_BOL()
<<EOF>>
<*>
YY_DECL
YY_START
YY_USER_ACTION
YY_USER_INIT
#line directives
%{}'s around actions
multiple actions on a line
```

plus almost all of the flex flags. The last feature in the list refers to the fact that with `flex` you can put

multiple actions on the same line, separated with semicolons, while with `lex`, the following

```
foo     handle_foo(); ++num_foos_seen;
```

is (rather surprisingly) truncated to

```
foo     handle_foo();
```

`flex` does not truncate the action. Actions that are not enclosed in braces are simply terminated at the end of the line.

Diagnostics

`warning, rule cannot be matched'

indicates that the given rule cannot be matched because it follows other rules that will always match the same text as it. For example, in the following "foo" cannot be matched because it comes after an identifier "catch-all" rule:

```
[a-z]+    got_identifier();
foo       got_foo();
```

Using `REJECT` in a scanner suppresses this warning.

`warning, -s option given but default rule can be matched'

means that it is possible (perhaps only in a particular start condition) that the default rule (match any single character) is the only one that will match a particular input. Since `-s' was given, presumably this is not intended.

`reject_used_but_not_detected undefined'

`yymore_used_but_not_detected undefined'

These errors can occur at compile time. They indicate that the scanner uses `REJECT` or `yymore()' but that `flex` failed to notice the fact, meaning that `flex` scanned the first two sections looking for occurrences of these actions and failed to find any, but somehow you snuck some in (via a #include file, for example). Use `%option reject' or `%option yymore' to indicate to flex that you really do use these features.

`flex scanner jammed'

a scanner compiled with `-s' has encountered an input string which wasn't matched by any of its rules. This error can also occur due to internal problems.

`token too large, exceeds YYLMAX'

your scanner uses `%array' and one of its rules matched a string longer than the `YYL-' `MAX` constant (8K bytes by default). You can increase the value by #define'ing `YYLMAX` in the definitions section of your `flex` input.

`scanner requires -8 flag to use the character 'x"

Your scanner specification includes recognizing the 8-bit character x and you did not specify the -8

flag, and your scanner defaulted to 7-bit because you used the `-Cf' or `-CF' table compression options. See the discussion of the `-7' flag for details.

`flex scanner push-back overflow'

you used `unput()' to push back so much text that the scanner's buffer could not hold both the pushed-back text and the current token in `yytext'. Ideally the scanner should dynamically resize the buffer in this case, but at present it does not.

`input buffer overflow, can't enlarge buffer because scanner uses REJECT'

the scanner was working on matching an extremely large token and needed to expand the input buffer. This doesn't work with scanners that use `REJECT'.

`fatal flex scanner internal error--end of buffer missed'

This can occur in an scanner which is reentered after a long-jump has jumped out (or over) the scanner's activation frame. Before reentering the scanner, use:

```
yyrestart( yyin );
```

or, as noted above, switch to using the C++ scanner class.

`too many start conditions in <> construct!'

you listed more start conditions in a <> construct than exist (so you must have listed at least one of them twice).

Files

`-lfl'

library with which scanners must be linked.

`lex.yy.c'

generated scanner (called `lexyy.c' on some systems).

`lex.yy.cc'

generated C++ scanner class, when using `-+'.

`<FlexLexer.h>'

header file defining the C++ scanner base class, `FlexLexer', and its derived class, `yyFlexLexer'.

`flex.skl'

skeleton scanner. This file is only used when building flex, not when flex executes.

`lex.backup'

backing-up information for `-b' flag (called `lex.bck' on some systems).

Deficiencies / Bugs

Some trailing context patterns cannot be properly matched and generate warning messages ("dangerous trailing context"). These are patterns where the ending of the first part of the rule matches the beginning of the second part, such as "zx*/xy*", where the 'x*' matches the 'x' at the beginning of the trailing context. (Note that the POSIX draft states that the text matched by such patterns is undefined.)

For some trailing context rules, parts which are actually fixed-length are not recognized as such, leading to the abovementioned performance loss. In particular, parts using '|' or {n} (such as "foo{3}") are always considered variable-length.

Combining trailing context with the special '|' action can result in *fixed* trailing context being turned into the more expensive variable trailing context. For example, in the following:

```
%%
abc      |
xyz/def
```

Use of `unput()' invalidates yytext and yyleng, unless the `%array' directive or the `-l' option has been used.

Pattern-matching of NUL's is substantially slower than matching other characters.

Dynamic resizing of the input buffer is slow, as it entails rescanning all the text matched so far by the current (generally huge) token.

Due to both buffering of input and read-ahead, you cannot intermix calls to <stdio.h> routines, such as, for example, `getchar()', with `flex` rules and expect it to work. Call `input()' instead.

The total table entries listed by the `-v' flag excludes the number of table entries needed to determine what rule has been matched. The number of entries is equal to the number of DFA states if the scanner does not use `REJECT`, and somewhat greater than the number of states if it does.

`REJECT` cannot be used with the `-f' or `-F' options.

The `flex` internal algorithms need documentation.

Thanks to Keith Bostic, Jon Forrest, Noah Friedman, John Gilmore, Craig Leres, John Levine, Bob Mulcahy, G.T. Nicol, Francois Pinard, Rich Salz, and Richard Stallman for help with various distribution headaches.

Thanks to Esmond Pitt and Earle Horton for 8-bit character support; to Benson Margulies and Fred Burke for C++ support; to Kent Williams and Tom Epperly for C++ class support; to Ove Ewerlid for support of NUL's; and to Eric Hughes for support of multiple buffers.

This work was primarily done when I was with the Real Time Systems Group at the Lawrence Berkeley Laboratory in Berkeley, CA. Many thanks to all there for the support I received.

Send comments to `vern@ee.lbl.gov'.

Using

The GNU Assembler

for the family

January 1994

Dean Elsner, Jay Fenlason & friends

Using

The Free Software Foundation Inc. thanks The Nice Computer Company of Australia for loaning Dean Elsner to write the first (Vax) version of `as` for Project GNU. The proprietors, management and staff of TNCCA thank FSF for distracting the boss while they got some work done.

Overview

This manual is a user guide to the GNU assembler . This version of the manual describes configured to generate code for architectures.

Here is a brief summary of how to invoke . For details, see section Command-Line Options.

```
 [ -a[cdhlns][=file] ] [ -D ]  [ --defsym sym=val ]
 [ -f ] [ --help ] [ -I dir ] [ -J ] [ -K ] [ -L ]
 [ -o objfile ] [ -R ] [ --statistics ] [ -v ] [ -version ]
 [ --version ] [ -W ] [ -w ] [ -x ] [ -Z ]

 [ -- | files ... ]
```

`-a[dhlns]`

Turn on listings, in any of a variety of ways:

`-ad`

omit debugging directives

`-ah`

include high-level source

`-al`

include assembly

`-an`

omit forms processing

`-as`

include symbols

`=file`

set the name of the listing file

You may combine these options; for example, use `-aln' for assembly listing without forms processing. The `=file' option, if used, must be the last one. By itself, `-a' defaults to `-ahls'---that is, all listings turned on.

- -D Ignored. This option is accepted for script compatibility with calls to other assemblers.
- --defsym sym=value Define the symbol sym to be value before assembling the input file. value must be an integer constant. As in C, a leading `0x' indicates a hexadecimal value, and a leading `0' indicates an octal value.
- -f "fast"---skip whitespace and comment preprocessing (assume source is compiler output).
- --help Print a summary of the command line options and exit.
- -I dir Add directory dir to the search list for `.include` directives.
- -J Don't warn about signed overflow.
- -K This option is accepted but has no effect on the family.
- -L Keep (in the symbol table) local symbols, starting with `L'.
- -o objfile Name the object-file output from objfile.
- -R Fold the data section into the text section.
- --statistics Print the maximum space (in bytes) and total time (in seconds) used by assembly.
- -v
- -version Print the `as` version.
- --version Print the `as` version and exit.
- -W Suppress warning messages.
- -w Ignored.
- -x Ignored.
- -Z Generate an object file even after errors.
- -- | files ... Standard input, or source files to assemble.

Structure of this Manual

This manual is intended to describe what you need to know to use GNU . We cover the syntax expected in source files, including notation for symbols, constants, and expressions; the directives that understands; and of course how to invoke .

We also cover special features in the configuration of , including assembler directives.

On the other hand, this manual is *not* intended as an introduction to programming in assembly language--let alone programming in general! In a similar vein, we make no attempt to introduce the machine architecture; we do *not* describe the instruction set, standard mnemonics, registers or addressing

modes that are standard to a particular architecture.

The GNU Assembler

GNU `as` is really a family of assemblers. This manual describes , a member of that family which is configured for the architectures. If you use (or have used) the GNU assembler on one architecture, you should find a fairly similar environment when you use it on another architecture. Each version has much in common with the others, including object file formats, most assembler directives (often called pseudo-ops) and assembler syntax.

is primarily intended to assemble the output of the GNU C compiler for use by the linker . Nevertheless, we've tried to make assemble correctly everything that other assemblers for the same machine would assemble.

Unlike older assemblers, is designed to assemble a source program in one pass of the source file. This has a subtle impact on the .org directive (see section `.org new-lc , fill`).

Object File Formats

The GNU assembler can be configured to produce several alternative object file formats. For the most part, this does not affect how you write assembly language programs; but directives for debugging symbols are typically different in different file formats. See section Symbol Attributes. On the , is configured to produce format object files.

Command Line

After the program name , the command line may contain options and file names. Options may appear in any order, and may be before, after, or between file names. The order of file names is significant.

`` `--' `` (two hyphens) by itself names the standard input file explicitly, as one of the files for to assemble.

Except for `--' any command line argument that begins with a hyphen (`-') is an option. Each option changes the behavior of . No option changes the way another option works. An option is a `-' followed by one or more letters; the case of the letter is important. All options are optional.

Some options expect exactly one file name to follow them. The file name may either immediately follow the option's letter (compatible with older assemblers) or it may be the next command argument (GNU standard). These two command lines are equivalent:

```
-o my-object-file.o mumble.s
-omy-object-file.o mumble.s
```

Input Files

We use the phrase source program, abbreviated source, to describe the program input to one run of . The program may be in one or more files; how the source is partitioned into files doesn't change the meaning of the source.

The source program is a concatenation of the text in all the files, in the order specified.

Each time you run it assembles exactly one source program. The source program is made up of one or more files. (The standard input is also a file.)

You give a command line that has zero or more input file names. The input files are read (from left file name to right). A command line argument (in any position) that has no special meaning is taken to be an input file name.

If you give no file names it attempts to read one input file from the standard input, which is normally your terminal. You may have to type ctl-D to tell there is no more program to assemble.

Use `--' if you need to explicitly name the standard input file in your command line.

If the source is empty, produces a small, empty object file.

Filenames and Line-numbers

There are two ways of locating a line in the input file (or files) and either may be used in reporting error messages. One way refers to a line number in a physical file; the other refers to a line number in a "logical" file. See section Error and Warning Messages.

Physical files are those files named in the command line given to .

Logical files are simply names declared explicitly by assembler directives; they bear no relation to physical files. Logical file names help error messages reflect the original source file, when source is itself synthesized from other files. See section `.app-file string`.

Output (Object) File

Every time you run it produces an output file, which is your assembly language program translated into numbers. This file is the object file. Its default name is `a.out`. `b.out` when is configured for the Intel 80960. You can give it another name by using the `-o` option. Conventionally, object file names end with `.o'. The default name is used for historical reasons: older assemblers were capable of assembling self-contained programs directly into a runnable program. (For some formats, this isn't currently possible, but it can be done for the `a.out` format.)

The object file is meant for input to the linker . It contains assembled program code, information to help integrate the assembled program into a runnable file, and (optionally) symbolic information for the debugger.

Error and Warning Messages

may write warnings and error messages to the standard error file (usually your terminal). This should not happen when a compiler runs automatically. Warnings report an assumption made so that could keep assembling a flawed program; errors report a grave problem that stops the assembly.

Warning messages have the format

```
file_name:NNN:Warning Message Text
```

(where **NNN** is a line number). If a logical file name has been given (see section `.app-file string`) it is used for the filename, otherwise the name of the current input file is used. If a logical line number was given (see section `.line line-number`) then it is used to calculate the number printed, otherwise the actual line in the current source file is printed. The message text is intended to be self explanatory (in the grand Unix tradition).

Error messages have the format

```
file_name:NNN:FATAL:Error Message Text
```

The file name and line number are derived as for warning messages. The actual message text may be rather less explanatory because many of them aren't supposed to happen.

Command-Line Options

This chapter describes command-line options available in *all* versions of the GNU assembler; @xref{Machine Dependencies}, for options specific to the .

If you are invoking via the GNU C compiler (version 2), you can use the `-Wa' option to pass arguments through to the assembler. The assembler arguments must be separated from each other (and the `-Wa') by commas. For example:

```
gcc -c -g -O -Wa,-alh,-L file.c
```

emits a listing to standard output with high-level and assembly source.

Usually you do not need to use this `-Wa' mechanism, since many compiler command-line options are automatically passed to the assembler by the compiler. (You can call the GNU compiler driver with the `-v' option to see precisely what options it passes to each compilation pass, including the assembler.)

Enable Listings: `-a[cdhlns]`

These options enable listing output from the assembler. By itself, `-a' requests high-level, assembly, and symbols listing. You can use other letters to select specific options for the list: `-ah' requests a high-level

language listing, `-al' requests an output-program assembly listing, and `-as' requests a symbol table listing. High-level listings require that a compiler debugging option like `-g' be used, and that assembly listings (`-al') be requested also.

Use the `-ac' option to omit false conditionals from a listing. Any lines which are not assembled because of a false `.if` (or `.ifdef`, or any other conditional), or a true `.if` followed by an `.else`, will be omitted from the listing.

Use the `-ad' option to omit debugging directives from the listing.

Once you have specified one of these options, you can further control listing output and its appearance using the directives `.list`, `.nolist`, `.psize`, `.eject`, `.title`, and `.sbttl`. The `-an' option turns off all forms processing. If you do not request listing output with one of the `-a' options, the listing-control directives have no effect.

The letters after `-a' may be combined into one option, *e.g.*, `-aln'.

`-D`

This option has no effect whatsoever, but it is accepted to make it more likely that scripts written for other assemblers also work with .

Work Faster: `-f`

`-f' should only be used when assembling programs written by a (trusted) compiler. `-f' stops the assembler from doing whitespace and comment preprocessing on the input file(s) before assembling them. See section Preprocessing.

> *Warning:* if you use `-f' when the files actually need to be preprocessed (if they contain comments, for example), does not work correctly.

`.include` search path: `-I` path

Use this option to add a path to the list of directories searches for files specified in `.include` directives (see section `.include "file"`). You may use `-I` as many times as necessary to include a variety of paths. The current working directory is always searched first; after that, searches any `-I' directories in the same order as they were specified (left to right) on the command line.

Difference Tables: `-K`

On the family, this option is allowed, but has no effect. It is permitted for compatibility with the GNU assembler on other platforms, where it can be used to warn when the assembler alters the machine code generated for `.word' directives in difference tables. The family does not have the addressing limitations that sometimes lead to this alteration on other platforms.

Include Local Labels: `-L`

Labels beginning with `L' (upper case only) are called local labels. See section Symbol Names. Normally you do not see such labels when debugging, because they are intended for the use of programs (like compilers) that compose assembler programs, not for your notice. Normally both and discard such labels, so you do not normally debug with them.

This option tells to retain those `L...' symbols in the object file. Usually if you do this you also tell the linker to preserve symbols whose names begin with `L'.

By default, a local label is any label beginning with `L', but each target is allowed to redefine the local label prefix.

Assemble in MRI Compatibility Mode: `-M`

The `-M` or `--mri` option selects MRI compatibility mode. This changes the syntax and pseudo-op handling of to make it compatible with the `ASM68K` or the `ASM960` (depending upon the configured target) assembler from Microtec Research. The exact nature of the MRI syntax will not be documented here; see the MRI manuals for more information. Note in particular that the handling of macros and macro arguments is somewhat different. The purpose of this option is to permit assembling existing MRI assembler code using .

The MRI compatibility is not complete. Certain operations of the MRI assembler depend upon its object file format, and can not be supported using other object file formats. Supporting these would require enhancing each object file format individually. These are:

- global symbols in common section

  The m68k MRI assembler supports common sections which are merged by the linker. Other object file formats do not support this. handles common sections by treating them as a single common symbol. It permits local symbols to be defined within a common section, but it can not support global symbols, since it has no way to describe them.

- complex relocations

  The MRI assemblers support relocations against a negated section address, and relocations which combine the start addresses of two or more sections. These are not support by other object file formats.

- `END` pseudo-op specifying start address

  The MRI `END` pseudo-op permits the specification of a start address. This is not supported by other object file formats. The start address may instead be specified using the `-e` option to the linker, or in a linker script.

- `IDNT`, `.ident` and `NAME` pseudo-ops

  The MRI `IDNT`, `.ident` and `NAME` pseudo-ops assign a module name to the output file. This is not supported by other object file formats.

- `ORG` pseudo-op

  The m68k MRI `ORG` pseudo-op begins an absolute section at a given address. This differs from the usual `.org` pseudo-op, which changes the location within the current section. Absolute sections are not supported by other object file formats. The address of a section may be assigned within a linker script.

There are some other features of the MRI assembler which are not supported by , typically either because they are difficult or because they seem of little consequence. Some of these may be supported in future releases.

- EBCDIC strings

  EBCDIC strings are not supported.

- packed binary coded decimal

  Packed binary coded decimal is not supported. This means that the `DC.P` and `DCB.P` pseudo-ops are not supported.

- `FEQU` pseudo-op

  The m68k `FEQU` pseudo-op is not supported.

- `NOOBJ` pseudo-op

  The m68k `NOOBJ` pseudo-op is not supported.

- `OPT` branch control options

  The m68k `OPT` branch control options---`B`, `BRS`, `BRB`, `BRL`, and `BRW`---are ignored. automatically relaxes all branches, whether forward or backward, to an appropriate size, so these options serve no purpose.

- `OPT` list control options

  The following m68k `OPT` list control options are ignored: `C`, `CEX`, `CL`, `CRE`, `E`, `G`, `I`, `M`, `MEX`, `MC`, `MD`, `X`.

- other `OPT` options

  The following m68k `OPT` options are ignored: `NEST`, `O`, `OLD`, `OP`, `P`, `PCO`, `PCR`, `PCS`, `R`.

- `OPT D` option is default

  The m68k `OPT D` option is the default, unlike the MRI assembler. `OPT NOD` may be used to turn it off.

- `XREF` pseudo-op.

  The m68k `XREF` pseudo-op is ignored.

- `.debug` pseudo-op

  The i960 `.debug` pseudo-op is not supported.

- `.extended` pseudo-op

  The i960 `.extended` pseudo-op is not supported.

- `.list` pseudo-op.

  The various options of the i960 `.list` pseudo-op are not supported.
- `.optimize` pseudo-op

  The i960 `.optimize` pseudo-op is not supported.
- `.output` pseudo-op

  The i960 `.output` pseudo-op is not supported.
- `.setreal` pseudo-op

  The i960 `.setreal` pseudo-op is not supported.

Name the Object File: `-o`

There is always one object file output when you run . By default it has the name `` `a.out' ``. `` `a.out' ``. You use this option (which takes exactly one filename) to give the object file a different name.

Whatever the object file is called, overwrites any existing file of the same name.

Join Data and Text Sections: `-R`

`-R` tells to write the object file as if all data-section data lives in the text section. This is only done at the very last moment: your binary data are the same, but data section parts are relocated differently. The data section part of your object file is zero bytes long because all its bytes are appended to the text section. (See section Sections and Relocation.)

When you specify `-R` it would be possible to generate shorter address displacements (because we do not have to cross between text and data section). We refrain from doing this simply for compatibility with older versions of . In future, `-R` may work this way.

Display Assembly Statistics: `--statistics`

Use `--statistics' to display two statistics about the resources used by : the maximum amount of space allocated during the assembly (in bytes), and the total execution time taken for the assembly (in CPU seconds).

Announce Version: `-v`

You can find out what version of as is running by including the option `-v' (which you can also spell as `-version') on the command line.

Suppress Warnings: -W

should never give a warning or error message when assembling compiler output. But programs written by people often cause to give a warning that a particular assumption was made. All such warnings are directed to the standard error file. If you use this option, no warnings are issued. This option only affects the warning messages: it does not change any particular of how assembles your file. Errors, which stop the assembly, are still reported.

Generate Object File in Spite of Errors: -Z

After an error message, normally produces no output. If for some reason you are interested in object file output even after gives an error message on your program, use the `-Z' option. If there are any errors, continues anyways, and writes an object file after a final warning message of the form `n errors, m warnings, generating bad object file.'

Syntax

This chapter describes the machine-independent syntax allowed in a source file. syntax is similar to what many other assemblers use; it is inspired by the BSD 4.2 assembler.

Preprocessing

The internal preprocessor:

- adjusts and removes extra whitespace. It leaves one space or tab before the keywords on a line, and turns any other whitespace on the line into a single space.
- removes all comments, replacing them with a single space, or an appropriate number of newlines.
- converts character constants into the appropriate numeric values.

It does not do macro processing, include file handling, or anything else you may get from your C compiler's preprocessor. You can do include file processing with the `.include` directive (see section `.include "file"`). You can use the GNU C compiler driver to get other "CPP" style preprocessing, by giving the input file a `.S' suffix. See section 'Options Controlling the Kind of Output' in Using GNU CC.

Excess whitespace, comments, and character constants cannot be used in the portions of the input text that are not preprocessed.

If the first line of an input file is `#NO_APP` or if you use the `-f' option, whitespace and comments are not removed from the input file. Within an input file, you can ask for whitespace and comment removal in specific portions of the by putting a line that says `#APP` before the text that may contain whitespace or comments, and putting a line that says `#NO_APP` after this text. This feature is mainly intend to support `asm` statements in compilers whose output is otherwise free of comments and whitespace.

Whitespace

Whitespace is one or more blanks or tabs, in any order. Whitespace is used to separate symbols, and to make programs neater for people to read. Unless within character constants (see section Character Constants), any whitespace means the same as exactly one space.

Comments

There are two ways of rendering comments to . In both cases the comment is equivalent to one space.

Anything from `/*' through the next `*/' is a comment. This means you may not nest these comments.

```
/*
  The only way to include a newline ('\n') in a comment
  is to use this sort of comment.
*/

/* This sort of comment does not nest. */
```

Anything from the line comment character to the next newline is considered a comment and is ignored. The line comment character is see @xref{Machine Dependencies}.

To be compatible with past assemblers, lines that begin with `#' have a special interpretation. Following the `#' should be an absolute expression (see section Expressions): the logical line number of the *next* line. Then a string (see section Strings) is allowed: if present it is a new logical file name. The rest of the line, if any, should be whitespace.

If the first non-whitespace characters on the line are not numeric, the line is ignored. (Just like a comment.)

```
                            # This is an ordinary comment.
# 42-6 "new_file_name"      # New logical file name
                            # This is logical line # 36.
```

This feature is deprecated, and may disappear from future versions of .

Symbols

A symbol is one or more characters chosen from the set of all letters (both upper and lower case), digits and the three characters `_.$'. No symbol may begin with a digit. Case is significant. There is no length limit: all characters are significant. Symbols are delimited by characters not in that set, or by the beginning of a file (since the source program must end with a newline, the end of a file is not a possible symbol delimiter). See section Symbols.

Statements

A statement ends at a newline character (`\n') or at a semicolon (`;'). The newline or semicolon is considered part of the preceding statement. Newlines and semicolons within character constants are an exception: they do not end statements.

It is an error to end any statement with end-of-file: the last character of any input file should be a newline.

You may write a statement on more than one line if you put a backslash (\) immediately in front of any newlines within the statement. When reads a backslashed newline both characters are ignored. You can even put backslashed newlines in the middle of symbol names without changing the meaning of your source program.

An empty statement is allowed, and may include whitespace. It is ignored.

A statement begins with zero or more labels, optionally followed by a key symbol which determines what kind of statement it is. The key symbol determines the syntax of the rest of the statement. If the symbol begins with a dot `.' then the statement is an assembler directive: typically valid for any computer. If the symbol begins with a letter the statement is an assembly language instruction: it assembles into a machine language instruction.

A label is a symbol immediately followed by a colon (`:`). Whitespace before a label or after a colon is permitted, but you may not have whitespace between a label's symbol and its colon. See section Labels.

```
label:     .directive    followed by something
another_label:           # This is an empty statement.
           instruction   operand_1, operand_2, ...
```

Constants

A constant is a number, written so that its value is known by inspection, without knowing any context. Like this:

```
.byte  74, 0112, 092, 0x4A, 0X4a, 'J, '\J # All the same value.
.ascii "Ring the bell\7"                  # A string constant.
.octa  0x123456789abcdef0123456789ABCDEF0 # A bignum.
.float 0f-314159265358979323846264338327\
95028841971.693993751E-40                 # - pi, a flonum.
```

Character Constants

There are two kinds of character constants. A character stands for one character in one byte and its value may be used in numeric expressions. String constants (properly called string *literals*) are potentially many bytes and their values may not be used in arithmetic expressions.

Strings

A string is written between double-quotes. It may contain double-quotes or null characters. The way to get special characters into a string is to escape these characters: precede them with a backslash `\' character. For example `\\' represents one backslash: the first \ is an escape which tells to interpret the second character literally as a backslash (which prevents from recognizing the second \ as an escape character). The complete list of escapes follows.

\b
: Mnemonic for backspace; for ASCII this is octal code 010.

\f
: Mnemonic for FormFeed; for ASCII this is octal code 014.

\n
: Mnemonic for newline; for ASCII this is octal code 012.

\r
: Mnemonic for carriage-Return; for ASCII this is octal code 015.

\t
: Mnemonic for horizontal Tab; for ASCII this is octal code 011.

\ digit digit digit
: An octal character code. The numeric code is 3 octal digits. For compatibility with other Unix systems, 8 and 9 are accepted as digits: for example, `\008` has the value 010, and `\009` the value 011.

\x hex-digits...
: A hex character code. All trailing hex digits are combined. Either upper or lower case `x` works.

\\
: Represents one `\' character.

\"
: Represents one `"' character. Needed in strings to represent this character, because an unescaped `"' would end the string.

\ anything-else
: Any other character when escaped by \ gives a warning, but assembles as if the `\' was not present. The idea is that if you used an escape sequence you clearly didn't want the literal interpretation of the following character. However has no other interpretation, so knows it is giving you the wrong code and warns you of the fact.

Which characters are escapable, and what those escapes represent, varies widely among assemblers. The current set is what we think the BSD 4.2 assembler recognizes, and is a subset of what most C compilers recognize. If you are in doubt, do not use an escape sequence.

Characters

A single character may be written as a single quote immediately followed by that character. The same

escapes apply to characters as to strings. So if you want to write the character backslash, you must w
'\\ where the first \ escapes the second \. As you can see, the quote is an acute accent, not a grave a
A newline (or semicolon `;') immediately following an acute accent is taken as a literal character and
does not count as the end of a statement. The value of a character constant in a numeric expression is the machine's byte-wide code for that character. assumes your character code is ASCII: 'A means 65, 'B means 66, and so on.

Number Constants

distinguishes three kinds of numbers according to how they are stored in the target machine. *Integers* are numbers that would fit into an `int` in the C language. *Bignums* are integers, but they are stored in more than 32 bits. *Flonums* are floating point numbers, described below.

Integers

A binary integer is `0b' or `0B' followed by zero or more of the binary digits `01'.

An octal integer is `0' followed by zero or more of the octal digits (`01234567').

A decimal integer starts with a non-zero digit followed by zero or more digits (`0123456789').

A hexadecimal integer is `0x' or `0X' followed by one or more hexadecimal digits chosen from `0123456789abcdefABCDEF'.

Integers have the usual values. To denote a negative integer, use the prefix operator `-' discussed under expressions (see section Prefix Operator).

Bignums

A bignum has the same syntax and semantics as an integer except that the number (or its negative) takes more than 32 bits to represent in binary. The distinction is made because in some places integers are permitted while bignums are not.

Flonums

A flonum represents a floating point number. The translation is indirect: a decimal floating point number from the text is converted by to a generic binary floating point number of more than sufficient precision. This generic floating point number is converted to a particular computer's floating point format (or formats) by a portion of specialized to that computer.

A flonum is written by writing (in order)

- The digit `0'.
- A letter, to tell the rest of the number is a flonum.
- An optional sign: either `+' or `-'.
- An optional integer part: zero or more decimal digits.
- An optional fractional part: `.' followed by zero or more decimal digits.

- An optional exponent, consisting of:
  - An `E' or `e'.
  - Optional sign: either `+' or `-'.
  - One or more decimal digits.

At least one of the integer part or the fractional part must be present. The floating point number has the usual base-10 value.

does all processing using integers. Flonums are computed independently of any floating point hardware in the computer running .

into a field whose width depends on which assembler directive has the bit-field as its argument. Overflow (a result from the bitwise and requiring more binary digits to represent) is not an error; instead, more constants are generated, of the specified width, beginning with the least significant digits.

The directives `.byte`, `.hword`, `.int`, `.long`, `.short`, and `.word` accept bit-field arguments.

Sections and Relocation

Background

Roughly, a section is a range of addresses, with no gaps; all data "in" those addresses is treated the same for some particular purpose. For example there may be a "read only" section.

The linker reads many object files (partial programs) and combines their contents to form a runnable program. When emits an object file, the partial program is assumed to start at address 0. assigns the final addresses for the partial program, so that different partial programs do not overlap. This is actually an oversimplification, but it suffices to explain how uses sections.

moves blocks of bytes of your program to their run-time addresses. These blocks slide to their run-time addresses as rigid units; their length does not change and neither does the order of bytes within them. Such a rigid unit is called a *section*. Assigning run-time addresses to sections is called relocation. It includes the task of adjusting mentions of object-file addresses so they refer to the proper run-time addresses.

An object file written by has at least three sections, any of which may be empty. These are named text, data and bss sections.

can also generate whatever other named sections you specify using the `.section' directive (see section `.section name`). If you do not use any directives that place output in the `.text' or `.data' sections, these sections still exist, but are empty.

can also generate whatever other named sections you specify using the `.space' and `.subspace' directives. See HP9000 Series 800 Assembly Language Reference Manual (HP 92432-90001) for details on the `.space' and `.subspace' assembler directives.

Within the object file, the text section starts at address `0`, the data section follows, and the bss section follows the data section.

To let know which data changes when the sections are relocated, and how to change that data, also writes to the object file details of the relocation needed. To perform relocation must know, each time an address in the object file is mentioned:

- Where in the object file is the beginning of this reference to an address?
- How long (in bytes) is this reference?
- Which section does the address refer to? What is the numeric value of

  ```
  (address) - (start-address of section)?
  ```
- Is the reference to an address "Program-Counter relative"?

In fact, every address ever uses is expressed as

```
(section) + (offset into section)
```

Further, most expressions computes have this section-relative nature.

In this manual we use the notation {secname N} to mean "offset N into section secname."

Apart from text, data and bss sections you need to know about the absolute section. When mixes partial programs, addresses in the absolute section remain unchanged. For example, address `{absolute 0}` is "relocated" to run-time address 0 by . Although the linker never arranges two partial programs' data sections with overlapping addresses after linking, *by definition* their absolute sections must overlap. Address `{absolute 239}` in one part of a program is always the same address when the program is running as address `{absolute 239}` in any other part of the program.

The idea of sections is extended to the undefined section. Any address whose section is unknown at assembly time is by definition rendered {undefined U}--where U is filled in later. Since numbers are always defined, the only way to generate an undefined address is to mention an undefined symbol. A reference to a named common block would be such a symbol: its value is unknown at assembly time so it has section *undefined*.

By analogy the word *section* is used to describe groups of sections in the linked program. puts all partial programs' text sections in contiguous addresses in the linked program. It is customary to refer to the *text section* of a program, meaning all the addresses of all partial programs' text sections. Likewise for data and bss sections.

Some sections are manipulated by ; others are invented for use of and have no meaning except during assembly.

Linker Sections

deals with just four kinds of sections, summarized below.

These sections hold your program. and treat them as separate but equal sections. Anything you can say of

one section is true another.

bss section

This section contains zeroed bytes when your program begins running. It is used to hold unitialized variables or common storage. The length of each partial program's bss section is important, but because it starts out containing zeroed bytes there is no need to store explicit zero bytes in the object file. The bss section was invented to eliminate those explicit zeros from object files.

absolute section

Address 0 of this section is always "relocated" to runtime address 0. This is useful if you want to refer to an address that must not change when relocating. In this sense we speak of absolute addresses being "unrelocatable": they do not change during relocation.

undefined section

This "section" is a catch-all for address references to objects not in the preceding sections.

An idealized example of three relocatable sections follows. Memory addresses are on the horizontal axis.

Assembler Internal Sections

These sections are meant only for the internal use of . They have no meaning at run-time. You do not really need to know about these sections for most purposes; but they can be mentioned in warning messages, so it might be helpful to have an idea of their meanings to . These sections are used to permit the value of every expression in your assembly language program to be a section-relative address.

ASSEMBLER-INTERNAL-LOGIC-ERROR!

An internal assembler logic error has been found. This means there is a bug in the assembler.

expr section

The assembler stores complex expression internally as combinations of symbols. When it needs to represent an expression as a symbol, it puts it in the expr section.

Sub-Sections

fall into two sections: text and data. You may have separate groups of data in named sections that you want to end up near to each other in the object file, even though they are not contiguous in the assembler source. allows you to use subsections for this purpose. Within each section, there can be numbered subsections with values from 0 to 8192. Objects assembled into the same subsection go into the object file together with other objects in the same subsection. For example, a compiler might want to store constants in the text section, but might not want to have them interspersed with the program being assembled. In this case, the compiler could issue a `.text 0' before each section of code being output, and a `.text 1' before each group of constants being output.

Subsections are optional. If you do not use subsections, everything goes in subsection number zero.

Subsections appear in your object file in numeric order, lowest numbered to highest. (All this to be compatible with other people's assemblers.) The object file contains no representation of subsections; and

other programs that manipulate object files see no trace of them. They just see all your text subsections as a text section, and all your data subsections as a data section.

To specify which subsection you want subsequent statements assembled into, use a numeric argument to specify it, in a `.text expression' or a `.data expression' statement. You can also use an extra subsection argument with arbitrary named sections: `.section name, expression'. Expression should be an absolute expression. (See section Expressions.) If you just say `.text' then `.text 0' is assumed. Likewise `.data' means `.data 0'. Assembly begins in `text 0'. For instance:

```
.text 0     # The default subsection is text 0 anyway.
.ascii "This lives in the first text subsection. *"
.text 1
.ascii "But this lives in the second text subsection."
.data 0
.ascii "This lives in the data section,"
.ascii "in the first data subsection."
.text 0
.ascii "This lives in the first text section,"
.ascii "immediately following the asterisk (*)."
```

Each section has a location counter incremented by one for every byte assembled into that section. Because subsections are merely a convenience restricted to there is no concept of a subsection location counter. There is no way to directly manipulate a location counter--but the `.align` directive changes it, and any label definition captures its current value. The location counter of the section where statements are being assembled is said to be the active location counter.

bss Section

The bss section is used for local common variable storage. You may allocate address space in the bss section, but you may not dictate data to load into it before your program executes. When your program starts running, all the contents of the bss section are zeroed bytes.

The `.lcomm` pseudo-op defines a symbol in the bss section; see section `.lcomm symbol, length`.

The `.comm` pseudo-op may be used to declare a common symbol, which is another form of uninitialized symbol; see See section `.comm symbol, length` .

Symbols

Symbols are a central concept: the programmer uses symbols to name things, the linker uses symbols to link, and the debugger uses symbols to debug.

> *Warning:* does not place symbols in the object file in the same order they were declared. This may break some debuggers.

Labels

A label is written as a symbol immediately followed by a colon `:'. The symbol then represents the current value of the active location counter, and is, for example, a suitable instruction operand. You are warned if you use the same symbol to represent two different locations: the first definition overrides any other definitions.

Giving Symbols Other Values

A symbol can be given an arbitrary value by writing a symbol, followed by an equals sign `=', followed by an expression (see section Expressions). This is equivalent to using the `.set` directive. See section `.set symbol, expression`.

Symbol Names

Symbol names begin with a letter or with one of `._'. On most machines, you can also use `$` in symbol names; exceptions are noted in @xref{Machine Dependencies}. That character may be followed by any string of digits, letters, dollar signs (unless otherwise noted in @xref{Machine Dependencies}), and underscores.

Case of letters is significant: `foo` is a different symbol name than `Foo`.

Each symbol has exactly one name. Each name in an assembly language program refers to exactly one symbol. You may use that symbol name any number of times in a program.

Local Symbol Names

Local symbols help compilers and programmers use names temporarily. There are ten local symbol names, which are re-used throughout the program. You may refer to them using the names `0' `1' ... `9'. To define a local symbol, write a label of the form `**N**:' (where **N** represents any digit). To refer to the most recent previous definition of that symbol write `**N**b', using the same digit as when you defined the label. To refer to the next definition of a local label, write `**N**f'---where **N** gives you a choice of 10 forward references. The `b' stands for "backwards" and the `f' stands for "forwards".

Local symbols are not emitted by the current GNU C compiler.

There is no restriction on how you can use these labels, but remember that at any point in the assembly you can refer to at most 10 prior local labels and to at most 10 forward local labels.

Local symbol names are only a notation device. They are immediately transformed into more conventional symbol names before the assembler uses them. The symbol names stored in the symbol table, appearing in error messages and optionally emitted to the object file have these parts:

`L`

All local labels begin with `L'. Normally both and forget symbols that start with `L'. These labels are used for symbols you are never intended to see. If you use the `-L' option then retains these symbols in the object file. If you also instruct to retain these symbols, you may use them in debugging.

`digit`

If the label is written `0:' then the digit is `0'. If the label is written `1:' then the digit is `1'. And so on up through `9:'.

`C-A`

This unusual character is included so you do not accidentally invent a symbol of the same name. The character has ASCII value `\001'.

`ordinal number`

This is a serial number to keep the labels distinct. The first `0:' gets the number `1'; The 15th `0:' gets the number `15'; *etc.*. Likewise for the other labels `1:' through `9:'.

For instance, the first `1:` is named `L1C-A1`, the 44th `3:` is named `L3C-A44`.

The Special Dot Symbol

The special symbol `.' refers to the current address that is assembling into. Thus, the expression `melvin: .long .' defines `melvin` to contain its own address. Assigning a value to `.` is treated the same as a `.org` directive. Thus, the expression `.=.+4' is the same as saying `.space 4'.

Symbol Attributes

Every symbol has, as well as its name, the attributes "Value" and "Type". Depending on output format, symbols can also have auxiliary attributes.

If you use a symbol without defining it, assumes zero for all these attributes, and probably won't warn you. This makes the symbol an externally defined symbol, which is generally what you would want.

Value

The value of a symbol is (usually) 32 bits. For a symbol which labels a location in the text, data, bss or absolute sections the value is the number of addresses from the start of that section to the label. Naturally for text, data and bss sections the value of a symbol changes as changes section base addresses during linking. Absolute symbols' values do not change during linking: that is why they are called absolute.

The value of an undefined symbol is treated in a special way. If it is 0 then the symbol is not defined in this assembler source file, and tries to determine its value from other files linked into the same program. You make this kind of symbol simply by mentioning a symbol name without defining it. A non-zero value represents a `.comm` common declaration. The value is how much common storage to reserve, in bytes (addresses). The symbol refers to the first address of the allocated storage.

Type

The type attribute of a symbol contains relocation (section) information, any flag settings indicating that a symbol is external, and (optionally), other information for linkers and debuggers. The exact format depends on the object-code output format in use.

Symbol Attributes: `a.out`

Descriptor

This is an arbitrary 16-bit value. You may establish a symbol's descriptor value by using a `.desc` statement (@xref{Desc,,`.desc`}). A descriptor value means nothing to .

Other

This is an arbitrary 8-bit value. It means nothing to .

Expressions

An expression specifies an address or numeric value. Whitespace may precede and/or follow an expression.

The result of an expression must be an absolute number, or else an offset into a particular section. If an expression is not absolute, and there is not enough information when sees the expression to know its section, a second pass over the source program might be necessary to interpret the expression--but the second pass is currently not implemented. aborts with an error message in this situation.

Empty Expressions

An empty expression has no value: it is just whitespace or null. Wherever an absolute expression is required, you may omit the expression, and assumes a value of (absolute) 0. This is compatible with other assemblers.

Integer Expressions

An integer expression is one or more *arguments* delimited by *operators*.

Arguments

Arguments are symbols, numbers or subexpressions. In other contexts arguments are sometimes called "arithmetic operands". In this manual, to avoid confusing them with the "instruction operands" of the machine language, we use the term "argument" to refer to parts of expressions only, reserving the word "operand" to refer only to machine instruction operands.

Symbols are evaluated to yield {section NNN} where section is one of text, data, bss, absolute, or undefined. NNN is a signed, 2's complement 32 bit integer.

Numbers are usually integers.

A number can be a flonum or bignum. In this case, you are warned that only the low order 32 bits are used, and pretends these 32 bits are an integer. You may write integer-manipulating instructions that act on exotic constants, compatible with other assemblers.

Subexpressions are a left parenthesis `(' followed by an integer expression, followed by a right parenthesis `)'; or a prefix operator followed by an argument.

Operators

Operators are arithmetic functions, like + or %. Prefix operators are followed by an argument. Infix operators appear between their arguments. Operators may be preceded and/or followed by whitespace.

Prefix Operator

has the following prefix operators. They each take one argument, which must be absolute.

-

Negation. Two's complement negation.

~

Complementation. Bitwise not.

Infix Operators

Infix operators take two arguments, one on either side. Operators have precedence, but operations with equal precedence are performed left to right. Apart from + or -, both arguments must be absolute, and the result is absolute.

1. Highest Precedence

   *

   Multiplication.

`/`
: Division. Truncation is the same as the C operator `/'

`%`
: Remainder.

`<`

`<<`
: Shift Left. Same as the C operator `<<'.

`>`

`>>`
: Shift Right. Same as the C operator `>>'.

2. Intermediate precedence

   `|`
   : Bitwise Inclusive Or.

   `&`
   : Bitwise And.

   `^`
   : Bitwise Exclusive Or.

   `!`
   : Bitwise Or Not.

3. Lowest Precedence

   `+`
   : Addition. If either argument is absolute, the result has the section of the other argument. You may not add together arguments from different sections.

   `-`
   : Subtraction. If the right argument is absolute, the result has the section of the left argument. If both arguments are in the same section, the result is absolute. You may not subtract arguments from different sections.

In short, it's only meaningful to add or subtract the *offsets* in an address; you can only have a defined section in one of the two arguments.

Assembler Directives

All assembler directives have names that begin with a period (`.'). The rest of the name is letters, usually in lower case.

This chapter discusses directives that are available regardless of the target machine configuration for the GNU assembler.

.abort

This directive stops the assembly immediately. It is for compatibility with other assemblers. The original idea was that the assembly language source would be piped into the assembler. If the sender of the source quit, it could use this directive tells to quit also. One day `.abort` will not be supported.

.align abs-expr, abs-expr, abs-expr

Pad the location counter (in the current subsection) to a particular storage boundary. The first expression (which must be absolute) is the alignment required, as described below.

The second expression (also absolute) gives the fill value to be stored in the padding bytes. It (and the comma) may be omitted. If it is omitted, the padding bytes are normally zero. However, on some systems, if the section is marked as containing code and the fill value is omitted, the space is filled with no-op instructions.

The third expression is also absolute, and is also optional. If it is present, it is the maximum number of bytes that should be skipped by this alignment directive. If doing the alignment would require skipping more bytes than the specified maximum, then the alignment is not done at all. You can omit the fill value (the second argument) entirely by simply using two commas after the required alignment; this can be useful if you want the alignment to be filled with no-op instructions when appropriate.

The way the required alignment is specified varies from system to system. For the a29k, hppa, m68k, m88k, w65, sparc, and Hitachi SH, and i386 using ELF format, the first expression is the alignment request in bytes. For example `.align 8' advances the location counter until it is a multiple of 8. If the location counter is already a multiple of 8, no change is needed.

For other systems, including the i386 using a.out format, it is the number of low-order zero bits the location counter must have after advancement. For example `.align 3' advances the location counter until it a multiple of 8. If the location counter is already a multiple of 8, no change is needed.

This inconsistency is due to the different behaviors of the various native assemblers for these systems which GAS must emulate. GAS also provides `.balign` and `.p2align` directives, described later, which have a consistent behavior across all architectures (but are specific to GAS).

.app-file string

`.app-file` (which may also be spelled `.file') tells that we are about to start a new logical file. string is the new file name. In general, the filename is recognized whether or not it is surrounded by quotes `"'; but if you wish to specify an empty file name is permitted, you must give the quotes--`""'. This statement may go away in future: it is only recognized to be compatible with old programs.

.ascii "string"...

`.ascii` expects zero or more string literals (see section Strings) separated by commas. It assembles each string (with no automatic trailing zero byte) into consecutive addresses.

.asciz "string"...

`.asciz` is just like `.ascii`, but each string is followed by a zero byte. The "z" in `.asciz' stands for "zero".

.balign[wl] abs-expr, abs-expr, abs-expr

Pad the location counter (in the current subsection) to a particular storage boundary. The first expression (which must be absolute) is the alignment request in bytes. For example `.balign 8' advances the location counter until it is a multiple of 8. If the location counter is already a multiple of 8, no change is needed.

The second expression (also absolute) gives the fill value to be stored in the padding bytes. It (and the comma) may be omitted. If it is omitted, the padding bytes are normally zero. However, on some systems, if the section is marked as containing code and the fill value is omitted, the space is filled with no-op instructions.

The third expression is also absolute, and is also optional. If it is present, it is the maximum number of bytes that should be skipped by this alignment directive. If doing the alignment would require skipping more bytes than the specified maximum, then the alignment is not done at all. You can omit the fill value (the second argument) entirely by simply using two commas after the required alignment; this can be useful if you want the alignment to be filled with no-op instructions when appropriate.

The `.balignw` and `.balignl` directives are variants of the `.balign` directive. The `.balignw` directive treats the fill pattern as a two byte word value. The `.balignl` directives treats the fill pattern as a four byte longword value. For example, `.balignw 4,0x368d` will align to a multiple of 4. If it skips two bytes, they will be filled in with the value 0x368d (the exact placement of the bytes depends upon the endianness of the processor). If it skips 1 or 3 bytes, the fill value is undefined.

.byte expressions

`.byte` expects zero or more expressions, separated by commas. Each expression is assembled into the next byte.

.comm symbol , length

`.comm` declares a common symbol named symbol. When linking, a common symbol in one object file may be merged with a defined or common symbol of the same name in another object file. If does not see a definition for the symbol--just one or more common symbols--then it will allocate length bytes of uninitialized memory. length must be an absolute expression. If sees multiple common symbols with the same name, and they do not all have the same size, it will allocate space using the largest size.

.data subsection

`.data` tells to assemble the following statements onto the end of the data subsection numbered subsection (which is an absolute expression). If subsection is omitted, it defaults to zero.

.double flonums

`.double` expects zero or more flonums, separated by commas. It assembles floating point numbers.

.eject

Force a page break at this point, when generating assembly listings.

.else

`.else` is part of the support for conditional assembly; see section `.if absolute expression`. It marks the beginning of a section of code to be assembled if the condition for the preceding `.if` was false.

.endif

`.endif` is part of the support for conditional assembly; it marks the end of a block of code that is only assembled conditionally. See section `.if absolute expression`.

.equ symbol, expression

This directive sets the value of symbol to expression. It is synonymous with `.set'; see section .set symbol, expression.

.equiv symbol, expression

The `.equiv` directive is like `.equ` and `.set`, except that the assembler will signal an error if symbol is already defined.

Except for the contents of the error message, this is roughly equivalent to

```
.ifdef SYM
.err
.endif
.equ SYM,VAL
```

.err

If assembles a `.err` directive, it will print an error message and, unless the `-Z` option was used, it will not generate an object file. This can be used to signal error an conditionally compiled code.

.extern

`.extern` is accepted in the source program--for compatibility with other assemblers--but it is ignored. treats all undefined symbols as external.

.file string

`.file` (which may also be spelled `.app-file') tells that we are about to start a new logical file. string is the new file name. In general, the filename is recognized whether or not it is surrounded by quotes `"'; but if you wish to specify an empty file name, you must give the quotes--`""'. This statement may go away in future: it is only recognized to be compatible with old programs.

.fill repeat , size , value

result, size and value are absolute expressions. This emits repeat copies of size bytes. Repeat may be zero or more. Size may be zero or more, but if it is more than 8, then it is deemed to have the value 8, compatible with other people's assemblers. The contents of each repeat bytes is taken from an 8-byte number. The highest order 4 bytes are zero. The lowest order 4 bytes are value rendered in the byte-order of an integer on the computer is assembling for. Each size bytes in a repetition is taken from the lowest

order size bytes of this number. Again, this bizarre behavior is compatible with other people's assemblers.

size and value are optional. If the second comma and value are absent, value is assumed zero. If the first comma and following tokens are absent, size is assumed to be 1.

.float flonums

This directive assembles zero or more flonums, separated by commas. It has the same effect as `.single`.

.global symbol, .globl symbol

`.global` makes the symbol visible to . If you define symbol in your partial program, its value is made available to other partial programs that are linked with it. Otherwise, symbol takes its attributes from a symbol of the same name from another file linked into the same program.

Both spellings (`.globl' and `.global') are accepted, for compatibility with other assemblers.

.hword expressions

This expects zero or more expressions, and emits a 16 bit number for each.

.ident

This directive is used by some assemblers to place tags in object files. simply accepts the directive for source-file compatibility with such assemblers, but does not actually emit anything for it.

.if absolute expression

`.if` marks the beginning of a section of code which is only considered part of the source program being assembled if the argument (which must be an absolute expression) is non-zero. The end of the conditional section of code must be marked by `.endif` (see section `.endif`); optionally, you may include code for the alternative condition, flagged by `.else` (see section `.else`).

The following variants of `.if` are also supported:

`.ifdef symbol`

Assembles the following section of code if the specified symbol has been defined.

`.ifndef symbol`

`.ifnotdef symbol`

Assembles the following section of code if the specified symbol has not been defined. Both

spelling variants are equivalent.

.include "file"

This directive provides a way to include supporting files at specified points in your source program. The code from file is assembled as if it followed the point of the `.include`; when the end of the included file is reached, assembly of the original file continues. You can control the search paths used with the `-I' command-line option (see section Command-Line Options). Quotation marks are required around file.

.int expressions

Expect zero or more expressions, of any section, separated by commas. For each expression, emit a number that, at run time, is the value of that expression. The byte order and bit size of the number depends on what kind of target the assembly is for.

.irp symbol,values…

Evaluate a sequence of statements assigning different values to symbol. The sequence of statements starts at the `.irp` directive, and is terminated by an `.endr` directive. For each value, symbol is set to value, and the sequence of statements is assembled. If no value is listed, the sequence of statements is assembled once, with symbol set to the null string. To refer to symbol within the sequence of statements, use \symbol.

For example, assembling

```
        .irp    param,1,2,3
        move    d\param,sp@-
        .endr
```

is equivalent to assembling

```
        move    d1,sp@-
        move    d2,sp@-
        move    d3,sp@-
```

.irpc symbol,values…

Evaluate a sequence of statements assigning different values to symbol. The sequence of statements starts at the `.irpc` directive, and is terminated by an `.endr` directive. For each character in value, symbol is set to the character, and the sequence of statements is assembled. If no value is listed, the sequence of statements is assembled once, with symbol set to the null string. To refer to symbol within the sequence of statements, use \symbol.

For example, assembling

```
        .irpc    param,123
        move    d\param,sp@-
        .endr
```

is equivalent to assembling

```
        move    d1,sp@-
        move    d2,sp@-
        move    d3,sp@-
```

.lcomm symbol , length

Reserve length (an absolute expression) bytes for a local common denoted by symbol. The section and value of symbol are those of the new local common. The addresses are allocated in the bss section, so that at run-time the bytes start off zeroed. Symbol is not declared global (see section `.global symbol`, `.globl symbol`), so is normally not visible to .

.lflags

accepts this directive, for compatibility with other assemblers, but ignores it.

.line line-number

Even though this is a directive associated with the `a.out` or `b.out` object-code formats, still recognizes it when producing COFF output, and treats `.line' as though it were the COFF `.ln' *if* it is found outside a `.def`/`.endef` pair.

Inside a `.def`, `.line' is, instead, one of the directives used by compilers to generate auxiliary symbol information for debugging.

.linkonce [type]

Mark the current section so that the linker only includes a single copy of it. This may be used to include the same section in several different object files, but ensure that the linker will only include it once in the final output file. The `.linkonce` pseudo-op must be used for each instance of the section. Duplicate sections are detected based on the section name, so it should be unique.

This directive is only supported by a few object file formats; as of this writing, the only object file format which supports it is the Portable Executable format used on Windows NT.

The type argument is optional. If specified, it must be one of the following strings. For example:

`.linkonce same_size`

Not all types may be supported on all object file formats.

`discard`

Silently discard duplicate sections. This is the default.

`one_only`

Warn if there are duplicate sections, but still keep only one copy.

`same_size`

Warn if any of the duplicates have different sizes.

`same_contents`

Warn if any of the duplicates do not have exactly the same contents.

`.ln line-number`

`.ln' is a synonym for `.line'.

`.mri val`

If val is non-zero, this tells to enter MRI mode. If val is zero, this tells to exit MRI mode. This change affects code assembled until the next `.mri` directive, or until the end of the file. See section Assemble in MRI Compatibility Mode: `-M`.

`.list`

Control (in conjunction with the `.nolist` directive) whether or not assembly listings are generated. These two directives maintain an internal counter (which is zero initially). `.list` increments the counter, and `.nolist` decrements it. Assembly listings are generated whenever the counter is greater than zero.

By default, listings are disabled. When you enable them (with the `-a' command line option; see section Command-Line Options), the initial value of the listing counter is one.

`.long expressions`

`.long` is the same as `.int', see section `.int expressions`.

.macro

The commands `.macro` and `.endm` allow you to define macros that generate assembly output. For example, this definition specifies a macro `sum` that puts a sequence of numbers into memory:

```
        .macro  sum from=0, to=5
        .long   \from
        .if     \to-\from
        sum     "(\from+1)",\to
        .endif
        .endm
```

With that definition, `SUM 0,5' is equivalent to this assembly input:

```
        .long   0
        .long   1
        .long   2
        .long   3
        .long   4
        .long   5
```

`.macro macname`

`.macro macname macargs ...`

Begin the definition of a macro called macname. If your macro definition requires arguments, specify their names after the macro name, separated by commas or spaces. You can supply a default value for any macro argument by following the name with `=deflt'. For example, these are all valid `.macro` statements:

`.macro comm`

Begin the definition of a macro called `comm`, which takes no arguments.

`.macro plus1 p, p1`

`.macro plus1 p p1`

Either statement begins the definition of a macro called `plus1`, which takes two arguments; within the macro definition, write `\p' or `\p1' to evaluate the arguments.

`.macro reserve_str p1=0 p2`

Begin the definition of a macro called `reserve_str`, with two arguments. The first argument has a default value, but not the second. After the definition is complete, you can call the macro either as `reserve_str a,b' (with `\p1' evaluating to a and `\p2' evaluating to b), or as `reserve_str ,b' (with `\p1' evaluating as the default, in this case `0', and `\p2' evaluating to b).

When you call a macro, you can specify the argument values either by position, or by keyword. For example, `sum 9,17' is equivalent to `sum to=17, from=9'.

- .endm Mark the end of a macro definition.

- .exitm Exit early from the current macro definition.
- \@ maintains a counter of how many macros it has executed in this pseudo-variable; you can copy that number to your output with `\@', but *only within a macro definition*.

.nolist

Control (in conjunction with the `.list` directive) whether or not assembly listings are generated. These two directives maintain an internal counter (which is zero initially). `.list` increments the counter, and `.nolist` decrements it. Assembly listings are generated whenever the counter is greater than zero.

.octa bignums

This directive expects zero or more bignums, separated by commas. For each bignum, it emits a 16-byte integer.

The term "octa" comes from contexts in which a "word" is two bytes; hence *octa*-word for 16 bytes.

.org new-lc , fill

Advance the location counter of the current section to new-lc. new-lc is either an absolute expression or an expression with the same section as the current subsection. That is, you can't use `.org` to cross sections: if new-lc has the wrong section, the `.org` directive is ignored. To be compatible with former assemblers, if the section of new-lc is absolute, issues a warning, then pretends the section of new-lc is the same as the current subsection.

`.org` may only increase the location counter, or leave it unchanged; you cannot use `.org` to move the location counter backwards.

Because tries to assemble programs in one pass, new-lc may not be undefined. If you really detest this restriction we eagerly await a chance to share your improved assembler.

Beware that the origin is relative to the start of the section, not to the start of the subsection. This is compatible with other people's assemblers.

When the location counter (of the current subsection) is advanced, the intervening bytes are filled with fill which should be an absolute expression. If the comma and fill are omitted, fill defaults to zero.

.p2align[wl] abs-expr, abs-expr, abs-expr

Pad the location counter (in the current subsection) to a particular storage boundary. The first expression (which must be absolute) is the number of low-order zero bits the location counter must have after advancement. For example `.p2align 3' advances the location counter until it a multiple of 8. If the location counter is already a multiple of 8, no change is needed.

The second expression (also absolute) gives the fill value to be stored in the padding bytes. It (and th comma) may be omitted. If it is omitted, the padding bytes are normally zero. However, on some systems, if the section is marked as containing code and the fill value is omitted, the space is filled with no-op instructions.

The third expression is also absolute, and is also optional. If it is present, it is the maximum number of bytes that should be skipped by this alignment directive. If doing the alignment would require skipping more bytes than the specified maximum, then the alignment is not done at all. You can omit the fill value (the second argument) entirely by simply using two commas after the required alignment; this can be useful if you want the alignment to be filled with no-op instructions when appropriate.

The `.p2alignw` and `.p2alignl` directives are variants of the `.p2align` directive. The `.p2alignw` directive treats the fill pattern as a two byte word value. The `.p2alignl` directives treats the fill pattern as a four byte longword value. For example, `.p2alignw 2,0x368d` will align to a multiple of 4. If it skips two bytes, they will be filled in with the value 0x368d (the exact placement of the bytes depends upon the endianness of the processor). If it skips 1 or 3 bytes, the fill value is undefined.

`.psize lines , columns`

Use this directive to declare the number of lines--and, optionally, the number of columns--to use for each page, when generating listings.

If you do not use `.psize`, listings use a default line-count of 60. You may omit the comma and columns specification; the default width is 200 columns.

generates formfeeds whenever the specified number of lines is exceeded (or whenever you explicitly request one, using `.eject`).

If you specify lines as `0`, no formfeeds are generated save those explicitly specified with `.eject`.

`.quad bignums`

`.quad` expects zero or more bignums, separated by commas. For each bignum, it emits an 8-byte integer. If the bignum won't fit in 8 bytes, it prints a warning message; and just takes the lowest order 8 bytes of the bignum.

The term "quad" comes from contexts in which a "word" is two bytes; hence *quad*-word for 8 bytes.

`.rept count`

Repeat the sequence of lines between the `.rept` directive and the next `.endr` directive count times.

For example, assembling

```
        .rept   3
```

```
        .long   0
        .endr
```

is equivalent to assembling

```
        .long   0
        .long   0
        .long   0
```

.sbttl "subheading"

Use subheading as the title (third line, immediately after the title line) when generating assembly listings.

This directive affects subsequent pages, as well as the current page if it appears within ten lines of the top of a page.

.section name

Use the `.section` directive to assemble the following code into a section named name.

This directive is only supported for targets that actually support arbitrarily named sections; on `a.out` targets, for example, it is not accepted, even with a standard `a.out` section name.

.set symbol, expression

Set the value of symbol to expression. This changes symbol's value and type to conform to expression. If symbol was flagged as external, it remains flagged (see section Symbol Attributes).

You may `.set` a symbol many times in the same assembly.

If you `.set` a global symbol, the value stored in the object file is the last value stored into it.

.short expressions

.single flonums

This directive assembles zero or more flonums, separated by commas. It has the same effect as `.float`.

.skip size , fill

This directive emits size bytes, each of value fill. Both size and fill are absolute expressions. If the comma and fill are omitted, fill is assumed to be zero. This is the same as `.space'.

.space size , fill

This directive emits size bytes, each of value fill. Both size and fill are absolute expressions. If the comma and fill are omitted, fill is assumed to be zero. This is the same as `.skip'.

.stabd, .stabn, .stabs

There are three directives that begin `.stab'. All emit symbols (see section Symbols), for use by symbolic debuggers. The symbols are not entered in the hash table: they cannot be referenced elsewhere in the source file. Up to five fields are required:

string

This is the symbol's name. It may contain any character except `\000', so is more general than ordinary symbol names. Some debuggers used to code arbitrarily complex structures into symbol names using this field.

type

An absolute expression. The symbol's type is set to the low 8 bits of this expression. Any bit pattern is permitted, but and debuggers choke on silly bit patterns.

other

An absolute expression. The symbol's "other" attribute is set to the low 8 bits of this expression.

desc

An absolute expression. The symbol's descriptor is set to the low 16 bits of this expression.

value

An absolute expression which becomes the symbol's value.

If a warning is detected while reading a `.stabd`, `.stabn`, or `.stabs` statement, the symbol has probably already been created; you get a half-formed symbol in your object file. This is compatible with earlier assemblers!

`.stabd type , other , desc`

The "name" of the symbol generated is not even an empty string. It is a null pointer, for compatibility. Older assemblers used a null pointer so they didn't waste space in object files with empty strings.

The symbol's value is set to the location counter, relocatably. When your program is linked, the value of this symbol is the address of the location counter when the `.stabd` was assembled.

`.stabn type , other , desc , value`

The name of the symbol is set to the empty string `""`.

`.stabs string , type , other , desc , value`

All five fields are specified.

.string "str"

Copy the characters in str to the object file. You may specify more than one string to copy, separated by commas. Unless otherwise specified for a particular machine, the assembler marks the end of each string with a 0 byte. You can use any of the escape sequences described in section Strings.

.text subsection

Tells to assemble the following statements onto the end of the text subsection numbered subsection, which is an absolute expression. If subsection is omitted, subsection number zero is used.

.title "heading"

Use heading as the title (second line, immediately after the source file name and pagenumber) when generating assembly listings.

This directive affects subsequent pages, as well as the current page if it appears within ten lines of the top of a page.

.word expressions

This directive expects zero or more expressions, of any section, separated by commas.

In order to assemble compiler output into something that works, occasionlly does strange things to `.word' directives. Directives of the form `.word sym1-sym2' are often emitted by compilers as part of jump tables. Therefore, when assembles a directive of the form `.word sym1-sym2', and the difference between `sym1` and `sym2` does not fit in 16 bits, creates a secondary jump table, immediately before the next label. This secondary jump table is preceded by a short-jump to the first byte after the secondary table. This short-jump prevents the flow of control from accidentally falling into the new table. Inside the table is a long-jump to `sym2`. The original `.word' contains `sym1` minus the address of the long-jump to `sym2`.

If there were several occurrences of `.word sym1-sym2' before the secondary jump table, all of them are adjusted. If there was a `.word sym3-sym4', that also did not fit in sixteen bits, a long-jump to `sym4` is included in the secondary jump table, and the `.word` directives are adjusted to contain `sym3` minus the address of the long-jump to `sym4`; and so on, for as many entries in the original jump table as necessary.

Deprecated Directives

One day these directives won't work. They are included for compatibility with older assemblers.

`.abort`

`.app-file`

Reporting Bugs

Your bug reports play an essential role in making reliable.

Reporting a bug may help you by bringing a solution to your problem, or it may not. But in any case the principal function of a bug report is to help the entire community by making the next version of work better. Bug reports are your contribution to the maintenance of .

In order for a bug report to serve its purpose, you must include the information that enables us to fix the bug.

Have you found a bug?

If you are not sure whether you have found a bug, here are some guidelines:

- If the assembler gets a fatal signal, for any input whatever, that is a bug. Reliable assemblers never crash.
- If produces an error message for valid input, that is a bug.
- If does not produce an error message for invalid input, that is a bug. However, you should note that your idea of "invalid input" might be our idea of "an extension" or "support for traditional practice".
- If you are an experienced user of assemblers, your suggestions for improvement of are welcome in any case.

How to report bugs

A number of companies and individuals offer support for GNU products. If you obtained from a support organization, we recommend you contact that organization first.

You can find contact information for many support companies and individuals in the file `` `etc/SERVICE' `` in the GNU Emacs distribution.

In any event, we also recommend that you send bug reports for to `bug-gnu-utils@prep.ai.mit.edu'.

The fundamental principle of reporting bugs usefully is this: **report all the facts**. If you are not sure whether to state a fact or leave it out, state it!

Often people omit facts because they think they know what causes the problem and assume that some details do not matter. Thus, you might assume that the name of a symbol you use in an example does not matter. Well, probably it does not, but one cannot be sure. Perhaps the bug is a stray memory reference which happens to fetch from the location where that name is stored in memory; perhaps, if the name

were different, the contents of that location would fool the assembler into doing the right thing despi
the bug. Play it safe and give a specific, complete example. That is the easiest thing for you to do, an
most helpful.

Keep in mind that the purpose of a bug report is to enable us to fix the bug if it is new to us. Therefore, always write your bug reports on the assumption that the bug has not been reported previously.

Sometimes people give a few sketchy facts and ask, "Does this ring a bell?" Those bug reports are useless, and we urge everyone to *refuse to respond to them* except to chide the sender to report bugs properly.

To enable us to fix the bug, you should include all these things:

- The version of . announces it if you start it with the `--version' argument.

  Without this, we will not know whether there is any point in looking for the bug in the current version of .
- Any patches you may have applied to the source.
- The type of machine you are using, and the operating system name and version number.
- What compiler (and its version) was used to compile ---e.g. "`gcc-2.7`".
- The command arguments you gave the assembler to assemble your example and observe the bug. To guarantee you will not omit something important, list them all. A copy of the Makefile (or the output from make) is sufficient.

  If we were to try to guess the arguments, we would probably guess wrong and then we might not encounter the bug.
- A complete input file that will reproduce the bug. If the bug is observed when the assembler is invoked via a compiler, send the assembler source, not the high level language source. Most compilers will produce the assembler source when run with the `-S' option. If you are using , use the options `-v --save-temps'; this will save the assembler source in a file with an extension of `` `.s' ``, and also show you exactly how is being run.
- A description of what behavior you observe that you believe is incorrect. For example, "It gets a fatal signal."

  Of course, if the bug is that gets a fatal signal, then we will certainly notice it. But if the bug is incorrect output, we might not notice unless it is glaringly wrong. You might as well not give us a chance to make a mistake.

  Even if the problem you experience is a fatal signal, you should still say so explicitly. Suppose something strange is going on, such as, your copy of is out of synch, or you have encountered a bug in the C library on your system. (This has happened!) Your copy might crash and ours would not. If you told us to expect a crash, then when ours fails to crash, we would know that the bug was not happening for us. If you had not told us to expect a crash, then we would not be able to draw any conclusion from our observations.
- If you wish to suggest changes to the source, send us context diffs, as generated by `diff` with the `-u', `-c', or `-p' option. Always send diffs from the old file to the new file. If you even discuss something in the source, refer to it by context, not by line number.

The line numbers in our development sources will not match those in your sources. Your line numbers would convey no useful information to us.

Here are some things that are not necessary:

- A description of the envelope of the bug.

  Often people who encounter a bug spend a lot of time investigating which changes to the input file will make the bug go away and which changes will not affect it.

  This is often time consuming and not very useful, because the way we will find the bug is by running a single example under the debugger with breakpoints, not by pure deduction from a series of examples. We recommend that you save your time for something else.

  Of course, if you can find a simpler example to report *instead* of the original one, that is a convenience for us. Errors in the output will be easier to spot, running under the debugger will take less time, and so on.

  However, simplification is not vital; if you do not want to do this, report the bug anyway and send us the entire test case you used.

- A patch for the bug.

  A patch for the bug does help us if it is a good one. But do not omit the necessary information, such as the test case, on the assumption that a patch is all we need. We might see problems with your patch and decide to fix the problem another way, or we might not understand it at all.

  Sometimes with a program as complicated as it is very hard to construct an example that will make the program follow a certain path through the code. If you do not send us the example, we will not be able to construct one, so we will not be able to verify that the bug is fixed.

  And if we cannot understand what bug you are trying to fix, or why your patch should be an improvement, we will not install it. A test case will help us to understand.

- A guess about what the bug is or what it depends on.

  Such guesses are usually wrong. Even we cannot guess right about such things without first using the debugger to find the facts.

Acknowledgements

If you have contributed to and your name isn't listed here, it is not meant as a slight. We just don't know about it. Send mail to the maintainer, and we'll correct the situation. Currently the maintainer is Ken Raeburn (email address `raeburn@cygnus.com`).

Dean Elsner wrote the original GNU assembler for the VAX.(1)

Jay Fenlason maintained GAS for a while, adding support for GDB-specific debug information and the 68k series machines, most of the preprocessing pass, and extensive changes in `` `messages.c' ``, `` `input-file.c' ``, `` `write.c' ``.

K. Richard Pixley maintained GAS for a while, adding various enhancements and many bug fixes, including merging support for several processors, breaking GAS up to handle multiple object file formats, adding back ends (including heavy rewrite, testing, an integration of the coff and b.out back ends), adding configuration including heavy testing and verification of cross assemblers and file splits and renaming, converted GAS to strictly ANSI C including full prototypes, added support for m680[34]0 and cpu32, did considerable work on i960 including a COFF port (including considerable amounts of reverse engineering), a SPARC opcode file rewrite, DECstation, rs6000, and hp300hpux host ports, updated "know" assertions and made them work, much other reorganization, cleanup, and lint.

Ken Raeburn wrote the high-level BFD interface code to replace most of the code in format-specific I/O modules.

The original VMS support was contributed by David L. Kashtan. Eric Youngdale has done much work with it since.

The Intel 80386 machine description was written by Eliot Dresselhaus.

Minh Tran-Le at IntelliCorp contributed some AIX 386 support.

The Motorola 88k machine description was contributed by Devon Bowen of Buffalo University and Torbjorn Granlund of the Swedish Institute of Computer Science.

Keith Knowles at the Open Software Foundation wrote the original MIPS back end (`tc-mips.c', `tc-mips.h'), and contributed Rose format support (which hasn't been merged in yet). Ralph Campbell worked with the MIPS code to support a.out format.

Support for the Zilog Z8k and Hitachi H8/300 and H8/500 processors (tc-z8k, tc-h8300, tc-h8500), and IEEE 695 object file format (obj-ieee), was written by Steve Chamberlain of Cygnus Support. Steve also modified the COFF back end to use BFD for some low-level operations, for use with the H8/300 and AMD 29k targets.

John Gilmore built the AMD 29000 support, added `.include` support, and simplified the configuration of which versions accept which directives. He updated the 68k machine description so that Motorola's opcodes always produced fixed-size instructions (e.g. `jsr`), while synthetic instructions remained shrinkable (`jbsr`). John fixed many bugs, including true tested cross-compilation support, and one bug in relaxation that took a week and required the proverbial one-bit fix.

Ian Lance Taylor of Cygnus Support merged the Motorola and MIT syntax for the 68k, completed support for some COFF targets (68k, i386 SVR3, and SCO Unix), added support for MIPS ECOFF and ELF targets, wrote the initial RS/6000 and PowerPC assembler, and made a few other minor patches.

Steve Chamberlain made able to generate listings.

Hewlett-Packard contributed support for the HP9000/300.

Jeff Law wrote GAS and BFD support for the native HPPA object format (SOM) along with a fairly extensive HPPA testsuite (for both SOM and ELF object formats). This work was supported by both the Center for Software Science at the University of Utah and Cygnus Support.

Support for ELF format files has been worked on by Mark Eichin of Cygnus Support (original,

incomplete implementation for SPARC), Pete Hoogenboom and Jeff Law at the University of Utah (HPPA mainly), Michael Meissner of the Open Software Foundation (i386 mainly), and Ken Raeburn Cygnus Support (sparc, and some initial 64-bit support).

Richard Henderson rewrote the Alpha assembler. Klaus Kaempf wrote GAS and BFD support for openVMS/Alpha.

Several engineers at Cygnus Support have also provided many small bug fixes and configuration enhancements.

Many others have contributed large or small bugfixes and enhancements. If you have contributed significant work and are not mentioned on this list, and want to be, let us know. Some of the history has been lost; we are not intentionally leaving anyone out.

AWK Language Programming

A User's Guide for GNU AWK

Edition 1.0

January 1996

Arnold D. Robbins Based on The GAWK Manual, by Robbins, Close, Rubin, and Stallman

Go to the next section.

This is Edition 1.0 of AWK Language Programming,
for the 3.0 (or later) version of the GNU implementation of AWK.

Published by the Free Software Foundation
59 Temple Place -- Suite 330
Boston, MA 02111-1307 USA
Phone: +1-617-542-5942
Fax (including Japan): +1-617-542-2652
Printed copies are available for $25 each.
ISBN 1-882114-26-4

Cover art by Etienne Suvasa.

To Miriam, for making me complete.

To Chana, for the joy you bring us.

To Rivka, for the exponential increase.

Preface

This book teaches you about the `awk` language and how you can use it effectively. You should already be familiar with basic system commands, such as `cat` and `ls`,(1) and basic shell facilities, such as Input/Output (I/O) redirection and pipes.

Implementations of the `awk` language are available for many different computing environments. This book, while describing the `awk` language in general, also describes a particular implementation of `awk` called `gawk` (which stands for "GNU Awk"). `gawk` runs on a broad range of Unix systems, ranging from 80386 PC-based computers, up through large scale systems, such as Crays. `gawk` has also been

ported to MS-DOS and OS/2 PC's, Atari and Amiga micro-computers, and VMS.

History of awk and gawk

The name `awk` comes from the initials of its designers: Alfred V. Aho, Peter J. Weinberger, and Brian W. Kernighan. The original version of `awk` was written in 1977 at AT&T Bell Laboratories. In 1985 a new version made the programming language more powerful, introducing user-defined functions, multiple input streams, and computed regular expressions. This new version became generally available with Unix System V Release 3.1. The version in System V Release 4 added some new features and also cleaned up the behavior in some of the "dark corners" of the language. The specification for `awk` in the POSIX Command Language and Utilities standard further clarified the language based on feedback from both the `gawk` designers, and the original Bell Labs `awk` designers.

The GNU implementation, `gawk`, was written in 1986 by Paul Rubin and Jay Fenlason, with advice from Richard Stallman. John Woods contributed parts of the code as well. In 1988 and 1989, David Trueman, with help from Arnold Robbins, thoroughly reworked `gawk` for compatibility with the newer `awk`. Current development focuses on bug fixes, performance improvements, standards compliance, and occasionally, new features.

The GNU Project and This Book

The Free Software Foundation (FSF) is a non-profit organization dedicated to the production and distribution of freely distributable software. It was founded by Richard M. Stallman, the author of the original Emacs editor. GNU Emacs is the most widely used version of Emacs today.

The GNU project is an on-going effort on the part of the Free Software Foundation to create a complete, freely distributable, POSIX compliant computing environment. (GNU stands for "GNU's not Unix".) The FSF uses the "GNU General Public License" (or GPL) to ensure that source code for their software is always available to the end user. A copy of the GPL is included for your reference (see section GNU GENERAL PUBLIC LICENSE). The GPL applies to the C language source code for `gawk`.

As of this writing (1995), the only major component of the GNU environment still uncompleted is the operating system kernel, and work proceeds apace on that. A shell, an editor (Emacs), highly portable optimizing C, C++, and Objective-C compilers, a symbolic debugger, and dozens of large and small utilities (such as `gawk`), have all been completed and are freely available.

Until the GNU operating system is released, the FSF recommends the use of Linux, a freely distributable, Unix-like operating system for 80386 and other systems. There are many books on Linux. One freely available one is Linux Installation and Getting Started, by Matt Welsh. Many Linux distributions are available, often in computer stores or bundled on CD-ROM with books about Linux. Also, the FSF provides a Linux distribution ("Debian"); contact them for more information. See section Getting the `gawk` Distribution, for the FSF's contact information. (There are two other freely available, Unix-like operating systems for 80386 and other systems, NetBSD and FreeBSD. Both are based on the 4.4-Lite Berkeley Software Distribution, and both use recent versions of `gawk` for their versions of `awk`.)

This book you are reading now is actually free. The information in it is freely available to anyone, th machine readable source code for the book comes with `gawk`, and anyone may take this book to a copying machine and make as many copies of it as they like. (Take a moment to check the copying permissions on the Copyright page.)

If you paid money for this book, what you actually paid for was the book's nice printing and binding, and the publisher's associated costs to produce it. We have made an effort to keep these costs reasonable; most people would prefer a bound book to over 300 pages of photo-copied text that would then have to be held in a loose-leaf binder (not to mention the time and labor involved in doing the copying). The same is true of producing this book from the machine readable source; the retail price is only slightly more than the cost per page of printing it on a laser printer.

This book itself has gone through several previous, preliminary editions. I started working on a preliminary draft of The GAWK Manual, by Diane Close, Paul Rubin, and Richard Stallman in the fall of 1988. It was around 90 pages long, and barely described the original, "old" version of `awk`. After substantial revision, the first version of the The GAWK Manual to be released was Edition 0.11 Beta in October of 1989. The manual then underwent more substantial revision for Edition 0.13 of December 1991. David Trueman, Pat Rankin, and Michal Jaegermann contributed sections of the manual for Edition 0.13. That edition was published by the FSF as a bound book early in 1992. Since then there have been several minor revisions, notably Edition 0.14 of November 1992 that was published by the FSF in January of 1993, and Edition 0.16 of August 1993.

Edition 1.0 of AWK Language Programming represents a significant re-working of The GAWK Manual, with much additional material. The FSF and I agree that I am now the primary author. I also felt that it needed a more descriptive title.

AWK Language Programming will undoubtedly continue to evolve. An electronic version comes with the `gawk` distribution from the FSF. If you find an error in this book, please report it! See section Reporting Problems and Bugs, for information on submitting problem reports electronically, or write to me in care of the FSF.

Acknowledgements

I would like to acknowledge Richard M. Stallman, for his vision of a better world, and for his courage in founding the FSF and starting the GNU project.

The initial draft of The GAWK Manual had the following acknowledgements:

> Many people need to be thanked for their assistance in producing this manual. Jay Fenlason contributed many ideas and sample programs. Richard Mlynarik and Robert Chassell gave helpful comments on drafts of this manual. The paper A Supplemental Document for `awk` by John W. Pierce of the Chemistry Department at UC San Diego, pinpointed several issues relevant both to `awk` implementation and to this manual, that would otherwise have escaped us.

The following people provided many helpful comments on Edition 0.13 of The GAWK Manual: Rick Adams, Michael Brennan, Rich Burridge, Diane Close, Christopher ("Topher") Eliot, Michael Lijewski, Pat Rankin, Miriam Robbins, and Michal Jaegermann.

The following people provided many helpful comments for Edition 1.0 of AWK Language Programming: Karl Berry, Michael Brennan, Darrel Hankerson, Michal Jaegermann, Michael Lijewski, and Miriam Robbins. Pat Rankin, Michal Jaegermann, Darrel Hankerson and Scott Deifik updated their respective sections for Edition 1.0.

Robert J. Chassell provided much valuable advice on the use of Texinfo. He also deserves special thanks for convincing me *not* to title this book How To Gawk Politely. Karl Berry helped significantly with the TeX part of Texinfo.

David Trueman deserves special credit; he has done a yeoman job of evolving `gawk` so that it performs well, and without bugs. Although he is no longer involved with `gawk`, working with him on this project was a significant pleasure.

Scott Deifik, Darrel Hankerson, Kai Uwe Rommel, Pat Rankin, and Michal Jaegermann (in no particular order) are long time members of the `gawk` "crack portability team." Without their hard work and help, `gawk` would not be nearly the fine program it is today. It has been and continues to be a pleasure working with this team of fine people.

Jeffrey Friedl provided invaluable help in tracking down a number of last minute problems with regular expressions in `gawk` 3.0.

David and I would like to thank Brian Kernighan of Bell Labs for invaluable assistance during the testing and debugging of `gawk`, and for help in clarifying numerous points about the language. We could not have done nearly as good a job on either `gawk` or its documentation without his help.

I would like to thank Marshall and Elaine Hartholz of Seattle, and Dr. Bert and Rita Schreiber of Detroit for large amounts of quiet vacation time in their homes, which allowed me to make significant progress on this book and on `gawk` itself. Phil Hughes of SSC contributed in a very important way by loaning me his laptop Linux system, not once, but twice, allowing me to do a lot of work while away from home.

Finally, I must thank my wonderful wife, Miriam, for her patience through the many versions of this project, for her proof-reading, and for sharing me with the computer. I would like to thank my parents for their love, and for the grace with which they raised and educated me. I also must acknowledge my gratitude to G-d, for the many opportunities He has sent my way, as well as for the gifts He has given me with which to take advantage of those opportunities.

Arnold Robbins

Go to the next section.

Go to the previous, next section.

Introduction

If you are like many computer users, you would frequently like to make changes in various text files wherever certain patterns appear, or extract data from parts of certain lines while discarding the rest. To write a program to do this in a language such as C or Pascal is a time-consuming inconvenience that may take many lines of code. The job may be easier with awk.

The awk utility interprets a special-purpose programming language that makes it possible to handle simple data-reformatting jobs with just a few lines of code.

The GNU implementation of awk is called gawk; it is fully upward compatible with the System V Release 4 version of awk. gawk is also upward compatible with the POSIX specification of the awk language. This means that all properly written awk programs should work with gawk. Thus, we usually don't distinguish between gawk and other awk implementations.

Using awk you can:

- manage small, personal databases
- generate reports
- validate data
- produce indexes, and perform other document preparation tasks
- even experiment with algorithms that can be adapted later to other computer languages

Using This Book

The term awk refers to a particular program, and to the language you use to tell this program what to do. When we need to be careful, we call the program "the awk utility" and the language "the awk language." The term gawk refers to a version of awk developed as part the GNU project. The purpose of this book is to explain both the awk language and how to run the awk utility.

The main purpose of the book is to explain the features of awk, as defined in the POSIX standard. It does so in the context of one particular implementation, gawk. While doing so, it will also attempt to describe important differences between gawk and other awk implementations. Finally, any gawk features that are not in the POSIX standard for awk will be noted.

This book has the difficult task of being both tutorial and reference. If you are a novice, feel free to skip over details that seem too complex. You should also ignore the many cross references; they are for the expert user, and for the on-line Info version of the document.

The term awk program refers to a program written by you in the awk programming language.

See section Getting Started with awk, for the bare essentials you need to know to start using awk.

Some useful "one-liners" are included to give you a feel for the awk language (see section Useful One

Line Programs).

Many sample `awk` programs have been provided for you (see section A Library of `awk` Functions; also see section Practical `awk` Programs).

The entire `awk` language is summarized for quick reference in section `gawk` Summary. Look there if you just need to refresh your memory about a particular feature.

If you find terms that you aren't familiar with, try looking them up in the glossary (see section Glossary).

Most of the time complete `awk` programs are used as examples, but in some of the more advanced sections, only the part of the `awk` program that illustrates the concept being described is shown.

While this book is aimed principally at people who have not been exposed to `awk`, there is a lot of information here that even the `awk` expert should find useful. In particular, the description of POSIX `awk`, and the example programs in section A Library of `awk` Functions, and section Practical `awk` Programs, should be of interest.

Dark Corners

Until the POSIX standard (and The Gawk Manual), many features of `awk` were either poorly documented, or not documented at all. Descriptions of such features (often called "dark corners") are noted in this book with "(d.c.)". They also appear in the index under the heading "dark corner."

Typographical Conventions

This book is written using Texinfo, the GNU documentation formatting language. A single Texinfo source file is used to produce both the printed and on-line versions of the documentation. Because of this, the typographical conventions are slightly different than in other books you may have read.

Examples you would type at the command line are preceded by the common shell primary and secondary prompts, `$' and `>'. Output from the command is preceded by the glyph "-|". This typically represents the command's standard output. Error messages, and other output on the command's standard error, are preceded by the glyph "error-->". For example:

```
$ echo hi on stdout
-| hi on stdout
$ echo hello on stderr 1>&2
error--> hello on stderr
```

In the text, command names appear in `this font`, while code segments appear in the same font and quoted, `like this'. Some things will be emphasized *like this*, and if a point needs to be made strongly, it will be done **like this**. The first occurrence of a new term is usually its definition, and appears in the same font as the previous occurrence of "definition" in this sentence. File names are indicated like this: `` `/path/to/ourfile' ``.

Characters that you type at the keyboard look like this. In particular, there are special characters calle "control characters." These are characters that you type by holding down both the CONTROL key ar another key, at the same time. For example, a Control-d is typed by first pressing and holding the CONTROL key, next pressing the d key, and finally releasing both keys.

Data Files for the Examples

Many of the examples in this book take their input from two sample data files. The first, called `BBS-list', represents a list of computer bulletin board systems together with information about those systems. The second data file, called `inventory-shipped', contains information about shipments on a monthly basis. In both files, each line is considered to be one record.

In the file `BBS-list', each record contains the name of a computer bulletin board, its phone number, the board's baud rate(s), and a code for the number of hours it is operational. An `A' in the last column means the board operates 24 hours a day. A `B' in the last column means the board operates evening and weekend hours, only. A `C' means the board operates only on weekends.

```
aardvark     555-5553     1200/300          B
alpo-net     555-3412     2400/1200/300     A
barfly       555-7685     1200/300          A
bites        555-1675     2400/1200/300     A
camelot      555-0542     300               C
core         555-2912     1200/300          C
fooey        555-1234     2400/1200/300     B
foot         555-6699     1200/300          B
macfoo       555-6480     1200/300          A
sdace        555-3430     2400/1200/300     A
sabafoo      555-2127     1200/300          C
```

The second data file, called `inventory-shipped', represents information about shipments during the year. Each record contains the month of the year, the number of green crates shipped, the number of red boxes shipped, the number of orange bags shipped, and the number of blue packages shipped, respectively. There are 16 entries, covering the 12 months of one year and four months of the next year.

Getting Started with awk

The basic function of awk is to search files for lines (or other units of text) that contain certain patterns. When a line matches one of the patterns, awk performs specified actions on that line. awk keeps processing input lines in this way until the end of the input files are reached.

Programs in awk are different from programs in most other languages, because awk programs are data-driven; that is, you describe the data you wish to work with, and then what to do when you find it. Most other languages are procedural; you have to describe, in great detail, every step the program is to take. When working with procedural languages, it is usually much harder to clearly describe the data your program will process. For this reason, awk programs are often refreshingly easy to both write and read.

When you run awk, you specify an awk program that tells awk what to do. The program consists of a series of rules. (It may also contain function definitions, an advanced feature which we will ignore for now. See section User-defined Functions.) Each rule specifies one pattern to search for, and one action to perform when that pattern is found.

Syntactically, a rule consists of a pattern followed by an action. The action is enclosed in curly braces to separate it from the pattern. Rules are usually separated by newlines. Therefore, an awk program looks like this:

```
pattern { action }
pattern { action }
...
```

A Rose By Any Other Name

The awk language has evolved over the years. Full details are provided in section The Evolution of the awk Language. The language described in this book is often referred to as "new awk."

Because of this, many systems have multiple versions of awk. Some systems have an awk utility that implements the original version of the awk language, and a nawk utility for the new version. Others have an oawk for the "old awk" language, and plain awk for the new one. Still others only have one version, usually the new one.(2)

All in all, this makes it difficult for you to know which version of awk you should run when writing your programs. The best advice we can give here is to check your local documentation. Look for awk, oawk, and nawk, as well as for gawk. Chances are, you will have some version of new awk on your system, and that is what you should use when running your programs. (Of course, if you're reading this book, chances are good that you have gawk!)

Throughout this book, whenever we refer to a language feature that should be available in any complete

implementation of POSIX awk, we simply use the term awk. When referring to a feature that is spec to the GNU implementation, we use the term gawk.

How to Run awk Programs

There are several ways to run an awk program. If the program is short, it is easiest to include it in the command that runs awk, like this:

```
awk 'program' input-file1 input-file2 ...
```

where program consists of a series of patterns and actions, as described earlier. (The reason for the single quotes is described below, in section One-shot Throw-away awk Programs.)

When the program is long, it is usually more convenient to put it in a file and run it with a command like this:

```
awk -f program-file input-file1 input-file2 ...
```

One-shot Throw-away awk Programs

Once you are familiar with awk, you will often type in simple programs the moment you want to use them. Then you can write the program as the first argument of the awk command, like this:

```
awk 'program' input-file1 input-file2 ...
```

where program consists of a series of patterns and actions, as described earlier.

This command format instructs the shell, or command interpreter, to start awk and use the program to process records in the input file(s). There are single quotes around program so that the shell doesn't interpret any awk characters as special shell characters. They also cause the shell to treat all of program as a single argument for awk and allow program to be more than one line long.

This format is also useful for running short or medium-sized awk programs from shell scripts, because it avoids the need for a separate file for the awk program. A self-contained shell script is more reliable since there are no other files to misplace.

section Useful One Line Programs, presents several short, self-contained programs.

As an interesting side point, the command

```
awk '/foo/' files ...
```

is essentially the same as

```
egrep foo files ...
```

Running awk without Input Files

You can also run awk without any input files. If you type the command line:

```
awk 'program'
```

then awk applies the program to the standard input, which usually means whatever you type on the terminal. This continues until you indicate end-of-file by typing Control-d. (On other operating systems, the end-of-file character may be different. For example, on OS/2 and MS-DOS, it is Control-z.)

For example, the following program prints a friendly piece of advice (from Douglas Adams' The Hitchhiker's Guide to the Galaxy), to keep you from worrying about the complexities of computer programming (`BEGIN' is a feature we haven't discussed yet).

```
$ awk "BEGIN { print \"Don't Panic!\" }"
-| Don't Panic!
```

This program does not read any input. The `\' before each of the inner double quotes is necessary because of the shell's quoting rules, in particular because it mixes both single quotes and double quotes.

This next simple awk program emulates the cat utility; it copies whatever you type at the keyboard to its standard output. (Why this works is explained shortly.)

```
$ awk '{ print }'
Now is the time for all good men
-| Now is the time for all good men
to come to the aid of their country.
-| to come to the aid of their country.
Four score and seven years ago, ...
-| Four score and seven years ago, ...
What, me worry?
-| What, me worry?
Control-d
```

Running Long Programs

Sometimes your awk programs can be very long. In this case it is more convenient to put the program into a separate file. To tell awk to use that file for its program, you type:

```
awk -f source-file input-file1 input-file2 ...
```

The `-f' instructs the awk utility to get the awk program from the file source-file. Any file name can be used for source-file. For example, you could put the program:

```
BEGIN { print "Don't Panic!" }
```

into the file `advice'. Then this command:

```
awk -f advice
```

does the same thing as this one:

```
awk "BEGIN { print \"Don't Panic!\" }"
```

which was explained earlier (see section Running awk without Input Files). Note that you don't usually need single quotes around the file name that you specify with `-f', because most file names don't contain any of the shell's special characters. Notice that in `advice', the awk program did not have single quotes around it. The quotes are only needed for programs that are provided on the awk command line.

If you want to identify your awk program files clearly as such, you can add the extension `.awk' to the file name. This doesn't affect the execution of the awk program, but it does make "housekeeping" easier.

Executable awk Programs

Once you have learned awk, you may want to write self-contained awk scripts, using the `#!' script mechanism. You can do this on many Unix systems(3) (and someday on the GNU system).

For example, you could update the file `advice' to look like this:

```
#! /bin/awk -f

BEGIN    { print "Don't Panic!" }
```

After making this file executable (with the chmod utility), you can simply type `advice' at the shell, and the system will arrange to run awk (4) as if you had typed `awk -f advice'.

```
$ advice
-| Don't Panic!
```

Self-contained awk scripts are useful when you want to write a program which users can invoke without their having to know that the program is written in awk.

Some older systems do not support the `#!' mechanism. You can get a similar effect using a regular shell script. It would look something like this:

```
: The colon ensures execution by the standard shell.
awk 'program' "$@"
```

Using this technique, it is *vital* to enclose the program in single quotes to protect it from interpretation by the shell. If you omit the quotes, only a shell wizard can predict the results.

The "$@" causes the shell to forward all the command line arguments to the awk program, without interpretation. The first line, which starts with a colon, is used so that this shell script will work even if

invoked by a user who uses the C shell. (Not all older systems obey this convention, but many do.)

Comments in awk Programs

A comment is some text that is included in a program for the sake of human readers; it is not really part of the program. Comments can explain what the program does, and how it works. Nearly all programming languages have provisions for comments, because programs are typically hard to understand without their extra help.

In the `awk` language, a comment starts with the sharp sign character, `#', and continues to the end of the line. The `#' does not have to be the first character on the line. The `awk` language ignores the rest of a line following a sharp sign. For example, we could have put the following into `advice':

```
# This program prints a nice friendly message.  It helps
# keep novice users from being afraid of the computer.
BEGIN    { print "Don't Panic!" }
```

You can put comment lines into keyboard-composed throw-away `awk` programs also, but this usually isn't very useful; the purpose of a comment is to help you or another person understand the program at a later time.

A Very Simple Example

The following command runs a simple `awk` program that searches the input file `BBS-list' for the string of characters: `foo'. (A string of characters is usually called a string. The term string is perhaps based on similar usage in English, such as "a string of pearls," or, "a string of cars in a train.")

```
awk '/foo/ { print $0 }' BBS-list
```

When lines containing `foo' are found, they are printed, because `print $0' means print the current line. (Just `print' by itself means the same thing, so we could have written that instead.)

You will notice that slashes, `/', surround the string `foo' in the `awk` program. The slashes indicate that `foo' is a pattern to search for. This type of pattern is called a regular expression, and is covered in more detail later (see section Regular Expressions). The pattern is allowed to match parts of words. There are single-quotes around the `awk` program so that the shell won't interpret any of it as special shell characters.

Here is what this program prints:

```
$ awk '/foo/ { print $0 }' BBS-list
-| fooey         555-1234     2400/1200/300     B
-| foot          555-6699     1200/300          B
-| macfoo        555-6480     1200/300          A
-| sabafoo       555-2127     1200/300          C
```

In an `awk` rule, either the pattern or the action can be omitted, but not both. If the pattern is omitted, the action is performed for *every* input line. If the action is omitted, the default action is to print all li that match the pattern.

Thus, we could leave out the action (the `print` statement and the curly braces) in the above example, and the result would be the same: all lines matching the pattern `foo' would be printed. By comparison, omitting the `print` statement but retaining the curly braces makes an empty action that does nothing; then no lines would be printed.

An Example with Two Rules

The `awk` utility reads the input files one line at a time. For each line, `awk` tries the patterns of each of the rules. If several patterns match then several actions are run, in the order in which they appear in the `awk` program. If no patterns match, then no actions are run.

After processing all the rules (perhaps none) that match the line, `awk` reads the next line (however, see section The `next` Statement, and also see section The `nextfile` Statement). This continues until the end of the file is reached.

For example, the `awk` program:

```
/12/  { print $0 }
/21/  { print $0 }
```

contains two rules. The first rule has the string `12' as the pattern and `print $0' as the action. The second rule has the string `21' as the pattern and also has `print $0' as the action. Each rule's action is enclosed in its own pair of braces.

This `awk` program prints every line that contains the string `12' *or* the string `21'. If a line contains both strings, it is printed twice, once by each rule.

This is what happens if we run this program on our two sample data files, `` `BBS-list' `` and `` `inventory-shipped' ``, as shown here:

```
$ awk '/12/ { print $0 }
>      /21/ { print $0 }' BBS-list inventory-shipped
-| aardvark     555-5553     1200/300          B
-| alpo-net     555-3412     2400/1200/300     A
-| barfly       555-7685     1200/300          A
-| bites        555-1675     2400/1200/300     A
-| core         555-2912     1200/300          C
-| fooey        555-1234     2400/1200/300     B
-| foot         555-6699     1200/300          B
-| macfoo       555-6480     1200/300          A
-| sdace        555-3430     2400/1200/300     A
-| sabafoo      555-2127     1200/300          C
```

```
-| sabafoo      555-2127     1200/300          C
-| Jan  21  36  64 620
-| Apr  21  70  74 514
```

Note how the line in `BBS-list' beginning with `sabafoo' was printed twice, once for each rule.

A More Complex Example

Here is an example to give you an idea of what typical `awk` programs do. This example shows how `awk` can be used to summarize, select, and rearrange the output of another utility. It uses features that haven't been covered yet, so don't worry if you don't understand all the details.

```
ls -lg | awk '$6 == "Nov" { sum += $5 }
             END { print sum }'
```

This command prints the total number of bytes in all the files in the current directory that were last modified in November (of any year). (In the C shell you would need to type a semicolon and then a backslash at the end of the first line; in a POSIX-compliant shell, such as the Bourne shell or Bash, the GNU Bourne-Again shell, you can type the example as shown.)

The `ls -lg' part of this example is a system command that gives you a listing of the files in a directory, including file size and the date the file was last modified. Its output looks like this:

```
-rw-r--r--  1 arnold   user   1933 Nov  7 13:05 Makefile
-rw-r--r--  1 arnold   user  10809 Nov  7 13:03 gawk.h
-rw-r--r--  1 arnold   user    983 Apr 13 12:14 gawk.tab.h
-rw-r--r--  1 arnold   user  31869 Jun 15 12:20 gawk.y
-rw-r--r--  1 arnold   user  22414 Nov  7 13:03 gawk1.c
-rw-r--r--  1 arnold   user  37455 Nov  7 13:03 gawk2.c
-rw-r--r--  1 arnold   user  27511 Dec  9 13:07 gawk3.c
-rw-r--r--  1 arnold   user   7989 Nov  7 13:03 gawk4.c
```

The first field contains read-write permissions, the second field contains the number of links to the file, and the third field identifies the owner of the file. The fourth field identifies the group of the file. The fifth field contains the size of the file in bytes. The sixth, seventh and eighth fields contain the month, day, and time, respectively, that the file was last modified. Finally, the ninth field contains the name of the file.

The `$6 == "Nov"' in our `awk` program is an expression that tests whether the sixth field of the output from `ls -lg' matches the string `Nov'. Each time a line has the string `Nov' for its sixth field, the action `sum += $5' is performed. This adds the fifth field (the file size) to the variable `sum`. As a result, when `awk` has finished reading all the input lines, `sum` is the sum of the sizes of files whose lines matched the pattern. (This works because `awk` variables are automatically initialized to zero.)

After the last line of output from `ls` has been processed, the `END` rule is executed, and the value of `sum` is printed. In this example, the value of `sum` would be 80600.

These more advanced `awk` techniques are covered in later sections (see section Overview of Actions). Before you can move on to more advanced `awk` programming, you have to know how `awk` interprets your input and displays your output. By manipulating fields and using `print` statements, you can produce some very useful and impressive looking reports.

awk Statements Versus Lines

Most often, each line in an `awk` program is a separate statement or separate rule, like this:

```
awk '/12/  { print $0 }
     /21/  { print $0 }' BBS-list inventory-shipped
```

However, `gawk` will ignore newlines after any of the following:

```
,    {    ?    :    ||    &&    do    else
```

A newline at any other point is considered the end of the statement. (Splitting lines after `?' and `:' is a minor `gawk` extension. The `?' and `:' referred to here is the three operand conditional expression described in section Conditional Expressions.)

If you would like to split a single statement into two lines at a point where a newline would terminate it, you can continue it by ending the first line with a backslash character, `\'. The backslash must be the final character on the line to be recognized as a continuation character. This is allowed absolutely anywhere in the statement, even in the middle of a string or regular expression. For example:

```
awk '/This regular expression is too long, so continue it\
 on the next line/ { print $1 }'
```

We have generally not used backslash continuation in the sample programs in this book. Since in `gawk` there is no limit on the length of a line, it is never strictly necessary; it just makes programs more readable. For this same reason, as well as for clarity, we have kept most statements short in the sample programs presented throughout the book. Backslash continuation is most useful when your `awk` program is in a separate source file, instead of typed in on the command line. You should also note that many `awk` implementations are more particular about where you may use backslash continuation. For example, they may not allow you to split a string constant using backslash continuation. Thus, for maximal portability of your `awk` programs, it is best not to split your lines in the middle of a regular expression or a string.

Caution: backslash continuation does not work as described above with the C shell. Continuation with backslash works for `awk` programs in files, and also for one-shot programs *provided* you are using a POSIX-compliant shell, such as the Bourne shell or Bash, the GNU Bourne-Again shell. But the C shell (`csh`) behaves differently! There, you must use two backslashes in a row, followed by a newline. Note also that when using the C shell, *every* newline in your awk program must be escaped with a backslash. To illustrate:

```
% awk 'BEGIN { \
```

```
?   print \\
?       "hello, world" \
? }'
-| hello, world
```

Here, the `%' and `?' are the C shell's primary and secondary prompts, analogous to the standard shell's `$' and `>'.

awk is a line-oriented language. Each rule's action has to begin on the same line as the pattern. To have the pattern and action on separate lines, you *must* use backslash continuation--there is no other way.

When awk statements within one rule are short, you might want to put more than one of them on a line. You do this by separating the statements with a semicolon, `;'.

This also applies to the rules themselves. Thus, the previous program could have been written:

```
/12/ { print $0 } ; /21/ { print $0 }
```

Note: the requirement that rules on the same line must be separated with a semicolon was not in the original awk language; it was added for consistency with the treatment of statements within an action.

Other Features of awk

The awk language provides a number of predefined, or built-in variables, which your programs can use to get information from awk. There are other variables your program can set to control how awk processes your data.

In addition, awk provides a number of built-in functions for doing common computational and string related operations.

As we develop our presentation of the awk language, we introduce most of the variables and many of the functions. They are defined systematically in section Built-in Variables, and section Built-in Functions.

When to Use awk

You might wonder how awk might be useful for you. Using utility programs, advanced patterns, field separators, arithmetic statements, and other selection criteria, you can produce much more complex output. The awk language is very useful for producing reports from large amounts of raw data, such as summarizing information from the output of other utility programs like ls. (See section A More Complex Example.)

Programs written with awk are usually much smaller than they would be in other languages. This makes awk programs easy to compose and use. Often, awk programs can be quickly composed at your terminal, used once, and thrown away. Since awk programs are interpreted, you can avoid the (usually lengthy) compilation part of the typical edit-compile-test-debug cycle of software development.

Complex programs have been written in awk, including a complete retargetable assembler for eight-bit

microprocessors (see section Glossary, for more information) and a microcode assembler for a special-purpose Prolog computer. However, awk's capabilities are strained by tasks of such complexity.

If you find yourself writing awk scripts of more than, say, a few hundred lines, you might consider using a different programming language. Emacs Lisp is a good choice if you need sophisticated string or pattern matching capabilities. The shell is also good at string and pattern matching; in addition, it allows powerful use of the system utilities. More conventional languages, such as C, C++, and Lisp, offer better facilities for system programming and for managing the complexity of large programs. Programs in these languages may require more lines of source code than the equivalent awk programs, but they are easier to maintain and usually run more efficiently.

Go to the previous, next section.

Go to the previous, next section.

Useful One Line Programs

Many useful `awk` programs are short, just a line or two. Here is a collection of useful, short programs to get you started. Some of these programs contain constructs that haven't been covered yet. The description of the program will give you a good idea of what is going on, but please read the rest of the book to become an `awk` expert!

Most of the examples use a data file named `` `data' ``. This is just a placeholder; if you were to use these programs yourself, you would substitute your own file names for `` `data' ``.

```
awk '{ if (length($0) > max) max = length($0) }
END { print max }' data
```

This program prints the length of the longest input line.

```
awk 'length($0) > 80' data
```

This program prints every line that is longer than 80 characters. The sole rule has a relational expression as its pattern, and has no action (so the default action, printing the record, is used).

```
expand data | awk '{ if (x < length()) x = length() }
END { print "maximum line length is " x }'
```

This program prints the length of the longest line in `` `data' ``. The input is processed by the `expand` program to change tabs into spaces, so the widths compared are actually the right-margin columns.

```
awk 'NF > 0' data
```

This program prints every line that has at least one field. This is an easy way to delete blank lines from a file (or rather, to create a new file similar to the old file but from which the blank lines have been deleted).

```
awk 'BEGIN { for (i = 1; i <= 7; i++)
print int(101 * rand()) }'
```

This program prints seven random numbers from zero to 100, inclusive.

```
ls -lg files | awk '{ x += $5 } ; END { print "total bytes: " x }'
```

This program prints the total number of bytes used by files.

```
ls -lg files | awk '{ x += $5 }
END { print "total K-bytes: " (x + 1023)/1024 }'
```

This program prints the total number of kilobytes used by files.

```
awk -F: '{ print $1 }' /etc/passwd | sort
```

This program prints a sorted list of the login names of all users.

```
awk 'END { print NR }' data
```

This program counts lines in a file.

```
awk 'NR % 2' data
```

This program prints the even numbered lines in the data file. If you were to use the expression 'NR % 2 == 1' instead, it would print the odd number lines.

Go to the previous, next section.

Go to the previous, next section.

Regular Expressions

A regular expression, or regexp, is a way of describing a set of strings. Because regular expressions are such a fundamental part of `awk` programming, their format and use deserve a separate chapter.

A regular expression enclosed in slashes (`/') is an `awk` pattern that matches every input record whose text belongs to that set.

The simplest regular expression is a sequence of letters, numbers, or both. Such a regexp matches any string that contains that sequence. Thus, the regexp `foo' matches any string containing `foo'. Therefore, the pattern `/foo/` matches any input record containing the three characters `foo', *anywhere* in the record. Other kinds of regexps let you specify more complicated classes of strings.

Initially, the examples will be simple. As we explain more about how regular expressions work, we will present more complicated examples.

How to Use Regular Expressions

A regular expression can be used as a pattern by enclosing it in slashes. Then the regular expression is tested against the entire text of each record. (Normally, it only needs to match some part of the text in order to succeed.) For example, this prints the second field of each record that contains the three characters `foo' anywhere in it:

```
$ awk '/foo/ { print $2 }' BBS-list
-| 555-1234
-| 555-6699
-| 555-6480
-| 555-2127
```

Regular expressions can also be used in matching expressions. These expressions allow you to specify the string to match against; it need not be the entire current input record. The two operators, `~' and `!~', perform regular expression comparisons. Expressions using these operators can be used as patterns or in `if`, `while`, `for`, and `do` statements.

`exp ~ /regexp/`

> This is true if the expression exp (taken as a string) is matched by regexp. The following example matches, or selects, all input records with the upper-case letter `J' somewhere in the first field:
>
> ```
> $ awk '$1 ~ /J/' inventory-shipped
> -| Jan  13  25  15 115
> -| Jun  31  42  75 492
> -| Jul  24  34  67 436
> -| Jan  21  36  64 620
> ```

So does this:

```
awk '{ if ($1 ~ /J/) print }' inventory-shipped
```

`exp !~ /regexp/`

This is true if the expression exp (taken as a character string) is *not* matched by regexp. The following example matches, or selects, all input records whose first field *does not* contain the upper-case letter `J':

```
$ awk '$1 !~ /J/' inventory-shipped
-| Feb  15  32  24 226
-| Mar  15  24  34 228
-| Apr  31  52  63 420
-| May  16  34  29 208
...
```

When a regexp is written enclosed in slashes, like `/foo/`, we call it a regexp constant, much like `5.27` is a numeric constant, and `"foo"` is a string constant.

Escape Sequences

Some characters cannot be included literally in string constants (`"foo"`) or regexp constants (`/foo/`). You represent them instead with escape sequences, which are character sequences beginning with a backslash (`\').

One use of an escape sequence is to include a double-quote character in a string constant. Since a plain double-quote would end the string, you must use `\"' to represent an actual double-quote character as a part of the string. For example:

```
$ awk 'BEGIN { print "He said \"hi!\" to her." }'
-| He said "hi!" to her.
```

The backslash character itself is another character that cannot be included normally; you write `\\' to put one backslash in the string or regexp. Thus, the string whose contents are the two characters `"' and `\' must be written `"\"\\"'.

Another use of backslash is to represent unprintable characters such as tab or newline. While there is nothing to stop you from entering most unprintable characters directly in a string constant or regexp constant, they may look ugly.

Here is a table of all the escape sequences used in `awk`, and what they represent. Unless noted otherwise, all of these escape sequences apply to both string constants and regexp constants.

`\\`

A literal backslash, `\'.

`\a`

The "alert" character, Control-g, ASCII code 7 (BEL).

`\b`

Backspace, Control-h, ASCII code 8 (BS).

`\f`

Formfeed, Control-l, ASCII code 12 (FF).

`\n`

Newline, Control-j, ASCII code 10 (LF).

`\r`

Carriage return, Control-m, ASCII code 13 (CR).

`\t`

Horizontal tab, Control-i, ASCII code 9 (HT).

`\v`

Vertical tab, Control-k, ASCII code 11 (VT).

`\nnn`

The octal value nnn, where nnn are one to three digits between `0' and `7'. For example, the code for the ASCII ESC (escape) character is `\033'.

`\xhh...`

The hexadecimal value hh, where hh are hexadecimal digits (`0' through `9' and either `A' through `F' or `a' through `f'). Like the same construct in ANSI C, the escape sequence continues until the first non-hexadecimal digit is seen. However, using more than two hexadecimal digits produces undefined results. (The `\x' escape sequence is not allowed in POSIX `awk`.)

`\/`

A literal slash (necessary for regexp constants only). You use this when you wish to write a regexp constant that contains a slash. Since the regexp is delimited by slashes, you need to escape the slash that is part of the pattern, in order to tell `awk` to keep processing the rest of the regexp.

`\"`

A literal double-quote (necessary for string constants only). You use this when you wish to write a string constant that contains a double-quote. Since the string is delimited by double-quotes, you need to escape the quote that is part of the string, in order to tell `awk` to keep processing the rest of the string.

In `gawk`, there are additional two character sequences that begin with backslash that have special meaning in regexps. See section Additional Regexp Operators Only in `gawk`.

In a string constant, what happens if you place a backslash before something that is not one of the characters listed above? POSIX `awk` purposely leaves this case undefined. There are two choices.

- Strip the backslash out. This is what Unix `awk` and `gawk` both do. For example, `"a\qc"` is the same as `"aqc"`.
- Leave the backslash alone. Some other `awk` implementations do this. In such implementations, `"a\qc"` is the same as if you had typed `"a\\qc"`.

In a regexp, a backslash before any character that is not in the above table, and not listed in section Additional Regexp Operators Only in gawk, means that the next character should be taken literally, if it would normally be a regexp operator. E.g., `/a\+b/` matches the three characters `a+b'.

For complete portability, do not use a backslash before any character not listed in the table above.

Another interesting question arises. Suppose you use an octal or hexadecimal escape to represent a regexp metacharacter (see section Regular Expression Operators). Does `awk` treat the character as literal character, or as a regexp operator?

It turns out that historically, such characters were taken literally (d.c.). However, the POSIX standard indicates that they should be treated as real metacharacters, and this is what `gawk` does. However, in compatibility mode (see section Command Line Options), `gawk` treats the characters represented by octal and hexadecimal escape sequences literally when used in regexp constants. Thus, `/a\52b/` is equivalent to `/a\*b/`.

To summarize:

1. The escape sequences in the table above are always processed first, for both string constants and regexp constants. This happens very early, as soon as `awk` reads your program.
2. `gawk` processes both regexp constants and dynamic regexps (see section Using Dynamic Regexps), for the special operators listed in section Additional Regexp Operators Only in `gawk`.
3. A backslash before any other character means to treat that character literally.

Regular Expression Operators

You can combine regular expressions with the following characters, called regular expression operators, or metacharacters, to increase the power and versatility of regular expressions.

The escape sequences described above in section Escape Sequences, are valid inside a regexp. They are introduced by a `\'. They are recognized and converted into the corresponding real characters as the very first step in processing regexps.

Here is a table of metacharacters. All characters that are not escape sequences and that are not listed in the table stand for themselves.

`\`

This is used to suppress the special meaning of a character when matching. For example:

```
\$
```

matches the character `$'.

`^`

This matches the beginning of a string. For example:

```
^@chapter
```

matches the `@chapter' at the beginning of a string, and can be used to identify chapter beginn in Texinfo source files. The `^' is known as an anchor, since it anchors the pattern to matching at the beginning of the string.

It is important to realize that `^' does not match the beginning of a line embedded in a string. In this example the condition is not true:

```
if ("line1\nLINE 2" ~ /^L/) ...
```

`$`

This is similar to `^', but it matches only at the end of a string. For example:

```
p$
```

matches a record that ends with a `p'. The `$' is also an anchor, and also does not match the end of a line embedded in a string. In this example the condition is not true:

```
if ("line1\nLINE 2" ~ /1$/) ...
```

`.`

The period, or dot, matches any single character, *including* the newline character. For example:

```
.P
```

matches any single character followed by a `P' in a string. Using concatenation we can make a regular expression like `U.A', which matches any three-character sequence that begins with `U' and ends with `A'.

In strict POSIX mode (see section Command Line Options), `.' does not match the NUL character, which is a character with all bits equal to zero. Otherwise, NUL is just another character. Other versions of `awk` may not be able to match the NUL character.

`[...]`

This is called a character list. It matches any *one* of the characters that are enclosed in the square brackets. For example:

```
[MVX]
```

matches any one of the characters `M', `V', or `X' in a string.

Ranges of characters are indicated by using a hyphen between the beginning and ending characters, and enclosing the whole thing in brackets. For example:

```
[0-9]
```

matches any digit. Multiple ranges are allowed. E.g., the list `[A-Za-z0-9]` is a common way to express the idea of "all alphanumeric characters."

To include one of the characters `\', `]', `-' or `^' in a character list, put a `\' in front of it. For example:

```
[d\]]
```

matches either `d', or `]'.

This treatment of `\' in character lists is compatible with other `awk` implementations, and is also mandated by POSIX. The regular expressions in `awk` are a superset of the POSIX specification for Extended Regular Expressions (EREs). POSIX EREs are based on the regular expressions accepted by the traditional `egrep` utility.

Character classes are a new feature introduced in the POSIX standard. A character class is a special notation for describing lists of characters that have a specific attribute, but where the actual characters themselves can vary from country to country and/or from character set to character set. For example, the notion of what is an alphabetic character differs in the USA and in France.

A character class is only valid in a regexp *inside* the brackets of a character list. Character classes consist of `[:', a keyword denoting the class, and `:]'. Here are the character classes defined by the POSIX standard.

`[:alnum:]`
: Alphanumeric characters.

`[:alpha:]`
: Alphabetic characters.

`[:blank:]`
: Space and tab characters.

`[:cntrl:]`
: Control characters.

`[:digit:]`
: Numeric characters.

`[:graph:]`
: Characters that are printable and are also visible. (A space is printable, but not visible, while an `a' is both.)

`[:lower:]`
: Lower-case alphabetic characters.

`[:print:]`
: Printable characters (characters that are not control characters.)

`[:punct:]`
: Punctuation characters (characters that are not letter, digits, control characters, or space characters).

`[:space:]`
: Space characters (such as space, tab, and formfeed, to name a few).

`[:upper:]`

Upper-case alphabetic characters.

`[:xdigit:]`

Characters that are hexadecimal digits.

For example, before the POSIX standard, to match alphanumeric characters, you had to write `/[A-Za-z0-9]/`. If your character set had other alphabetic characters in it, this would not match them. With the POSIX character classes, you can write `/[[:alnum:]]/`, and this will match *all* the alphabetic and numeric characters in your character set.

Two additional special sequences can appear in character lists. These apply to non-ASCII character sets, which can have single symbols (called collating elements) that are represented with more than one character, as well as several characters that are equivalent for collating, or sorting, purposes. (E.g., in French, a plain "e" and a grave-accented "`e" are equivalent.)

Collating Symbols

A collating symbol is a multi-character collating element enclosed in `[.' and `.]'. For example, if `ch' is a collating element, then `[[.ch.]]` is a regexp that matches this collating element, while `[ch]` is a regexp that matches either `c' or `h'.

Equivalence Classes

An equivalence class is a list of equivalent characters enclosed in `[=' and `=]'. Thus, `[[=e`e=]]` is regexp that matches either `e' or ``e'.

These features are very valuable in non-English speaking locales.

Caution: The library functions that `gawk` uses for regular expression matching currently only recognize POSIX character classes; they do not recognize collating symbols or equivalence classes.

- [^ ...] This is a complemented character list. The first character after the `[' *must* be a `^'. It matches any characters *except* those in the square brackets, or newline. For example:

```
[^0-9]
```

matches any character that is not a digit.

- | This is the alternation operator, and it is used to specify alternatives. For example:

```
^P|[0-9]
```

matches any string that matches either `^P' or `[0-9]'. This means it matches any string that starts with `P' or contains a digit.

The alternation applies to the largest possible regexps on either side. In other words, `|' has the lowest precedence of all the regular expression operators.

- (...) Parentheses are used for grouping in regular expressions as in arithmetic. They can be used to concatenate regular expressions containing the alternation operator, `|'. For example, `@(samp|code)\{[^}]+\}' matches both `@code{foo}' and `@samp{bar}'. (These are Texinfo formatting

control sequences.)

- * This symbol means that the preceding regular expression is to be repeated as many times as necessary to find a match. For example:

```
ph*
```

applies the `*' symbol to the preceding `h' and looks for matches of one `p' followed by any number of `h's. This will also match just `p' if no `h's are present.

The `*' repeats the *smallest* possible preceding expression. (Use parentheses if you wish to repeat a larger expression.) It finds as many repetitions as possible. For example:

```
awk '/\(c[ad][ad]*r x\)/ { print }' sample
```

prints every record in `sample' containing a string of the form `(car x)', `(cdr x)', `(cadr x)', and so on. Notice the escaping of the parentheses by preceding them with backslashes.

- + This symbol is similar to `*', but the preceding expression must be matched at least once. This means that:

```
wh+y
```

would match `why' and `whhy' but not `wy', whereas `wh*y' would match all three of these strings. This is a simpler way of writing the last `*' example:

```
awk '/\(c[ad]+r x\)/ { print }' sample
```

- ? This symbol is similar to `*', but the preceding expression can be matched either once or not at all. For example:

```
fe?d
```

will match `fed' and `fd', but nothing else.

- {n}
- {n,}
- {n,m} One or two numbers inside braces denote an interval expression. If there is one number in the braces, the preceding regexp is repeated n times. If there are two numbers separated by a comma, the preceding regexp is repeated n to m times. If there is one number followed by a comma, then the preceding regexp is repeated at least n times.

`wh{3}y`
: matches `whhhy' but not `why' or `whhhhy'.

`wh{3,5}y`
: matches `whhhy' or `whhhhy' or `whhhhhy', only.

`wh{2,}y`
: matches `whhy' or `whhhy', and so on.

Interval expressions were not traditionally available in `awk`. As part of the POSIX standard they were added, to make `awk` and `egrep` consistent with each other.

However, since old programs may use `{' and `}' in regexp constants, by default `gawk` does *not* match interval expressions in regexps. If either `--posix' or `--re-interval' are specified (see section Command Line Options), then interval expressions are allowed in regexps.

In regular expressions, the `*', `+', and `?' operators, as well as the braces `{' and `}', have the highest precedence, followed by concatenation, and finally by `|'. As in arithmetic, parentheses can change how operators are grouped.

If `gawk` is in compatibility mode (see section Command Line Options), character classes and interval expressions are not available in regular expressions.

The next section discusses the GNU-specific regexp operators, and provides more detail concerning how command line options affect the way `gawk` interprets the characters in regular expressions.

Additional Regexp Operators Only in gawk

GNU software that deals with regular expressions provides a number of additional regexp operators. These operators are described in this section, and are specific to `gawk`; they are not available in other `awk` implementations.

Most of the additional operators are for dealing with word matching. For our purposes, a word is a sequence of one or more letters, digits, or underscores (`_').

`\w`

This operator matches any word-constituent character, i.e. any letter, digit, or underscore. Think of it as a short-hand for `[[:alnum:]_]`.

`\W`

This operator matches any character that is not word-constituent. Think of it as a short-hand for `[^[:alnum:]_]`.

`\<`

This operator matches the empty string at the beginning of a word. For example, `/\<away/` matches `away', but not `stowaway'.

`\>`

This operator matches the empty string at the end of a word. For example, `/stow\>/` matches `stow', but not `stowaway'.

`\y`

This operator matches the empty string at either the beginning or the end of a word (the word boundary). For example, `\yballs?\y' matches either `ball' or `balls' as a separate word.

`\B`

This operator matches the empty string within a word. In other words, `\B' matches the empty string that occurs between two word-constituent characters. For example, `/\Brat\B/` matches

`crate', but it does not match `dirty rat'. `\B' is essentially the opposite of `\y'.

There are two other operators that work on buffers. In Emacs, a buffer is, naturally, an Emacs buffer. For other programs, the regexp library routines that `gawk` uses consider the entire string to be matched as the buffer.

For `awk`, since `^' and `$' always work in terms of the beginning and end of strings, these operators don't add any new capabilities. They are provided for compatibility with other GNU software.

`\``

This operator matches the empty string at the beginning of the buffer.

`\'`

This operator matches the empty string at the end of the buffer.

In other GNU software, the word boundary operator is `\b'. However, that conflicts with the `awk` language's definition of `\b' as backspace, so `gawk` uses a different letter.

An alternative method would have been to require two backslashes in the GNU operators, but this was deemed to be too confusing, and the current method of using `\y' for the GNU `\b' appears to be the lesser of two evils.

The various command line options (see section Command Line Options) control how `gawk` interprets characters in regexps.

No options

In the default case, `gawk` provide all the facilities of POSIX regexps and the GNU regexp operators described above. However, interval expressions are not supported.

`--posix`

Only POSIX regexps are supported, the GNU operators are not special (e.g., `\w' matches a literal `w'). Interval expressions are allowed.

`--traditional`

Traditional Unix `awk` regexps are matched. The GNU operators are not special, interval expressions are not available, and neither are the POSIX character classes (`[[:alnum:]]` and so on). Characters described by octal and hexadecimal escape sequences are treated literally, even if they represent regexp metacharacters.

`--re-interval`

Allow interval expressions in regexps, even if `--traditional' has been provided.

Case-sensitivity in Matching

Case is normally significant in regular expressions, both when matching ordinary characters (i.e. not metacharacters), and inside character sets. Thus a `w' in a regular expression matches only a lower-case `w' and not an upper-case `W'.

The simplest way to do a case-independent match is to use a character list: `[Ww]'. However, this can be cumbersome if you need to use it often; and it can make the regular expressions harder to read. There are

two alternatives that you might prefer.

One way to do a case-insensitive match at a particular point in the program is to convert the data to a single case, using the `tolower` or `toupper` built-in string functions (which we haven't discussed yet; see section Built-in Functions for String Manipulation). For example:

```
tolower($1) ~ /foo/  { ... }
```

converts the first field to lower-case before matching against it. This will work in any POSIX-compliant implementation of `awk`.

Another method, specific to `gawk`, is to set the variable `IGNORECASE` to a non-zero value (see section Built-in Variables). When `IGNORECASE` is not zero, *all* regexp and string operations ignore case. Changing the value of `IGNORECASE` dynamically controls the case sensitivity of your program as it runs. Case is significant by default because `IGNORECASE` (like most variables) is initialized to zero.

```
x = "aB"
if (x ~ /ab/) ...   # this test will fail

IGNORECASE = 1
if (x ~ /ab/) ...   # now it will succeed
```

In general, you cannot use `IGNORECASE` to make certain rules case-insensitive and other rules case-sensitive, because there is no way to set `IGNORECASE` just for the pattern of a particular rule. To do this, you must use character lists or `tolower`. However, one thing you can do only with `IGNORECASE` is turn case-sensitivity on or off dynamically for all the rules at once.

`IGNORECASE` can be set on the command line, or in a `BEGIN` rule (see section Other Command Line Arguments; also see section Startup and Cleanup Actions). Setting `IGNORECASE` from the command line is a way to make a program case-insensitive without having to edit it.

Prior to version 3.0 of `gawk`, the value of `IGNORECASE` only affected regexp operations. It did not affect string comparison with `==', `!=', and so on. Beginning with version 3.0, both regexp and string comparison operations are affected by `IGNORECASE`.

Beginning with version 3.0 of `gawk`, the equivalences between upper-case and lower-case characters are based on the ISO-8859-1 (ISO Latin-1) character set. This character set is a superset of the traditional 128 ASCII characters, that also provides a number of characters suitable for use with European languages.

The value of `IGNORECASE` has no effect if `gawk` is in compatibility mode (see section Command Line Options). Case is always significant in compatibility mode.

How Much Text Matches?

Consider the following example:

```
echo aaaabcd | awk '{ sub(/a+/, "<A>"); print }'
```

This example uses the `sub` function (which we haven't discussed yet, see section Built-in Functions for String Manipulation) to make a change to the input record. Here, the regexp `/a+/` indicates "one or more `a' characters," and the replacement text is `<A>'.

The input contains four `a' characters. What will the output be? In other words, how many is "one or more"---will `awk` match two, three, or all four `a' characters?

The answer is, `awk` (and POSIX) regular expressions always match the leftmost, *longest* sequence of input characters that can match. Thus, in this example, all four `a' characters are replaced with `<A>'.

```
$ echo aaaabcd | awk '{ sub(/a+/, "<A>"); print }'
-| <A>bcd
```

For simple match/no-match tests, this is not so important. But when doing regexp-based field and record splitting, and text matching and substitutions with the `match`, `sub`, `gsub`, and `gensub` functions, it is very important. Understanding this principle is also important for regexp-based record and field splitting (see section How Input is Split into Records, and also see section Specifying How Fields are Separated).

Using Dynamic Regexps

The right hand side of a `~' or `!~' operator need not be a regexp constant (i.e. a string of characters between slashes). It may be any expression. The expression is evaluated, and converted if necessary to a string; the contents of the string are used as the regexp. A regexp that is computed in this way is called a dynamic regexp. For example:

```
BEGIN { identifier_regexp = "[A-Za-z_][A-Za-z_0-9]+" }
$0 ~ identifier_regexp    { print }
```

sets `identifier_regexp` to a regexp that describes `awk` variable names, and tests if the input record matches this regexp.

Caution: When using the `~' and `!~' operators, there is a difference between a regexp constant enclosed in slashes, and a string constant enclosed in double quotes. If you are going to use a string constant, you have to understand that the string is in essence scanned *twice*; the first time when `awk` reads your program, and the second time when it goes to match the string on the left-hand side of the operator with the pattern on the right. This is true of any string valued expression (such as `identifier_regexp` above), not just string constants.

What difference does it make if the string is scanned twice? The answer has to do with escape sequences,

and particularly with backslashes. To get a backslash into a regular expression inside a string, you ha to type two backslashes.

For example, `/\*/` is a regexp constant for a literal `*'. Only one backslash is needed. To do the same thing with a string, you would have to type `"*"`. The first backslash escapes the second one, so that the string actually contains the two characters `\' and `*'.

Given that you can use both regexp and string constants to describe regular expressions, which should you use? The answer is "regexp constants," for several reasons.

1. String constants are more complicated to write, and more difficult to read. Using regexp constants makes your programs less error-prone. Not understanding the difference between the two kinds of constants is a common source of errors.
2. It is also more efficient to use regexp constants: `awk` can note that you have supplied a regexp and store it internally in a form that makes pattern matching more efficient. When using a string constant, `awk` must first convert the string into this internal form, and then perform the pattern matching.
3. Using regexp constants is better style; it shows clearly that you intend a regexp match.

Go to the previous, next section.

Go to the previous, next section.

Reading Input Files

In the typical `awk` program, all input is read either from the standard input (by default the keyboard, but often a pipe from another command) or from files whose names you specify on the `awk` command line. If you specify input files, `awk` reads them in order, reading all the data from one before going on to the next. The name of the current input file can be found in the built-in variable `FILENAME` (see section Built-in Variables).

The input is read in units called records, and processed by the rules of your program one record at a time. By default, each record is one line. Each record is automatically split into chunks called fields. This makes it more convenient for programs to work on the parts of a record.

On rare occasions you will need to use the `getline` command. The `getline` command is valuable, both because it can do explicit input from any number of files, and because the files used with it do not have to be named on the `awk` command line (see section Explicit Input with `getline`).

How Input is Split into Records

The `awk` utility divides the input for your `awk` program into records and fields. Records are separated by a character called the record separator. By default, the record separator is the newline character. This is why records are, by default, single lines. You can use a different character for the record separator by assigning the character to the built-in variable `RS`.

You can change the value of `RS` in the `awk` program, like any other variable, with the assignment operator, `=' (see section Assignment Expressions). The new record-separator character should be enclosed in quotation marks, which indicate a string constant. Often the right time to do this is at the beginning of execution, before any input has been processed, so that the very first record will be read with the proper separator. To do this, use the special `BEGIN` pattern (see section The `BEGIN` and `END` Special Patterns). For example:

```
awk 'BEGIN { RS = "/" } ; { print $0 }' BBS-list
```

changes the value of `RS` to `"/"`, before reading any input. This is a string whose first character is a slash; as a result, records are separated by slashes. Then the input file is read, and the second rule in the `awk` program (the action with no pattern) prints each record. Since each `print` statement adds a newline at the end of its output, the effect of this `awk` program is to copy the input with each slash changed to a newline. Here are the results of running the program on `` `BBS-list' ``:

```
$ awk 'BEGIN { RS = "/" } ; { print $0 }' BBS-list
-| aardvark     555-5553     1200
-| 300          B
-| alpo-net     555-3412     2400
```

```
-| 1200
-| 300     A
-| barfly        555-7685     1200
-| 300           A
-| bites         555-1675     2400
-| 1200
-| 300     A
-| camelot       555-0542     300                C
-| core          555-2912     1200
-| 300           C
-| fooey         555-1234     2400
-| 1200
-| 300     B
-| foot          555-6699     1200
-| 300           B
-| macfoo        555-6480     1200
-| 300           A
-| sdace         555-3430     2400
-| 1200
-| 300     A
-| sabafoo       555-2127     1200
-| 300           C
-|
```

Note that the entry for the `camelot' BBS is not split. In the original data file (see section Data Files for the Examples), the line looks like this:

```
camelot       555-0542     300                C
```

It only has one baud rate; there are no slashes in the record.

Another way to change the record separator is on the command line, using the variable-assignment feature (see section Other Command Line Arguments).

```
awk '{ print $0 }' RS="/" BBS-list
```

This sets RS to `/' before processing `BBS-list'.

Using an unusual character such as `/' for the record separator produces correct behavior in the vast majority of cases. However, the following (extreme) pipeline prints a surprising `1'. There is one field, consisting of a newline. The value of the built-in variable NF is the number of fields in the current record.

```
$ echo | awk 'BEGIN { RS = "a" } ; { print NF }'
-| 1
```

Reaching the end of an input file terminates the current input record, even if the last character in the file is not the character in RS (d.c.).

The empty string, "" (a string of no characters), has a special meaning as the value of RS: it means that records are separated by one or more blank lines, and nothing else. See section Multiple-Line Records for more details.

If you change the value of RS in the middle of an awk run, the new value is used to delimit subsequent records, but the record currently being processed (and records already processed) are not affected.

After the end of the record has been determined, gawk sets the variable RT to the text in the input that matched RS.

The value of RS is in fact not limited to a one-character string. It can be any regular expression (see section Regular Expressions). In general, each record ends at the next string that matches the regular expression; the next record starts at the end of the matching string. This general rule is actually at work in the usual case, where RS contains just a newline: a record ends at the beginning of the next matching string (the next newline in the input) and the following record starts just after the end of this string (at the first character of the following line). The newline, since it matches RS, is not part of either record.

When RS is a single character, RT will contain the same single character. However, when RS is a regular expression, then RT becomes more useful; it contains the actual input text that matched the regular expression.

The following example illustrates both of these features. It sets RS equal to a regular expression that matches either a newline, or a series of one or more upper-case letters with optional leading and/or trailing white space (see section Regular Expressions).

```
$ echo record 1 AAAA record 2 BBBB record 3 |
> gawk 'BEGIN { RS = "\n|( *[[:upper:]]+ *)" }
>             { print "Record =", $0, "and RT =", RT }'
-| Record = record 1 and RT =  AAAA
-| Record = record 2 and RT =  BBBB
-| Record = record 3 and RT =
-|
```

The final line of output has an extra blank line. This is because the value of RT is a newline, and then the print statement supplies its own terminating newline.

See section A Simple Stream Editor, for a more useful example of RS as a regexp and RT.

The use of RS as a regular expression and the RT variable are gawk extensions; they are not available in compatibility mode (see section Command Line Options). In compatibility mode, only the first character of the value of RS is used to determine the end of the record.

The awk utility keeps track of the number of records that have been read so far from the current input file. This value is stored in a built-in variable called FNR. It is reset to zero when a new file is started. Another built-in variable, NR, is the total number of input records read so far from all data files. It starts at zero but is never automatically reset to zero.

Examining Fields

When `awk` reads an input record, the record is automatically separated or parsed by the interpreter into chunks called fields. By default, fields are separated by whitespace, like words in a line. Whitespace in `awk` means any string of one or more spaces and/or tabs; other characters such as newline, formfeed, and so on, that are considered whitespace by other languages are *not* considered whitespace by `awk`.

The purpose of fields is to make it more convenient for you to refer to these pieces of the record. You don't have to use them--you can operate on the whole record if you wish--but fields are what make simple `awk` programs so powerful.

To refer to a field in an `awk` program, you use a dollar-sign, `$', followed by the number of the field you want. Thus, `$1` refers to the first field, `$2` to the second, and so on. For example, suppose the following is a line of input:

```
This seems like a pretty nice example.
```

Here the first field, or `$1`, is `This'; the second field, or `$2`, is `seems'; and so on. Note that the last field, `$7`, is `example.'. Because there is no space between the `e' and the `.', the period is considered part of the seventh field.

`NF` is a built-in variable whose value is the number of fields in the current record. `awk` updates the value of `NF` automatically, each time a record is read.

No matter how many fields there are, the last field in a record can be represented by `$NF`. So, in the example above, `$NF` would be the same as `$7`, which is `example.'. Why this works is explained below (see section Non-constant Field Numbers). If you try to reference a field beyond the last one, such as `$8` when the record has only seven fields, you get the empty string.

`$0`, which looks like a reference to the "zeroth" field, is a special case: it represents the whole input record. `$0` is used when you are not interested in fields.

Here are some more examples:

```
$ awk '$1 ~ /foo/ { print $0 }' BBS-list
-| fooey         555-1234     2400/1200/300     B
-| foot          555-6699     1200/300          B
-| macfoo        555-6480     1200/300          A
-| sabafoo       555-2127     1200/300          C
```

This example prints each record in the file `BBS-list` whose first field contains the string `foo'. The operator `~' is called a matching operator (see section How to Use Regular Expressions); it tests whether a string (here, the field `$1`) matches a given regular expression.

By contrast, the following example looks for `foo' in *the entire record* and prints the first field and the last field for each input record containing a match.

```
$ awk '/foo/ { print $1, $NF }' BBS-list
-| fooey B
-| foot B
-| macfoo A
-| sabafoo C
```

Non-constant Field Numbers

The number of a field does not need to be a constant. Any expression in the `awk` language can be used after a `$' to refer to a field. The value of the expression specifies the field number. If the value is a string, rather than a number, it is converted to a number. Consider this example:

```
awk '{ print $NR }'
```

Recall that `NR` is the number of records read so far: one in the first record, two in the second, etc. So this example prints the first field of the first record, the second field of the second record, and so on. For the twentieth record, field number 20 is printed; most likely, the record has fewer than 20 fields, so this prints a blank line.

Here is another example of using expressions as field numbers:

```
awk '{ print $(2*2) }' BBS-list
```

`awk` must evaluate the expression `(2*2)' and use its value as the number of the field to print. The `*' sign represents multiplication, so the expression `2*2' evaluates to four. The parentheses are used so that the multiplication is done before the `$' operation; they are necessary whenever there is a binary operator in the field-number expression. This example, then, prints the hours of operation (the fourth field) for every line of the file `BBS-list'. (All of the `awk` operators are listed, in order of decreasing precedence, in section Operator Precedence (How Operators Nest).)

If the field number you compute is zero, you get the entire record. Thus, `$(2-2)` has the same value as `$0`. Negative field numbers are not allowed; trying to reference one will usually terminate your running `awk` program. (The POSIX standard does not define what happens when you reference a negative field number. `gawk` will notice this and terminate your program. Other `awk` implementations may behave differently.)

As mentioned in section Examining Fields, the number of fields in the current record is stored in the built-in variable `NF` (also see section Built-in Variables). The expression `$NF` is not a special feature: it is the direct consequence of evaluating `NF` and using its value as a field number.

Changing the Contents of a Field

You can change the contents of a field as seen by `awk` within an `awk` program; this changes what `awk` perceives as the current input record. (The actual input is untouched; `awk` *never* modifies the input file.)

Consider this example and its output:

```
$ awk '{ $3 = $2 - 10; print $2, $3 }' inventory-shipped
-| 13 3
-| 15 5
-| 15 5
...
```

The `-' sign represents subtraction, so this program reassigns field three, `$3', to be the value of field two minus ten, `$2 - 10'. (See section Arithmetic Operators.) Then field two, and the new value for field three, are printed.

In order for this to work, the text in field `$2' must make sense as a number; the string of characters must be converted to a number in order for the computer to do arithmetic on it. The number resulting from the subtraction is converted back to a string of characters which then becomes field three. See section Conversion of Strings and Numbers.

When you change the value of a field (as perceived by `awk'), the text of the input record is recalculated to contain the new field where the old one was. Therefore, `$0' changes to reflect the altered field. Thus, this program prints a copy of the input file, with 10 subtracted from the second field of each line.

```
$ awk '{ $2 = $2 - 10; print $0 }' inventory-shipped
-| Jan 3 25 15 115
-| Feb 5 32 24 226
-| Mar 5 24 34 228
...
```

You can also assign contents to fields that are out of range. For example:

```
$ awk '{ $6 = ($5 + $4 + $3 + $2)
>        print $6 }' inventory-shipped
-| 168
-| 297
-| 301
...
```

We've just created `$6', whose value is the sum of fields `$2', `$3', `$4', and `$5'. The `+' sign represents addition. For the file `inventory-shipped', `$6' represents the total number of parcels shipped for a particular month.

Creating a new field changes `awk''s internal copy of the current input record--the value of `$0'. Thus, if you do `print $0' after adding a field, the record printed includes the new field, with the appropriate number of field separators between it and the previously existing fields.

This recomputation affects and is affected by `NF' (the number of fields; see section Examining Fields), and by a feature that has not been discussed yet, the output field separator, `OFS', which is used to separate the fields (see section Output Separators). For example, the value of `NF' is set to the number of

the highest field you create.

Note, however, that merely *referencing* an out-of-range field does *not* change the value of either `$0` or `NF`. Referencing an out-of-range field only produces an empty string. For example:

```
if ($(NF+1) != "")
    print "can't happen"
else
    print "everything is normal"
```

should print `everything is normal', because `NF+1` is certain to be out of range. (See section The `if-else` Statement, for more information about `awk`'s `if-else` statements. See section Variable Typing and Comparison Expressions, for more information about the `!=' operator.)

It is important to note that making an assignment to an existing field will change the value of `$0`, but will not change the value of `NF`, even when you assign the empty string to a field. For example:

```
$ echo a b c d | awk '{ OFS = ":"; $2 = ""
>                       print $0; print NF }'
-| a::c:d
-| 4
```

The field is still there; it just has an empty value. You can tell because there are two colons in a row.

This example shows what happens if you create a new field.

```
$ echo a b c d | awk '{ OFS = ":"; $2 = ""; $6 = "new"
>                       print $0; print NF }'
-| a::c:d::new
-| 6
```

The intervening field, `$5` is created with an empty value (indicated by the second pair of adjacent colons), and `NF` is updated with the value six.

Specifying How Fields are Separated

This section is rather long; it describes one of the most fundamental operations in `awk`.

The Basics of Field Separating

The field separator, which is either a single character or a regular expression, controls the way `awk` splits an input record into fields. `awk` scans the input record for character sequences that match the separator; the fields themselves are the text between the matches.

In the examples below, we use the bullet symbol "*" to represent spaces in the output.

If the field separator is `oo', then the following line:

```
moo goo gai pan
```

would be split into three fields: `m', `*g' and `*gai*pan'. Note the leading spaces in the values of the second and third fields.

The field separator is represented by the built-in variable `FS`. Shell programmers take note! `awk` does *not* use the name `IFS` which is used by the POSIX compatible shells (such as the Bourne shell, `sh`, or the GNU Bourne-Again Shell, Bash).

You can change the value of `FS` in the `awk` program with the assignment operator, `=' (see section Assignment Expressions). Often the right time to do this is at the beginning of execution, before any input has been processed, so that the very first record will be read with the proper separator. To do this, use the special `BEGIN` pattern (see section The `BEGIN` and `END` Special Patterns). For example, here we set the value of `FS` to the string `","`:

```
awk 'BEGIN { FS = "," } ; { print $2 }'
```

Given the input line,

```
John Q. Smith, 29 Oak St., Walamazoo, MI 42139
```

this `awk` program extracts and prints the string `*29*Oak*St.'.

Sometimes your input data will contain separator characters that don't separate fields the way you thought they would. For instance, the person's name in the example we just used might have a title or suffix attached, such as `John Q. Smith, LXIX'. From input containing such a name:

```
John Q. Smith, LXIX, 29 Oak St., Walamazoo, MI 42139
```

the above program would extract `*LXIX', instead of `*29*Oak*St.'. If you were expecting the program to print the address, you would be surprised. The moral is: choose your data layout and separator characters carefully to prevent such problems.

As you know, normally, fields are separated by whitespace sequences (spaces and tabs), not by single spaces: two spaces in a row do not delimit an empty field. The default value of the field separator `FS` is a string containing a single space, `" "`. If this value were interpreted in the usual way, each space character would separate fields, so two spaces in a row would make an empty field between them. The reason this does not happen is that a single space as the value of `FS` is a special case: it is taken to specify the default manner of delimiting fields.

If `FS` is any other single character, such as `","`, then each occurrence of that character separates two fields. Two consecutive occurrences delimit an empty field. If the character occurs at the beginning or the end of the line, that too delimits an empty field. The space character is the only single character which does not follow these rules.

Using Regular Expressions to Separate Fields

The previous subsection discussed the use of single characters or simple strings as the value of FS. More generally, the value of FS may be a string containing any regular expression. In this case, each match in the record for the regular expression separates fields. For example, the assignment:

```
FS = ", \t"
```

makes every area of an input line that consists of a comma followed by a space and a tab, into a field separator. (`\t' is an escape sequence that stands for a tab; see section Escape Sequences, for the complete list of similar escape sequences.)

For a less trivial example of a regular expression, suppose you want single spaces to separate fields the way single commas were used above. You can set FS to "[ ]" (left bracket, space, right bracket). This regular expression matches a single space and nothing else (see section Regular Expressions).

There is an important difference between the two cases of `FS = " "' (a single space) and `FS = "[\t]+"' (left bracket, space, backslash, "t", right bracket, which is a regular expression matching one or more spaces or tabs). For both values of FS, fields are separated by runs of spaces and/or tabs. However, when the value of FS is " ", awk will first strip leading and trailing whitespace from the record, and then decide where the fields are.

For example, the following pipeline prints `b':

```
$ echo ' a b c d ' | awk '{ print $2 }'
-| b
```

However, this pipeline prints `a' (note the extra spaces around each letter):

```
$ echo ' a  b  c  d ' | awk 'BEGIN { FS = "[ \t]+" }
>                                  { print $2 }'
-| a
```

In this case, the first field is null, or empty.

The stripping of leading and trailing whitespace also comes into play whenever $0 is recomputed. For instance, study this pipeline:

```
$ echo '   a b c d' | awk '{ print; $2 = $2; print }'
-|    a b c d
-| a b c d
```

The first print statement prints the record as it was read, with leading whitespace intact. The assignment to $2 rebuilds $0 by concatenating $1 through $NF together, separated by the value of OFS. Since the leading whitespace was ignored when finding $1, it is not part of the new $0. Finally, the last print statement prints the new $0.

Making Each Character a Separate Field

There are times when you may want to examine each character of a record separately. In gawk, this is easy to do, you simply assign the null string ("") to FS. In this case, each individual character in the record will become a separate field. Here is an example:

```
echo a b | gawk 'BEGIN { FS = "" }
                 {
                     for (i = 1; i <= NF; i = i + 1)
                         print "Field", i, "is", $i
                 }'
```

The output from this is:

```
Field 1 is a
Field 2 is
Field 3 is b
```

Traditionally, the behavior for FS equal to "" was not defined. In this case, Unix awk would simply treat the entire record as only having one field (d.c.). In compatibility mode (see section Command Line Options), if FS is the null string, then gawk will also behave this way.

Setting FS from the Command Line

FS can be set on the command line. You use the `-F' option to do so. For example:

```
awk -F, 'program' input-files
```

sets FS to be the `,' character. Notice that the option uses a capital `F'. Contrast this with `-f', which specifies a file containing an awk program. Case is significant in command line options: the `-F' and `-f' options have nothing to do with each other. You can use both options at the same time to set the FS variable *and* get an awk program from a file.

The value used for the argument to `-F' is processed in exactly the same way as assignments to the built-in variable FS. This means that if the field separator contains special characters, they must be escaped appropriately. For example, to use a `\' as the field separator, you would have to type:

```
# same as FS = "\\"
awk -F\\\\ '...' files ...
```

Since `\' is used for quoting in the shell, awk will see `-F\\'. Then awk processes the `\\' for escape characters (see section Escape Sequences), finally yielding a single `\' to be used for the field separator.

As a special case, in compatibility mode (see section Command Line Options), if the argument to `-F' is `t', then FS is set to the tab character. This is because if you type `-F\t' at the shell, without any quotes, the `\' gets deleted, so awk figures that you really want your fields to be separated with tabs, and not `t's.

Use `-v FS="t"' on the command line if you really do want to separate your fields with `t's (see section Command Line Options).

For example, let's use an awk program file called `baud.awk' that contains the pattern /300/, and the action `print $1'. Here is the program:

```
/300/   { print $1 }
```

Let's also set FS to be the `-' character, and run the program on the file `BBS-list'. The following command prints a list of the names of the bulletin boards that operate at 300 baud and the first three digits of their phone numbers:

```
$ awk -F- -f baud.awk BBS-list
-| aardvark     555
-| alpo
-| barfly       555
...
```

Note the second line of output. In the original file (see section Data Files for the Examples), the second line looked like this:

```
alpo-net     555-3412     2400/1200/300     A
```

The `-' as part of the system's name was used as the field separator, instead of the `-' in the phone number that was originally intended. This demonstrates why you have to be careful in choosing your field and record separators.

On many Unix systems, each user has a separate entry in the system password file, one line per user. The information in these lines is separated by colons. The first field is the user's logon name, and the second is the user's encrypted password. A password file entry might look like this:

```
arnold:xyzzy:2076:10:Arnold Robbins:/home/arnold:/bin/sh
```

The following program searches the system password file, and prints the entries for users who have no password:

```
awk -F: '$2 == ""' /etc/passwd
```

Field Splitting Summary

According to the POSIX standard, awk is supposed to behave as if each record is split into fields at the time that it is read. In particular, this means that you can change the value of FS after a record is read, and the value of the fields (i.e. how they were split) should reflect the old value of FS, not the new one.

However, many implementations of awk do not work this way. Instead, they defer splitting the fields until a field is actually referenced. The fields will be split using the *current* value of FS! (d.c.) This

behavior can be difficult to diagnose. The following example illustrates the difference between the tw methods. (The `sed`(5) command prints just the first line of `/etc/passwd'.)

```
sed 1q /etc/passwd | awk '{ FS = ":" ; print $1 }'
```

will usually print

```
root
```

on an incorrect implementation of `awk`, while `gawk` will print something like

```
root:nSijPlPhZZwgE:0:0:Root:/:
```

The following table summarizes how fields are split, based on the value of `FS`. (`==' means "is equal to.")

`FS == " "`
: Fields are separated by runs of whitespace. Leading and trailing whitespace are ignored. This is the default.

`FS == any other single character`
: Fields are separated by each occurrence of the character. Multiple successive occurrences delimit empty fields, as do leading and trailing occurrences. The character can even be a regexp metacharacter; it does not need to be escaped.

`FS == regexp`
: Fields are separated by occurrences of characters that match regexp. Leading and trailing matches of regexp delimit empty fields.

`FS == ""`
: Each individual character in the record becomes a separate field.

Reading Fixed-width Data

(This section discusses an advanced, experimental feature. If you are a novice `awk` user, you may wish to skip it on the first reading.)

`gawk` version 2.13 introduced a new facility for dealing with fixed-width fields with no distinctive field separator. Data of this nature arises, for example, in the input for old FORTRAN programs where numbers are run together; or in the output of programs that did not anticipate the use of their output as input for other programs.

An example of the latter is a table where all the columns are lined up by the use of a variable number of spaces and *empty fields are just spaces*. Clearly, `awk`'s normal field splitting based on `FS` will not work well in this case. Although a portable `awk` program can use a series of `substr` calls on `$0` (see section Built-in Functions for String Manipulation), this is awkward and inefficient for a large number of fields.

The splitting of an input record into fixed-width fields is specified by assigning a string containing

space-separated numbers to the built-in variable `FIELDWIDTHS`. Each number specifies the width of a field *including* columns between fields. If you want to ignore the columns between fields, you can specify the width as a separate field that is subsequently ignored.

The following data is the output of the Unix `w` utility. It is useful to illustrate the use of `FIELDWIDTHS`.

```
 10:06pm  up 21 days, 14:04,  23 users
User     tty       login  idle   JCPU   PCPU  what
hzuo     ttyV0     8:58pm            9      5  vi p24.tex
hzang    ttyV3     6:37pm    50                -csh
eklye    ttyV5     9:53pm             7      1  em thes.tex
dportein ttyV6     8:17pm  1:47                -csh
gierd    ttyD3    10:00pm     1                elm
dave     ttyD4     9:47pm             4      4  w
brent    ttyp0    26Jun91  4:46  26:46   4:41  bash
dave     ttyq4    26Jun9115days     46     46  wnewmail
```

The following program takes the above input, converts the idle time to number of seconds and prints out the first two fields and the calculated idle time. (This program uses a number of `awk` features that haven't been introduced yet.)

```
BEGIN  { FIELDWIDTHS = "9 6 10 6 7 7 35" }
NR > 2 {
    idle = $4
    sub(/^  */, "", idle)   # strip leading spaces
    if (idle == "")
        idle = 0
    if (idle ~ /:/) {
        split(idle, t, ":")
        idle = t[1] * 60 + t[2]
    }
    if (idle ~ /days/)
        idle *= 24 * 60 * 60

    print $1, $2, idle
}
```

Here is the result of running the program on the data:

```
hzuo      ttyV0  0
hzang     ttyV3  50
eklye     ttyV5  0
dportein  ttyV6  107
gierd     ttyD3  1
dave      ttyD4  0
brent     ttyp0  286
```

```
dave      ttyq4  1296000
```

Another (possibly more practical) example of fixed-width input data would be the input from a deck of balloting cards. In some parts of the United States, voters mark their choices by punching holes in computer cards. These cards are then processed to count the votes for any particular candidate or on any particular issue. Since a voter may choose not to vote on some issue, any column on the card may be empty. An `awk` program for processing such data could use the `FIELDWIDTHS` feature to simplify reading the data. (Of course, getting `gawk` to run on a system with card readers is another story!)

Assigning a value to `FS` causes `gawk` to return to using `FS` for field splitting. Use `FS = FS' to make this happen, without having to know the current value of `FS`.

This feature is still experimental, and may evolve over time. Note that in particular, `gawk` does not attempt to verify the sanity of the values used in the value of `FIELDWIDTHS`.

Multiple-Line Records

In some data bases, a single line cannot conveniently hold all the information in one entry. In such cases, you can use multi-line records.

The first step in doing this is to choose your data format: when records are not defined as single lines, how do you want to define them? What should separate records?

One technique is to use an unusual character or string to separate records. For example, you could use the formfeed character (written `\f' in `awk`, as in C) to separate them, making each record a page of the file. To do this, just set the variable `RS` to `"\f"` (a string containing the formfeed character). Any other character could equally well be used, as long as it won't be part of the data in a record.

Another technique is to have blank lines separate records. By a special dispensation, an empty string as the value of `RS` indicates that records are separated by one or more blank lines. If you set `RS` to the empty string, a record always ends at the first blank line encountered. And the next record doesn't start until the first non-blank line that follows--no matter how many blank lines appear in a row, they are considered one record-separator.

You can achieve the same effect as `RS = "" by assigning the string `"\n\n+"` to `RS`. This regexp matches the newline at the end of the record, and one or more blank lines after the record. In addition, a regular expression always matches the longest possible sequence when there is a choice (see section How Much Text Matches?) So the next record doesn't start until the first non-blank line that follows--no matter how many blank lines appear in a row, they are considered one record-separator.

There is an important difference between `RS = "" and `RS = "\n\n+"'. In the first case, leading newlines in the input data file are ignored, and if a file ends without extra blank lines after the last record, the final newline is removed from the record. In the second case, this special processing is not done (d.c.).

Now that the input is separated into records, the second step is to separate the fields in the record. One way to do this is to divide each of the lines into fields in the normal manner. This happens by default as the result of a special feature: when `RS` is set to the empty string, the newline character *always* acts as a field separator. This is in addition to whatever field separations result from `FS`.

The original motivation for this special exception was probably to provide useful behavior in the default case (i.e. FS is equal to " "). This feature can be a problem if you really don't want the newline character to separate fields, since there is no way to prevent it. However, you can work around this by using the `split` function to break up the record manually (see section Built-in Functions for String Manipulation).

Another way to separate fields is to put each field on a separate line: to do this, just set the variable FS to the string `"\n"`. (This simple regular expression matches a single newline.)

A practical example of a data file organized this way might be a mailing list, where each entry is separated by blank lines. If we have a mailing list in a file named `` `addresses' ``, that looks like this:

```
Jane Doe
123 Main Street
Anywhere, SE 12345-6789

John Smith
456 Tree-lined Avenue
Smallville, MW 98765-4321

...
```

A simple program to process this file would look like this:

```
# addrs.awk -- simple mailing list program

# Records are separated by blank lines.
# Each line is one field.
BEGIN { RS = "" ; FS = "\n" }

{
      print "Name is:", $1
      print "Address is:", $2
      print "City and State are:", $3
      print ""
}
```

Running the program produces the following output:

```
$ awk -f addrs.awk addresses
-| Name is: Jane Doe
-| Address is: 123 Main Street
-| City and State are: Anywhere, SE 12345-6789
-|
-| Name is: John Smith
-| Address is: 456 Tree-lined Avenue
```

```
-| City and State are: Smallville, MW 98765-4321
-|
...
```

See section Printing Mailing Labels, for a more realistic program that deals with address lists.

The following table summarizes how records are split, based on the value of RS. (`==' means "is equal to.")

`RS == "\n"`

Records are separated by the newline character (`\n'). In effect, every line in the data file is a separate record, including blank lines. This is the default.

`RS == any single character`

Records are separated by each occurrence of the character. Multiple successive occurrences delimit empty records.

`RS == ""`

Records are separated by runs of blank lines. The newline character always serves as a field separator, in addition to whatever value FS may have. Leading and trailing newlines in a file are ignored.

`RS == regexp`

Records are separated by occurrences of characters that match regexp. Leading and trailing matches of regexp delimit empty records.

In all cases, gawk sets RT to the input text that matched the value specified by RS.

Explicit Input with `getline`

So far we have been getting our input data from awk's main input stream--either the standard input (usually your terminal, sometimes the output from another program) or from the files specified on the command line. The awk language has a special built-in command called `getline` that can be used to read input under your explicit control.

Introduction to `getline`

This command is used in several different ways, and should *not* be used by beginners. It is covered here because this is the chapter on input. The examples that follow the explanation of the `getline` command include material that has not been covered yet. Therefore, come back and study the `getline` command *after* you have reviewed the rest of this book and have a good knowledge of how awk works.

`getline` returns one if it finds a record, and zero if the end of the file is encountered. If there is some error in getting a record, such as a file that cannot be opened, then `getline` returns -1. In this case, gawk sets the variable ERRNO to a string describing the error that occurred.

In the following examples, command stands for a string value that represents a shell command.

Using `getline` with No Arguments

The `getline` command can be used without arguments to read input from the current input file. All it does in this case is read the next input record and split it up into fields. This is useful if you've finished processing the current record, but you want to do some special processing *right now* on the next record. Here's an example:

```
awk '{
     if ((t = index($0, "/*")) != 0) {
          # value will be "" if t is 1
          tmp = substr($0, 1, t - 1)
          u = index(substr($0, t + 2), "*/")
          while (u == 0) {
               if (getline <= 0) {
                    m = "unexpected EOF or error"
                    m = (m ": " ERRNO)
                    print m > "/dev/stderr"
                    exit
               }
               t = -1
               u = index($0, "*/")
          }
          # substr expression will be "" if */
          # occurred at end of line
          $0 = tmp substr($0, t + u + 3)
     }
     print $0
}'
```

This `awk` program deletes all C-style comments, `/* ... */', from the input. By replacing the `print $0' with other statements, you could perform more complicated processing on the decommented input, like searching for matches of a regular expression. This program has a subtle problem--it does not work if one comment ends and another begins on the same line.

This form of the `getline` command sets `NF` (the number of fields; see section Examining Fields), `NR` (the number of records read so far; see section How Input is Split into Records), `FNR` (the number of records read from this input file), and the value of `$0`.

Note: the new value of `$0` is used in testing the patterns of any subsequent rules. The original value of `$0` that triggered the rule which executed `getline` is lost (d.c.). By contrast, the `next` statement reads a new record but immediately begins processing it normally, starting with the first rule in the program. See section The `next` Statement.

Using `getline` Into a Variable

You can use `getline var' to read the next record from `awk`'s input into the variable var. No other processing is done.

For example, suppose the next line is a comment, or a special string, and you want to read it, without triggering any rules. This form of `getline` allows you to read that line and store it in a variable so that the main read-a-line-and-check-each-rule loop of `awk` never sees it.

The following example swaps every two lines of input. For example, given:

```
wan
tew
free
phore
```

it outputs:

```
tew
wan
phore
free
```

Here's the program:

```
awk '{
     if ((getline tmp) > 0) {
          print tmp
          print $0
     } else
          print $0
}'
```

The `getline` command used in this way sets only the variables `NR` and `FNR` (and of course, var). The record is not split into fields, so the values of the fields (including `$0`) and the value of `NF` do not change.

Using `getline` from a File

Use `getline < file' to read the next record from the file file. Here file is a string-valued expression that specifies the file name. `< file' is called a redirection since it directs input to come from a different place.

For example, the following program reads its input record from the file `` `secondary.input' `` when it encounters a first field with a value equal to 10 in the current input file.

```
awk '{
```

```
    if ($1 == 10) {
         getline < "secondary.input"
         print
    } else
         print
}'
```

Since the main input stream is not used, the values of `NR` and `FNR` are not changed. But the record read is split into fields in the normal manner, so the values of `$0` and other fields are changed. So is the value of `NF`.

Using `getline` Into a Variable from a File

Use `getline var < file' to read input the file file and put it in the variable var. As above, file is a string-valued expression that specifies the file from which to read.

In this version of `getline`, none of the built-in variables are changed, and the record is not split into fields. The only variable changed is var.

For example, the following program copies all the input files to the output, except for records that say `@include filename'. Such a record is replaced by the contents of the file filename.

```
awk '{
     if (NF == 2 && $1 == "@include") {
          while ((getline line < $2) > 0)
               print line
          close($2)
     } else
          print
}'
```

Note here how the name of the extra input file is not built into the program; it is taken directly from the data, from the second field on the `@include' line.

The `close` function is called to ensure that if two identical `@include' lines appear in the input, the entire specified file is included twice. See section Closing Input and Output Files and Pipes.

One deficiency of this program is that it does not process nested `@include' statements (`@include' statements in included files) the way a true macro preprocessor would. See section An Easy Way to Use Library Functions, for a program that does handle nested `@include' statements.

Using `getline` from a Pipe

You can pipe the output of a command into `getline`, using `command | getline'. In this case, the string command is run as a shell command and its output is piped into `awk` to be used as input. This form of `getline` reads one record at a time from the pipe.

For example, the following program copies its input to its output, except for lines that begin with `@execute', which are replaced by the output produced by running the rest of the line as a shell command:

```
awk '{
     if ($1 == "@execute") {
          tmp = substr($0, 10)
          while ((tmp | getline) > 0)
               print
          close(tmp)
     } else
          print
}'
```

The `close` function is called to ensure that if two identical `@execute' lines appear in the input, the command is run for each one. See section Closing Input and Output Files and Pipes.

Given the input:

```
foo
bar
baz
@execute who
bletch
```

the program might produce:

```
foo
bar
baz
arnold     ttyv0   Jul 13 14:22
miriam     ttyp0   Jul 13 14:23     (murphy:0)
bill       ttyp1   Jul 13 14:23     (murphy:0)
bletch
```

Notice that this program ran the command `who` and printed the result. (If you try this program yourself, you will of course get different results, showing you who is logged in on your system.)

This variation of `getline` splits the record into fields, sets the value of `NF` and recomputes the value of `$0`. The values of `NR` and `FNR` are not changed.

Using `getline` Into a Variable from a Pipe

When you use `command | getline var', the output of the command command is sent through a pipe to `getline` and into the variable var. For example, the following program reads the current date and time into the variable `current_time`, using the `date` utility, and then prints it.

```
awk 'BEGIN {
     "date" | getline current_time
     close("date")
     print "Report printed on " current_time
}'
```

In this version of `getline`, none of the built-in variables are changed, and the record is not split into fields.

Summary of `getline` Variants

With all the forms of `getline`, even though `$0` and `NF`, may be updated, the record will not be tested against all the patterns in the `awk` program, in the way that would happen if the record were read normally by the main processing loop of `awk`. However the new record is tested against any subsequent rules.

Many `awk` implementations limit the number of pipelines an `awk` program may have open to just one! In `gawk`, there is no such limit. You can open as many pipelines as the underlying operating system will permit.

The following table summarizes the six variants of `getline`, listing which built-in variables are set by each one.

`getline`
: sets `$0`, `NF`, `FNR`, and `NR`.

`getline var`
: sets var, `FNR`, and `NR`.

`getline < file`
: sets `$0`, and `NF`.

`getline var < file`
: sets var.

`command | getline`
: sets `$0`, and `NF`.

`command | getline var`
: sets var.

Printing Output

One of the most common actions is to print, or output, some or all of the input. You use the `print` statement for simple output. You use the `printf` statement for fancier formatting. Both are described in this chapter.

The `print` Statement

The `print` statement does output with simple, standardized formatting. You specify only the strings or numbers to be printed, in a list separated by commas. They are output, separated by single spaces, followed by a newline. The statement looks like this:

```
print item1, item2, ...
```

The entire list of items may optionally be enclosed in parentheses. The parentheses are necessary if any of the item expressions uses the `>' relational operator; otherwise it could be confused with a redirection (see section Redirecting Output of `print` and `printf`).

The items to be printed can be constant strings or numbers, fields of the current record (such as `$1`), variables, or any `awk` expressions. Numeric values are converted to strings, and then printed.

The `print` statement is completely general for computing *what* values to print. However, with two exceptions, you cannot specify *how* to print them--how many columns, whether to use exponential notation or not, and so on. (For the exceptions, see section Output Separators, and section Controlling Numeric Output with `print`.) For that, you need the `printf` statement (see section Using `printf` Statements for Fancier Printing).

The simple statement `print' with no items is equivalent to `print $0': it prints the entire current record. To print a blank line, use `print "", where `""` is the empty string.

To print a fixed piece of text, use a string constant such as `"Don't Panic"` as one item. If you forget to use the double-quote characters, your text will be taken as an `awk` expression, and you will probably get an error. Keep in mind that a space is printed between any two items.

Each `print` statement makes at least one line of output. But it isn't limited to one line. If an item value is a string that contains a newline, the newline is output along with the rest of the string. A single `print` can make any number of lines this way.

Examples of `print` Statements

Here is an example of printing a string that contains embedded newlines (the `\n' is an escape sequence, used to represent the newline character; see section Escape Sequences):

```
$ awk 'BEGIN { print "line one\nline two\nline three" }'
-| line one
-| line two
-| line three
```

Here is an example that prints the first two fields of each input record, with a space between them:

```
$ awk '{ print $1, $2 }' inventory-shipped
-| Jan 13
-| Feb 15
-| Mar 15
...
```

A common mistake in using the `print` statement is to omit the comma between two items. This often has the effect of making the items run together in the output, with no space. The reason for this is that juxtaposing two string expressions in `awk` means to concatenate them. Here is the same program, without the comma:

```
$ awk '{ print $1 $2 }' inventory-shipped
-| Jan13
-| Feb15
-| Mar15
...
```

To someone unfamiliar with the file `inventory-shipped', neither example's output makes much sense. A heading line at the beginning would make it clearer. Let's add some headings to our table of months (`$1`) and green crates shipped (`$2`). We do this using the `BEGIN` pattern (see section The `BEGIN` and `END` Special Patterns) to force the headings to be printed only once:

```
awk 'BEGIN {  print "Month Crates"
              print "-----  ------" }
           {  print $1, $2 }' inventory-shipped
```

Did you already guess what happens? When run, the program prints the following:

```
Month Crates
-----  ------
Jan 13
Feb 15
Mar 15
```

```
...
```

The headings and the table data don't line up! We can fix this by printing some spaces between the two fields:

```
awk 'BEGIN { print "Month Crates"
             print "-----  ------" }
           { print $1, "     ", $2 }' inventory-shipped
```

You can imagine that this way of lining up columns can get pretty complicated when you have many columns to fix. Counting spaces for two or three columns can be simple, but more than this and you can get lost quite easily. This is why the `printf` statement was created (see section Using `printf` Statements for Fancier Printing); one of its specialties is lining up columns of data.

As a side point, you can continue either a `print` or `printf` statement simply by putting a newline after any comma (see section `awk` Statements Versus Lines).

Output Separators

As mentioned previously, a `print` statement contains a list of items, separated by commas. In the output, the items are normally separated by single spaces. This need not be the case; a single space is only the default. You can specify any string of characters to use as the output field separator by setting the built-in variable `OFS`. The initial value of this variable is the string `" "`, that is, a single space.

The output from an entire `print` statement is called an output record. Each `print` statement outputs one output record and then outputs a string called the output record separator. The built-in variable `ORS` specifies this string. The initial value of `ORS` is the string `"\n"`, i.e. a newline character; thus, normally each `print` statement makes a separate line.

You can change how output fields and records are separated by assigning new values to the variables `OFS` and/or `ORS`. The usual place to do this is in the `BEGIN` rule (see section The `BEGIN` and `END` Special Patterns), so that it happens before any input is processed. You may also do this with assignments on the command line, before the names of your input files, or using the `-v' command line option (see section Command Line Options).

The following example prints the first and second fields of each input record separated by a semicolon, with a blank line added after each line:

```
$ awk 'BEGIN { OFS = ";"; ORS = "\n\n" }
>            { print $1, $2 }' BBS-list
-| aardvark;555-5553
-|
-| alpo-net;555-3412
-|
-| barfly;555-7685
...
```

If the value of `ORS` does not contain a newline, all your output will be run together on a single line, unless you output newlines some other way.

Controlling Numeric Output with `print`

When you use the `print` statement to print numeric values, `awk` internally converts the number to a string of characters, and prints that string. `awk` uses the `sprintf` function to do this conversion (see section Built-in Functions for String Manipulation). For now, it suffices to say that the `sprintf` function accepts a format specification that tells it how to format numbers (or strings), and that there are a number of different ways in which numbers can be formatted. The different format specifications are discussed more fully in section Format-Control Letters.

The built-in variable `OFMT` contains the default format specification that `print` uses with `sprintf` when it wants to convert a number to a string for printing. The default value of `OFMT` is `"%.6g"`. By supplying different format specifications as the value of `OFMT`, you can change how `print` will print your numbers. As a brief example:

```
$ awk 'BEGIN {
>   OFMT = "%.0f"  # print numbers as integers (rounds)
>   print 17.23 }'
-| 17
```

According to the POSIX standard, `awk`'s behavior will be undefined if `OFMT` contains anything but a floating point conversion specification (d.c.).

Using `printf` Statements for Fancier Printing

If you want more precise control over the output format than `print` gives you, use `printf`. With `printf` you can specify the width to use for each item, and you can specify various formatting choices for numbers (such as what radix to use, whether to print an exponent, whether to print a sign, and how many digits to print after the decimal point). You do this by supplying a string, called the format string, which controls how and where to print the other arguments.

Introduction to the `printf` Statement

The `printf` statement looks like this:

```
printf format, item1, item2, ...
```

The entire list of arguments may optionally be enclosed in parentheses. The parentheses are necessary if any of the item expressions use the `>' relational operator; otherwise it could be confused with a redirection (see section Redirecting Output of `print` and `printf`).

The difference between `printf` and `print` is the format argument. This is an expression whose value

is taken as a string; it specifies how to output each of the other arguments. It is called the format strin

The format string is very similar to that in the ANSI C library function `printf`. Most of format is text to be output verbatim. Scattered among this text are format specifiers, one per item. Each format specifier says to output the next item in the argument list at that place in the format.

The `printf` statement does not automatically append a newline to its output. It outputs only what the format string specifies. So if you want a newline, you must include one in the format string. The output separator variables `OFS` and `ORS` have no effect on `printf` statements. For example:

```
BEGIN {
   ORS = "\nOUCH!\n"; OFS = "!"
   msg = "Don't Panic!"; printf "%s\n", msg
}
```

This program still prints the familiar `Don't Panic!' message.

Format-Control Letters

A format specifier starts with the character `%' and ends with a format-control letter; it tells the `printf` statement how to output one item. (If you actually want to output a `%', write `%%'.) The format-control letter specifies what kind of value to print. The rest of the format specifier is made up of optional modifiers which are parameters to use, such as the field width.

Here is a list of the format-control letters:

`c`

This prints a number as an ASCII character. Thus, `printf "%c", 65' outputs the letter `A'. The output for a string value is the first character of the string.

`d`

`i`

These are equivalent. They both print a decimal integer. The `%i' specification is for compatibility with ANSI C.

`e`

`E`

This prints a number in scientific (exponential) notation. For example,

```
printf "%4.3e\n", 1950
```

prints `1.950e+03', with a total of four significant figures of which three follow the decimal point. The `4.3' are modifiers, discussed below. `%E' uses `E' instead of `e' in the output.

`f`

This prints a number in floating point notation. For example,

```
printf "%4.3f", 1950
```

prints `1950.000', with a total of four significant figures of which three follow the decimal po
The `4.3' are modifiers, discussed below.

`g`
`G`

This prints a number in either scientific notation or floating point notation, whichever uses fewer characters. If the result is printed in scientific notation, `%G' uses `E' instead of `e'.

`o`

This prints an unsigned octal integer. (In octal, or base-eight notation, the digits run from `0' to `7'; the decimal number eight is represented as `10' in octal.)

`s`

This prints a string.

`x`
`X`

This prints an unsigned hexadecimal integer. (In hexadecimal, or base-16 notation, the digits are `0' through `9' and `a' through `f'. The hexadecimal digit `f' represents the decimal number 15.) `%X' uses the letters `A' through `F' instead of `a' through `f'.

`%`

This isn't really a format-control letter, but it does have a meaning when used after a `%': the sequence `%%' outputs one `%'. It does not consume an argument, and it ignores any modifiers.

When using the integer format-control letters for values that are outside the range of a C `long` integer, `gawk` will switch to the `%g' format specifier. Other versions of `awk` may print invalid values, or do something else entirely (d.c.).

Modifiers for `printf` Formats

A format specification can also include modifiers that can control how much of the item's value is printed and how much space it gets. The modifiers come between the `%' and the format-control letter. In the examples below, we use the bullet symbol "*" to represent spaces in the output. Here are the possible modifiers, in the order in which they may appear:

`-`

The minus sign, used before the width modifier (see below), says to left-justify the argument within its specified width. Normally the argument is printed right-justified in the specified width. Thus,

```
printf "%-4s", "foo"
```

prints `foo*'.

`space`

For numeric conversions, prefix positive values with a space, and negative values with a minus sign.

`+`

The plus sign, used before the width modifier (see below), says to always supply a sign for numeric conversions, even if the data to be formatted is positive. The `+' overrides the space modifier.

`#`

Use an "alternate form" for certain control letters. For `%o', supply a leading zero. For `%x', and `%X', supply a leading `0x' or `0X' for a non-zero result. For `%e', `%E', and `%f', the result will always contain a decimal point. For `%g', and `%G', trailing zeros are not removed from the result.

`0`

A leading `0' (zero) acts as a flag, that indicates output should be padded with zeros instead of spaces. This applies even to non-numeric output formats (d.c.). This flag only has an effect when the field width is wider than the value to be printed.

`width`

This is a number specifying the desired minimum width of a field. Inserting any number between the `%' sign and the format control character forces the field to be expanded to this width. The default way to do this is to pad with spaces on the left. For example,

```
printf "%4s", "foo"
```

prints `*foo'.

The value of width is a minimum width, not a maximum. If the item value requires more than width characters, it can be as wide as necessary. Thus,

```
printf "%4s", "foobar"
```

prints `foobar'.

Preceding the width with a minus sign causes the output to be padded with spaces on the right, instead of on the left.

`.prec`

This is a number that specifies the precision to use when printing. For the `e', `E', and `f' formats, this specifies the number of digits you want printed to the right of the decimal point. For the `g', and `G' formats, it specifies the maximum number of significant digits. For the `d', `o', `i', `u', `x', and `X' formats, it specifies the minimum number of digits to print. For a string, it specifies the maximum number of characters from the string that should be printed. Thus,

```
printf "%.4s", "foobar"
```

prints `foob'.

The C library `printf`'s dynamic width and prec capability (for example, `"%*.*s"`) is supported. Instead of supplying explicit width and/or prec values in the format string, you pass them in the argument list. For example:

```
w = 5
p = 3
s = "abcdefg"
printf "%*.*s\n", w, p, s
```

is exactly equivalent to

```
s = "abcdefg"
printf "%5.3s\n", s
```

Both programs output `**abc'.

Earlier versions of `awk` did not support this capability. If you must use such a version, you may simulate this feature by using concatenation to build up the format string, like so:

```
w = 5
p = 3
s = "abcdefg"
printf "%" w "." p "s\n", s
```

This is not particularly easy to read, but it does work.

C programmers may be used to supplying additional `l' and `h' flags in `printf` format strings. These are not valid in `awk`. Most `awk` implementations silently ignore these flags. If `--lint' is provided on the command line (see section Command Line Options), `gawk` will warn about their use. If `--posix' is supplied, their use is a fatal error.

Examples Using `printf`

Here is how to use `printf` to make an aligned table:

```
awk '{ printf "%-10s %s\n", $1, $2 }' BBS-list
```

prints the names of bulletin boards (`$1`) of the file `` `BBS-list' `` as a string of 10 characters, left justified. It also prints the phone numbers (`$2`) afterward on the line. This produces an aligned two-column table of names and phone numbers:

```
$ awk '{ printf "%-10s %s\n", $1, $2 }' BBS-list
-| aardvark   555-5553
-| alpo-net   555-3412
-| barfly     555-7685
-| bites      555-1675
-| camelot    555-0542
-| core       555-2912
-| fooey      555-1234
```

```
-| foot       555-6699
-| macfoo     555-6480
-| sdace      555-3430
-| sabafoo    555-2127
```

Did you notice that we did not specify that the phone numbers be printed as numbers? They had to be printed as strings because the numbers are separated by a dash. If we had tried to print the phone numbers as numbers, all we would have gotten would have been the first three digits, `555'. This would have been pretty confusing.

We did not specify a width for the phone numbers because they are the last things on their lines. We don't need to put spaces after them.

We could make our table look even nicer by adding headings to the tops of the columns. To do this, we use the `BEGIN` pattern (see section The `BEGIN` and `END` Special Patterns) to force the header to be printed only once, at the beginning of the `awk` program:

```
awk 'BEGIN { print "Name      Number"
             print "----      ------" }
     { printf "%-10s %s\n", $1, $2 }' BBS-list
```

Did you notice that we mixed `print` and `printf` statements in the above example? We could have used just `printf` statements to get the same results:

```
awk 'BEGIN { printf "%-10s %s\n", "Name", "Number"
             printf "%-10s %s\n", "----", "------" }
     { printf "%-10s %s\n", $1, $2 }' BBS-list
```

By printing each column heading with the same format specification used for the elements of the column, we have made sure that the headings are aligned just like the columns.

The fact that the same format specification is used three times can be emphasized by storing it in a variable, like this:

```
awk 'BEGIN { format = "%-10s %s\n"
             printf format, "Name", "Number"
             printf format, "----", "------" }
     { printf format, $1, $2 }' BBS-list
```

See if you can use the `printf` statement to line up the headings and table data for our `inventory-shipped' example covered earlier in the section on the `print` statement (see section The `print` Statement).

Redirecting Output of `print` and `printf`

So far we have been dealing only with output that prints to the standard output, usually your terminal. Both `print` and `printf` can also send their output to other places. This is called redirection.

A redirection appears after the `print` or `printf` statement. Redirections in `awk` are written just like redirections in shell commands, except that they are written inside the `awk` program.

There are three forms of output redirection: output to a file, output appended to a file, and output through a pipe to another command. They are all shown for the `print` statement, but they work identically for `printf` also.

`print items > output-file`

This type of redirection prints the items into the output file output-file. The file name output-file can be any expression. Its value is changed to a string and then used as a file name (see section Expressions).

When this type of redirection is used, the output-file is erased before the first output is written to it. Subsequent writes to the same output-file do not erase output-file, but append to it. If output-file does not exist, then it is created.

For example, here is how an `awk` program can write a list of BBS names to a file `` `name-list' `` and a list of phone numbers to a file `` `phone-list' ``. Each output file contains one name or number per line.

```
$ awk '{ print $2 > "phone-list"
>        print $1 > "name-list" }' BBS-list
$ cat phone-list
-| 555-5553
-| 555-3412
...
$ cat name-list
-| aardvark
-| alpo-net
...
```

`print items >> output-file`

This type of redirection prints the items into the pre-existing output file output-file. The difference between this and the single-`>' redirection is that the old contents (if any) of output-file are not erased. Instead, the `awk` output is appended to the file. If output-file does not exist, then it is created.

`print items | command`

It is also possible to send output to another program through a pipe instead of into a file. This type of redirection opens a pipe to command and writes the values of items through this pipe, to another process created to execute command.

The redirection argument command is actually an `awk` expression. Its value is converted to a

string, whose contents give the shell command to be run.

For example, this produces two files, one unsorted list of BBS names and one list sorted in reverse alphabetical order:

```
awk '{ print $1 > "names.unsorted"
       command = "sort -r > names.sorted"
       print $1 | command }' BBS-list
```

Here the unsorted list is written with an ordinary redirection while the sorted list is written by piping through the `sort` utility.

This example uses redirection to mail a message to a mailing list `bug-system'. This might be useful when trouble is encountered in an `awk` script run periodically for system maintenance.

```
report = "mail bug-system"
print "Awk script failed:", $0 | report
m = ("at record number " FNR " of " FILENAME)
print m | report
close(report)
```

The message is built using string concatenation and saved in the variable `m`. It is then sent down the pipeline to the `mail` program.

We call the `close` function here because it's a good idea to close the pipe as soon as all the intended output has been sent to it. See section Closing Input and Output Files and Pipes, for more information on this. This example also illustrates the use of a variable to represent a file or command: it is not necessary to always use a string constant. Using a variable is generally a good idea, since `awk` requires you to spell the string value identically every time.

Redirecting output using `>', `>>', or `|' asks the system to open a file or pipe only if the particular file or command you've specified has not already been written to by your program, or if it has been closed since it was last written to.

Many `awk` implementations limit the number of pipelines an `awk` program may have open to just one! In `gawk`, there is no such limit. You can open as many pipelines as the underlying operating system will permit.

Special File Names in gawk

Running programs conventionally have three input and output streams already available to them for reading and writing. These are known as the standard input, standard output, and standard error output. These streams are, by default, connected to your terminal, but they are often redirected with the shell, via the `<', `<<', `>', `>>', `>&' and `|' operators. Standard error is typically used for writing error messages; the reason we have two separate streams, standard output and standard error, is so that they can be redirected separately.

In other implementations of `awk`, the only way to write an error message to standard error in an `awk` program is as follows:

```
print "Serious error detected!" | "cat 1>&2"
```

This works by opening a pipeline to a shell command which can access the standard error stream which it inherits from the `awk` process. This is far from elegant, and is also inefficient, since it requires a separate process. So people writing `awk` programs often neglect to do this. Instead, they send the error messages to the terminal, like this:

```
print "Serious error detected!" > "/dev/tty"
```

This usually has the same effect, but not always: although the standard error stream is usually the terminal, it can be redirected, and when that happens, writing to the terminal is not correct. In fact, if `awk` is run from a background job, it may not have a terminal at all. Then opening `` `/dev/tty' `` will fail.

`gawk` provides special file names for accessing the three standard streams. When you redirect input or output in `gawk`, if the file name matches one of these special names, then `gawk` directly uses the stream it stands for.

`` `/dev/stdin' ``
: The standard input (file descriptor 0).

`` `/dev/stdout' ``
: The standard output (file descriptor 1).

`` `/dev/stderr' ``
: The standard error output (file descriptor 2).

`` `/dev/fd/N' ``
: The file associated with file descriptor N. Such a file must have been opened by the program initiating the `awk` execution (typically the shell). Unless you take special pains in the shell from which you invoke `gawk`, only descriptors 0, 1 and 2 are available.

The file names `` `/dev/stdin' ``, `` `/dev/stdout' ``, and `` `/dev/stderr' `` are aliases for `` `/dev/fd/0' ``, `` `/dev/fd/1' ``, and `` `/dev/fd/2' ``, respectively, but they are more self-explanatory.

The proper way to write an error message in a `gawk` program is to use `` `/dev/stderr' ``, like this:

```
print "Serious error detected!" > "/dev/stderr"
```

`gawk` also provides special file names that give access to information about the running `gawk` process. Each of these "files" provides a single record of information. To read them more than once, you must first close them with the `close` function (see section Closing Input and Output Files and Pipes). The filenames are:

`` `/dev/pid' ``

Reading this file returns the process ID of the current process, in decimal, terminated with a newline.

`/dev/ppid'

Reading this file returns the parent process ID of the current process, in decimal, terminated with a newline.

`/dev/pgrpid'

Reading this file returns the process group ID of the current process, in decimal, terminated with a newline.

`/dev/user'

Reading this file returns a single record terminated with a newline. The fields are separated with spaces. The fields represent the following information:

$1

The return value of the `getuid` system call (the real user ID number).

$2

The return value of the `geteuid` system call (the effective user ID number).

$3

The return value of the `getgid` system call (the real group ID number).

$4

The return value of the `getegid` system call (the effective group ID number).

If there are any additional fields, they are the group IDs returned by `getgroups` system call. (Multiple groups may not be supported on all systems.)

These special file names may be used on the command line as data files, as well as for I/O redirections within an `awk` program. They may not be used as source files with the `-f' option.

Recognition of these special file names is disabled if `gawk` is in compatibility mode (see section Command Line Options).

Caution: Unless your system actually has a `/dev/fd' directory (or any of the other above listed special files), the interpretation of these file names is done by `gawk` itself. For example, using `/dev/fd/4' for output will actually write on file descriptor 4, and not on a new file descriptor that was `dup`'ed from file descriptor 4. Most of the time this does not matter; however, it is important to *not* close any of the files related to file descriptors 0, 1, and 2. If you do close one of these files, unpredictable behavior will result.

The special files that provide process-related information may disappear in a future version of `gawk`. See section Probable Future Extensions.

Closing Input and Output Files and Pipes

If the same file name or the same shell command is used with `getline` (see section Explicit Input with `getline`) more than once during the execution of an `awk` program, the file is opened (or the command is executed) only the first time. At that time, the first record of input is read from that file or command. The next time the same file or command is used in `getline`, another record is read from it, and so on.

Similarly, when a file or pipe is opened for output, the file name or command associated with it is remembered by `awk` and subsequent writes to the same file or command are appended to the previous writes. The file or pipe stays open until `awk` exits.

This implies that if you want to start reading the same file again from the beginning, or if you want to rerun a shell command (rather than reading more output from the command), you must take special steps. What you must do is use the `close` function, as follows:

```
close(filename)
```

or

```
close(command)
```

The argument filename or command can be any expression. Its value must *exactly* match the string that was used to open the file or start the command (spaces and other "irrelevant" characters included). For example, if you open a pipe with this:

```
"sort -r names" | getline foo
```

then you must close it with this:

```
close("sort -r names")
```

Once this function call is executed, the next `getline` from that file or command, or the next `print` or `printf` to that file or command, will reopen the file or rerun the command.

Because the expression that you use to close a file or pipeline must exactly match the expression used to open the file or run the command, it is good practice to use a variable to store the file name or command. The previous example would become

```
sortcom = "sort -r names"
sortcom | getline foo
...
close(sortcom)
```

This helps avoid hard-to-find typographical errors in your `awk` programs.

Here are some reasons why you might need to close an output file:

- To write a file and read it back later on in the same `awk` program. Close the file when you are finished writing it; then you can start reading it with `getline`.
- To write numerous files, successively, in the same `awk` program. If you don't close the files, eventually you may exceed a system limit on the number of open files in one process. So close each one when you are finished writing it.
- To make a command finish. When you redirect output through a pipe, the command reading the pipe normally continues to try to read input as long as the pipe is open. Often this means the command cannot really do its work until the pipe is closed. For example, if you redirect output to the `mail` program, the message is not actually sent until the pipe is closed.
- To run the same program a second time, with the same arguments. This is not the same thing as giving more input to the first run!

  For example, suppose you pipe output to the `mail` program. If you output several lines redirected to this pipe without closing it, they make a single message of several lines. By contrast, if you close the pipe after each line of output, then each line makes a separate message.

`close` returns a value of zero if the close succeeded. Otherwise, the value will be non-zero. In this case, `gawk` sets the variable `ERRNO` to a string describing the error that occurred.

If you use more files than the system allows you to have open, `gawk` will attempt to multiplex the available open files among your data files. `gawk`'s ability to do this depends upon the facilities of your operating system: it may not always work. It is therefore both good practice and good portability advice to always use `close` on your files when you are done with them.

Go to the previous, next section.

Go to the previous, next section.

Expressions

Expressions are the basic building blocks of `awk` patterns and actions. An expression evaluates to a value, which you can print, test, store in a variable or pass to a function. Additionally, an expression can assign a new value to a variable or a field, with an assignment operator.

An expression can serve as a pattern or action statement on its own. Most other kinds of statements contain one or more expressions which specify data on which to operate. As in other languages, expressions in `awk` include variables, array references, constants, and function calls, as well as combinations of these with various operators.

Constant Expressions

The simplest type of expression is the constant, which always has the same value. There are three types of constants: numeric constants, string constants, and regular expression constants.

Numeric and String Constants

A numeric constant stands for a number. This number can be an integer, a decimal fraction, or a number in scientific (exponential) notation.(6) Here are some examples of numeric constants, which all have the same value:

```
105
1.05e+2
1050e-1
```

A string constant consists of a sequence of characters enclosed in double-quote marks. For example:

```
"parrot"
```

represents the string whose contents are `parrot'. Strings in `gawk` can be of any length and they can contain any of the possible eight-bit ASCII characters including ASCII NUL (character code zero). Other `awk` implementations may have difficulty with some character codes.

Regular Expression Constants

A regexp constant is a regular expression description enclosed in slashes, such as `/^beginning and end$/`. Most regexps used in `awk` programs are constant, but the `~' and `!~' matching operators can also match computed or "dynamic" regexps (which are just ordinary strings or variables that contain a regexp).

Using Regular Expression Constants

When used on the right hand side of the `~' or `!~' operators, a regexp constant merely stands for the regexp that is to be matched.

Regexp constants (such as `/foo/') may be used like simple expressions. When a regexp constant appears by itself, it has the same meaning as if it appeared in a pattern, i.e. `($0 ~ /foo/)' (d.c.) (see section Expressions as Patterns). This means that the two code segments,

```
if ($0 ~ /barfly/ || $0 ~ /camelot/)
    print "found"
```

and

```
if (/barfly/ || /camelot/)
    print "found"
```

are exactly equivalent.

One rather bizarre consequence of this rule is that the following boolean expression is valid, but does not do what the user probably intended:

```
# note that /foo/ is on the left of the ~
if (/foo/ ~ $1) print "found foo"
```

This code is "obviously" testing `$1` for a match against the regexp `/foo/`. But in fact, the expression `/foo/ ~ $1' actually means `($0 ~ /foo/) ~ $1'. In other words, first match the input record against the regexp `/foo/`. The result will be either zero or one, depending upon the success or failure of the match. Then match that result against the first field in the record.

Since it is unlikely that you would ever really wish to make this kind of test, `gawk` will issue a warning when it sees this construct in a program.

Another consequence of this rule is that the assignment statement

```
matches = /foo/
```

will assign either zero or one to the variable `matches`, depending upon the contents of the current input record.

This feature of the language was never well documented until the POSIX specification.

Constant regular expressions are also used as the first argument for the `gensub`, `sub` and `gsub` functions, and as the second argument of the `match` function (see section Built-in Functions for String Manipulation). Modern implementations of `awk`, including `gawk`, allow the third argument of `split` to be a regexp constant, while some older implementations do not (d.c.).

This can lead to confusion when attempting to use regexp constants as arguments to user defined functions (see section User-defined Functions). For example:

```
function mysub(pat, repl, str, global)
{
    if (global)
        gsub(pat, repl, str)
    else
        sub(pat, repl, str)
    return str
}

{
    ...
    text = "hi! hi yourself!"
    mysub(/hi/, "howdy", text, 1)
    ...
}
```

In this example, the programmer wishes to pass a regexp constant to the user-defined function `mysub`, which will in turn pass it on to either `sub` or `gsub`. However, what really happens is that the `pat` parameter will be either one or zero, depending upon whether or not `$0` matches `/hi/`.

As it is unlikely that you would ever really wish to pass a truth value in this way, `gawk` will issue a warning when it sees a regexp constant used as a parameter to a user-defined function.

Variables

Variables are ways of storing values at one point in your program for use later in another part of your program. You can manipulate them entirely within your program text, and you can also assign values to them on the `awk` command line.

Using Variables in a Program

Variables let you give names to values and refer to them later. You have already seen variables in many of the examples. The name of a variable must be a sequence of letters, digits and underscores, but it may not begin with a digit. Case is significant in variable names; `a` and `A` are distinct variables.

A variable name is a valid expression by itself; it represents the variable's current value. Variables are given new values with assignment operators, increment operators and decrement operators. See section Assignment Expressions.

A few variables have special built-in meanings, such as `FS`, the field separator, and `NF`, the number of fields in the current input record. See section Built-in Variables, for a list of them. These built-in variables can be used and assigned just like all other variables, but their values are also used or changed

automatically by `awk`. All built-in variables names are entirely upper-case.

Variables in `awk` can be assigned either numeric or string values. By default, variables are initialized to the empty string, which is zero if converted to a number. There is no need to "initialize" each variable explicitly in `awk`, the way you would in C and in most other traditional languages.

Assigning Variables on the Command Line

You can set any `awk` variable by including a variable assignment among the arguments on the command line when you invoke `awk` (see section Other Command Line Arguments). Such an assignment has this form:

```
variable=text
```

With it, you can set a variable either at the beginning of the `awk` run or in between input files.

If you precede the assignment with the `-v' option, like this:

```
-v variable=text
```

then the variable is set at the very beginning, before even the `BEGIN` rules are run. The `-v' option and its assignment must precede all the file name arguments, as well as the program text. (See section Command Line Options, for more information about the `-v' option.)

Otherwise, the variable assignment is performed at a time determined by its position among the input file arguments: after the processing of the preceding input file argument. For example:

```
awk '{ print $n }' n=4 inventory-shipped n=2 BBS-list
```

prints the value of field number `n` for all input records. Before the first file is read, the command line sets the variable `n` equal to four. This causes the fourth field to be printed in lines from the file `` `inventory-shipped' ``. After the first file has finished, but before the second file is started, `n` is set to two, so that the second field is printed in lines from `` `BBS-list' ``.

```
$ awk '{ print $n }' n=4 inventory-shipped n=2 BBS-list
-| 15
-| 24
...
-| 555-5553
-| 555-3412
...
```

Command line arguments are made available for explicit examination by the `awk` program in an array named `ARGV` (see section Using ARGC and ARGV).

`awk` processes the values of command line assignments for escape sequences (d.c.) (see section Escape Sequences).

Conversion of Strings and Numbers

Strings are converted to numbers, and numbers to strings, if the context of the `awk` program demands it. For example, if the value of either `foo` or `bar` in the expression `foo + bar' happens to be a string, it is converted to a number before the addition is performed. If numeric values appear in string concatenation, they are converted to strings. Consider this:

```
two = 2; three = 3
print (two three) + 4
```

This prints the (numeric) value 27. The numeric values of the variables `two` and `three` are converted to strings and concatenated together, and the resulting string is converted back to the number 23, to which four is then added.

If, for some reason, you need to force a number to be converted to a string, concatenate the empty string, `""`, with that number. To force a string to be converted to a number, add zero to that string.

A string is converted to a number by interpreting any numeric prefix of the string as numerals: `"2.5"` converts to 2.5, `"1e3"` converts to 1000, and `"25fix"` has a numeric value of 25. Strings that can't be interpreted as valid numbers are converted to zero.

The exact manner in which numbers are converted into strings is controlled by the `awk` built-in variable `CONVFMT` (see section Built-in Variables). Numbers are converted using the `sprintf` function (see section Built-in Functions for String Manipulation) with `CONVFMT` as the format specifier.

`CONVFMT`'s default value is `"%.6g"`, which prints a value with at least six significant digits. For some applications you will want to change it to specify more precision. Double precision on most modern machines gives you 16 or 17 decimal digits of precision.

Strange results can happen if you set `CONVFMT` to a string that doesn't tell `sprintf` how to format floating point numbers in a useful way. For example, if you forget the `%' in the format, all numbers will be converted to the same constant string.

As a special case, if a number is an integer, then the result of converting it to a string is *always* an integer, no matter what the value of `CONVFMT` may be. Given the following code fragment:

```
CONVFMT = "%2.2f"
a = 12
b = a ""
```

`b` has the value `"12"`, not `"12.00"` (d.c.).

Prior to the POSIX standard, `awk` specified that the value of `OFMT` was used for converting numbers to strings. `OFMT` specifies the output format to use when printing numbers with `print`. `CONVFMT` was introduced in order to separate the semantics of conversion from the semantics of printing. Both `CONVFMT` and `OFMT` have the same default value: `"%.6g"`. In the vast majority of cases, old `awk`

programs will not change their behavior. However, this use of `OFMT` is something to keep in mind if you must port your program to other implementations of `awk`; we recommend that instead of changing your programs, you just port `gawk` itself! See section The `print` Statement, for more information on the `print` statement.

Arithmetic Operators

The `awk` language uses the common arithmetic operators when evaluating expressions. All of these arithmetic operators follow normal precedence rules, and work as you would expect them to.

Here is a file `` `grades' `` containing a list of student names and three test scores per student (it's a small class):

```
Pat   100 97 58
Sandy  84 72 93
Chris  72 92 89
```

This programs takes the file `` `grades' ``, and prints the average of the scores.

```
$ awk '{ sum = $2 + $3 + $4 ; avg = sum / 3
>        print $1, avg }' grades
-| Pat 85
-| Sandy 83
-| Chris 84.3333
```

This table lists the arithmetic operators in `awk`, in order from highest precedence to lowest:

`- x`

Negation.

`+ x`

Unary plus. The expression is converted to a number.

`x ^ y`

`x ** y`

Exponentiation: x raised to the y power. `2 ^ 3' has the value eight. The character sequence `**' is equivalent to `^'. (The POSIX standard only specifies the use of `^' for exponentiation.)

`x * y`

Multiplication.

`x / y`

Division. Since all numbers in `awk` are real numbers, the result is not rounded to an integer: `3 / 4' has the value 0.75.

`x % y`

Remainder. The quotient is rounded toward zero to an integer, multiplied by y and this result is subtracted from x. This operation is sometimes known as "trunc-mod." The following relation

always holds:

```
b * int(a / b) + (a % b) == a
```

One possibly undesirable effect of this definition of remainder is that `x % y` is negative if x is negative. Thus,

```
-17 % 8 = -1
```

In other `awk` implementations, the signedness of the remainder may be machine dependent.

`x + y`

Addition.

`x - y`

Subtraction.

For maximum portability, do not use the `**' operator.

Unary plus and minus have the same precedence, the multiplication operators all have the same precedence, and addition and subtraction have the same precedence.

String Concatenation

There is only one string operation: concatenation. It does not have a specific operator to represent it. Instead, concatenation is performed by writing expressions next to one another, with no operator. For example:

```
$ awk '{ print "Field number one: " $1 }' BBS-list
-| Field number one: aardvark
-| Field number one: alpo-net
...
```

Without the space in the string constant after the `:', the line would run together. For example:

```
$ awk '{ print "Field number one:" $1 }' BBS-list
-| Field number one:aardvark
-| Field number one:alpo-net
...
```

Since string concatenation does not have an explicit operator, it is often necessary to insure that it happens where you want it to by using parentheses to enclose the items to be concatenated. For example, the following code fragment does not concatenate `file` and `name` as you might expect:

```
file = "file"
name = "name"
print "something meaningful" > file name
```

It is necessary to use the following:

```
print "something meaningful" > (file name)
```

We recommend that you use parentheses around concatenation in all but the most common contexts (such as on the right-hand side of `=').

Assignment Expressions

An assignment is an expression that stores a new value into a variable. For example, let's assign the value one to the variable `z`:

```
z = 1
```

After this expression is executed, the variable `z` has the value one. Whatever old value `z` had before the assignment is forgotten.

Assignments can store string values also. For example, this would store the value `"this food is good"` in the variable `message`:

```
thing = "food"
predicate = "good"
message = "this " thing " is " predicate
```

(This also illustrates string concatenation.)

The `=' sign is called an assignment operator. It is the simplest assignment operator because the value of the right-hand operand is stored unchanged.

Most operators (addition, concatenation, and so on) have no effect except to compute a value. If you ignore the value, you might as well not use the operator. An assignment operator is different; it does produce a value, but even if you ignore the value, the assignment still makes itself felt through the alteration of the variable. We call this a side effect.

The left-hand operand of an assignment need not be a variable (see section Variables); it can also be a field (see section Changing the Contents of a Field) or an array element (see section Arrays in `awk`). These are all called lvalues, which means they can appear on the left-hand side of an assignment operator. The right-hand operand may be any expression; it produces the new value which the assignment stores in the specified variable, field or array element. (Such values are called rvalues).

It is important to note that variables do *not* have permanent types. The type of a variable is simply the type of whatever value it happens to hold at the moment. In the following program fragment, the variable `foo` has a numeric value at first, and a string value later on:

```
foo = 1
print foo
```

```
foo = "bar"
print foo
```

When the second assignment gives `foo` a string value, the fact that it previously had a numeric value is forgotten.

String values that do not begin with a digit have a numeric value of zero. After executing this code, the value of `foo` is five:

```
foo = "a string"
foo = foo + 5
```

(Note that using a variable as a number and then later as a string can be confusing and is poor programming style. The above examples illustrate how `awk` works, *not* how you should write your own programs!)

An assignment is an expression, so it has a value: the same value that is assigned. Thus, `z = 1' as an expression has the value one. One consequence of this is that you can write multiple assignments together:

```
x = y = z = 0
```

stores the value zero in all three variables. It does this because the value of `z = 0', which is zero, is stored into `y`, and then the value of `y = z = 0', which is zero, is stored into `x`.

You can use an assignment anywhere an expression is called for. For example, it is valid to write `x != (y = 1)' to set `y` to one and then test whether `x` equals one. But this style tends to make programs hard to read; except in a one-shot program, you should not use such nesting of assignments.

Aside from `=', there are several other assignment operators that do arithmetic with the old value of the variable. For example, the operator `+=' computes a new value by adding the right-hand value to the old value of the variable. Thus, the following assignment adds five to the value of `foo`:

```
foo += 5
```

This is equivalent to the following:

```
foo = foo + 5
```

Use whichever one makes the meaning of your program clearer.

There are situations where using `+=' (or any assignment operator) is *not* the same as simply repeating the left-hand operand in the right-hand expression. For example:

```
# Thanks to Pat Rankin for this example
BEGIN  {
    foo[rand()] += 5
    for (x in foo)
```

```
        print x, foo[x]

    bar[rand()] = bar[rand()] + 5
    for (x in bar)
        print x, bar[x]
}
```

The indices of `bar` are guaranteed to be different, because `rand` will return different values each time it is called. (Arrays and the `rand` function haven't been covered yet. See section Arrays in `awk`, and see section Numeric Built-in Functions, for more information). This example illustrates an important fact about the assignment operators: the left-hand expression is only evaluated *once*.

It is also up to the implementation as to which expression is evaluated first, the left-hand one or the right-hand one. Consider this example:

```
i = 1
a[i += 2] = i + 1
```

The value of `a[3]` could be either two or four.

Here is a table of the arithmetic assignment operators. In each case, the right-hand operand is an expression whose value is converted to a number.

`lvalue += increment`
: Adds increment to the value of lvalue to make the new value of lvalue.

`lvalue -= decrement`
: Subtracts decrement from the value of lvalue.

`lvalue *= coefficient`
: Multiplies the value of lvalue by coefficient.

`lvalue /= divisor`
: Divides the value of lvalue by divisor.

`lvalue %= modulus`
: Sets lvalue to its remainder by modulus.

`lvalue ^= power`
`lvalue **= power`
: Raises lvalue to the power power. (Only the `^=' operator is specified by POSIX.)

For maximum portability, do not use the `**=' operator.

Increment and Decrement Operators

Increment and decrement operators increase or decrease the value of a variable by one. You could do the same thing with an assignment operator, so the increment operators add no power to the `awk` language; but they are convenient abbreviations for very common operations.

The operator to add one is written `++'. It can be used to increment a variable either before or after ta its value.

To pre-increment a variable v, write `++v'. This adds one to the value of v and that new value is also the value of this expression. The assignment expression `v += 1' is completely equivalent.

Writing the `++' after the variable specifies post-increment. This increments the variable value just the same; the difference is that the value of the increment expression itself is the variable's *old* value. Thus, if `foo` has the value four, then the expression `foo++' has the value four, but it changes the value of `foo` to five.

The post-increment `foo++' is nearly equivalent to writing `(foo += 1) - 1'. It is not perfectly equivalent because all numbers in `awk` are floating point: in floating point, `foo + 1 - 1' does not necessarily equal `foo`. But the difference is minute as long as you stick to numbers that are fairly small (less than 10e12).

Any lvalue can be incremented. Fields and array elements are incremented just like variables. (Use `$(i++)' when you wish to do a field reference and a variable increment at the same time. The parentheses are necessary because of the precedence of the field reference operator, `$'.)

The decrement operator `--' works just like `++' except that it subtracts one instead of adding. Like `++', it can be used before the lvalue to pre-decrement or after it to post-decrement.

Here is a summary of increment and decrement expressions.

`++lvalue`
: This expression increments lvalue and the new value becomes the value of the expression.

`lvalue++`
: This expression increments lvalue, but the value of the expression is the *old* value of lvalue.

`--lvalue`
: Like `++lvalue', but instead of adding, it subtracts. It decrements lvalue and delivers the value that results.

`lvalue--`
: Like `lvalue++', but instead of adding, it subtracts. It decrements lvalue. The value of the expression is the *old* value of lvalue.

True and False in awk

Many programming languages have a special representation for the concepts of "true" and "false." Such languages usually use the special constants `true` and `false`, or perhaps their upper-case equivalents.

`awk` is different. It borrows a very simple concept of true and false from C. In `awk`, any non-zero numeric value, *or* any non-empty string value is true. Any other value (zero or the null string, `""`) is false. The following program will print `A strange truth value' three times:

```
BEGIN {
   if (3.1415927)
```

```
        print "A strange truth value"
    if ("Four Score And Seven Years Ago")
        print "A strange truth value"
    if (j = 57)
        print "A strange truth value"
}
```

There is a surprising consequence of the "non-zero or non-null" rule: The string constant `"0"` is actually true, since it is non-null (d.c.).

Variable Typing and Comparison Expressions

Unlike other programming languages, `awk` variables do not have a fixed type. Instead, they can be either a number or a string, depending upon the value that is assigned to them.

The 1992 POSIX standard introduced the concept of a numeric string, which is simply a string that looks like a number, for example, `" +2"`. This concept is used for determining the type of a variable.

The type of the variable is important, since the types of two variables determine how they are compared.

In `gawk`, variable typing follows these rules.

1. A numeric literal or the result of a numeric operation has the numeric attribute.
2. A string literal or the result of a string operation has the string attribute.
3. Fields, `getline` input, `FILENAME`, `ARGV` elements, `ENVIRON` elements and the elements of an array created by `split` that are numeric strings have the strnum attribute. Otherwise, they have the string attribute. Uninitialized variables also have the strnum attribute.
4. Attributes propagate across assignments, but are not changed by any use.

The last rule is particularly important. In the following program, `a` has numeric type, even though it is later used in a string operation.

```
BEGIN {
        a = 12.345
        b = a " is a cute number"
        print b
}
```

When two operands are compared, either string comparison or numeric comparison may be used, depending on the attributes of the operands, according to the following, symmetric, matrix:

The basic idea is that user input that looks numeric, and *only* user input, should be treated as numeric, even though it is actually made of characters, and is therefore also a string.

Comparison expressions compare strings or numbers for relationships such as equality. They are written using relational operators, which are a superset of those in C. Here is a table of them:

`x < y`

True if x is less than y.

`x <= y`

True if x is less than or equal to y.

`x > y`

True if x is greater than y.

`x >= y`

True if x is greater than or equal to y.

`x == y`

True if x is equal to y.

`x != y`

True if x is not equal to y.

`x ~ y`

True if the string x matches the regexp denoted by y.

`x !~ y`

True if the string x does not match the regexp denoted by y.

`subscript in array`

True if the array array has an element with the subscript subscript.

Comparison expressions have the value one if true and zero if false.

When comparing operands of mixed types, numeric operands are converted to strings using the value of `CONVFMT` (see section Conversion of Strings and Numbers).

Strings are compared by comparing the first character of each, then the second character of each, and so on. Thus `"10"` is less than `"9"`. If there are two strings where one is a prefix of the other, the shorter string is less than the longer one. Thus `"abc"` is less than `"abcd"`.

It is very easy to accidentally mistype the `==' operator, and leave off one of the `='s. The result is still valid `awk` code, but the program will not do what you mean:

```
if (a = b)   # oops! should be a == b
   ...
else
   ...
```

Unless `b` happens to be zero or the null string, the `if` part of the test will always succeed. Because the operators are so similar, this kind of error is very difficult to spot when scanning the source code.

Here are some sample expressions, how `gawk` compares them, and what the result of the comparison is.

`1.5 <= 2.0`

numeric comparison (true)

`"abc" >= "xyz"`

string comparison (false)

```
1.5 != " +2"
```

string comparison (true)

```
"1e2" < "3"
```

string comparison (true)

```
a = 2; b = "2"
a == b
```

string comparison (true)

```
a = 2; b = " +2"
a == b
```

string comparison (false)

In this example,

```
$ echo 1e2 3 | awk '{ print ($1 < $2) ? "true" : "false" }'
-| false
```

the result is `false' since both `$1` and `$2` are numeric strings and thus both have the strnum attribute, dictating a numeric comparison.

The purpose of the comparison rules and the use of numeric strings is to attempt to produce the behavior that is "least surprising," while still "doing the right thing."

String comparisons and regular expression comparisons are very different. For example,

```
x == "foo"
```

has the value of one, or is true, if the variable `x` is precisely `foo'. By contrast,

```
x ~ /foo/
```

has the value one if `x` contains `foo', such as `"Oh, what a fool am I!"`.

The right hand operand of the `~' and `!~' operators may be either a regexp constant (`/.../`), or an ordinary expression, in which case the value of the expression as a string is used as a dynamic regexp (see section How to Use Regular Expressions; also see section Using Dynamic Regexps).

In recent implementations of `awk`, a constant regular expression in slashes by itself is also an expression. The regexp `/regexp/` is an abbreviation for this comparison expression:

```
$0 ~ /regexp/
```

One special place where `/foo/` is *not* an abbreviation for `$0 ~ /foo/' is when it is the right-hand operand of `~' or `!~'! See section Using Regular Expression Constants, where this is discussed in more detail.

Boolean Expressions

A boolean expression is a combination of comparison expressions or matching expressions, using the boolean operators "or" (`||'), "and" (`&&'), and "not" (`!'), along with parentheses to control nesting. The truth value of the boolean expression is computed by combining the truth values of the component expressions. Boolean expressions are also referred to as logical expressions. The terms are equivalent.

Boolean expressions can be used wherever comparison and matching expressions can be used. They can be used in `if`, `while`, `do` and `for` statements (see section Control Statements in Actions). They have numeric values (one if true, zero if false), which come into play if the result of the boolean expression is stored in a variable, or used in arithmetic.

In addition, every boolean expression is also a valid pattern, so you can use one as a pattern to control the execution of rules.

Here are descriptions of the three boolean operators, with examples.

`boolean1 && boolean2`

True if both boolean1 and boolean2 are true. For example, the following statement prints the current input record if it contains both `2400' and `foo'.

```
if ($0 ~ /2400/ && $0 ~ /foo/) print
```

The subexpression boolean2 is evaluated only if boolean1 is true. This can make a difference when boolean2 contains expressions that have side effects: in the case of `$0 ~ /foo/ && ($2 == bar++)', the variable `bar` is not incremented if there is no `foo' in the record.

`boolean1 || boolean2`

True if at least one of boolean1 or boolean2 is true. For example, the following statement prints all records in the input that contain *either* `2400' or `foo', or both.

```
if ($0 ~ /2400/ || $0 ~ /foo/) print
```

The subexpression boolean2 is evaluated only if boolean1 is false. This can make a difference when boolean2 contains expressions that have side effects.

`! boolean`

True if boolean is false. For example, the following program prints all records in the input file `` `BBS-list' `` that do *not* contain the string `foo'.

```
awk '{ if (! ($0 ~ /foo/)) print }' BBS-list
```

The `&&' and `||' operators are called short-circuit operators because of the way they work. Evaluation of the full expression is "short-circuited" if the result can be determined part way through its evaluation.

You can continue a statement that uses `&&' or `||' simply by putting a newline after them. But you cannot put a newline in front of either of these operators without using backslash continuation (see

section awk Statements Versus Lines).

The actual value of an expression using the `!' operator will be either one or zero, depending upon the truth value of the expression it is applied to.

The `!' operator is often useful for changing the sense of a flag variable from false to true and back again. For example, the following program is one way to print lines in between special bracketing lines:

```
$1 == "START"   { interested = ! interested }
interested == 1 { print }
$1 == "END"     { interested = ! interested }
```

The variable `interested`, like all `awk` variables, starts out initialized to zero, which is also false. When a line is seen whose first field is `START', the value of `interested` is toggled to true, using `!'. The next rule prints lines as long as `interested` is true. When a line is seen whose first field is `END', `interested` is toggled back to false.

Conditional Expressions

A conditional expression is a special kind of expression with three operands. It allows you to use one expression's value to select one of two other expressions.

The conditional expression is the same as in the C language:

```
selector ? if-true-exp : if-false-exp
```

There are three subexpressions. The first, selector, is always computed first. If it is "true" (not zero and not null) then if-true-exp is computed next and its value becomes the value of the whole expression. Otherwise, if-false-exp is computed next and its value becomes the value of the whole expression.

For example, this expression produces the absolute value of `x`:

```
x > 0 ? x : -x
```

Each time the conditional expression is computed, exactly one of if-true-exp and if-false-exp is computed; the other is ignored. This is important when the expressions contain side effects. For example, this conditional expression examines element `i` of either array `a` or array `b`, and increments `i`.

```
x == y ? a[i++] : b[i++]
```

This is guaranteed to increment `i` exactly once, because each time only one of the two increment expressions is executed, and the other is not. See section Arrays in awk, for more information about arrays.

As a minor `gawk` extension, you can continue a statement that uses `?:' simply by putting a newline after either character. However, you cannot put a newline in front of either character without using backslash continuation (see section awk Statements Versus Lines).

Function Calls

A function is a name for a particular calculation. Because it has a name, you can ask for it by name at any point in the program. For example, the function `sqrt` computes the square root of a number.

A fixed set of functions are built-in, which means they are available in every `awk` program. The `sqrt` function is one of these. See section Built-in Functions, for a list of built-in functions and their descriptions. In addition, you can define your own functions for use in your program. See section User-defined Functions, for how to do this.

The way to use a function is with a function call expression, which consists of the function name followed immediately by a list of arguments in parentheses. The arguments are expressions which provide the raw materials for the function's calculations. When there is more than one argument, they are separated by commas. If there are no arguments, write just `()' after the function name. Here are some examples:

```
sqrt(x^2 + y^2)         one argument
atan2(y, x)             two arguments
rand()                  no arguments
```

Do not put any space between the function name and the open-parenthesis! A user-defined function name looks just like the name of a variable, and space would make the expression look like concatenation of a variable with an expression inside parentheses. Space before the parenthesis is harmless with built-in functions, but it is best not to get into the habit of using space to avoid mistakes with user-defined functions.

Each function expects a particular number of arguments. For example, the `sqrt` function must be called with a single argument, the number to take the square root of:

```
sqrt(argument)
```

Some of the built-in functions allow you to omit the final argument. If you do so, they use a reasonable default. See section Built-in Functions, for full details. If arguments are omitted in calls to user-defined functions, then those arguments are treated as local variables, initialized to the empty string (see section User-defined Functions).

Like every other expression, the function call has a value, which is computed by the function based on the arguments you give it. In this example, the value of `sqrt(argument)' is the square root of argument. A function can also have side effects, such as assigning values to certain variables or doing I/O.

Here is a command to read numbers, one number per line, and print the square root of each one:

```
$ awk '{ print "The square root of", $1, "is", sqrt($1) }'
1
-| The square root of 1 is 1
```

```
3
-| The square root of 3 is 1.73205
5
-| The square root of 5 is 2.23607
Control-d
```

Operator Precedence (How Operators Nest)

Operator precedence determines how operators are grouped, when different operators appear close by in one expression. For example, `*' has higher precedence than `+'; thus, `a + b * c' means to multiply `b' and `c', and then add `a' to the product (i.e. `a + (b * c)').

You can overrule the precedence of the operators by using parentheses. You can think of the precedence rules as saying where the parentheses are assumed to be if you do not write parentheses yourself. In fact, it is wise to always use parentheses whenever you have an unusual combination of operators, because other people who read the program may not remember what the precedence is in this case. You might forget, too; then you could make a mistake. Explicit parentheses will help prevent any such mistake.

When operators of equal precedence are used together, the leftmost operator groups first, except for the assignment, conditional and exponentiation operators, which group in the opposite order. Thus, `a - b + c' groups as `(a - b) + c', and `a = b = c' groups as `a = (b = c)'.

The precedence of prefix unary operators does not matter as long as only unary operators are involved, because there is only one way to interpret them--innermost first. Thus, `$++i' means `$(++i)' and `++$x' means `++($x)'. However, when another operator follows the operand, then the precedence of the unary operators can matter. Thus, `$x^2' means `($x)^2', but `-x^2' means `-(x^2)', because `-' has lower precedence than `^' while `$' has higher precedence.

Here is a table of `awk''s operators, in order from highest precedence to lowest:

`(...)`
: Grouping.

`$`
: Field.

`++ --`
: Increment, decrement.

`^ **`
: Exponentiation. These operators group right-to-left. (The `**' operator is not specified by POSIX.)

`+ - !`
: Unary plus, minus, logical "not".

`* / %`
: Multiplication, division, modulus.

`+ -`
: Addition, subtraction.

`Concatenation`

No special token is used to indicate concatenation. The operands are simply written side by side.

`< <= == !=`

`> >= >> |`

Relational, and redirection. The relational operators and the redirections have the same precedence level. Characters such as `>' serve both as relationals and as redirections; the context distinguishes between the two meanings.

Note that the I/O redirection operators in `print` and `printf` statements belong to the statement level, not to expressions. The redirection does not produce an expression which could be the operand of another operator. As a result, it does not make sense to use a redirection operator near another operator of lower precedence, without parentheses. Such combinations, for example `print foo > a ? b : c', result in syntax errors. The correct way to write this statement is `print foo > (a ? b : c)'.

`~ !~`

Matching, non-matching.

`in`

Array membership.

`&&`

Logical "and".

`||`

Logical "or".

`?:`

Conditional. This operator groups right-to-left.

`= += -= *=`

`/= %= ^= **=`

Assignment. These operators group right-to-left. (The `**=' operator is not specified by POSIX.)

Go to the previous, next section.

Go to the previous, next section.

Patterns and Actions

As you have already seen, each `awk` statement consists of a pattern with an associated action. This chapter describes how you build patterns and actions.

Pattern Elements

Patterns in `awk` control the execution of rules: a rule is executed when its pattern matches the current input record. This section explains all about how to write patterns.

Kinds of Patterns

Here is a summary of the types of patterns supported in `awk`.

`/regular expression/`

A regular expression as a pattern. It matches when the text of the input record fits the regular expression. (See section Regular Expressions.)

`expression`

A single expression. It matches when its value is non-zero (if a number) or non-null (if a string). (See section Expressions as Patterns.)

`pat1, pat2`

A pair of patterns separated by a comma, specifying a range of records. The range includes both the initial record that matches pat1, and the final record that matches pat2. (See section Specifying Record Ranges with Patterns.)

`BEGIN`

`END`

Special patterns for you to supply start-up or clean-up actions for your `awk` program. (See section The `BEGIN` and `END` Special Patterns.)

`empty`

The empty pattern matches every input record. (See section The Empty Pattern.)

Regular Expressions as Patterns

We have been using regular expressions as patterns since our early examples. This kind of pattern is simply a regexp constant in the pattern part of a rule. Its meaning is `$0 ~ /pattern/'. The pattern matches when the input record matches the regexp. For example:

```
/foo|bar|baz/  { buzzwords++ }
```

```
END             { print buzzwords, "buzzwords seen" }
```

Expressions as Patterns

Any `awk` expression is valid as an `awk` pattern. Then the pattern matches if the expression's value is non-zero (if a number) or non-null (if a string).

The expression is reevaluated each time the rule is tested against a new input record. If the expression uses fields such as `$1`, the value depends directly on the new input record's text; otherwise, it depends only on what has happened so far in the execution of the `awk` program, but that may still be useful.

A very common kind of expression used as a pattern is the comparison expression, using the comparison operators described in section Variable Typing and Comparison Expressions.

Regexp matching and non-matching are also very common expressions. The left operand of the `~' and `!~' operators is a string. The right operand is either a constant regular expression enclosed in slashes (`/regexp/`), or any expression, whose string value is used as a dynamic regular expression (see section Using Dynamic Regexps).

The following example prints the second field of each input record whose first field is precisely `foo'.

```
$ awk '$1 == "foo" { print $2 }' BBS-list
```

(There is no output, since there is no BBS site named "foo".) Contrast this with the following regular expression match, which would accept any record with a first field that contains `foo':

```
$ awk '$1 ~ /foo/ { print $2 }' BBS-list
-| 555-1234
-| 555-6699
-| 555-6480
-| 555-2127
```

Boolean expressions are also commonly used as patterns. Whether the pattern matches an input record depends on whether its subexpressions match.

For example, the following command prints all records in `BBS-list' that contain both `2400' and `foo'.

```
$ awk '/2400/ && /foo/' BBS-list
-| fooey         555-1234     2400/1200/300     B
```

The following command prints all records in `BBS-list' that contain *either* `2400' or `foo', or both.

```
$ awk '/2400/ || /foo/' BBS-list
-| alpo-net     555-3412     2400/1200/300     A
-| bites         555-1675     2400/1200/300     A
-| fooey         555-1234     2400/1200/300     B
```

```
-| foot          555-6699     1200/300          B
-| macfoo        555-6480     1200/300          A
-| sdace         555-3430     2400/1200/300     A
-| sabafoo       555-2127     1200/300          C
```

The following command prints all records in `BBS-list' that do *not* contain the string `foo'.

```
$ awk '! /foo/' BBS-list
-| aardvark     555-5553     1200/300          B
-| alpo-net     555-3412     2400/1200/300     A
-| barfly       555-7685     1200/300          A
-| bites        555-1675     2400/1200/300     A
-| camelot      555-0542     300               C
-| core         555-2912     1200/300          C

```

The subexpressions of a boolean operator in a pattern can be constant regular expressions, comparisons, or any other `awk` expressions. Range patterns are not expressions, so they cannot appear inside boolean patterns. Likewise, the special patterns `BEGIN` and `END`, which never match any input record, are not expressions and cannot appear inside boolean patterns.

A regexp constant as a pattern is also a special case of an expression pattern. `/foo/` as an expression has the value one if `foo' appears in the current input record; thus, as a pattern, `/foo/` matches any record containing `foo'.

Specifying Record Ranges with Patterns

A range pattern is made of two patterns separated by a comma, of the form `begpat, endpat'. It matches ranges of consecutive input records. The first pattern, begpat, controls where the range begins, and the second one, endpat, controls where it ends. For example,

```
awk '$1 == "on", $1 == "off"'
```

prints every record between `on'/`off' pairs, inclusive.

A range pattern starts out by matching begpat against every input record; when a record matches begpat, the range pattern becomes turned on. The range pattern matches this record. As long as it stays turned on, it automatically matches every input record read. It also matches endpat against every input record; when that succeeds, the range pattern is turned off again for the following record. Then it goes back to checking begpat against each record.

The record that turns on the range pattern and the one that turns it off both match the range pattern. If you don't want to operate on these records, you can write `if` statements in the rule's action to distinguish them from the records you are interested in.

It is possible for a pattern to be turned both on and off by the same record, if the record satisfies both conditions. Then the action is executed for just that record.

For example, suppose you have text between two identical markers (say the `%' symbol) that you wish to ignore. You might try to combine a range pattern that describes the delimited text with the `next' statement (not discussed yet, see section The `next' Statement), which causes `awk' to skip any further processing of the current record and start over again with the next input record. Such a program would like this:

```
/^%$/,/^%$/     { next }
                { print }
```

This program fails because the range pattern is both turned on and turned off by the first line with just a `%' on it. To accomplish this task, you must write the program this way, using a flag:

```
/^%$/      { skip = ! skip; next }
skip == 1  { next } # skip lines with `skip' set
```

Note that in a range pattern, the `,' has the lowest precedence (is evaluated last) of all the operators. Thus, for example, the following program attempts to combine a range pattern with another, simpler test.

```
echo Yes | awk '/1/,/2/ || /Yes/'
```

The author of this program intended it to mean `(/1/,/2/) || /Yes/'. However, `awk' interprets this as `/1/,(/2/ || /Yes/)'. This cannot be changed or worked around; range patterns do not combine with other patterns.

The `BEGIN' and `END' Special Patterns

`BEGIN' and `END' are special patterns. They are not used to match input records. Rather, they supply start-up or clean-up actions for your `awk' script.

Startup and Cleanup Actions

A `BEGIN' rule is executed, once, before the first input record has been read. An `END' rule is executed, once, after all the input has been read. For example:

```
$ awk '
> BEGIN { print "Analysis of \"foo\"" }
> /foo/ { ++n }
> END   { print "\"foo\" appears " n " times." }' BBS-list
-| Analysis of "foo"
-| "foo" appears 4 times.
```

This program finds the number of records in the input file `BBS-list' that contain the string `foo'. The `BEGIN' rule prints a title for the report. There is no need to use the `BEGIN' rule to initialize the counter `n' to zero, as `awk' does this automatically (see section Variables).

The second rule increments the variable `n' every time a record containing the pattern `foo' is read. The

END rule prints the value of n at the end of the run.

The special patterns BEGIN and END cannot be used in ranges or with boolean operators (indeed, they cannot be used with any operators).

An awk program may have multiple BEGIN and/or END rules. They are executed in the order they appear, all the BEGIN rules at start-up and all the END rules at termination. BEGIN and END rules may be intermixed with other rules. This feature was added in the 1987 version of awk, and is included in the POSIX standard. The original (1978) version of awk required you to put the BEGIN rule at the beginning of the program, and the END rule at the end, and only allowed one of each. This is no longer required, but it is a good idea in terms of program organization and readability.

Multiple BEGIN and END rules are useful for writing library functions, since each library file can have its own BEGIN and/or END rule to do its own initialization and/or cleanup. Note that the order in which library functions are named on the command line controls the order in which their BEGIN and END rules are executed. Therefore you have to be careful to write such rules in library files so that the order in which they are executed doesn't matter. See section Command Line Options, for more information on using library functions. See section A Library of awk Functions, for a number of useful library functions.

If an awk program only has a BEGIN rule, and no other rules, then the program exits after the BEGIN rule has been run. (The original version of awk used to keep reading and ignoring input until end of file was seen.) However, if an END rule exists, then the input will be read, even if there are no other rules in the program. This is necessary in case the END rule checks the FNR and NR variables (d.c.).

BEGIN and END rules must have actions; there is no default action for these rules since there is no current record when they run.

Input/Output from BEGIN and END Rules

There are several (sometimes subtle) issues involved when doing I/O from a BEGIN or END rule.

The first has to do with the value of $0 in a BEGIN rule. Since BEGIN rules are executed before any input is read, there simply is no input record, and therefore no fields, when executing BEGIN rules. References to $0 and the fields yield a null string or zero, depending upon the context. One way to give $0 a real value is to execute a getline command without a variable (see section Explicit Input with getline). Another way is to simply assign a value to it.

The second point is similar to the first, but from the other direction. Inside an END rule, what is the value of $0 and NF? Traditionally, due largely to implementation issues, $0 and NF were *undefined* inside an END rule. The POSIX standard specified that NF was available in an END rule, containing the number of fields from the last input record. Due most probably to an oversight, the standard does not say that $0 is also preserved, although logically one would think that it should be. In fact, gawk does preserve the value of $0 for use in END rules. Be aware, however, that Unix awk, and possibly other implementations, do not.

The third point follows from the first two. What is the meaning of `print' inside a BEGIN or END rule? The meaning is the same as always, `print $0'. If $0 is the null string, then this prints an empty line. Many long time awk programmers use `print' in BEGIN and END rules, to mean `print ""', relying on $0

being null. While you might generally get away with this in `BEGIN` rules, in `gawk` at least, it is a very bad idea in `END` rules. It is also poor style, since if you want an empty line in the output, you should say so explicitly in your program.

The Empty Pattern

An empty (i.e. non-existent) pattern is considered to match *every* input record. For example, the program:

```
awk '{ print $1 }' BBS-list
```

prints the first field of every record.

Overview of Actions

An `awk` program or script consists of a series of rules and function definitions, interspersed. (Functions are described later. See section User-defined Functions.)

A rule contains a pattern and an action, either of which (but not both) may be omitted. The purpose of the action is to tell `awk` what to do once a match for the pattern is found. Thus, in outline, an `awk` program generally looks like this:

```
[pattern] [{ action }]
[pattern] [{ action }]
...
function name(args) { ... }
...
```

An action consists of one or more `awk` statements, enclosed in curly braces (`{' and `}'). Each statement specifies one thing to be done. The statements are separated by newlines or semicolons.

The curly braces around an action must be used even if the action contains only one statement, or even if it contains no statements at all. However, if you omit the action entirely, omit the curly braces as well. An omitted action is equivalent to `{ print $0 }'.

```
/foo/  { }  # match foo, do nothing - empty action
/foo/       # match foo, print the record - omitted action
```

Here are the kinds of statements supported in `awk`:

- Expressions, which can call functions or assign values to variables (see section Expressions). Executing this kind of statement simply computes the value of the expression. This is useful when the expression has side effects (see section Assignment Expressions).
- Control statements, which specify the control flow of `awk` programs. The `awk` language gives you C-like constructs (`if`, `for`, `while`, and `do`) as well as a few special ones (see section Control Statements in Actions).

- Compound statements, which consist of one or more statements enclosed in curly braces. A compound statement is used in order to put several statements together in the body of an `if`, `while`, `do` or `for` statement.
- Input statements, using the `getline` command (see section Explicit Input with `getline`), the `next` statement (see section The `next` Statement), and the `nextfile` statement (see section The `nextfile` Statement).
- Output statements, `print` and `printf`. See section Printing Output.
- Deletion statements, for deleting array elements. See section The `delete` Statement.

The next chapter covers control statements in detail.

Go to the previous, next section.

Go to the previous, next section.

Control Statements in Actions

Control statements such as `if`, `while`, and so on control the flow of execution in `awk` programs. Most of the control statements in `awk` are patterned on similar statements in C.

All the control statements start with special keywords such as `if` and `while`, to distinguish them from simple expressions.

Many control statements contain other statements; for example, the `if` statement contains another statement which may or may not be executed. The contained statement is called the body. If you want to include more than one statement in the body, group them into a single compound statement with curly braces, separating them with newlines or semicolons.

The `if-else` Statement

The `if-else` statement is `awk`'s decision-making statement. It looks like this:

```
if (condition) then-body [else else-body]
```

The condition is an expression that controls what the rest of the statement will do. If condition is true, then-body is executed; otherwise, else-body is executed. The `else` part of the statement is optional. The condition is considered false if its value is zero or the null string, and true otherwise.

Here is an example:

```
if (x % 2 == 0)
    print "x is even"
else
    print "x is odd"
```

In this example, if the expression `x % 2 == 0' is true (that is, the value of `x` is evenly divisible by two), then the first `print` statement is executed, otherwise the second `print` statement is executed.

If the `else` appears on the same line as then-body, and then-body is not a compound statement (i.e. not surrounded by curly braces), then a semicolon must separate then-body from `else`. To illustrate this, let's rewrite the previous example:

```
if (x % 2 == 0) print "x is even"; else
        print "x is odd"
```

If you forget the `;', `awk` won't be able to interpret the statement, and you will get a syntax error.

We would not actually write this example this way, because a human reader might fail to see the `else` if

it were not the first thing on its line.

The `while` Statement

In programming, a loop means a part of a program that can be executed two or more times in succession.

The `while` statement is the simplest looping statement in `awk`. It repeatedly executes a statement as long as a condition is true. It looks like this:

```
while (condition)
  body
```

Here body is a statement that we call the body of the loop, and condition is an expression that controls how long the loop keeps running.

The first thing the `while` statement does is test condition. If condition is true, it executes the statement body. After body has been executed, condition is tested again, and if it is still true, body is executed again. This process repeats until condition is no longer true. If condition is initially false, the body of the loop is never executed, and `awk` continues with the statement following the loop.

This example prints the first three fields of each record, one per line.

```
awk '{ i = 1
       while (i <= 3) {
           print $i
           i++
       }
}' inventory-shipped
```

Here the body of the loop is a compound statement enclosed in braces, containing two statements.

The loop works like this: first, the value of `i` is set to one. Then, the `while` tests whether `i` is less than or equal to three. This is true when `i` equals one, so the `i`-th field is printed. Then the `i++' increments the value of `i` and the loop repeats. The loop terminates when `i` reaches four.

As you can see, a newline is not required between the condition and the body; but using one makes the program clearer unless the body is a compound statement or is very simple. The newline after the open-brace that begins the compound statement is not required either, but the program would be harder to read without it.

The `do-while` Statement

The `do` loop is a variation of the `while` looping statement. The `do` loop executes the body once, and then repeats body as long as condition is true. It looks like this:

```
do
```

```
  body
while (condition)
```

Even if condition is false at the start, body is executed at least once (and only once, unless executing body makes condition true). Contrast this with the corresponding `while` statement:

```
while (condition)
  body
```

This statement does not execute body even once if condition is false to begin with.

Here is an example of a `do` statement:

```
awk '{ i = 1
       do {
          print $0
          i++
       } while (i <= 10)
}'
```

This program prints each input record ten times. It isn't a very realistic example, since in this case an ordinary `while` would do just as well. But this reflects actual experience; there is only occasionally a real use for a `do` statement.

The `for` Statement

The `for` statement makes it more convenient to count iterations of a loop. The general form of the `for` statement looks like this:

```
for (initialization; condition; increment)
  body
```

The initialization, condition and increment parts are arbitrary `awk` expressions, and body stands for any `awk` statement.

The `for` statement starts by executing initialization. Then, as long as condition is true, it repeatedly executes body and then increment. Typically initialization sets a variable to either zero or one, increment adds one to it, and condition compares it against the desired number of iterations.

Here is an example of a `for` statement:

```
awk '{ for (i = 1; i <= 3; i++)
          print $i
}' inventory-shipped
```

This prints the first three fields of each input record, one field per line.

You cannot set more than one variable in the initialization part unless you use a multiple assignment statement such as `x = y = 0', which is possible only if all the initial values are equal. (But you can initialize additional variables by writing their assignments as separate statements preceding the `for` loop.)

The same is true of the increment part; to increment additional variables, you must write separate statements at the end of the loop. The C compound expression, using C's comma operator, would be useful in this context, but it is not supported in `awk`.

Most often, increment is an increment expression, as in the example above. But this is not required; it can be any expression whatever. For example, this statement prints all the powers of two between one and 100:

```
for (i = 1; i <= 100; i *= 2)
  print i
```

Any of the three expressions in the parentheses following the `for` may be omitted if there is nothing to be done there. Thus, `for (; x > 0;)' is equivalent to `while (x > 0)'. If the condition is omitted, it is treated as true, effectively yielding an infinite loop (i.e. a loop that will never terminate).

In most cases, a `for` loop is an abbreviation for a `while` loop, as shown here:

```
initialization
while (condition) {
  body
  increment
}
```

The only exception is when the `continue` statement (see section The `continue` Statement) is used inside the loop; changing a `for` statement to a `while` statement in this way can change the effect of the `continue` statement inside the loop.

There is an alternate version of the `for` loop, for iterating over all the indices of an array:

```
for (i in array)
    do something with array[i]
```

See section Scanning All Elements of an Array, for more information on this version of the `for` loop.

The `awk` language has a `for` statement in addition to a `while` statement because often a `for` loop is both less work to type and more natural to think of. Counting the number of iterations is very common in loops. It can be easier to think of this counting as part of looping rather than as something to do inside the loop.

The next section has more complicated examples of `for` loops.

The `break` Statement

The `break` statement jumps out of the innermost `for`, `while`, or `do` loop that encloses it. The following example finds the smallest divisor of any integer, and also identifies prime numbers:

```
awk '# find smallest divisor of num
     { num = $1
       for (div = 2; div*div <= num; div++)
         if (num % div == 0)
           break
       if (num % div == 0)
         printf "Smallest divisor of %d is %d\n", num, div
       else
         printf "%d is prime\n", num
     }'
```

When the remainder is zero in the first `if` statement, `awk` immediately breaks out of the containing `for` loop. This means that `awk` proceeds immediately to the statement following the loop and continues processing. (This is very different from the `exit` statement which stops the entire `awk` program. See section The `exit` Statement.)

Here is another program equivalent to the previous one. It illustrates how the condition of a `for` or `while` could just as well be replaced with a `break` inside an `if`:

```
awk '# find smallest divisor of num
     { num = $1
       for (div = 2; ; div++) {
         if (num % div == 0) {
           printf "Smallest divisor of %d is %d\n", num, div
           break
         }
         if (div*div > num) {
           printf "%d is prime\n", num
           break
         }
       }
}'
```

As described above, the `break` statement has no meaning when used outside the body of a loop. However, although it was never documented, historical implementations of `awk` have treated the `break` statement outside of a loop as if it were a `next` statement (see section The `next` Statement). Recent versions of Unix `awk` no longer allow this usage. `gawk` will support this use of `break` only if `--traditional' has been specified on the command line (see section Command Line Options). Otherwise, it will be treated as an error, since the POSIX standard specifies that `break` should only be used inside the body of a loop (d.c.).

The `continue` Statement

The `continue` statement, like `break`, is used only inside `for`, `while`, and `do` loops. It skips over the rest of the loop body, causing the next cycle around the loop to begin immediately. Contrast this with `break`, which jumps out of the loop altogether.

The `continue` statement in a `for` loop directs `awk` to skip the rest of the body of the loop, and resume execution with the increment-expression of the `for` statement. The following program illustrates this fact:

```
awk 'BEGIN {
     for (x = 0; x <= 20; x++) {
         if (x == 5)
             continue
         printf "%d ", x
     }
     print ""
}'
```

This program prints all the numbers from zero to 20, except for five, for which the `printf` is skipped. Since the increment `x++' is not skipped, `x` does not remain stuck at five. Contrast the `for` loop above with this `while` loop:

```
awk 'BEGIN {
     x = 0
     while (x <= 20) {
         if (x == 5)
             continue
         printf "%d ", x
         x++
     }
     print ""
}'
```

This program loops forever once `x` gets to five.

As described above, the `continue` statement has no meaning when used outside the body of a loop. However, although it was never documented, historical implementations of `awk` have treated the `continue` statement outside of a loop as if it were a `next` statement (see section The `next` Statement). Recent versions of Unix `awk` no longer allow this usage. `gawk` will support this use of `continue` only if `--traditional' has been specified on the command line (see section Command Line Options). Otherwise, it will be treated as an error, since the POSIX standard specifies that `continue` should only be used inside the body of a loop (d.c.).

The `next` Statement

The `next` statement forces `awk` to immediately stop processing the current record and go on to the next record. This means that no further rules are executed for the current record. The rest of the current rule's action is not executed either.

Contrast this with the effect of the `getline` function (see section Explicit Input with `getline`). That too causes `awk` to read the next record immediately, but it does not alter the flow of control in any way. So the rest of the current action executes with a new input record.

At the highest level, `awk` program execution is a loop that reads an input record and then tests each rule's pattern against it. If you think of this loop as a `for` statement whose body contains the rules, then the `next` statement is analogous to a `continue` statement: it skips to the end of the body of this implicit loop, and executes the increment (which reads another record).

For example, if your `awk` program works only on records with four fields, and you don't want it to fail when given bad input, you might use this rule near the beginning of the program:

```
NF != 4 {
  err = sprintf("%s:%d: skipped: NF != 4\n", FILENAME, FNR)
  print err > "/dev/stderr"
  next
}
```

so that the following rules will not see the bad record. The error message is redirected to the standard error output stream, as error messages should be. See section Special File Names in `gawk`.

According to the POSIX standard, the behavior is undefined if the `next` statement is used in a `BEGIN` or `END` rule. `gawk` will treat it as a syntax error. Although POSIX permits it, some other `awk` implementations don't allow the `next` statement inside function bodies (see section User-defined Functions). Just as any other `next` statement, a `next` inside a function body reads the next record and starts processing it with the first rule in the program.

If the `next` statement causes the end of the input to be reached, then the code in any `END` rules will be executed. See section The `BEGIN` and `END` Special Patterns.

The `nextfile` Statement

`gawk` provides the `nextfile` statement, which is similar to the `next` statement. However, instead of abandoning processing of the current record, the `nextfile` statement instructs `gawk` to stop processing the current data file.

Upon execution of the `nextfile` statement, `FILENAME` is updated to the name of the next data file listed on the command line, `FNR` is reset to one, `ARGIND` is incremented, and processing starts over with the first rule in the progam. See section Built-in Variables.

If the `nextfile` statement causes the end of the input to be reached, then the code in any `END` rules will be executed. See section The `BEGIN` and `END` Special Patterns.

The `nextfile` statement is a `gawk` extension; it is not (currently) available in any other `awk` implementation. See section Implementing `nextfile` as a Function, for a user-defined function you can use to simulate the `nextfile` statement.

The `nextfile` statement would be useful if you have many data files to process, and you expect that you would not want to process every record in every file. Normally, in order to move on to the next data file, you would have to continue scanning the unwanted records. The `nextfile` statement accomplishes this much more efficiently.

Caution: Versions of `gawk` prior to 3.0 used two words (`next file') for the `nextfile` statement. This was changed in 3.0 to one word, since the treatment of `file' was inconsistent. When it appeared after `next`, it was a keyword. Otherwise, it was a regular identifier. The old usage is still accepted. However, `gawk` will generate a warning message, and support for `next file` will eventually be discontinued in a future version of `gawk`.

The `exit` Statement

The `exit` statement causes `awk` to immediately stop executing the current rule and to stop processing input; any remaining input is ignored. It looks like this:

```
exit [return code]
```

If an `exit` statement is executed from a `BEGIN` rule the program stops processing everything immediately. No input records are read. However, if an `END` rule is present, it is executed (see section The `BEGIN` and `END` Special Patterns).

If `exit` is used as part of an `END` rule, it causes the program to stop immediately.

An `exit` statement that is not part of a `BEGIN` or `END` rule stops the execution of any further automatic rules for the current record, skips reading any remaining input records, and executes the `END` rule if there is one.

If you do not want the `END` rule to do its job in this case, you can set a variable to non-zero before the `exit` statement, and check that variable in the `END` rule. See section Assertions, for an example that does this.

If an argument is supplied to `exit`, its value is used as the exit status code for the `awk` process. If no argument is supplied, `exit` returns status zero (success). In the case where an argument is supplied to a first `exit` statement, and then `exit` is called a second time with no argument, the previously supplied exit value is used (d.c.).

For example, let's say you've discovered an error condition you really don't know how to handle. Conventionally, programs report this by exiting with a non-zero status. Your `awk` program can do this using an `exit` statement with a non-zero argument. Here is an example:

```
BEGIN {
       if (("date" | getline date_now) < 0) {
         print "Can't get system date" > "/dev/stderr"
         exit 1
       }
       print "current date is", date_now
       close("date")
}
```

Go to the previous, next section.

Go to the previous, next section.

Built-in Variables

Most `awk` variables are available for you to use for your own purposes; they never change except when your program assigns values to them, and never affect anything except when your program examines them. However, a few variables in `awk` have special built-in meanings. Some of them `awk` examines automatically, so that they enable you to tell `awk` how to do certain things. Others are set automatically by `awk`, so that they carry information from the internal workings of `awk` to your program.

This chapter documents all the built-in variables of `gawk`. Most of them are also documented in the chapters describing their areas of activity.

Built-in Variables that Control awk

This is an alphabetical list of the variables which you can change to control how `awk` does certain things. Those variables that are specific to `gawk` are marked with an asterisk, `*'.

`CONVFMT`

This string controls conversion of numbers to strings (see section Conversion of Strings and Numbers). It works by being passed, in effect, as the first argument to the `sprintf` function (see section Built-in Functions for String Manipulation). Its default value is `"%.6g"`. `CONVFMT` was introduced by the POSIX standard.

`FIELDWIDTHS *`

This is a space separated list of columns that tells `gawk` how to split input with fixed, columnar boundaries. It is an experimental feature. Assigning to `FIELDWIDTHS` overrides the use of `FS` for field splitting. See section Reading Fixed-width Data, for more information.

If `gawk` is in compatibility mode (see section Command Line Options), then `FIELDWIDTHS` has no special meaning, and field splitting operations are done based exclusively on the value of `FS`.

`FS`

`FS` is the input field separator (see section Specifying How Fields are Separated). The value is a single-character string or a multi-character regular expression that matches the separations between fields in an input record. If the value is the null string (`""`), then each character in the record becomes a separate field.

The default value is `" "`, a string consisting of a single space. As a special exception, this value means that any sequence of spaces and tabs is a single separator. It also causes spaces and tabs at the beginning and end of a record to be ignored.

You can set the value of `FS` on the command line using the `-F' option:

```
awk -F, 'program' input-files
```

If gawk is using FIELDWIDTHS for field-splitting, assigning a value to FS will cause gawk to return to the normal, FS-based, field splitting. An easy way to do this is to simply say `FS = FS', perhaps with an explanatory comment.

IGNORECASE *

If IGNORECASE is non-zero or non-null, then all string comparisons, and all regular expression matching are case-independent. Thus, regexp matching with `~' and `!~', and the gensub, gsub, index, match, split and sub functions, record termination with RS, and field splitting with FS all ignore case when doing their particular regexp operations. See section Case-sensitivity in Matching.

If gawk is in compatibility mode (see section Command Line Options), then IGNORECASE has no special meaning, and string and regexp operations are always case-sensitive.

OFMT

This string controls conversion of numbers to strings (see section Conversion of Strings and Numbers) for printing with the print statement. It works by being passed, in effect, as the first argument to the sprintf function (see section Built-in Functions for String Manipulation). Its default value is "%.6g". Earlier versions of awk also used OFMT to specify the format for converting numbers to strings in general expressions; this is now done by CONVFMT.

OFS

This is the output field separator (see section Output Separators). It is output between the fields output by a print statement. Its default value is " ", a string consisting of a single space.

ORS

This is the output record separator. It is output at the end of every print statement. Its default value is "\n". (See section Output Separators.)

RS

This is awk's input record separator. Its default value is a string containing a single newline character, which means that an input record consists of a single line of text. It can also be the null string, in which case records are separated by runs of blank lines, or a regexp, in which case records are separated by matches of the regexp in the input text. (See section How Input is Split into Records.)

SUBSEP

SUBSEP is the subscript separator. It has the default value of "\034", and is used to separate the parts of the indices of a multi-dimensional array. Thus, the expression foo["A", "B"] really accesses foo["A\034B"] (see section Multi-dimensional Arrays).

Built-in Variables that Convey Information

This is an alphabetical list of the variables that are set automatically by awk on certain occasions in order to provide information to your program. Those variables that are specific to gawk are marked with an asterisk, `*'.

ARGC

ARGV

The command-line arguments available to `awk` programs are stored in an array called `ARGV`. `ARGC` is the number of command-line arguments present. See section Other Command Line Arguments. Unlike most `awk` arrays, `ARGV` is indexed from zero to `ARGC` - 1. For example:

```
$ awk 'BEGIN {
>         for (i = 0; i < ARGC; i++)
>             print ARGV[i]
>       }' inventory-shipped BBS-list
-| awk
-| inventory-shipped
-| BBS-list
```

In this example, `ARGV[0]` contains `"awk"`, `ARGV[1]` contains `"inventory-shipped"`, and `ARGV[2]` contains `"BBS-list"`. The value of `ARGC` is three, one more than the index of the last element in `ARGV`, since the elements are numbered from zero.

The names `ARGC` and `ARGV`, as well as the convention of indexing the array from zero to `ARGC` - 1, are derived from the C language's method of accessing command line arguments. See section Using ARGC and ARGV, for information about how `awk` uses these variables.

ARGIND *

The index in `ARGV` of the current file being processed. Every time `gawk` opens a new data file for processing, it sets `ARGIND` to the index in `ARGV` of the file name. When `gawk` is processing the input files, it is always true that `FILENAME == ARGV[ARGIND]'.

This variable is useful in file processing; it allows you to tell how far along you are in the list of data files, and to distinguish between successive instances of the same filename on the command line.

While you can change the value of `ARGIND` within your `awk` program, `gawk` will automatically set it to a new value when the next file is opened.

This variable is a `gawk` extension. In other `awk` implementations, or if `gawk` is in compatibility mode (see section Command Line Options), it is not special.

ENVIRON

An associative array that contains the values of the environment. The array indices are the environment variable names; the values are the values of the particular environment variables. For example, `ENVIRON["HOME"]` might be `/home/arnold'. Changing this array does not affect the environment passed on to any programs that `awk` may spawn via redirection or the `system` function. (In a future version of `gawk`, it may do so.)

Some operating systems may not have environment variables. On such systems, the `ENVIRON` array is empty (except for `ENVIRON["AWKPATH"]`).

ERRNO *

If a system error occurs either doing a redirection for `getline`, during a read for `getline`, or during a `close` operation, then `ERRNO` will contain a string describing the error.

This variable is a `gawk` extension. In other `awk` implementations, or if `gawk` is in compatibility mode (see section Command Line Options), it is not special.

`FILENAME`

This is the name of the file that `awk` is currently reading. When no data files are listed on the command line, `awk` reads from the standard input, and `FILENAME` is set to `"-"`. `FILENAME` is changed each time a new file is read (see section Reading Input Files). Inside a `BEGIN` rule, the value of `FILENAME` is `""`, since there are no input files being processed yet.(7) (d.c.)

`FNR`

`FNR` is the current record number in the current file. `FNR` is incremented each time a new record is read (see section Explicit Input with `getline`). It is reinitialized to zero each time a new input file is started.

`NF`

`NF` is the number of fields in the current input record. `NF` is set each time a new record is read, when a new field is created, or when `$0` changes (see section Examining Fields).

`NR`

This is the number of input records `awk` has processed since the beginning of the program's execution (see section How Input is Split into Records). `NR` is set each time a new record is read.

`RLENGTH`

`RLENGTH` is the length of the substring matched by the `match` function (see section Built-in Functions for String Manipulation). `RLENGTH` is set by invoking the `match` function. Its value is the length of the matched string, or -1 if no match was found.

`RSTART`

`RSTART` is the start-index in characters of the substring matched by the `match` function (see section Built-in Functions for String Manipulation). `RSTART` is set by invoking the `match` function. Its value is the position of the string where the matched substring starts, or zero if no match was found.

`RT` *

`RT` is set each time a record is read. It contains the input text that matched the text denoted by `RS`, the record separator.

This variable is a `gawk` extension. In other `awk` implementations, or if `gawk` is in compatibility mode (see section Command Line Options), it is not special.

A side note about `NR` and `FNR`. `awk` simply increments both of these variables each time it reads a record, instead of setting them to the absolute value of the number of records read. This means that your program can change these variables, and their new values will be incremented for each record (d.c.). For example:

```
$ echo '1
```

```
> 2
> 3
> 4' | awk 'NR == 2 { NR = 17 }
> { print NR }'
-| 1
-| 17
-| 18
-| 19
```

Before FNR was added to the awk language (see section Major Changes between V7 and SVR3.1), many awk programs used this feature to track the number of records in a file by resetting NR to zero when FILENAME changed.

Using ARGC and ARGV

In section Built-in Variables that Convey Information, you saw this program describing the information contained in ARGC and ARGV:

```
$ awk 'BEGIN {
>         for (i = 0; i < ARGC; i++)
>             print ARGV[i]
>       }' inventory-shipped BBS-list
-| awk
-| inventory-shipped
-| BBS-list
```

In this example, ARGV[0] contains "awk", ARGV[1] contains "inventory-shipped", and ARGV[2] contains "BBS-list".

Notice that the awk program is not entered in ARGV. The other special command line options, with their arguments, are also not entered. But variable assignments on the command line *are* treated as arguments, and do show up in the ARGV array.

Your program can alter ARGC and the elements of ARGV. Each time awk reaches the end of an input file, it uses the next element of ARGV as the name of the next input file. By storing a different string there, your program can change which files are read. You can use "-" to represent the standard input. By storing additional elements and incrementing ARGC you can cause additional files to be read.

If you decrease the value of ARGC, that eliminates input files from the end of the list. By recording the old value of ARGC elsewhere, your program can treat the eliminated arguments as something other than file names.

To eliminate a file from the middle of the list, store the null string ("") into ARGV in place of the file's name. As a special feature, awk ignores file names that have been replaced with the null string. You may also use the delete statement to remove elements from ARGV (see section The delete Statement).

All of these actions are typically done from the BEGIN rule, before actual processing of the input begins.

See section Splitting a Large File Into Pieces, and see section Duplicating Output Into Multiple Files for an example of each way of removing elements from ARGV.

The following fragment processes ARGV in order to examine, and then remove, command line options.

```
BEGIN {
    for (i = 1; i < ARGC; i++) {
        if (ARGV[i] == "-v")
            verbose = 1
        else if (ARGV[i] == "-d")
            debug = 1
        else if (ARGV[i] ~ /^-?/) {
            e = sprintf("%s: unrecognized option -- %c",
                    ARGV[0], substr(ARGV[i], 1, ,1))
            print e > "/dev/stderr"
        } else
            break
        delete ARGV[i]
    }
}
```

Go to the previous, next section.

Go to the previous, next section.

Arrays in awk

An array is a table of values, called elements. The elements of an array are distinguished by their indices. Indices may be either numbers or strings. `awk` maintains a single set of names that may be used for naming variables, arrays and functions (see section User-defined Functions). Thus, you cannot have a variable and an array with the same name in the same `awk` program.

Introduction to Arrays

The `awk` language provides one-dimensional arrays for storing groups of related strings or numbers.

Every `awk` array must have a name. Array names have the same syntax as variable names; any valid variable name would also be a valid array name. But you cannot use one name in both ways (as an array and as a variable) in one `awk` program.

Arrays in `awk` superficially resemble arrays in other programming languages; but there are fundamental differences. In `awk`, you don't need to specify the size of an array before you start to use it. Additionally, any number or string in `awk` may be used as an array index, not just consecutive integers.

In most other languages, you have to declare an array and specify how many elements or components it contains. In such languages, the declaration causes a contiguous block of memory to be allocated for that many elements. An index in the array usually must be a positive integer; for example, the index zero specifies the first element in the array, which is actually stored at the beginning of the block of memory. Index one specifies the second element, which is stored in memory right after the first element, and so on. It is impossible to add more elements to the array, because it has room for only as many elements as you declared. (Some languages allow arbitrary starting and ending indices, e.g., `15 .. 27', but the size of the array is still fixed when the array is declared.)

A contiguous array of four elements might look like this, conceptually, if the element values are eight, `"foo"`, `""` and 30:

Only the values are stored; the indices are implicit from the order of the values. Eight is the value at index zero, because eight appears in the position with zero elements before it.

Arrays in `awk` are different: they are associative. This means that each array is a collection of pairs: an index, and its corresponding array element value:

```
Element 4     Value 30
Element 2     Value "foo"
Element 1     Value 8
Element 3     Value ""
```

We have shown the pairs in jumbled order because their order is irrelevant.

One advantage of associative arrays is that new pairs can be added at any time. For example, suppose we add to the above array a tenth element whose value is `"number ten"`. The result is this:

```
Element 10    Value "number ten"
Element 4     Value 30
Element 2     Value "foo"
Element 1     Value 8
Element 3     Value ""
```

Now the array is sparse, which just means some indices are missing: it has elements 1--4 and 10, but doesn't have elements 5, 6, 7, 8, or 9.

Another consequence of associative arrays is that the indices don't have to be positive integers. Any number, or even a string, can be an index. For example, here is an array which translates words from English into French:

```
Element "dog" Value "chien"
Element "cat" Value "chat"
Element "one" Value "un"
Element 1     Value "un"
```

Here we decided to translate the number one in both spelled-out and numeric form--thus illustrating that a single array can have both numbers and strings as indices. (In fact, array subscripts are always strings; this is discussed in more detail in section Using Numbers to Subscript Arrays.)

When `awk` creates an array for you, e.g., with the `split` built-in function, that array's indices are consecutive integers starting at one. (See section Built-in Functions for String Manipulation.)

Referring to an Array Element

The principal way of using an array is to refer to one of its elements. An array reference is an expression which looks like this:

```
array[index]
```

Here, array is the name of an array. The expression index is the index of the element of the array that you want.

The value of the array reference is the current value of that array element. For example, `foo[4.3]` is an expression for the element of array `foo` at index `4.3'.

If you refer to an array element that has no recorded value, the value of the reference is `""`, the null string. This includes elements to which you have not assigned any value, and elements that have been deleted (see section The `delete` Statement). Such a reference automatically creates that array element, with the null string as its value. (In some cases, this is unfortunate, because it might waste memory inside `awk`.)

You can find out if an element exists in an array at a certain index with the expression:

```
index in array
```

This expression tests whether or not the particular index exists, without the side effect of creating that element if it is not present. The expression has the value one (true) if `array[index]` exists, and zero (false) if it does not exist.

For example, to test whether the array `frequencies` contains the index `2', you could write this statement:

```
if (2 in frequencies)
    print "Subscript 2 is present."
```

Note that this is *not* a test of whether or not the array `frequencies` contains an element whose *value* is two. (There is no way to do that except to scan all the elements.) Also, this *does not* create `frequencies[2]`, while the following (incorrect) alternative would do so:

```
if (frequencies[2] != "")
    print "Subscript 2 is present."
```

Assigning Array Elements

Array elements are lvalues: they can be assigned values just like `awk` variables:

```
array[subscript] = value
```

Here array is the name of your array. The expression subscript is the index of the element of the array that you want to assign a value. The expression value is the value you are assigning to that element of the array.

Basic Array Example

The following program takes a list of lines, each beginning with a line number, and prints them out in order of line number. The line numbers are not in order, however, when they are first read: they are scrambled. This program sorts the lines by making an array using the line numbers as subscripts. It then prints out the lines in sorted order of their numbers. It is a very simple program, and gets confused if it encounters repeated numbers, gaps, or lines that don't begin with a number.

```
{
  if ($1 > max)
    max = $1
  arr[$1] = $0
}
```

```
END {
  for (x = 1; x <= max; x++)
    print arr[x]
}
```

The first rule keeps track of the largest line number seen so far; it also stores each line into the array `arr`, at an index that is the line's number.

The second rule runs after all the input has been read, to print out all the lines.

When this program is run with the following input:

```
5  I am the Five man
2  Who are you?  The new number two!
4  . . . And four on the floor
1  Who is number one?
3  I three you.
```

its output is this:

```
1  Who is number one?
2  Who are you?  The new number two!
3  I three you.
4  . . . And four on the floor
5  I am the Five man
```

If a line number is repeated, the last line with a given number overrides the others.

Gaps in the line numbers can be handled with an easy improvement to the program's `END` rule:

```
END {
  for (x = 1; x <= max; x++)
    if (x in arr)
      print arr[x]
}
```

Scanning All Elements of an Array

In programs that use arrays, you often need a loop that executes once for each element of an array. In other languages, where arrays are contiguous and indices are limited to positive integers, this is easy: you can find all the valid indices by counting from the lowest index up to the highest. This technique won't do the job in `awk`, since any number or string can be an array index. So `awk` has a special kind of `for` statement for scanning an array:

```
for (var in array)
```

```
body
```

This loop executes body once for each index in array that your program has previously used, with the variable var set to that index.

Here is a program that uses this form of the `for` statement. The first rule scans the input records and notes which words appear (at least once) in the input, by storing a one into the array `used` with the word as index. The second rule scans the elements of `used` to find all the distinct words that appear in the input. It prints each word that is more than 10 characters long, and also prints the number of such words. See section Built-in Functions for String Manipulation, for more information on the built-in function `length`.

```
# Record a 1 for each word that is used at least once.
{
    for (i = 1; i <= NF; i++)
        used[$i] = 1
}

# Find number of distinct words more than 10 characters long.
END {
    for (x in used)
        if (length(x) > 10) {
            ++num_long_words
            print x
        }
    print num_long_words, "words longer than 10 characters"
}
```

See section Generating Word Usage Counts, for a more detailed example of this type.

The order in which elements of the array are accessed by this statement is determined by the internal arrangement of the array elements within `awk` and cannot be controlled or changed. This can lead to problems if new elements are added to array by statements in the loop body; you cannot predict whether or not the `for` loop will reach them. Similarly, changing var inside the loop may produce strange results. It is best to avoid such things.

The `delete` Statement

You can remove an individual element of an array using the `delete` statement:

```
delete array[index]
```

Once you have deleted an array element, you can no longer obtain any value the element once had. It is as if you had never referred to it and had never given it any value.

Here is an example of deleting elements in an array:

```
for (i in frequencies)
  delete frequencies[i]
```

This example removes all the elements from the array `frequencies`.

If you delete an element, a subsequent `for` statement to scan the array will not report that element, and the `in` operator to check for the presence of that element will return zero (i.e. false):

```
delete foo[4]
if (4 in foo)
    print "This will never be printed"
```

It is important to note that deleting an element is *not* the same as assigning it a null value (the empty string, `""`).

```
foo[4] = ""
if (4 in foo)
  print "This is printed, even though foo[4] is empty"
```

It is not an error to delete an element that does not exist.

You can delete all the elements of an array with a single statement, by leaving off the subscript in the `delete` statement.

```
delete array
```

This ability is a `gawk` extension; it is not available in compatibility mode (see section Command Line Options).

Using this version of the `delete` statement is about three times more efficient than the equivalent loop that deletes each element one at a time.

The following statement provides a portable, but non-obvious way to clear out an array.

```
# thanks to Michael Brennan for pointing this out
split("", array)
```

The `split` function (see section Built-in Functions for String Manipulation) clears out the target array first. This call asks it to split apart the null string. Since there is no data to split out, the function simply clears the array and then returns.

Using Numbers to Subscript Arrays

An important aspect of arrays to remember is that *array subscripts are always strings*. If you use a numeric value as a subscript, it will be converted to a string value before it is used for subscripting (see section Conversion of Strings and Numbers).

This means that the value of the built-in variable `CONVFMT` can potentially affect how your program accesses elements of an array. For example:

```
xyz = 12.153
data[xyz] = 1
CONVFMT = "%2.2f"
if (xyz in data)
    printf "%s is in data\n", xyz
else
    printf "%s is not in data\n", xyz
```

This prints `12.15 is not in data'. The first statement gives `xyz` a numeric value. Assigning to `data[xyz]` subscripts `data` with the string value `"12.153"` (using the default conversion value of `CONVFMT`, `"%.6g"`), and assigns one to `data["12.153"]`. The program then changes the value of `CONVFMT`. The test `(xyz in data)' generates a new string value from `xyz`, this time `"12.15"`, since the value of `CONVFMT` only allows two significant digits. This test fails, since `"12.15"` is a different string from `"12.153"`.

According to the rules for conversions (see section Conversion of Strings and Numbers), integer values are always converted to strings as integers, no matter what the value of `CONVFMT` may happen to be. So the usual case of:

```
for (i = 1; i <= maxsub; i++)
    do something with array[i]
```

will work, no matter what the value of `CONVFMT`.

Like many things in `awk`, the majority of the time things work as you would expect them to work. But it is useful to have a precise knowledge of the actual rules, since sometimes they can have a subtle effect on your programs.

Using Uninitialized Variables as Subscripts

Suppose you want to print your input data in reverse order. A reasonable attempt at a program to do so (with some test data) might look like this:

```
$ echo 'line 1
> line 2
> line 3' | awk '{ l[lines] = $0; ++lines }
> END {
>     for (i = lines-1; i >= 0; --i)
>        print l[i]
> }'
-| line 3
-| line 2
```

Unfortunately, the very first line of input data did not come out in the output!

At first glance, this program should have worked. The variable `lines` is uninitialized, and uninitialized variables have the numeric value zero. So, the value of `l[0]` should have been printed.

The issue here is that subscripts for `awk` arrays are **always** strings. And uninitialized variables, when used as strings, have the value `""`, not zero. Thus, `line 1' ended up stored in `l[""]`.

The following version of the program works correctly:

```
{ l[lines++] = $0 }
END {
    for (i = lines - 1; i >= 0; --i)
       print l[i]
}
```

Here, the `++' forces `l` to be numeric, thus making the "old value" numeric zero, which is then converted to `"0"` as the array subscript.

As we have just seen, even though it is somewhat unusual, the null string (`""`) is a valid array subscript (d.c.). If `--lint' is provided on the command line (see section Command Line Options), `gawk` will warn about the use of the null string as a subscript.

Multi-dimensional Arrays

A multi-dimensional array is an array in which an element is identified by a sequence of indices, instead of a single index. For example, a two-dimensional array requires two indices. The usual way (in most languages, including `awk`) to refer to an element of a two-dimensional array named `grid` is with `grid[x,y]`.

Multi-dimensional arrays are supported in `awk` through concatenation of indices into one string. What happens is that `awk` converts the indices into strings (see section Conversion of Strings and Numbers) and concatenates them together, with a separator between them. This creates a single string that describes the values of the separate indices. The combined string is used as a single index into an ordinary, one-dimensional array. The separator used is the value of the built-in variable SUBSEP.

For example, suppose we evaluate the expression `foo[5,12] = "value"' when the value of SUBSEP is `"@"`. The numbers five and 12 are converted to strings and concatenated with an `@' between them, yielding `"5@12"`; thus, the array element `foo["5@12"]` is set to `"value"`.

Once the element's value is stored, `awk` has no record of whether it was stored with a single index or a sequence of indices. The two expressions `foo[5,12]' and `foo[5 SUBSEP 12]' are always equivalent.

The default value of SUBSEP is the string `"\034"`, which contains a non-printing character that is unlikely to appear in an `awk` program or in most input data.

The usefulness of choosing an unlikely character comes from the fact that index values that contain a

string matching SUBSEP lead to combined strings that are ambiguous. Suppose that SUBSEP were '@', then `foo["a@b", "c"]' and `foo["a", "b@c"]' would be indistinguishable because both would actually be stored as `foo["a@b@c"]'.

You can test whether a particular index-sequence exists in a "multi-dimensional" array with the same operator `in' used for single dimensional arrays. Instead of a single index as the left-hand operand, write the whole sequence of indices, separated by commas, in parentheses:

```
(subscript1, subscript2, ...) in array
```

The following example treats its input as a two-dimensional array of fields; it rotates this array 90 degrees clockwise and prints the result. It assumes that all lines have the same number of elements.

```
awk '{
     if (max_nf < NF)
          max_nf = NF
     max_nr = NR
     for (x = 1; x <= NF; x++)
          vector[x, NR] = $x
}

END {
     for (x = 1; x <= max_nf; x++) {
          for (y = max_nr; y >= 1; --y)
               printf("%s ", vector[x, y])
          printf("\n")
     }
}'
```

When given the input:

```
1 2 3 4 5 6
2 3 4 5 6 1
3 4 5 6 1 2
4 5 6 1 2 3
```

it produces:

```
4 3 2 1
5 4 3 2
6 5 4 3
1 6 5 4
2 1 6 5
3 2 1 6
```

Scanning Multi-dimensional Arrays

There is no special `for` statement for scanning a "multi-dimensional" array; there cannot be one, because in truth there are no multi-dimensional arrays or elements; there is only a multi-dimensional *way of accessing* an array.

However, if your program has an array that is always accessed as multi-dimensional, you can get the effect of scanning it by combining the scanning `for` statement (see section Scanning All Elements of an Array) with the `split` built-in function (see section Built-in Functions for String Manipulation). It works like this:

```
for (combined in array) {
  split(combined, separate, SUBSEP)
  ...
}
```

This sets `combined` to each concatenated, combined index in the array, and splits it into the individual indices by breaking it apart where the value of `SUBSEP` appears. The split-out indices become the elements of the array `separate`.

Thus, suppose you have previously stored a value in `array[1, "foo"]`; then an element with index `"1\034foo"` exists in `array`. (Recall that the default value of `SUBSEP` is the character with code 034.) Sooner or later the `for` statement will find that index and do an iteration with `combined` set to `"1\034foo"`. Then the `split` function is called as follows:

```
split("1\034foo", separate, "\034")
```

The result of this is to set `separate[1]` to `"1"` and `separate[2]` to `"foo"`. Presto, the original sequence of separate indices has been recovered.

Go to the previous, next section.

Go to the previous, next section.

Built-in Functions

Built-in functions are functions that are always available for your `awk` program to call. This chapter defines all the built-in functions in `awk`; some of them are mentioned in other sections, but they are summarized here for your convenience. (You can also define new functions yourself. See section User-defined Functions.)

Calling Built-in Functions

To call a built-in function, write the name of the function followed by arguments in parentheses. For example, `atan2(y + z, 1)' is a call to the function `atan2`, with two arguments.

Whitespace is ignored between the built-in function name and the open-parenthesis, but we recommend that you avoid using whitespace there. User-defined functions do not permit whitespace in this way, and you will find it easier to avoid mistakes by following a simple convention which always works: no whitespace after a function name.

Each built-in function accepts a certain number of arguments. In some cases, arguments can be omitted. The defaults for omitted arguments vary from function to function and are described under the individual functions. In some `awk` implementations, extra arguments given to built-in functions are ignored. However, in `gawk`, it is a fatal error to give extra arguments to a built-in function.

When a function is called, expressions that create the function's actual parameters are evaluated completely before the function call is performed. For example, in the code fragment:

```
i = 4
j = sqrt(i++)
```

the variable `i` is set to five before `sqrt` is called with a value of four for its actual parameter.

The order of evaluation of the expressions used for the function's parameters is undefined. Thus, you should not write programs that assume that parameters are evaluated from left to right or from right to left. For example,

```
i = 5
j = atan2(i++, i *= 2)
```

If the order of evaluation is left to right, then `i` first becomes six, and then 12, and `atan2` is called with the two arguments six and 12. But if the order of evaluation is right to left, `i` first becomes 10, and then 11, and `atan2` is called with the two arguments 11 and 10.

Numeric Built-in Functions

Here is a full list of built-in functions that work with numbers. Optional parameters are enclosed in square brackets ("[" and "]").

`int(x)`

This produces the nearest integer to x, located between x and zero, truncated toward zero.

For example, `int(3)` is three, `int(3.9)` is three, `int(-3.9)` is -3, and `int(-3)` is -3 as well.

`sqrt(x)`

This gives you the positive square root of x. It reports an error if x is negative. Thus, `sqrt(4)` is two.

`exp(x)`

This gives you the exponential of x (`e ^ x`), or reports an error if x is out of range. The range of values x can have depends on your machine's floating point representation.

`log(x)`

This gives you the natural logarithm of x, if x is positive; otherwise, it reports an error.

`sin(x)`

This gives you the sine of x, with x in radians.

`cos(x)`

This gives you the cosine of x, with x in radians.

`atan2(y, x)`

This gives you the arctangent of `y / x` in radians.

`rand()`

This gives you a random number. The values of `rand` are uniformly-distributed between zero and one. The value is never zero and never one.

Often you want random integers instead. Here is a user-defined function you can use to obtain a random non-negative integer less than n:

```
function randint(n) {
     return int(n * rand())
}
```

The multiplication produces a random real number greater than zero and less than `n`. We then make it an integer (using `int`) between zero and `n` - 1, inclusive.

Here is an example where a similar function is used to produce random integers between one and n. This program prints a new random number for each input record.

```
awk '
# Function to roll a simulated die.
```

```
function roll(n) { return 1 + int(rand() * n) }

# Roll 3 six-sided dice and
# print total number of points.
{
      printf("%d points\n",
             roll(6)+roll(6)+roll(6))
}'
```

Caution: In most awk implementations, including gawk, rand starts generating numbers from the same starting number, or seed, each time you run awk. Thus, a program will generate the same results each time you run it. The numbers are random within one awk run, but predictable from run to run. This is convenient for debugging, but if you want a program to do different things each time it is used, you must change the seed to a value that will be different in each run. To do this, use srand.

`srand([x])`

The function srand sets the starting point, or seed, for generating random numbers to the value x.

Each seed value leads to a particular sequence of random numbers.(8) Thus, if you set the seed to the same value a second time, you will get the same sequence of random numbers again.

If you omit the argument x, as in `srand()`, then the current date and time of day are used for a seed. This is the way to get random numbers that are truly unpredictable.

The return value of srand is the previous seed. This makes it easy to keep track of the seeds for use in consistently reproducing sequences of random numbers.

Built-in Functions for String Manipulation

The functions in this section look at or change the text of one or more strings. Optional parameters are enclosed in square brackets ("[" and "]").

`index(in, find)`

This searches the string in for the first occurrence of the string find, and returns the position in characters where that occurrence begins in the string in. For example:

```
$ awk 'BEGIN { print index("peanut", "an") }'
-| 3
```

If find is not found, index returns zero. (Remember that string indices in awk start at one.)

`length([string])`

This gives you the number of characters in string. If string is a number, the length of the digit string representing that number is returned. For example, `length("abcde")` is five. By contrast, `length(15 * 35)` works out to three. How? Well, 15 * 35 = 525, and 525 is then converted to the string `"525"`, which has three characters.

If no argument is supplied, `length` returns the length of `$0`.

In older versions of `awk`, you could call the `length` function without any parentheses. Doing so is marked as "deprecated" in the POSIX standard. This means that while you can do this in your programs, it is a feature that can eventually be removed from a future version of the standard. Therefore, for maximal portability of your `awk` programs, you should always supply the parentheses.

`match(string, regexp)`

The `match` function searches the string, string, for the longest, leftmost substring matched by the regular expression, regexp. It returns the character position, or index, of where that substring begins (one, if it starts at the beginning of string). If no match is found, it returns zero.

The `match` function sets the built-in variable `RSTART` to the index. It also sets the built-in variable `RLENGTH` to the length in characters of the matched substring. If no match is found, `RSTART` is set to zero, and `RLENGTH` to -1.

For example:

```
awk '{
       if ($1 == "FIND")
         regex = $2
       else {
         where = match($0, regex)
         if (where != 0)
           print "Match of", regex, "found at", \
                     where, "in", $0
       }
}'
```

This program looks for lines that match the regular expression stored in the variable `regex`. This regular expression can be changed. If the first word on a line is `FIND', `regex` is changed to be the second word on that line. Therefore, given:

```
FIND ru+n
My program runs
but not very quickly
FIND Melvin
JF+KM
This line is property of Reality Engineering Co.
Melvin was here.
```

`awk` prints:

```
Match of ru+n found at 12 in My program runs
Match of Melvin found at 1 in Melvin was here.
```

`split(string, array [, fieldsep])`

This divides string into pieces separated by fieldsep, and stores the pieces in array. The first pi is stored in `array[1]`, the second piece in `array[2]`, and so forth. The string value of the third argument, fieldsep, is a regexp describing where to split string (much as `FS` can be a regexp describing where to split input records). If the fieldsep is omitted, the value of `FS` is used. `split` returns the number of elements created.

The `split` function splits strings into pieces in a manner similar to the way input lines are split into fields. For example:

```
split("cul-de-sac", a, "-")
```

splits the string `cul-de-sac' into three fields using `-' as the separator. It sets the contents of the array `a` as follows:

```
a[1] = "cul"
a[2] = "de"
a[3] = "sac"
```

The value returned by this call to `split` is three.

As with input field-splitting, when the value of fieldsep is `" "`, leading and trailing whitespace is ignored, and the elements are separated by runs of whitespace.

Also as with input field-splitting, if fieldsep is the null string, each individual character in the string is split into its own array element. (This is a `gawk`-specific extension.)

Recent implementations of `awk`, including `gawk`, allow the third argument to be a regexp constant (`/abc/`), as well as a string (d.c.). The POSIX standard allows this as well.

Before splitting the string, `split` deletes any previously existing elements in the array array (d.c.).

`sprintf(format, expression1,...)`

This returns (without printing) the string that `printf` would have printed out with the same arguments (see section Using `printf` Statements for Fancier Printing). For example:

```
sprintf("pi = %.2f (approx.)", 22/7)
```

returns the string `"pi = 3.14 (approx.)"`.

`sub(regexp, replacement [, target])`

The `sub` function alters the value of target. It searches this value, which is treated as a string, for the leftmost longest substring matched by the regular expression, regexp, extending this match as far as possible. Then the entire string is changed by replacing the matched text with replacement. The modified string becomes the new value of target.

This function is peculiar because target is not simply used to compute a value, and not just any expression will do: it must be a variable, field or array element, so that `sub` can store a modified value there. If this argument is omitted, then the default is to use and alter `$0`.

For example:

```
str = "water, water, everywhere"
sub(/at/, "ith", str)
```

sets `str` to `"wither, water, everywhere"`, by replacing the leftmost, longest occurrence of `at' with `ith'.

The `sub` function returns the number of substitutions made (either one or zero).

If the special character `&' appears in replacement, it stands for the precise substring that was matched by regexp. (If the regexp can match more than one string, then this precise substring may vary.) For example:

```
awk '{ sub(/candidate/, "& and his wife"); print }'
```

changes the first occurrence of `candidate' to `candidate and his wife' on each input line.

Here is another example:

```
awk 'BEGIN {
        str = "daabaaa"
        sub(/a*/, "c&c", str)
        print str
}'
-| dcaacbaaa
```

This shows how `&' can represent a non-constant string, and also illustrates the "leftmost, longest" rule in regexp matching (see section How Much Text Matches?).

The effect of this special character (`&') can be turned off by putting a backslash before it in the string. As usual, to insert one backslash in the string, you must write two backslashes. Therefore, write `\\&' in a string constant to include a literal `&' in the replacement. For example, here is how to replace the first `|' on each line with an `&':

```
awk '{ sub(/\|/, "\\&"); print }'
```

Note: As mentioned above, the third argument to `sub` must be a variable, field or array reference. Some versions of `awk` allow the third argument to be an expression which is not an lvalue. In such a case, `sub` would still search for the pattern and return zero or one, but the result of the substitution (if any) would be thrown away because there is no place to put it. Such versions of `awk` accept expressions like this:

```
sub(/USA/, "United States", "the USA and Canada")
```

This is considered erroneous in `gawk`.

```
gsub(regexp, replacement [, target])
```

This is similar to the `sub` function, except `gsub` replaces *all* of the longest, leftmost, *non-overlapping* matching substrings it can find. The `g' in `gsub` stands for "global," which means replace everywhere. For example:

```
awk '{ gsub(/Britain/, "United Kingdom"); print }'
```

replaces all occurrences of the string `Britain' with `United Kingdom' for all input records.

The `gsub` function returns the number of substitutions made. If the variable to be searched and altered, target, is omitted, then the entire input record, `$0`, is used.

As in `sub`, the characters `&' and `\' are special, and the third argument must be an lvalue.

`gensub(regexp, replacement, how [, target])`

`gensub` is a general substitution function. Like `sub` and `gsub`, it searches the target string target for matches of the regular expression regexp. Unlike `sub` and `gsub`, the modified string is returned as the result of the function, and the original target string is *not* changed. If how is a string beginning with `g' or `G', then it replaces all matches of regexp with replacement. Otherwise, how is a number indicating which match of regexp to replace. If no target is supplied, `$0` is used instead.

`gensub` provides an additional feature that is not available in `sub` or `gsub`: the ability to specify components of a regexp in the replacement text. This is done by using parentheses in the regexp to mark the components, and then specifying `\n' in the replacement text, where n is a digit from one to nine. For example:

```
$ gawk '
> BEGIN {
>       a = "abc def"
>       b = gensub(/(.+) (.+)/, "\\2 \\1", "g", a)
>       print b
> }'
-| def abc
```

As described above for `sub`, you must type two backslashes in order to get one into the string.

In the replacement text, the sequence `\0' represents the entire matched text, as does the character `&'.

This example shows how you can use the third argument to control which match of the regexp should be changed.

```
$ echo a b c a b c |
> gawk '{ print gensub(/a/, "AA", 2) }'
-| a b c AA b c
```

In this case, `$0` is used as the default target string. `gensub` returns the new string as its result, which is passed directly to `print` for printing.

If the how argument is a string that does not begin with `g' or `G', or if it is a number that is less than zero, only one substitution is performed.

`gensub` is a `gawk` extension; it is not available in compatibility mode (see section Command Line Options).

`substr(string, start [, length])`

This returns a length-character-long substring of string, starting at character number start. The first character of a string is character number one. For example, `substr("washington", 5, 3)` returns `"ing"`.

If length is not present, this function returns the whole suffix of string that begins at character number start. For example, `substr("washington", 5)` returns `"ington"`. The whole suffix is also returned if length is greater than the number of characters remaining in the string, counting from character number start.

`tolower(string)`

This returns a copy of string, with each upper-case character in the string replaced with its corresponding lower-case character. Non-alphabetic characters are left unchanged. For example, `tolower("MiXeD cAsE 123")` returns `"mixed case 123"`.

`toupper(string)`

This returns a copy of string, with each lower-case character in the string replaced with its corresponding upper-case character. Non-alphabetic characters are left unchanged. For example, `toupper("MiXeD cAsE 123")` returns `"MIXED CASE 123"`.

More About `\' and `&' with sub, gsub and gensub

When using `sub`, `gsub` or `gensub`, and trying to get literal backslashes and ampersands into the replacement text, you need to remember that there are several levels of escape processing going on.

First, there is the lexical level, which is when `awk` reads your program, and builds an internal copy of your program that can be executed.

Then there is the run-time level, when `awk` actually scans the replacement string to determine what to generate.

At both levels, `awk` looks for a defined set of characters that can come after a backslash. At the lexical level, it looks for the escape sequences listed in section Escape Sequences. Thus, for every `\' that `awk` will process at the run-time level, you type two `\'s at the lexical level. When a character that is not valid for an escape sequence follows the `\', Unix `awk` and `gawk` both simply remove the initial `\', and put the following character into the string. Thus, for example, `"a\qb"` is treated as `"aqb"`.

At the run-time level, the various functions handle sequences of `\' and `&' differently. The situation is (sadly) somewhat complex.

Historically, the `sub` and `gsub` functions treated the two character sequence `\&' specially; this sequence was replaced in the generated text with a single `&'. Any other `\' within the replacement string that did not precede an `&' was passed through unchanged. To illustrate with a table:

This table shows both the lexical level processing, where an odd number of backslashes becomes an even number at the run time level, and the run-time processing done by `sub`. (For the sake of simplicity, the rest of the tables below only show the case of even numbers of `\'s entered at the lexical level.)

The problem with the historical approach is that there is no way to get a literal `\' followed by the matched text.

The 1992 POSIX standard attempted to fix this problem. The standard says that `sub` and `gsub` look for either a `\' or an `&' after the `\'. If either one follows a `\', that character is output literally. The interpretation of `\' and `&' then becomes like this:

This would appear to solve the problem. Unfortunately, the phrasing of the standard is unusual. It says, in effect, that `\' turns off the special meaning of any following character, but that for anything other than `\' and `&', such special meaning is undefined. This wording leads to two problems.

1. Backslashes must now be doubled in the replacement string, breaking historical `awk` programs.
2. To make sure that an `awk` program is portable, *every* character in the replacement string must be preceded with a backslash.(9)

The POSIX standard is under revision.(10) Because of the above problems, proposed text for the revised standard reverts to rules that correspond more closely to the original existing practice. The proposed rules have special cases that make it possible to produce a `\' preceding the matched text.

In a nutshell, at the run-time level, there are now three special sequences of characters, `\\\&', `\\&' and `\&', whereas historically, there was only one. However, as in the historical case, any `\' that is not part of one of these three sequences is not special, and appears in the output literally.

`gawk` 3.0 follows these proposed POSIX rules for `sub` and `gsub`. Whether these proposed rules will actually become codified into the standard is unknown at this point. Subsequent `gawk` releases will track the standard and implement whatever the final version specifies; this book will be updated as well.

The rules for `gensub` are considerably simpler. At the run-time level, whenever `gawk` sees a `\', if the following character is a digit, then the text that matched the corresponding parenthesized subexpression is placed in the generated output. Otherwise, no matter what the character after the `\' is, that character will appear in the generated text, and the `\' will not.

Because of the complexity of the lexical and run-time level processing, and the special cases for `sub` and `gsub`, we recommend the use of `gawk` and `gensub` for when you have to do substitutions.

Built-in Functions for Input/Output

The following functions are related to Input/Output (I/O). Optional parameters are enclosed in square brackets ("[" and "]").

`close(filename)`

Close the file filename, for input or output. The argument may alternatively be a shell command that was used for redirecting to or from a pipe; then the pipe is closed. See section Closing Input and Output Files and Pipes, for more information.

`fflush([filename])`

Flush any buffered output associated filename, which is either a file opened for writing, or a shell command for redirecting output to a pipe.

Many utility programs will buffer their output; they save information to be written to a disk file or terminal in memory, until there is enough for it to be worthwhile to send the data to the ouput device. This is often more efficient than writing every little bit of information as soon as it is ready. However, sometimes it is necessary to force a program to flush its buffers; that is, write the information to its destination, even if a buffer is not full. This is the purpose of the `fflush` function; `gawk` too buffers its output, and the `fflush` function can be used to force `gawk` to flush its buffers.

`fflush` is a recent (1994) addition to the Bell Labs research version of `awk`; it is not part of the POSIX standard, and will not be available if `--posix' has been specified on the command line (see section Command Line Options).

`gawk` extends the `fflush` function in two ways. This first is to allow no argument at all. In this case, the buffer for the standard output is flushed. The second way is to allow the null string (`""`) as the argument. In this case, the buffers for *all* open output files and pipes are flushed.

`fflush` returns zero if the buffer was successfully flushed, and nonzero otherwise.

`system(command)`

The system function allows the user to execute operating system commands and then return to the `awk` program. The `system` function executes the command given by the string command. It returns, as its value, the status returned by the command that was executed.

For example, if the following fragment of code is put in your `awk` program:

```
END {
     system("date | mail -s 'awk run done' root")
}
```

the system administrator will be sent mail when the `awk` program finishes processing input and begins its end-of-input processing.

Note that redirecting `print` or `printf` into a pipe is often enough to accomplish your task. However, if your `awk` program is interactive, `system` is useful for cranking up large self-contained programs, such as a shell or an editor.

Some operating systems cannot implement the `system` function. `system` causes a fatal error if it is not supported.

Controlling Output Buffering with `system`

The `fflush` function provides explicit control over output buffering for individual files and pipes. However, its use is not portable to many other `awk` implementations. An alternative method to flush output buffers is by calling `system` with a null string as its argument:

```
system("")   # flush output
```

gawk treats this use of the system function as a special case, and is smart enough not to run a shell (or other command interpreter) with the empty command. Therefore, with gawk, this idiom is not only useful, it is efficient. While this method should work with other awk implementations, it will not necessarily avoid starting an unnecessary shell. (Other implementations may only flush the buffer associated with the standard output, and not necessarily all buffered output.)

If you think about what a programmer expects, it makes sense that system should flush any pending output. The following program:

```
BEGIN {
     print "first print"
     system("echo system echo")
     print "second print"
}
```

must print

```
first print
system echo
second print
```

and not

```
system echo
first print
second print
```

If awk did not flush its buffers before calling system, the latter (undesirable) output is what you would see.

Functions for Dealing with Time Stamps

A common use for awk programs is the processing of log files containing time stamp information, indicating when a particular log record was written. Many programs log their time stamp in the form returned by the time system call, which is the number of seconds since a particular epoch. On POSIX systems, it is the number of seconds since Midnight, January 1, 1970, UTC.

In order to make it easier to process such log files, and to produce useful reports, gawk provides two functions for working with time stamps. Both of these are gawk extensions; they are not specified in the POSIX standard, nor are they in any other known version of awk.

Optional parameters are enclosed in square brackets ("[" and "]").

```
systime()
```

This function returns the current time as the number of seconds since the system epoch. On P[illegible] systems, this is the number of seconds since Midnight, January 1, 1970, UTC. It may be a diff[illegible] number on other systems.

`strftime([format [, timestamp]])`

This function returns a string. It is similar to the function of the same name in ANSI C. The time specified by timestamp is used to produce a string, based on the contents of the format string. The timestamp is in the same format as the value returned by the `systime` function. If no timestamp argument is supplied, `gawk` will use the current time of day as the time stamp. If no format argument is supplied, `strftime` uses `"%a %b %d %H:%M:%S %Z %Y"`. This format string produces output (almost) equivalent to that of the `date` utility. (Versions of `gawk` prior to 3.0 require the format argument.)

The `systime` function allows you to compare a time stamp from a log file with the current time of day. In particular, it is easy to determine how long ago a particular record was logged. It also allows you to produce log records using the "seconds since the epoch" format.

The `strftime` function allows you to easily turn a time stamp into human-readable information. It is similar in nature to the `sprintf` function (see section Built-in Functions for String Manipulation), in that it copies non-format specification characters verbatim to the returned string, while substituting date and time values for format specifications in the format string.

`strftime` is guaranteed by the ANSI C standard to support the following date format specifications:

`%a`

The locale's abbreviated weekday name.

`%A`

The locale's full weekday name.

`%b`

The locale's abbreviated month name.

`%B`

The locale's full month name.

`%c`

The locale's "appropriate" date and time representation.

`%d`

The day of the month as a decimal number (01--31).

`%H`

The hour (24-hour clock) as a decimal number (00--23).

`%I`

The hour (12-hour clock) as a decimal number (01--12).

`%j`

The day of the year as a decimal number (001--366).

`%m`

The month as a decimal number (01--12).

`%M`

The minute as a decimal number (00--59).

`%p`

The locale's equivalent of the AM/PM designations associated with a 12-hour clock.

`%S`

The second as a decimal number (00--61).(11)

`%U`

The week number of the year (the first Sunday as the first day of week one) as a decimal number (00--53).

`%w`

The weekday as a decimal number (0--6). Sunday is day zero.

`%W`

The week number of the year (the first Monday as the first day of week one) as a decimal number (00--53).

`%x`

The locale's "appropriate" date representation.

`%X`

The locale's "appropriate" time representation.

`%y`

The year without century as a decimal number (00--99).

`%Y`

The year with century as a decimal number (e.g., 1995).

`%Z`

The time zone name or abbreviation, or no characters if no time zone is determinable.

`%%`

A literal `%'.

If a conversion specifier is not one of the above, the behavior is undefined.(12)

Informally, a locale is the geographic place in which a program is meant to run. For example, a common way to abbreviate the date September 4, 1991 in the United States would be "9/4/91". In many countries in Europe, however, it would be abbreviated "4.9.91". Thus, the `%x' specification in a `"US"` locale might produce `9/4/91', while in a `"EUROPE"` locale, it might produce `4.9.91'. The ANSI C standard defines a default `"C"` locale, which is an environment that is typical of what most C programmers are used to.

A public-domain C version of `strftime` is supplied with `gawk` for systems that are not yet fully ANSI-compliant. If that version is used to compile `gawk` (see section Installing `gawk`), then the following additional format specifications are available:

`%D`

Equivalent to specifying `%m/%d/%y'.

`%e`

The day of the month, padded with a space if it is only one digit.

`%h`

Equivalent to `%b', above.

`%n`

A newline character (ASCII LF).

`%r`

Equivalent to specifying `%I:%M:%S %p'.

`%R`

Equivalent to specifying `%H:%M'.

`%T`

Equivalent to specifying `%H:%M:%S'.

`%t`

A tab character.

`%k`

The hour (24-hour clock) as a decimal number (0-23). Single digit numbers are padded with a space.

`%l`

The hour (12-hour clock) as a decimal number (1-12). Single digit numbers are padded with a space.

`%C`

The century, as a number between 00 and 99.

`%u`

The weekday as a decimal number [1 (Monday)--7].

`%V`

The week number of the year (the first Monday as the first day of week one) as a decimal number (01--53). The method for determining the week number is as specified by ISO 8601 (to wit: if the week containing January 1 has four or more days in the new year, then it is week one, otherwise it is week 53 of the previous year and the next week is week one).

`%G`

The year with century of the ISO week number, as a decimal number.

For example, January 1, 1993, is in week 53 of 1992. Thus, the year of its ISO week number is 1992, even though its year is 1993. Similarly, December 31, 1973, is in week 1 of 1974. Thus, the year of its ISO week number is 1974, even though its year is 1973.

`%g`

The year without century of the ISO week number, as a decimal number (00--99).

`%Ec %EC %Ex %Ey %EY %Od %Oe %OH %OI`

`%Om %OM %OS %Ou %OU %OV %Ow %OW %Oy`

These are "alternate representations" for the specifications that use only the second letter (`%c', `%C', and so on). They are recognized, but their normal representations are used.(13) (These facilitate compliance with the POSIX `date` utility.)

`%v`

The date in VMS format (e.g., 20-JUN-1991).

`%z`

The timezone offset in a +HHMM format (e.g., the format necessary to produce RFC-822/RFC-1036 date headers).

This example is an `awk` implementation of the POSIX `date` utility. Normally, the `date` utility prints the current date and time of day in a well known format. However, if you provide an argument to it that begins with a `+', `date` will copy non-format specifier characters to the standard output, and will interpret the current time according to the format specifiers in the string. For example:

```
$ date '+Today is %A, %B %d, %Y.'
-| Today is Thursday, July 11, 1991.
```

Here is the `gawk` version of the `date` utility. It has a shell "wrapper", to handle the `-u' option, which requires that `date` run as if the time zone was set to UTC.

```
#! /bin/sh
#
# date -- approximate the P1003.2 'date' command

case $1 in
-u)  TZ=GMT0     # use UTC
     export TZ
     shift ;;
esac

gawk 'BEGIN  {
    format = "%a %b %d %H:%M:%S %Z %Y"
    exitval = 0

    if (ARGC > 2)
        exitval = 1
    else if (ARGC == 2) {
        format = ARGV[1]
        if (format ~ /^\+/)
            format = substr(format, 2)   # remove leading +
    }
    print strftime(format)
```

```
    exit exitval
}' "$@"
```

Go to the previous, next section.

User-defined Functions

Complicated `awk` programs can often be simplified by defining your own functions. User-defined functions can be called just like built-in ones (see section Function Calls), but it is up to you to define them--to tell `awk` what they should do.

Function Definition Syntax

Definitions of functions can appear anywhere between the rules of an `awk` program. Thus, the general form of an `awk` program is extended to include sequences of rules *and* user-defined function definitions. There is no need in `awk` to put the definition of a function before all uses of the function. This is because `awk` reads the entire program before starting to execute any of it.

The definition of a function named name looks like this:

```
function name(parameter-list)
{
     body-of-function
}
```

name is the name of the function to be defined. A valid function name is like a valid variable name: a sequence of letters, digits and underscores, not starting with a digit. Within a single `awk` program, any particular name can only be used as a variable, array or function.

parameter-list is a list of the function's arguments and local variable names, separated by commas. When the function is called, the argument names are used to hold the argument values given in the call. The local variables are initialized to the empty string. A function cannot have two parameters with the same name.

The body-of-function consists of `awk` statements. It is the most important part of the definition, because it says what the function should actually *do*. The argument names exist to give the body a way to talk about the arguments; local variables, to give the body places to keep temporary values.

Argument names are not distinguished syntactically from local variable names; instead, the number of arguments supplied when the function is called determines how many argument variables there are. Thus, if three argument values are given, the first three names in parameter-list are arguments, and the rest are local variables.

It follows that if the number of arguments is not the same in all calls to the function, some of the names in parameter-list may be arguments on some occasions and local variables on others. Another way to think of this is that omitted arguments default to the null string.

Usually when you write a function you know how many names you intend to use for arguments and how

many you intend to use as local variables. It is conventional to place some extra space between the arguments and the local variables, to document how your function is supposed to be used.

During execution of the function body, the arguments and local variable values hide or shadow any variables of the same names used in the rest of the program. The shadowed variables are not accessible in the function definition, because there is no way to name them while their names have been taken away for the local variables. All other variables used in the `awk` program can be referenced or set normally in the function's body.

The arguments and local variables last only as long as the function body is executing. Once the body finishes, you can once again access the variables that were shadowed while the function was running.

The function body can contain expressions which call functions. They can even call this function, either directly or by way of another function. When this happens, we say the function is recursive.

In many `awk` implementations, including `gawk`, the keyword `function` may be abbreviated `func`. However, POSIX only specifies the use of the keyword `function`. This actually has some practical implications. If `gawk` is in POSIX-compatibility mode (see section Command Line Options), then the following statement will *not* define a function:

```
func foo() { a = sqrt($1) ; print a }
```

Instead it defines a rule that, for each record, concatenates the value of the variable `func' with the return value of the function `foo'. If the resulting string is non-null, the action is executed. This is probably not what was desired. (`awk` accepts this input as syntactically valid, since functions may be used before they are defined in `awk` programs.)

To ensure that your `awk` programs are portable, always use the keyword `function` when defining a function.

Function Definition Examples

Here is an example of a user-defined function, called `myprint`, that takes a number and prints it in a specific format.

```
function myprint(num)
{
     printf "%6.3g\n", num
}
```

To illustrate, here is an `awk` rule which uses our `myprint` function:

```
$3 > 0     { myprint($3) }
```

This program prints, in our special format, all the third fields that contain a positive number in our input. Therefore, when given:

```
 1.2   3.4    5.6   7.8
 9.10 11.12 -13.14 15.16
17.18 19.20  21.22 23.24
```

this program, using our function to format the results, prints:

```
   5.6
  21.2
```

This function deletes all the elements in an array.

```
function delarray(a,    i)
{
    for (i in a)
       delete a[i]
}
```

When working with arrays, it is often necessary to delete all the elements in an array and start over with a new list of elements (see section The `delete` Statement). Instead of having to repeat this loop everywhere in your program that you need to clear out an array, your program can just call `delarray`.

Here is an example of a recursive function. It takes a string as an input parameter, and returns the string in backwards order.

```
function rev(str, start)
{
    if (start == 0)
        return ""

    return (substr(str, start, 1) rev(str, start - 1))
}
```

If this function is in a file named `` `rev.awk' ``, we can test it this way:

```
$ echo "Don't Panic!" |
> gawk --source '{ print rev($0, length($0)) }' -f rev.awk
-| !cinaP t'noD
```

Here is an example that uses the built-in function `strftime`. (See section Functions for Dealing with Time Stamps, for more information on `strftime`.) The C `ctime` function takes a timestamp and returns it in a string, formatted in a well known fashion. Here is an `awk` version:

```
# ctime.awk
#
# awk version of C ctime(3) function
```

```
function ctime(ts,    format)
{
    format = "%a %b %d %H:%M:%S %Z %Y"
    if (ts == 0)
        ts = systime()       # use current time as default
    return strftime(format, ts)
}
```

Calling User-defined Functions

Calling a function means causing the function to run and do its job. A function call is an expression, and its value is the value returned by the function.

A function call consists of the function name followed by the arguments in parentheses. What you write in the call for the arguments are `awk` expressions; each time the call is executed, these expressions are evaluated, and the values are the actual arguments. For example, here is a call to `foo` with three arguments (the first being a string concatenation):

```
foo(x y, "lose", 4 * z)
```

Caution: whitespace characters (spaces and tabs) are not allowed between the function name and the open-parenthesis of the argument list. If you write whitespace by mistake, `awk` might think that you mean to concatenate a variable with an expression in parentheses. However, it notices that you used a function name and not a variable name, and reports an error.

When a function is called, it is given a *copy* of the values of its arguments. This is known as call by value. The caller may use a variable as the expression for the argument, but the called function does not know this: it only knows what value the argument had. For example, if you write this code:

```
foo = "bar"
z = myfunc(foo)
```

then you should not think of the argument to `myfunc` as being "the variable `foo`." Instead, think of the argument as the string value, `"bar"`.

If the function `myfunc` alters the values of its local variables, this has no effect on any other variables. Thus, if `myfunc` does this:

```
function myfunc(str)
{
  print str
  str = "zzz"
  print str
}
```

to change its first argument variable `str`, this *does not* change the value of `foo` in the caller. The role of

`foo` in calling `myfunc` ended when its value, `"bar"`, was computed. If `str` also exists outside of `myfunc`, the function body cannot alter this outer value, because it is shadowed during the execution of `myfunc` and cannot be seen or changed from there.

However, when arrays are the parameters to functions, they are *not* copied. Instead, the array itself is made available for direct manipulation by the function. This is usually called call by reference. Changes made to an array parameter inside the body of a function *are* visible outside that function. *This can be very dangerous if you do not watch what you are doing.* For example:

```
function changeit(array, ind, nvalue)
{
     array[ind] = nvalue
}

BEGIN {
    a[1] = 1; a[2] = 2; a[3] = 3
    changeit(a, 2, "two")
    printf "a[1] = %s, a[2] = %s, a[3] = %s\n",
            a[1], a[2], a[3]
}
```

This program prints `a[1] = 1, a[2] = two, a[3] = 3', because `changeit` stores `"two"` in the second element of `a`.

Some `awk` implementations allow you to call a function that has not been defined, and only report a problem at run-time when the program actually tries to call the function. For example:

```
BEGIN {
    if (0)
        foo()
    else
        bar()
}
function bar() { ... }
# note that `foo' is not defined
```

Since the `if' statement will never be true, it is not really a problem that `foo` has not been defined. Usually though, it is a problem if a program calls an undefined function.

If `--lint' has been specified (see section Command Line Options), `gawk` will report about calls to undefined functions.

The `return` Statement

The body of a user-defined function can contain a `return` statement. This statement returns control to the rest of the `awk` program. It can also be used to return a value for use in the rest of the `awk` program. It looks like this:

```
return [expression]
```

The expression part is optional. If it is omitted, then the returned value is undefined and, therefore, unpredictable.

A `return` statement with no value expression is assumed at the end of every function definition. So if control reaches the end of the function body, then the function returns an unpredictable value. `awk` will *not* warn you if you use the return value of such a function.

Sometimes, you want to write a function for what it does, not for what it returns. Such a function corresponds to a `void` function in C or to a `procedure` in Pascal. Thus, it may be appropriate to not return any value; you should simply bear in mind that if you use the return value of such a function, you do so at your own risk.

Here is an example of a user-defined function that returns a value for the largest number among the elements of an array:

```
function maxelt(vec,   i, ret)
{
     for (i in vec) {
          if (ret == "" || vec[i] > ret)
               ret = vec[i]
     }
     return ret
}
```

You call `maxelt` with one argument, which is an array name. The local variables `i` and `ret` are not intended to be arguments; while there is nothing to stop you from passing two or three arguments to `maxelt`, the results would be strange. The extra space before `i` in the function parameter list indicates that `i` and `ret` are not supposed to be arguments. This is a convention that you should follow when you define functions.

Here is a program that uses our `maxelt` function. It loads an array, calls `maxelt`, and then reports the maximum number in that array:

```
awk '
function maxelt(vec,   i, ret)
{
     for (i in vec) {
          if (ret == "" || vec[i] > ret)
```

```
                ret = vec[i]
        }
        return ret
}

# Load all fields of each record into nums.
{
        for(i = 1; i <= NF; i++)
                nums[NR, i] = $i
}

END {
        print maxelt(nums)
}'
```

Given the following input:

```
 1 5 23 8 16
44 3 5 2 8 26
256 291 1396 2962 100
-6 467 998 1101
99385 11 0 225
```

our program tells us (predictably) that `99385` is the largest number in our array.

Go to the previous, next section.

Go to the previous, next section.

Running awk

There are two ways to run `awk`: with an explicit program, or with one or more program files. Here are templates for both of them; items enclosed in `[...]' in these templates are optional.

Besides traditional one-letter POSIX-style options, `gawk` also supports GNU long options.

```
awk [options] -f progfile [--] file ...
awk [options] [--] 'program' file ...
```

It is possible to invoke `awk` with an empty program:

```
$ awk " datafile1 datafile2
```

Doing so makes little sense though; `awk` will simply exit silently when given an empty program (d.c.). If `--lint' has been specified on the command line, `gawk` will issue a warning that the program is empty.

Command Line Options

Options begin with a dash, and consist of a single character. GNU style long options consist of two dashes and a keyword. The keyword can be abbreviated, as long the abbreviation allows the option to be uniquely identified. If the option takes an argument, then the keyword is either immediately followed by an equals sign (`=') and the argument's value, or the keyword and the argument's value are separated by whitespace. For brevity, the discussion below only refers to the traditional short options; however the long and short options are interchangeable in all contexts.

Each long option for `gawk` has a corresponding POSIX-style option. The options and their meanings are as follows:

`-F fs`

`--field-separator fs`

> Sets the `FS` variable to fs (see section Specifying How Fields are Separated).

`-f source-file`

`--file source-file`

> Indicates that the `awk` program is to be found in source-file instead of in the first non-option argument.

`-v var=val`

`--assign var=val`

> Sets the variable var to the value val **before** execution of the program begins. Such variable values are available inside the `BEGIN` rule (see section Other Command Line Arguments).

The `-v' option can only set one variable, but you can use it more than once, setting another variable each time, like this: `awk -v foo=1 -v bar=2 ...'.

`-mf=NNN`

`-mr=NNN`

Set various memory limits to the value NNN. The `f' flag sets the maximum number of fields, and the `r' flag sets the maximum record size. These two flags and the `-m' option are from the Bell Labs research version of Unix `awk`. They are provided for compatibility, but otherwise ignored by `gawk`, since `gawk` has no predefined limits.

`-W gawk-opt`

Following the POSIX standard, options that are implementation specific are supplied as arguments to the `-W' option. With `gawk`, these arguments may be separated by commas, or quoted and separated by whitespace. Case is ignored when processing these options. These options also have corresponding GNU style long options. See below.

`--`

Signals the end of the command line options. The following arguments are not treated as options even if they begin with `-'. This interpretation of `--' follows the POSIX argument parsing conventions.

This is useful if you have file names that start with `-', or in shell scripts, if you have file names that will be specified by the user which could start with `-'.

The following `gawk`-specific options are available:

`-W traditional`

`-W compat`

`--traditional`

`--compat`

Specifies compatibility mode, in which the GNU extensions to the `awk` language are disabled, so that `gawk` behaves just like the Bell Labs research version of Unix `awk`. `--traditional' is the preferred form of this option. See section Extensions in `gawk` Not in POSIX `awk`, which summarizes the extensions. Also see section Downward Compatibility and Debugging.

`-W copyleft`

`-W copyright`

`--copyleft`

`--copyright`

Print the short version of the General Public License. This option may disappear in a future version of `gawk`.

`-W help`

`-W usage`

`--help`

`--usage`

Print a "usage" message summarizing the short and long style options that `gawk` accepts, and exit.

`-W lint`

`--lint`

Warn about constructs that are dubious or non-portable to other `awk` implementations. Some warnings are issued when `gawk` first reads your program. Others are issued at run-time, as your program executes.

`-W lint-old`

`--lint-old`

Warn about constructs that are not available in the original Version 7 Unix version of `awk` (see section Major Changes between V7 and SVR3.1).

`-W posix`

`--posix`

Operate in strict POSIX mode. This disables all `gawk` extensions (just like `--traditional'), and adds the following additional restrictions:

`\x` escape sequences are not recognized (see section Escape Sequences).

The synonym `func` for the keyword `function` is not recognized (see section Function Definition Syntax).

The operators `**' and `**=' cannot be used in place of `^' and `^=' (see section Arithmetic Operators, and also see section Assignment Expressions).

Specifying `-Ft' on the command line does not set the value of `FS` to be a single tab character (see section Specifying How Fields are Separated).

The `fflush` built-in function is not supported (see section Built-in Functions for Input/Output).

If you supply both `--traditional' and `--posix' on the command line, `--posix' will take precedence. `gawk` will also issue a warning if both options are supplied.

`-W re-interval`

`--re-interval`

Allow interval expressions (see section Regular Expression Operators), in regexps. Because interval expressions were traditionally not available in `awk`, `gawk` does not provide them by default. This prevents old `awk` programs from breaking.

`-W source program-text`

`--source program-text`

Program source code is taken from the program-text. This option allows you to mix source code in files with source code that you enter on the command line. This is particularly useful when you have library functions that you wish to use from your command line programs (see section The `AWKPATH` Environment Variable).

`-W version`

`--version`

> Prints version information for this particular copy of `gawk`. This allows you to determine if your copy of `gawk` is up to date with respect to whatever the Free Software Foundation is currently distributing. It is also useful for bug reports (see section Reporting Problems and Bugs).

Any other options are flagged as invalid with a warning message, but are otherwise ignored.

In compatibility mode, as a special case, if the value of fs supplied to the `-F' option is `t', then `FS` is set to the tab character (`"\t"`). This is only true for `--traditional', and not for `--posix' (see section Specifying How Fields are Separated).

The `-f' option may be used more than once on the command line. If it is, `awk` reads its program source from all of the named files, as if they had been concatenated together into one big file. This is useful for creating libraries of `awk` functions. Useful functions can be written once, and then retrieved from a standard place, instead of having to be included into each individual program.

You can type in a program at the terminal and still use library functions, by specifying `-f /dev/tty'. `awk` will read a file from the terminal to use as part of the `awk` program. After typing your program, type Control-d (the end-of-file character) to terminate it. (You may also use `-f -' to read program source from the standard input, but then you will not be able to also use the standard input as a source of data.)

Because it is clumsy using the standard `awk` mechanisms to mix source file and command line `awk` programs, `gawk` provides the `--source' option. This does not require you to pre-empt the standard input for your source code, and allows you to easily mix command line and library source code (see section The `AWKPATH` Environment Variable).

If no `-f' or `--source' option is specified, then `gawk` will use the first non-option command line argument as the text of the program source code.

If the environment variable `POSIXLY_CORRECT` exists, then `gawk` will behave in strict POSIX mode, exactly as if you had supplied the `--posix' command line option. Many GNU programs look for this environment variable to turn on strict POSIX mode. If you supply `--lint' on the command line, and `gawk` turns on POSIX mode because of `POSIXLY_CORRECT`, then it will print a warning message indicating that POSIX mode is in effect.

You would typically set this variable in your shell's startup file. For a Bourne compatible shell (such as Bash), you would add these lines to the `.profile'` file in your home directory.

```
POSIXLY_CORRECT=true
export POSIXLY_CORRECT
```

For a `csh` compatible shell,(14) you would add this line to the `.login'` file in your home directory.

```
setenv POSIXLY_CORRECT true
```

Other Command Line Arguments

Any additional arguments on the command line are normally treated as input files to be processed in the order specified. However, an argument that has the form `var=value`, assigns the value value to the variable var---it does not specify a file at all.

All these arguments are made available to your `awk` program in the `ARGV` array (see section Built-in Variables). Command line options and the program text (if present) are omitted from `ARGV`. All other arguments, including variable assignments, are included. As each element of `ARGV` is processed, `gawk` sets the variable `ARGIND` to the index in `ARGV` of the current element.

The distinction between file name arguments and variable-assignment arguments is made when `awk` is about to open the next input file. At that point in execution, it checks the "file name" to see whether it is really a variable assignment; if so, `awk` sets the variable instead of reading a file.

Therefore, the variables actually receive the given values after all previously specified files have been read. In particular, the values of variables assigned in this fashion are *not* available inside a `BEGIN` rule (see section The `BEGIN` and `END` Special Patterns), since such rules are run before `awk` begins scanning the argument list.

The variable values given on the command line are processed for escape sequences (d.c.) (see section Escape Sequences).

In some earlier implementations of `awk`, when a variable assignment occurred before any file names, the assignment would happen *before* the `BEGIN` rule was executed. `awk`'s behavior was thus inconsistent; some command line assignments were available inside the `BEGIN` rule, while others were not. However, some applications came to depend upon this "feature." When `awk` was changed to be more consistent, the `-v' option was added to accommodate applications that depended upon the old behavior.

The variable assignment feature is most useful for assigning to variables such as `RS`, `OFS`, and `ORS`, which control input and output formats, before scanning the data files. It is also useful for controlling state if multiple passes are needed over a data file. For example:

```
awk 'pass == 1  { pass 1 stuff }
     pass == 2  { pass 2 stuff }' pass=1 mydata pass=2 mydata
```

Given the variable assignment feature, the `-F' option for setting the value of `FS` is not strictly necessary. It remains for historical compatibility.

The `AWKPATH` Environment Variable

The previous section described how `awk` program files can be named on the command line with the `-f' option. In most `awk` implementations, you must supply a precise path name for each program file, unless the file is in the current directory.

But in `gawk`, if the file name supplied to the `-f' option does not contain a `/', then `gawk` searches a list

of directories (called the search path), one by one, looking for a file with the specified name.

The search path is a string consisting of directory names separated by colons. `gawk` gets its search path from the `AWKPATH` environment variable. If that variable does not exist, `gawk` uses a default path, which is `.:/usr/local/share/awk'.(15) (Programs written for use by system administrators should use an `AWKPATH` variable that does not include the current directory, `.'.)

The search path feature is particularly useful for building up libraries of useful `awk` functions. The library files can be placed in a standard directory that is in the default path, and then specified on the command line with a short file name. Otherwise, the full file name would have to be typed for each file.

By using both the `--source' and `-f' options, your command line `awk` programs can use facilities in `awk` library files. See section A Library of awk Functions.

Path searching is not done if `gawk` is in compatibility mode. This is true for both `--traditional' and `--posix'. See section Command Line Options.

Note: if you want files in the current directory to be found, you must include the current directory in the path, either by including `.' explicitly in the path, or by writing a null entry in the path. (A null entry is indicated by starting or ending the path with a colon, or by placing two colons next to each other (`::').) If the current directory is not included in the path, then files cannot be found in the current directory. This path search mechanism is identical to the shell's.

Starting with version 3.0, if `AWKPATH` is not defined in the environment, `gawk` will place its default search path into `ENVIRON["AWKPATH"]`. This makes it easy to determine the actual search path `gawk` will use.

Obsolete Options and/or Features

This section describes features and/or command line options from previous releases of `gawk` that are either not available in the current version, or that are still supported but deprecated (meaning that they will *not* be in the next release).

For version 3.0 of `gawk`, there are no command line options or other deprecated features from the previous version of `gawk`. This section is thus essentially a place holder, in case some option becomes obsolete in a future version of `gawk`.

Undocumented Options and Features

This section intentionally left blank.

Known Bugs in gawk

- The `-F' option for changing the value of `FS` (see section Command Line Options) is not necessary given the command line variable assignment feature; it remains only for backwards compatibility.

- If your system actually has support for `/dev/fd' and the associated `/dev/stdin', `/dev/stdout', and `/dev/stderr' files, you may get different output from gawk than you would get on a system without those files. When gawk interprets these files internally, it synchronizes output to the standard output with output to `/dev/stdout', while on a system with those files, the output is actually to different open files (see section Special File Names in gawk).
- Syntactically invalid single character programs tend to overflow the parse stack, generating a rather unhelpful message. Such programs are surprisingly difficult to diagnose in the completely general case, and the effort to do so really is not worth it.
- The word "GNU" is incorrectly capitalized in at least one file in the source code.

Go to the previous, next section.

A Library of awk Functions

This chapter presents a library of useful `awk` functions. The sample programs presented later (see section Practical `awk` Programs) use these functions. The functions are presented here in a progression from simple to complex.

section Extracting Programs from Texinfo Source Files, presents a program that you can use to extract the source code for these example library functions and programs from the Texinfo source for this book. (This has already been done as part of the `gawk` distribution.)

If you have written one or more useful, general purpose `awk` functions, and would like to contribute them for a subsequent edition of this book, please contact the author. See section Reporting Problems and Bugs, for information on doing this. Don't just send code, as you will be required to either place your code in the public domain, publish it under the GPL (see section GNU GENERAL PUBLIC LICENSE), or assign the copyright in it to the Free Software Foundation.

Simulating gawk-specific Features

The programs in this chapter and in section Practical `awk` Programs, freely use features that are specific to `gawk`. This section briefly discusses how you can rewrite these programs for different implementations of `awk`.

Diagnostic error messages are sent to `` `/dev/stderr' ``. Use `` `| "cat 1>&2"' `` instead of `` `> "/dev/stderr"' ``, if your system does not have a `` `/dev/stderr' ``, or if you cannot use `gawk`.

A number of programs use `nextfile` (see section The `nextfile` Statement), to skip any remaining input in the input file. section Implementing `nextfile` as a Function, shows you how to write a function that will do the same thing.

Finally, some of the programs choose to ignore upper-case and lower-case distinctions in their input. They do this by assigning one to `IGNORECASE`. You can achieve the same effect by adding the following rule to the beginning of the program:

```
# ignore case
{ $0 = tolower($0) }
```

Also, verify that all regexp and string constants used in comparisons only use lower-case letters.

Implementing `nextfile` as a Function

The `nextfile` statement presented in section The `nextfile` Statement, is a `gawk`-specific extension. It is not available in other implementations of `awk`. This section shows two versions of a `nextfile` function that you can use to simulate `gawk`'s `nextfile` statement if you cannot use `gawk`.

Here is a first attempt at writing a `nextfile` function.

```
# nextfile -- skip remaining records in current file

# this should be read in before the "main" awk program

function nextfile()    { _abandon_ = FILENAME; next }

_abandon_ == FILENAME  { next }
```

This file should be included before the main program, because it supplies a rule that must be executed first. This rule compares the current data file's name (which is always in the `FILENAME` variable) to a private variable named `_abandon_`. If the file name matches, then the action part of the rule executes a `next` statement, to go on to the next record. (The use of `_' in the variable name is a convention. It is discussed more fully in section Naming Library Function Global Variables.)

The use of the `next` statement effectively creates a loop that reads all the records from the current data file. Eventually, the end of the file is reached, and a new data file is opened, changing the value of `FILENAME`. Once this happens, the comparison of `_abandon_` to `FILENAME` fails, and execution continues with the first rule of the "real" program.

The `nextfile` function itself simply sets the value of `_abandon_` and then executes a `next` statement to start the loop going.(16)

This initial version has a subtle problem. What happens if the same data file is listed *twice* on the command line, one right after the other, or even with just a variable assignment between the two occurrences of the file name?

In such a case, this code will skip right through the file, a second time, even though it should stop when it gets to the end of the first occurrence. Here is a second version of `nextfile` that remedies this problem.

```
# nextfile -- skip remaining records in current file
# correctly handle successive occurrences of the same file
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May, 1993

# this should be read in before the "main" awk program

function nextfile()   { _abandon_ = FILENAME; next }
```

```
_abandon_ == FILENAME {
      if (FNR == 1)
          _abandon_ = ""
      else
          next
}
```

The `nextfile` function has not changed. It sets `_abandon_` equal to the current file name and then executes a `next` satement. The `next` statement reads the next record and increments `FNR`, so `FNR` is guaranteed to have a value of at least two. However, if `nextfile` is called for the last record in the file, then `awk` will close the current data file and move on to the next one. Upon doing so, `FILENAME` will be set to the name of the new file, and `FNR` will be reset to one. If this next file is the same as the previous one, `_abandon_` will still be equal to `FILENAME`. However, `FNR` will be equal to one, telling us that this is a new occurrence of the file, and not the one we were reading when the `nextfile` function was executed. In that case, `_abandon_` is reset to the empty string, so that further executions of this rule will fail (until the next time that `nextfile` is called).

If `FNR` is not one, then we are still in the original data file, and the program executes a `next` statement to skip through it.

An important question to ask at this point is: "Given that the functionality of `nextfile` can be provided with a library file, why is it built into `gawk`?" This is an important question. Adding features for little reason leads to larger, slower programs that are harder to maintain.

The answer is that building `nextfile` into `gawk` provides significant gains in efficiency. If the `nextfile` function is executed at the beginning of a large data file, `awk` still has to scan the entire file, splitting it up into records, just to skip over it. The built-in `nextfile` can simply close the file immediately and proceed to the next one, saving a lot of time. This is particularly important in `awk`, since `awk` programs are generally I/O bound (i.e. they spend most of their time doing input and output, instead of performing computations).

Assertions

When writing large programs, it is often useful to be able to know that a condition or set of conditions is true. Before proceeding with a particular computation, you make a statement about what you believe to be the case. Such a statement is known as an "assertion." The C language provides an `<assert.h>` header file and corresponding `assert` macro that the programmer can use to make assertions. If an assertion fails, the `assert` macro arranges to print a diagnostic message describing the condition that should have been true but was not, and then it kills the program. In C, using `assert` looks this:

```
#include <assert.h>

int myfunc(int a, double b)
{
     assert(a <= 5 && b >= 17);
```

```
     ...
}
```

If the assertion failed, the program would print a message similar to this:

```
prog.c:5: assertion failed: a <= 5 && b >= 17
```

The ANSI C language makes it possible to turn the condition into a string for use in printing the diagnostic message. This is not possible in `awk`, so this `assert` function also requires a string version of the condition that is being tested.

```
# assert -- assert that a condition is true. Otherwise exit.
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May, 1993

function assert(condition, string)
{
    if (! condition) {
        printf("%s:%d: assertion failed: %s\n",
            FILENAME, FNR, string) > "/dev/stderr"
        _assert_exit = 1
        exit 1
    }
}

END {
    if (_assert_exit)
        exit 1
}
```

The `assert` function tests the `condition` parameter. If it is false, it prints a message to standard error, using the `string` parameter to describe the failed condition. It then sets the variable `_assert_exit` to one, and executes the `exit` statement. The `exit` statement jumps to the `END` rule. If the `END` rules finds `_assert_exit` to be true, then it exits immediately.

The purpose of the `END` rule with its test is to keep any other `END` rules from running. When an assertion fails, the program should exit immediately. If no assertions fail, then `_assert_exit` will still be false when the `END` rule is run normally, and the rest of the program's `END` rules will execute. For all of this to work correctly, `` `assert.awk' `` must be the first source file read by `awk`.

You would use this function in your programs this way:

```
function myfunc(a, b)
{
     assert(a <= 5 && b >= 17, "a <= 5 && b >= 17")
     ...
}
```

If the assertion failed, you would see a message like this:

```
mydata:1357: assertion failed: a <= 5 && b >= 17
```

There is a problem with this version of `assert`, that it may not be possible to work around. An `END` rule is automatically added to the program calling `assert`. Normally, if a program consists of just a `BEGIN` rule, the input files and/or standard input are not read. However, now that the program has an `END` rule, `awk` will attempt to read the input data files, or standard input (see section Startup and Cleanup Actions), most likely causing the program to hang, waiting for input.

Just a note on programming style. You may have noticed that the `END` rule uses backslash continuation, with the open brace on a line by itself. This is so that it more closely resembles the way functions are written. Many of the examples in this chapter and the next one use this style. You can decide for yourself if you like writing your `BEGIN` and `END` rules this way, or not.

Translating Between Characters and Numbers

One commercial implementation of `awk` supplies a built-in function, `ord`, which takes a character and returns the numeric value for that character in the machine's character set. If the string passed to `ord` has more than one character, only the first one is used.

The inverse of this function is `chr` (from the function of the same name in Pascal), which takes a number and returns the corresponding character.

Both functions can be written very nicely in `awk`; there is no real reason to build them into the `awk` interpreter.

```
# ord.awk -- do ord and chr
#
# Global identifiers:
#    _ord_:        numerical values indexed by characters
#    _ord_init:    function to initialize _ord_
#
# Arnold Robbins
# arnold@gnu.ai.mit.edu
# Public Domain
# 16 January, 1992
# 20 July, 1992, revised

BEGIN    { _ord_init() }

function _ord_init(    low, high, i, t)
{
    low = sprintf("%c", 7) # BEL is ascii 7
    if (low == "\a") {    # regular ascii
```

```
        low = 0
        high = 127
    } else if (sprintf("%c", 128 + 7) == "\a") {
        # ascii, mark parity
        low = 128
        high = 255
    } else {        # ebcdic(!)
        low = 0
        high = 255
    }

    for (i = low; i <= high; i++) {
        t = sprintf("%c", i)
        _ord_[t] = i
    }
}
```

Some explanation of the numbers used by `chr` is worthwhile. The most prominent character set in use today is ASCII. Although an eight-bit byte can hold 256 distinct values (from zero to 255), ASCII only defines characters that use the values from zero to 127.(17) At least one computer manufacturer that we know of uses ASCII, but with mark parity, meaning that the leftmost bit in the byte is always one. What this means is that on those systems, characters have numeric values from 128 to 255. Finally, large mainframe systems use the EBCDIC character set, which uses all 256 values. While there are other character sets in use on some older systems, they are not really worth worrying about.

```
function ord(str,    c)
{
    # only first character is of interest
    c = substr(str, 1, 1)
    return _ord_[c]
}

function chr(c)
{
    # force c to be numeric by adding 0
    return sprintf("%c", c + 0)
}

#### test code ####
# BEGIN    \
# {
#    for (;;) {
#        printf("enter a character: ")
#        if (getline var <= 0)
#            break
```

```
#         printf("ord(%s) = %d\n", var, ord(var))
#     }
# }
```

An obvious improvement to these functions would be to move the code for the `_ord_init` function into the body of the `BEGIN` rule. It was written this way initially for ease of development.

There is a "test program" in a `BEGIN` rule, for testing the function. It is commented out for production use.

Merging an Array Into a String

When doing string processing, it is often useful to be able to join all the strings in an array into one long string. The following function, `join`, accomplishes this task. It is used later in several of the application programs (see section Practical `awk` Programs).

Good function design is important; this function needs to be general, but it should also have a reasonable default behavior. It is called with an array and the beginning and ending indices of the elements in the array to be merged. This assumes that the array indices are numeric--a reasonable assumption since the array was likely created with `split` (see section Built-in Functions for String Manipulation).

```
# join.awk -- join an array into a string
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

function join(array, start, end, sep,    result, i)
{
    if (sep == "")
       sep = " "
    else if (sep == SUBSEP) # magic value
       sep = ""
    result = array[start]
    for (i = start + 1; i <= end; i++)
        result = result sep array[i]
    return result
}
```

An optional additional argument is the separator to use when joining the strings back together. If the caller supplies a non-empty value, `join` uses it. If it is not supplied, it will have a null value. In this case, `join` uses a single blank as a default separator for the strings. If the value is equal to `SUBSEP`, then `join` joins the strings with no separator between them. `SUBSEP` serves as a "magic" value to indicate that there should be no separation between the component strings.

It would be nice if `awk` had an assignment operator for concatenation. The lack of an explicit operator for concatenation makes string operations more difficult than they really need to be.

Turning Dates Into Timestamps

The `systime` function built in to `gawk` returns the current time of day as a timestamp in "seconds since the Epoch." This timestamp can be converted into a printable date of almost infinitely variable format using the built-in `strftime` function. (For more information on `systime` and `strftime`, see section Functions for Dealing with Time Stamps.)

An interesting but difficult problem is to convert a readable representation of a date back into a timestamp. The ANSI C library provides a `mktime` function that does the basic job, converting a canonical representation of a date into a timestamp.

It would appear at first glance that `gawk` would have to supply a `mktime` built-in function that was simply a "hook" to the C language version. In fact though, `mktime` can be implemented entirely in `awk`.

Here is a version of `mktime` for `awk`. It takes a simple representation of the date and time, and converts it into a timestamp.

The code is presented here intermixed with explanatory prose. In section Extracting Programs from Texinfo Source Files, you will see how the Texinfo source file for this book can be processed to extract the code into a single source file.

The program begins with a descriptive comment and a `BEGIN` rule that initializes a table `_tm_months`. This table is a two-dimensional array that has the lengths of the months. The first index is zero for regular years, and one for leap years. The values are the same for all the months in both kinds of years, except for February; thus the use of multiple assignment.

```
# mktime.awk -- convert a canonical date representation
#               into a timestamp
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

BEGIN    \
{
    # Initialize table of month lengths
    _tm_months[0,1] = _tm_months[1,1] = 31
    _tm_months[0,2] = 28; _tm_months[1,2] = 29
    _tm_months[0,3] = _tm_months[1,3] = 31
    _tm_months[0,4] = _tm_months[1,4] = 30
    _tm_months[0,5] = _tm_months[1,5] = 31
    _tm_months[0,6] = _tm_months[1,6] = 30
    _tm_months[0,7] = _tm_months[1,7] = 31
    _tm_months[0,8] = _tm_months[1,8] = 31
    _tm_months[0,9] = _tm_months[1,9] = 30
    _tm_months[0,10] = _tm_months[1,10] = 31
    _tm_months[0,11] = _tm_months[1,11] = 30
    _tm_months[0,12] = _tm_months[1,12] = 31
```

```
}
```

The benefit of merging multiple `BEGIN` rules (see section The `BEGIN` and `END` Special Patterns) is particularly clear when writing library files. Functions in library files can cleanly initialize their own private data and also provide clean-up actions in private `END` rules.

The next function is a simple one that computes whether a given year is or is not a leap year. If a year is evenly divisible by four, but not evenly divisible by 100, or if it is evenly divisible by 400, then it is a leap year. Thus, 1904 was a leap year, 1900 was not, but 2000 will be.

```
# decide if a year is a leap year
function _tm_isleap(year,    ret)
{
    ret = (year % 4 == 0 && year % 100 != 0) ||
            (year % 400 == 0)

    return ret
}
```

This function is only used a few times in this file, and its computation could have been written in-line (at the point where it's used). Making it a separate function made the original development easier, and also avoids the possibility of typing errors when duplicating the code in multiple places.

The next function is more interesting. It does most of the work of generating a timestamp, which is converting a date and time into some number of seconds since the Epoch. The caller passes an array (rather imaginatively named `a`) containing six values: the year including century, the month as a number between one and 12, the day of the month, the hour as a number between zero and 23, the minute in the hour, and the seconds within the minute.

The function uses several local variables to precompute the number of seconds in an hour, seconds in a day, and seconds in a year. Often, similar C code simply writes out the expression in-line, expecting the compiler to do constant folding. E.g., most C compilers would turn `60 * 60' into `3600' at compile time, instead of recomputing it every time at run time. Precomputing these values makes the function more efficient.

```
# convert a date into seconds
function _tm_addup(a,    total, yearsecs, daysecs,
                         hoursecs, i, j)
{
    hoursecs = 60 * 60
    daysecs = 24 * hoursecs
    yearsecs = 365 * daysecs

    total = (a[1] - 1970) * yearsecs

    # extra day for leap years
    for (i = 1970; i < a[1]; i++)
```

```
        if (_tm_isleap(i))
            total += daysecs

    j = _tm_isleap(a[1])
    for (i = 1; i < a[2]; i++)
        total += _tm_months[j, i] * daysecs

    total += (a[3] - 1) * daysecs
    total += a[4] * hoursecs
    total += a[5] * 60
    total += a[6]

    return total
}
```

The function starts with a first approximation of all the seconds between Midnight, January 1, 1970,(18) and the beginning of the current year. It then goes through all those years, and for every leap year, adds an additional day's worth of seconds.

The variable `j` holds either one or zero, if the current year is or is not a leap year. For every month in the current year prior to the current month, it adds the number of seconds in the month, using the appropriate entry in the `_tm_months` array.

Finally, it adds in the seconds for the number of days prior to the current day, and the number of hours, minutes, and seconds in the current day.

The result is a count of seconds since January 1, 1970. This value is not yet what is needed though. The reason why is described shortly.

The main `mktime` function takes a single character string argument. This string is a representation of a date and time in a "canonical" (fixed) form. This string should be `"year month day hour minute second"`.

```
# mktime -- convert a date into seconds,
#           compensate for time zone

function mktime(str,    res1, res2, a, b, i, j, t, diff)
{
    i = split(str, a, " ")    # don't rely on FS

    if (i != 6)
        return -1

    # force numeric
    for (j in a)
        a[j] += 0
```

```
    # validate
    if (a[1] < 1970 ||
        a[2] < 1 || a[2] > 12 ||
        a[3] < 1 || a[3] > 31 ||
        a[4] < 0 || a[4] > 23 ||
        a[5] < 0 || a[5] > 59 ||
        a[6] < 0 || a[6] > 61 )
            return -1

    res1 = _tm_addup(a)
    t = strftime("%Y %m %d %H %M %S", res1)

    if (_tm_debug)
        printf("(%s) -> (%s)\n", str, t) > "/dev/stderr"

    split(t, b, " ")
    res2 = _tm_addup(b)

    diff = res1 - res2

    if (_tm_debug)
        printf("diff = %d seconds\n", diff) > "/dev/stderr"

    res1 += diff

    return res1
}
```

The function first splits the string into an array, using spaces and tabs as separators. If there are not six elements in the array, it returns an error, signaled as the value -1. Next, it forces each element of the array to be numeric, by adding zero to it. The following `if' statement then makes sure that each element is within an allowable range. (This checking could be extended further, e.g., to make sure that the day of the month is within the correct range for the particular month supplied.) All of this is essentially preliminary set-up and error checking.

Recall that `_tm_addup` generated a value in seconds since Midnight, January 1, 1970. This value is not directly usable as the result we want, *since the calculation does not account for the local timezone*. In other words, the value represents the count in seconds since the Epoch, but only for UTC (Universal Coordinated Time). If the local timezone is east or west of UTC, then some number of hours should be either added to, or subtracted from the resulting timestamp.

For example, 6:23 p.m. in Atlanta, Georgia (USA), is normally five hours west of (behind) UTC. It is only four hours behind UTC if daylight savings time is in effect. If you are calling `mktime` in Atlanta, with the argument `"1993 5 23 18 23 12"`, the result from `_tm_addup` will be for 6:23 p.m. UTC, which is only 2:23 p.m. in Atlanta. It is necessary to add another four hours worth of seconds to the result.

How can `mktime` determine how far away it is from UTC? This is surprisingly easy. The returned timestamp represents the time passed to `mktime` *as UTC*. This timestamp can be fed back to `strftime`, which will format it as a *local* time; i.e. as if it already had the UTC difference added in to it. This is done by giving `"%Y %m %d %H %M %S"` to `strftime` as the format argument. It returns the computed timestamp in the original string format. The result represents a time that accounts for the UTC difference. When the new time is converted back to a timestamp, the difference between the two timestamps is the difference (in seconds) between the local timezone and UTC. This difference is then added back to the original result. An example demonstrating this is presented below.

Finally, there is a "main" program for testing the function.

```
BEGIN  {
    if (_tm_test) {
        printf "Enter date as yyyy mm dd hh mm ss: "
        getline _tm_test_date

        t = mktime(_tm_test_date)
        r = strftime("%Y %m %d %H %M %S", t)
        printf "Got back (%s)\n", r
    }
}
```

The entire program uses two variables that can be set on the command line to control debugging output and to enable the test in the final `BEGIN` rule. Here is the result of a test run. (Note that debugging output is to standard error, and test output is to standard output.)

```
$ gawk -f mktime.awk -v _tm_test=1 -v _tm_debug=1
-| Enter date as yyyy mm dd hh mm ss: 1993 5 23 15 35 10
error--> (1993 5 23 15 35 10) -> (1993 05 23 11 35 10)
error--> diff = 14400 seconds
-| Got back (1993 05 23 15 35 10)
```

The time entered was 3:35 p.m. (15:35 on a 24-hour clock), on May 23, 1993. The first line of debugging output shows the resulting time as UTC--four hours ahead of the local time zone. The second line shows that the difference is 14400 seconds, which is four hours. (The difference is only four hours, since daylight savings time is in effect during May.) The final line of test output shows that the timezone compensation algorithm works; the returned time is the same as the entered time.

This program does not solve the general problem of turning an arbitrary date representation into a timestamp. That problem is very involved. However, the `mktime` function provides a foundation upon which to build. Other software can convert month names into numeric months, and AM/PM times into 24-hour clocks, to generate the "canonical" format that `mktime` requires.

TOC

Managing the Time of Day

The `systime` and `strftime` functions described in section Functions for Dealing with Time Stamps, provide the minimum functionality necessary for dealing with the time of day in human readable form. While `strftime` is extensive, the control formats are not necessarily easy to remember or intuitively obvious when reading a program.

The following function, `gettimeofday`, populates a user-supplied array with pre-formatted time information. It returns a string with the current time formatted in the same way as the `date` utility.

```
# gettimeofday -- get the time of day in a usable format
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain, May 1993
#
# Returns a string in the format of output of date(1)
# Populates the array argument time with individual values:
#    time["second"]       -- seconds (0 - 59)
#    time["minute"]       -- minutes (0 - 59)
#    time["hour"]         -- hours (0 - 23)
#    time["althour"]      -- hours (0 - 12)
#    time["monthday"]     -- day of month (1 - 31)
#    time["month"]        -- month of year (1 - 12)
#    time["monthname"]    -- name of the month
#    time["shortmonth"]   -- short name of the month
#    time["year"]         -- year within century (0 - 99)
#    time["fullyear"]     -- year with century (19xx or 20xx)
#    time["weekday"]      -- day of week (Sunday = 0)
#    time["altweekday"]   -- day of week (Monday = 0)
#    time["weeknum"]      -- week number, Sunday first day
#    time["altweeknum"]   -- week number, Monday first day
#    time["dayname"]      -- name of weekday
#    time["shortdayname"] -- short name of weekday
#    time["yearday"]      -- day of year (0 - 365)
#    time["timezone"]     -- abbreviation of timezone name
#    time["ampm"]         -- AM or PM designation

function gettimeofday(time,    ret, now, i)
{
    # get time once, avoids unnecessary system calls
    now = systime()

    # return date(1)-style output
    ret = strftime("%a %b %d %H:%M:%S %Z %Y", now)

    # clear out target array
    for (i in time)
```

```
        delete time[i]

    # fill in values, force numeric values to be
    # numeric by adding 0
    time["second"]       = strftime("%S", now) + 0
    time["minute"]       = strftime("%M", now) + 0
    time["hour"]         = strftime("%H", now) + 0
    time["althour"]      = strftime("%I", now) + 0
    time["monthday"]     = strftime("%d", now) + 0
    time["month"]        = strftime("%m", now) + 0
    time["monthname"]    = strftime("%B", now)
    time["shortmonth"]   = strftime("%b", now)
    time["year"]         = strftime("%y", now) + 0
    time["fullyear"]     = strftime("%Y", now) + 0
    time["weekday"]      = strftime("%w", now) + 0
    time["altweekday"]   = strftime("%u", now) + 0
    time["dayname"]      = strftime("%A", now)
    time["shortdayname"] = strftime("%a", now)
    time["yearday"]      = strftime("%j", now) + 0
    time["timezone"]     = strftime("%Z", now)
    time["ampm"]         = strftime("%p", now)
    time["weeknum"]      = strftime("%U", now) + 0
    time["altweeknum"]   = strftime("%W", now) + 0

    return ret
}
```

The string indices are easier to use and read than the various formats required by `strftime`. The `alarm` program presented in section An Alarm Clock Program, uses this function.

The `gettimeofday` function is presented above as it was written. A more general design for this function would have allowed the user to supply an optional timestamp value that would have been used instead of the current time.

Noting Data File Boundaries

The `BEGIN` and `END` rules are each executed exactly once, at the beginning and end respectively of your `awk` program (see section The `BEGIN` and `END` Special Patterns). We (the `gawk` authors) once had a user who mistakenly thought that the `BEGIN` rule was executed at the beginning of each data file and the `END` rule was executed at the end of each data file. When informed that this was not the case, the user requested that we add new special patterns to `gawk`, named `BEGIN_FILE` and `END_FILE`, that would have the desired behavior. He even supplied us the code to do so.

However, after a little thought, I came up with the following library program. It arranges to call two user-supplied functions, `beginfile` and `endfile`, at the beginning and end of each data file. Besides solving the problem in only nine(!) lines of code, it does so *portably*; this will work with any

implementation of awk.

```
# transfile.awk
#
# Give the user a hook for filename transitions
#
# The user must supply functions beginfile() and endfile()
# that each take the name of the file being started or
# finished, respectively.
#
# Arnold Robbins, arnold@gnu.ai.mit.edu, January 1992
# Public Domain

FILENAME != _oldfilename \
{
    if (_oldfilename != "")
        endfile(_oldfilename)
    _oldfilename = FILENAME
    beginfile(FILENAME)
}

END   { endfile(FILENAME) }
```

This file must be loaded before the user's "main" program, so that the rule it supplies will be executed first.

This rule relies on awk's FILENAME variable that automatically changes for each new data file. The current file name is saved in a private variable, _oldfilename. If FILENAME does not equal _oldfilename, then a new data file is being processed, and it is necessary to call endfile for the old file. Since endfile should only be called if a file has been processed, the program first checks to make sure that _oldfilename is not the null string. The program then assigns the current file name to _oldfilename, and calls beginfile for the file. Since, like all awk variables, _oldfilename will be initialized to the null string, this rule executes correctly even for the first data file.

The program also supplies an END rule, to do the final processing for the last file. Since this END rule comes before any END rules supplied in the "main" program, endfile will be called first. Once again the value of multiple BEGIN and END rules should be clear.

This version has same problem as the first version of nextfile (see section Implementing nextfile as a Function). If the same data file occurs twice in a row on command line, then endfile and beginfile will not be executed at the end of the first pass and at the beginning of the second pass. This version solves the problem.

```
# ftrans.awk -- handle data file transitions
#
# user supplies beginfile() and endfile() functions
```

```
#
# Arnold Robbins, arnold@gnu.ai.mit.edu. November 1992
# Public Domain

FNR == 1 {
    if (_filename_ != "")
        endfile(_filename_)
    _filename_ = FILENAME
    beginfile(FILENAME)
}

END  { endfile(_filename_) }
```

In section Counting Things, you will see how this library function can be used, and how it simplifies writing the main program.

Processing Command Line Options

Most utilities on POSIX compatible systems take options or "switches" on the command line that can be used to change the way a program behaves. `awk` is an example of such a program (see section Command Line Options). Often, options take arguments, data that the program needs to correctly obey the command line option. For example, `awk`'s `-F' option requires a string to use as the field separator. The first occurrence on the command line of either `--' or a string that does not begin with `-' ends the options.

Most Unix systems provide a C function named `getopt` for processing command line arguments. The programmer provides a string describing the one letter options. If an option requires an argument, it is followed in the string with a colon. `getopt` is also passed the count and values of the command line arguments, and is called in a loop. `getopt` processes the command line arguments for option letters. Each time around the loop, it returns a single character representing the next option letter that it found, or `?' if it found an invalid option. When it returns -1, there are no options left on the command line.

When using `getopt`, options that do not take arguments can be grouped together. Furthermore, options that take arguments require that the argument be present. The argument can immediately follow the option letter, or it can be a separate command line argument.

Given a hypothetical program that takes three command line options, `-a', `-b', and `-c', and `-b' requires an argument, all of the following are valid ways of invoking the program:

```
prog -a -b foo -c data1 data2 data3
prog -ac -bfoo -- data1 data2 data3
prog -acbfoo data1 data2 data3
```

Notice that when the argument is grouped with its option, the rest of the command line argument is considered to be the option's argument. In the above example, `-acbfoo' indicates that all of the `-a', `-b', and `-c' options were supplied, and that `foo' is the argument to the `-b' option.

`getopt` provides four external variables that the programmer can use.

`optind`

The index in the argument value array (`argv`) where the first non-option command line argument can be found.

`optarg`

The string value of the argument to an option.

`opterr`

Usually `getopt` prints an error message when it finds an invalid option. Setting `opterr` to zero disables this feature. (An application might wish to print its own error message.)

`optopt`

The letter representing the command line option. While not usually documented, most versions supply this variable.

The following C fragment shows how `getopt` might process command line arguments for `awk`.

```
int
main(int argc, char *argv[])
{
    ...
    /* print our own message */
    opterr = 0;
    while ((c = getopt(argc, argv, "v:f:F:W:")) != -1) {
        switch (c) {
        case 'f':    /* file */
            ...
            break;
        case 'F':    /* field separator */
            ...
            break;
        case 'v':    /* variable assignment */
            ...
            break;
        case 'W':    /* extension */
            ...
            break;
        case '?':
        default:
            usage();
            break;
        }
    }
    ...
}
```

As a side point, `gawk` actually uses the GNU `getopt_long` function to process both normal and GNU-style long options (see section Command Line Options).

The abstraction provided by `getopt` is very useful, and would be quite handy in `awk` programs as well. Here is an `awk` version of `getopt`. This function highlights one of the greatest weaknesses in `awk`, which is that it is very poor at manipulating single characters. Repeated calls to `substr` are necessary for accessing individual characters (see section Built-in Functions for String Manipulation).

The discussion walks through the code a bit at a time.

```
# getopt -- do C library getopt(3) function in awk
#
# arnold@gnu.ai.mit.edu
# Public domain
#
# Initial version: March, 1991
# Revised: May, 1993

# External variables:
#    Optind -- index of ARGV for first non-option argument
#    Optarg -- string value of argument to current option
#    Opterr -- if non-zero, print our own diagnostic
#    Optopt -- current option letter

# Returns
#    -1     at end of options
#    ?      for unrecognized option
#    <c>    a character representing the current option

# Private Data
#    _opti  index in multi-flag option, e.g., -abc
```

The function starts out with some documentation: who wrote the code, and when it was revised, followed by a list of the global variables it uses, what the return values are and what they mean, and any global variables that are "private" to this library function. Such documentation is essential for any program, and particularly for library functions.

```
function getopt(argc, argv, options,    optl, thisopt, i)
{
    optl = length(options)
    if (optl == 0)        # no options given
        return -1

    if (argv[Optind] == "--") {  # all done
        Optind++
        _opti = 0
```

```
        return -1
    } else if (argv[Optind] !~ /^-[^: \t\n\f\r\v\b]/) {
        _opti = 0
        return -1
    }
```

The function first checks that it was indeed called with a string of options (the `options` parameter). If `options` has a zero length, `getopt` immediately returns -1.

The next thing to check for is the end of the options. A `--' ends the command line options, as does any command line argument that does not begin with a `-'. `Optind` is used to step through the array of command line arguments; it retains its value across calls to `getopt`, since it is a global variable.

The regexp used, `/^-[^: \t\n\f\r\v\b]/`, is perhaps a bit of overkill; it checks for a `-' followed by anything that is not whitespace and not a colon. If the current command line argument does not match this pattern, it is not an option, and it ends option processing.

```
    if (_opti == 0)
        _opti = 2
    thisopt = substr(argv[Optind], _opti, 1)
    Optopt = thisopt
    i = index(options, thisopt)
    if (i == 0) {
        if (Opterr)
            printf("%c -- invalid option\n",
                                    thisopt) > "/dev/stderr"
        if (_opti >= length(argv[Optind])) {
            Optind++
            _opti = 0
        } else
            _opti++
        return "?"
    }
```

The `_opti` variable tracks the position in the current command line argument (`argv[Optind]`). In the case that multiple options were grouped together with one `-' (e.g., `-abx'), it is necessary to return them to the user one at a time.

If `_opti` is equal to zero, it is set to two, the index in the string of the next character to look at (we skip the `-', which is at position one). The variable `thisopt` holds the character, obtained with `substr`. It is saved in `Optopt` for the main program to use.

If `thisopt` is not in the `options` string, then it is an invalid option. If `Opterr` is non-zero, `getopt` prints an error message on the standard error that is similar to the message from the C version of `getopt`.

Since the option is invalid, it is necessary to skip it and move on to the next option character. If `_opti` is greater than or equal to the length of the current command line argument, then it is necessary to move on

to the next one, so `Optind` is incremented and `_opti` is reset to zero. Otherwise, `Optind` is left al and `_opti` is merely incremented.

In any case, since the option was invalid, `getopt` returns `?'. The main program can examine `Optopt` if it needs to know what the invalid option letter actually was.

```
    if (substr(options, i + 1, 1) == ":") {
        # get option argument
        if (length(substr(argv[Optind], _opti + 1)) > 0)
            Optarg = substr(argv[Optind], _opti + 1)
        else
            Optarg = argv[++Optind]
        _opti = 0
    } else
        Optarg = ""
```

If the option requires an argument, the option letter is followed by a colon in the `options` string. If there are remaining characters in the current command line argument (`argv[Optind]`), then the rest of that string is assigned to `Optarg`. Otherwise, the next command line argument is used (`-xFOO' vs. `-x FOO'). In either case, `_opti` is reset to zero, since there are no more characters left to examine in the current command line argument.

```
    if (_opti == 0 || _opti >= length(argv[Optind])) {
        Optind++
        _opti = 0
    } else
        _opti++
    return thisopt
}
```

Finally, if `_opti` is either zero or greater than the length of the current command line argument, it means this element in `argv` is through being processed, so `Optind` is incremented to point to the next element in `argv`. If neither condition is true, then only `_opti` is incremented, so that the next option letter can be processed on the next call to `getopt`.

```
BEGIN {
    Opterr = 1    # default is to diagnose
    Optind = 1    # skip ARGV[0]

    # test program
    if (_getopt_test) {
        while ((_go_c = getopt(ARGC, ARGV, "ab:cd")) != -1)
            printf("c = <%c>, optarg = <%s>\n",
                                        _go_c, Optarg)
        printf("non-option arguments:\n")
        for (; Optind < ARGC; Optind++)
```

```
            printf("\tARGV[%d] = <%s>\n",
                                    Optind, ARGV[Optind])
    }
}
```

The `BEGIN` rule initializes both `Opterr` and `Optind` to one. `Opterr` is set to one, since the default behavior is for `getopt` to print a diagnostic message upon seeing an invalid option. `Optind` is set to one, since there's no reason to look at the program name, which is in `ARGV[0]`.

The rest of the `BEGIN` rule is a simple test program. Here is the result of two sample runs of the test program.

```
$ awk -f getopt.awk -v _getopt_test=1 -- -a -cbARG bax -x
-| c = <a>, optarg = <>
-| c = <c>, optarg = <>
-| c = <b>, optarg = <ARG>
-| non-option arguments:
-|         ARGV[3] = <bax>
-|         ARGV[4] = <-x>

$ awk -f getopt.awk -v _getopt_test=1 -- -a -x -- xyz abc
-| c = <a>, optarg = <>
error--> x -- invalid option
-| c = <?>, optarg = <>
-| non-option arguments:
-|         ARGV[4] = <xyz>
-|         ARGV[5] = <abc>
```

The first `--' terminates the arguments to `awk`, so that it does not try to interpret the `-a' etc. as its own options.

Several of the sample programs presented in section Practical `awk` Programs, use `getopt` to process their arguments.

Reading the User Database

The `/dev/user' special file (see section Special File Names in `gawk`) provides access to the current user's real and effective user and group id numbers, and if available, the user's supplementary group set. However, since these are numbers, they do not provide very useful information to the average user. There needs to be some way to find the user information associated with the user and group numbers. This section presents a suite of functions for retrieving information from the user database. See section Reading the Group Database, for a similar suite that retrieves information from the group database.

The POSIX standard does not define the file where user information is kept. Instead, it provides the `<pwd.h>` header file and several C language subroutines for obtaining user information. The primary function is `getpwent`, for "get password entry." The "password" comes from the original user database

file, `/etc/passwd', which kept user information, along with the encrypted passwords (hence th name).

While an `awk` program could simply read `/etc/passwd' directly (the format is well known), because of the way password files are handled on networked systems, this file may not contain complete information about the system's set of users.

To be sure of being able to produce a readable, complete version of the user database, it is necessary to write a small C program that calls `getpwent`. `getpwent` is defined to return a pointer to a `struct passwd`. Each time it is called, it returns the next entry in the database. When there are no more entries, it returns `NULL`, the null pointer. When this happens, the C program should call `endpwent` to close the database. Here is `pwcat`, a C program that "cats" the password database.

```
/*
 * pwcat.c
 *
 * Generate a printable version of the password database
 *
 * Arnold Robbins
 * arnold@gnu.ai.mit.edu
 * May 1993
 * Public Domain
 */

#include <stdio.h>
#include <pwd.h>

int
main(argc, argv)
int argc;
char **argv;
{
    struct passwd *p;

    while ((p = getpwent()) != NULL)
        printf("%s:%s:%d:%d:%s:%s:%s\n",
            p->pw_name, p->pw_passwd, p->pw_uid,
            p->pw_gid, p->pw_gecos, p->pw_dir, p->pw_shell);

    endpwent();
    exit(0);
}
```

If you don't understand C, don't worry about it. The output from `pwcat` is the user database, in the traditional `/etc/passwd' format of colon-separated fields. The fields are:

Login name

The user's login name.

Encrypted password

The user's encrypted password. This may not be available on some systems.

User-ID

The user's numeric user-id number.

Group-ID

The user's numeric group-id number.

Full name

The user's full name, and perhaps other information associated with the user.

Home directory

The user's login, or "home" directory (familiar to shell programmers as `$HOME`).

Login shell

The program that will be run when the user logs in. This is usually a shell, such as Bash (the Gnu Bourne-Again shell).

Here are a few lines representative of `pwcat`'s output.

```
$ pwcat
-| root:3Ov02d5VaUPB6:0:1:Operator:/:/bin/sh
-| nobody:*:65534:65534::/:
-| daemon:*:1:1::/:
-| sys:*:2:2::/:/bin/csh
-| bin:*:3:3::/bin:
-| arnold:xyzzy:2076:10:Arnold Robbins:/home/arnold:/bin/sh
-| miriam:yxaay:112:10:Miriam Robbins:/home/miriam:/bin/sh
...
```

With that introduction, here is a group of functions for getting user information. There are several functions here, corresponding to the C functions of the same name.

```
# passwd.awk -- access password file information
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

BEGIN {
    # tailor this to suit your system
    _pw_awklib = "/usr/local/libexec/awk/"
}

function _pw_init(    oldfs, oldrs, olddol0, pwcat)
{
    if (_pw_inited)
        return
```

```
    oldfs = FS
    oldrs = RS
    olddol0 = $0
    FS = ":"
    RS = "\n"
    pwcat = _pw_awklib "pwcat"
    while ((pwcat | getline) > 0) {
        _pw_byname[$1] = $0
        _pw_byuid[$3] = $0
        _pw_bycount[++_pw_total] = $0
    }
    close(pwcat)
    _pw_count = 0
    _pw_inited = 1
    FS = oldfs
    RS = oldrs
    $0 = olddol0
}
```

The `BEGIN` rule sets a private variable to the directory where `pwcat` is stored. Since it is used to help out an `awk` library routine, we have chosen to put it in `` `/usr/local/libexec/awk' ``. You might want it to be in a different directory on your system.

The function `_pw_init` keeps three copies of the user information in three associative arrays. The arrays are indexed by user name (`_pw_byname`), by user-id number (`_pw_byuid`), and by order of occurrence (`_pw_bycount`).

The variable `_pw_inited` is used for efficiency; `_pw_init` only needs to be called once.

Since this function uses `getline` to read information from `pwcat`, it first saves the values of `FS`, `RS`, and `$0`. Doing so is necessary, since these functions could be called from anywhere within a user's program, and the user may have his or her own values for `FS` and `RS`.

The main part of the function uses a loop to read database lines, split the line into fields, and then store the line into each array as necessary. When the loop is done, `_pw_init` cleans up by closing the pipeline, setting `_pw_inited` to one, and restoring `FS`, `RS`, and `$0`. The use of `_pw_count` will be explained below.

```
function getpwnam(name)
{
    _pw_init()
    if (name in _pw_byname)
        return _pw_byname[name]
    return ""
}
```

The `getpwnam` function takes a user name as a string argument. If that user is in the database, it returns

the appropriate line. Otherwise it returns the null string.

```
function getpwuid(uid)
{
    _pw_init()
    if (uid in _pw_byuid)
        return _pw_byuid[uid]
    return ""
}
```

Similarly, the `getpwuid` function takes a user-id number argument. If that user number is in the database, it returns the appropriate line. Otherwise it returns the null string.

```
function getpwent()
{
    _pw_init()
    if (_pw_count < _pw_total)
        return _pw_bycount[++_pw_count]
    return ""
}
```

The `getpwent` function simply steps through the database, one entry at a time. It uses `_pw_count` to track its current position in the `_pw_bycount` array.

```
function endpwent()
{
    _pw_count = 0
}
```

The `endpwent` function resets `_pw_count` to zero, so that subsequent calls to `getpwent` will start over again.

A conscious design decision in this suite is that each subroutine calls `_pw_init` to initialize the database arrays. The overhead of running a separate process to generate the user database, and the I/O to scan it, will only be incurred if the user's main program actually calls one of these functions. If this library file is loaded along with a user's program, but none of the routines are ever called, then there is no extra run-time overhead. (The alternative would be to move the body of `_pw_init` into a `BEGIN` rule, which would always run `pwcat`. This simplifies the code but runs an extra process that may never be needed.)

In turn, calling `_pw_init` is not too expensive, since the `_pw_inited` variable keeps the program from reading the data more than once. If you are worried about squeezing every last cycle out of your `awk` program, the check of `_pw_inited` could be moved out of `_pw_init` and duplicated in all the other functions. In practice, this is not necessary, since most `awk` programs are I/O bound, and it would clutter up the code.

The `id` program in section Printing Out User Information, uses these functions.

Reading the Group Database

Much of the discussion presented in section Reading the User Database, applies to the group database as well. Although there has traditionally been a well known file, `/etc/group', in a well known format, the POSIX standard only provides a set of C library routines (<grp.h> and getgrent) for accessing the information. Even though this file may exist, it likely does not have complete information. Therefore, as with the user database, it is necessary to have a small C program that generates the group database as its output.

Here is grcat, a C program that "cats" the group database.

```
/*
 * grcat.c
 *
 * Generate a printable version of the group database
 *
 * Arnold Robbins, arnold@gnu.ai.mit.edu
 * May 1993
 * Public Domain
 */

#include <stdio.h>
#include <grp.h>

int
main(argc, argv)
int argc;
char **argv;
{
    struct group *g;
    int i;

    while ((g = getgrent()) != NULL) {
        printf("%s:%s:%d:", g->gr_name, g->gr_passwd,
                                            g->gr_gid);
        for (i = 0; g->gr_mem[i] != NULL; i++) {
            printf("%s", g->gr_mem[i]);
            if (g->gr_mem[i+1] != NULL)
                putchar(',');
        }
        putchar('\n');
    }
    endgrent();
    exit(0);
```

```
}
```

Each line in the group database represent one group. The fields are separated with colons, and represent the following information.

Group Name

The name of the group.

Group Password

The encrypted group password. In practice, this field is never used. It is usually empty, or set to `*'.

Group ID Number

The numeric group-id number. This number should be unique within the file.

Group Member List

A comma-separated list of user names. These users are members of the group. Most Unix systems allow users to be members of several groups simultaneously. If your system does, then reading `/dev/user' will return those group-id numbers in $5 through $NF. (Note that `/dev/user' is a gawk extension; see section Special File Names in gawk.)

Here is what running grcat might produce:

```
$ grcat
-| wheel:*:0:arnold
-| nogroup:*:65534:
-| daemon:*:1:
-| kmem:*:2:
-| staff:*:10:arnold,miriam,andy
-| other:*:20:
...
```

Here are the functions for obtaining information from the group database. There are several, modeled after the C library functions of the same names.

```
# group.awk -- functions for dealing with the group file
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

BEGIN    \
{
    # Change to suit your system
    _gr_awklib = "/usr/local/libexec/awk/"
}

function _gr_init(    oldfs, oldrs, olddol0, grcat, n, a, i)
{
    if (_gr_inited)
```

```
        return

    oldfs = FS
    oldrs = RS
    olddol0 = $0
    FS = ":"
    RS = "\n"

    grcat = _gr_awklib "grcat"
    while ((grcat | getline) > 0) {
        if ($1 in _gr_byname)
            _gr_byname[$1] = _gr_byname[$1] "," $4
        else
            _gr_byname[$1] = $0
        if ($3 in _gr_bygid)
            _gr_bygid[$3] = _gr_bygid[$3] "," $4
        else
            _gr_bygid[$3] = $0

        n = split($4, a, "[ \t]*,[ \t]*")
        for (i = 1; i <= n; i++)
            if (a[i] in _gr_groupsbyuser)
                _gr_groupsbyuser[a[i]] = \
                    _gr_groupsbyuser[a[i]] " " $1
            else
                _gr_groupsbyuser[a[i]] = $1

        _gr_bycount[++_gr_count] = $0
    }
    close(grcat)
    _gr_count = 0
    _gr_inited++
    FS = oldfs
    RS = oldrs
    $0 = olddol0
}
```

The `BEGIN` rule sets a private variable to the directory where `grcat` is stored. Since it is used to help out an `awk` library routine, we have chosen to put it in `` `/usr/local/libexec/awk' ``. You might want it to be in a different directory on your system.

These routines follow the same general outline as the user database routines (see section Reading the User Database). The `_gr_inited` variable is used to ensure that the database is scanned no more than once. The `_gr_init` function first saves `FS`, `RS`, and `$0`, and then sets `FS` and `RS` to the correct values for scanning the group information.

The group information is stored is several associative arrays. The arrays are indexed by group name (`_gr_byname`), by group-id number (`_gr_bygid`), and by position in the database (`_gr_bycou`). There is an additional array indexed by user name (`_gr_groupsbyuser`), that is a space separated list of groups that each user belongs to.

Unlike the user database, it is possible to have multiple records in the database for the same group. This is common when a group has a large number of members. Such a pair of entries might look like:

```
tvpeople:*:101:johny,jay,arsenio
tvpeople:*:101:david,conan,tom,joan
```

For this reason, `_gr_init` looks to see if a group name or group-id number has already been seen. If it has, then the user names are simply concatenated onto the previous list of users. (There is actually a subtle problem with the code presented above. Suppose that the first time there were no names. This code adds the names with a leading comma. It also doesn't check that there is a `$4`.)

Finally, `_gr_init` closes the pipeline to `grcat`, restores `FS`, `RS`, and `$0`, initializes `_gr_count` to zero (it is used later), and makes `_gr_inited` non-zero.

```
function getgrnam(group)
{
    _gr_init()
    if (group in _gr_byname)
        return _gr_byname[group]
    return ""
}
```

The `getgrnam` function takes a group name as its argument, and if that group exists, it is returned. Otherwise, `getgrnam` returns the null string.

```
function getgrgid(gid)
{
    _gr_init()
    if (gid in _gr_bygid)
        return _gr_bygid[gid]
    return ""
}
```

The `getgrgid` function is similar, it takes a numeric group-id, and looks up the information associated with that group-id.

```
function getgruser(user)
{
    _gr_init()
    if (user in _gr_groupsbyuser)
        return _gr_groupsbyuser[user]
```

```
    return ""
}
```

The `getgruser` function does not have a C counterpart. It takes a user name, and returns the list of groups that have the user as a member.

```
function getgrent()
{
    _gr_init()
    if (++gr_count in _gr_bycount)
        return _gr_bycount[_gr_count]
    return ""
}
```

The `getgrent` function steps through the database one entry at a time. It uses `_gr_count` to track its position in the list.

```
function endgrent()
{
    _gr_count = 0
}
```

`endgrent` resets `_gr_count` to zero so that `getgrent` can start over again.

As with the user database routines, each function calls `_gr_init` to initialize the arrays. Doing so only incurs the extra overhead of running `grcat` if these functions are used (as opposed to moving the body of `_gr_init` into a `BEGIN` rule).

Most of the work is in scanning the database and building the various associative arrays. The functions that the user calls are themselves very simple, relying on `awk`'s associative arrays to do work.

The `id` program in section Printing Out User Information, uses these functions.

Naming Library Function Global Variables

Due to the way the `awk` language evolved, variables are either global (usable by the entire program), or local (usable just by a specific function). There is no intermediate state analogous to `static` variables in C.

Library functions often need to have global variables that they can use to preserve state information between calls to the function. For example, `getopt`'s variable `_opti` (see section Processing Command Line Options), and the `_tm_months` array used by `mktime` (see section Turning Dates Into Timestamps). Such variables are called private, since the only functions that need to use them are the ones in the library.

When writing a library function, you should try to choose names for your private variables so that they will not conflict with any variables used by either another library function or a user's main program. For

example, a name like `i' or `j' is not a good choice, since user programs often use variable names like these for their own purposes.

The example programs shown in this chapter all start the names of their private variables with an underscore (`_'). Users generally don't use leading underscores in their variable names, so this convention immediately decreases the chances that the variable name will be accidentally shared with the user's program.

In addition, several of the library functions use a prefix that helps indicate what function or set of functions uses the variables. For example, `_tm_months` in `mktime` (see section Turning Dates Into Timestamps), and `_pw_byname` in the user data base routines (see section Reading the User Database). This convention is recommended, since it even further decreases the chance of inadvertent conflict among variable names. Note that this convention can be used equally well both for variable names and for private function names too.

While I could have re-written all the library routines to use this convention, I did not do so, in order to show how my own `awk` programming style has evolved, and to provide some basis for this discussion.

As a final note on variable naming, if a function makes global variables available for use by a main program, it is a good convention to start that variable's name with a capital letter. For example, `getopt`'s `Opterr` and `Optind` variables (see section Processing Command Line Options). The leading capital letter indicates that it is global, while the fact that the variable name is not all capital letters indicates that the variable is not one of `awk`'s built-in variables, like `FS`.

It is also important that *all* variables in library functions that do not need to save state are in fact declared local. If this is not done, the variable could accidentally be used in the user's program, leading to bugs that are very difficult to track down.

```
function lib_func(x, y,    l1, l2)
{
    ...
    use variable some_var  # some_var could be local
    ...                    # but is not by oversight
}
```

A different convention, common in the Tcl community, is to use a single associative array to hold the values needed by the library function(s), or "package." This significantly decreases the number of actual global names in use. For example, the functions described in section Reading the User Database, might have used `PW_data["inited"]`, `PW_data["total"]`, `PW_data["count"]` and `PW_data["awklib"]`, instead of `_pw_inited`, `_pw_awklib`, `_pw_total`, and `_pw_count`.

The conventions presented in this section are exactly that, conventions. You are not required to write your programs this way, we merely recommend that you do so.

Go to the previous, next section.

Go to the previous, next section.

Practical awk Programs

This chapter presents a potpourri of `awk` programs for your reading enjoyment. There are two sections. The first presents `awk` versions of several common POSIX utilities. The second is a grab-bag of interesting programs.

Many of these programs use the library functions presented in section A Library of `awk` Functions.

Re-inventing Wheels for Fun and Profit

This section presents a number of POSIX utilities that are implemented in `awk`. Re-inventing these programs in `awk` is often enjoyable, since the algorithms can be very clearly expressed, and usually the code is very concise and simple. This is true because `awk` does so much for you.

It should be noted that these programs are not necessarily intended to replace the installed versions on your system. Instead, their purpose is to illustrate `awk` language programming for "real world" tasks.

The programs are presented in alphabetical order.

Cutting Out Fields and Columns

The `cut` utility selects, or "cuts," either characters or fields from its standard input and sends them to its standard output. `cut` can cut out either a list of characters, or a list of fields. By default, fields are separated by tabs, but you may supply a command line option to change the field delimiter, i.e. the field separator character. `cut`'s definition of fields is less general than `awk`'s.

A common use of `cut` might be to pull out just the login name of logged-on users from the output of `who`. For example, the following pipeline generates a sorted, unique list of the logged on users:

```
who | cut -c1-8 | sort | uniq
```

The options for `cut` are:

`-c list`
: Use list as the list of characters to cut out. Items within the list may be separated by commas, and ranges of characters can be separated with dashes. The list `1-8,15,22-35' specifies characters one through eight, 15, and 22 through 35.

`-f list`
: Use list as the list of fields to cut out.

`-d delim`
: Use delim as the field separator character instead of the tab character.

`-s`

TOC

Suppress printing of lines that do not contain the field delimiter.

The `awk` implementation of `cut` uses the `getopt` library function (see section Processing Command Line Options), and the `join` library function (see section Merging an Array Into a String).

The program begins with a comment describing the options and a `usage` function which prints out a usage message and exits. `usage` is called if invalid arguments are supplied.

```
# cut.awk -- implement cut in awk
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

# Options:
#    -f list        Cut fields
#    -d c           Field delimiter character
#    -c list        Cut characters
#
#    -s        Suppress lines without the delimiter character

function usage(    e1, e2)
{
    e1 = "usage: cut [-f list] [-d c] [-s] [files...]"
    e2 = "usage: cut [-c list] [files...]"
    print e1 > "/dev/stderr"
    print e2 > "/dev/stderr"
    exit 1
}
```

The variables `e1` and `e2` are used so that the function fits nicely on the page.

Next comes a `BEGIN` rule that parses the command line options. It sets `FS` to a single tab character, since that is `cut`'s default field separator. The output field separator is also set to be the same as the input field separator. Then `getopt` is used to step through the command line options. One or the other of the variables `by_fields` or `by_chars` is set to true, to indicate that processing should be done by fields or by characters respectively. When cutting by characters, the output field separator is set to the null string.

```
BEGIN    \
{
    FS = "\t"    # default
    OFS = FS
    while ((c = getopt(ARGC, ARGV, "sf:c:d:")) != -1) {
        if (c == "f") {
            by_fields = 1
            fieldlist = Optarg
        } else if (c == "c") {
```

```
            by_chars = 1
            fieldlist = Optarg
            OFS = ""
        } else if (c == "d") {
            if (length(Optarg) > 1) {
                printf("Using first character of %s" \
                " for delimiter\n", Optarg) > "/dev/stderr"
                Optarg = substr(Optarg, 1, 1)
            }
            FS = Optarg
            OFS = FS
            if (FS == " ")    # defeat awk semantics
                FS = "[ ]"
        } else if (c == "s")
            suppress++
        else
            usage()
    }

    for (i = 1; i < Optind; i++)
        ARGV[i] = ""
```

Special care is taken when the field delimiter is a space. Using `" "` (a single space) for the value of `FS` is incorrect---`awk` would separate fields with runs of spaces and/or tabs, and we want them to be separated with individual spaces. Also, note that after `getopt` is through, we have to clear out all the elements of `ARGV` from one to `Optind`, so that `awk` will not try to process the command line options as file names.

After dealing with the command line options, the program verifies that the options make sense. Only one or the other of `-c' and `-f' should be used, and both require a field list. Then either `set_fieldlist` or `set_charlist` is called to pull apart the list of fields or characters.

```
    if (by_fields && by_chars)
        usage()

    if (by_fields == 0 && by_chars == 0)
        by_fields = 1    # default

    if (fieldlist == "") {
        print "cut: needs list for -c or -f" > "/dev/stderr"
        exit 1
    }

    if (by_fields)
        set_fieldlist()
    else
        set_charlist()
```

```
}
```

Here is `set_fieldlist`. It first splits the field list apart at the commas, into an array. Then, for each element of the array, it looks to see if it is actually a range, and if so splits it apart. The range is verified to make sure the first number is smaller than the second. Each number in the list is added to the `flist` array, which simply lists the fields that will be printed. Normal field splitting is used. The program lets `awk` handle the job of doing the field splitting.

```
function set_fieldlist(        n, m, i, j, k, f, g)
{
    n = split(fieldlist, f, ",")
    j = 1    # index in flist
    for (i = 1; i <= n; i++) {
        if (index(f[i], "-") != 0) { # a range
            m = split(f[i], g, "-")
            if (m != 2 || g[1] >= g[2]) {
                printf("bad field list: %s\n",
                                    f[i]) > "/dev/stderr"
                exit 1
            }
            for (k = g[1]; k <= g[2]; k++)
                flist[j++] = k
        } else
            flist[j++] = f[i]
    }
    nfields = j - 1
}
```

The `set_charlist` function is more complicated than `set_fieldlist`. The idea here is to use `gawk`'s `FIELDWIDTHS` variable (see section Reading Fixed-width Data), which describes constant width input. When using a character list, that is exactly what we have.

Setting up `FIELDWIDTHS` is more complicated than simply listing the fields that need to be printed. We have to keep track of the fields to be printed, and also the intervening characters that have to be skipped. For example, suppose you wanted characters one through eight, 15, and 22 through 35. You would use `-c 1-8,15,22-35'. The necessary value for `FIELDWIDTHS` would be `"8 6 1 6 14"`. This gives us five fields, and what should be printed are `$1`, `$3`, and `$5`. The intermediate fields are "filler," stuff in between the desired data.

`flist` lists the fields to be printed, and `t` tracks the complete field list, including filler fields.

```
function set_charlist(    field, i, j, f, g, t,
                          filler, last, len)
{
    field = 1   # count total fields
    n = split(fieldlist, f, ",")
```

```
    j = 1       # index in flist
    for (i = 1; i <= n; i++) {
        if (index(f[i], "-") != 0) { # range
            m = split(f[i], g, "-")
            if (m != 2 || g[1] >= g[2]) {
                printf(bad character list: %s\n",
                                f[i]) > "/dev/stderr"
                exit 1
            }
            len = g[2] - g[1] + 1
            if (g[1] > 1)  # compute length of filler
                filler = g[1] - last - 1
            else
                filler = 0
            if (filler)
                t[field++] = filler
            t[field++] = len  # length of field
            last = g[2]
            flist[j++] = field - 1
        } else {
            if (f[i] > 1)
                filler = f[i] - last - 1
            else
                filler = 0
            if (filler)
                t[field++] = filler
            t[field++] = 1
            last = f[i]
            flist[j++] = field - 1
        }
    }
    FIELDWIDTHS = join(t, 1, field - 1)
    nfields = j - 1
}
```

Here is the rule that actually processes the data. If the `-s' option was given, then `suppress` will be true. The first `if` statement makes sure that the input record does have the field separator. If `cut` is processing fields, `suppress` is true, and the field separator character is not in the record, then the record is skipped.

If the record is valid, then at this point, `gawk` has split the data into fields, either using the character in `FS` or using fixed-length fields and `FIELDWIDTHS`. The loop goes through the list of fields that should be printed. If the corresponding field has data in it, it is printed. If the next field also has data, then the separator character is written out in between the fields.

```
{
```

```
    if (by_fields && suppress && $0 !~ FS)
        next

    for (i = 1; i <= nfields; i++) {
        if ($flist[i] != "") {
            printf "%s", $flist[i]
            if (i < nfields && $flist[i+1] != "")
                printf "%s", OFS
        }
    }
    print ""
}
```

This version of `cut` relies on `gawk`'s `FIELDWIDTHS` variable to do the character-based cutting. While it would be possible in other `awk` implementations to use `substr` (see section Built-in Functions for String Manipulation), it would also be extremely painful to do so. The `FIELDWIDTHS` variable supplies an elegant solution to the problem of picking the input line apart by characters.

Searching for Regular Expressions in Files

The `egrep` utility searches files for patterns. It uses regular expressions that are almost identical to those available in `awk` (see section Regular Expression Constants). It is used this way:

```
egrep [ options ] 'pattern' files ...
```

The pattern is a regexp. In typical usage, the regexp is quoted to prevent the shell from expanding any of the special characters as file name wildcards. Normally, `egrep` prints the lines that matched. If multiple file names are provided on the command line, each output line is preceded by the name of the file and a colon.

The options are:

`-c`
: Print out a count of the lines that matched the pattern, instead of the lines themselves.

`-s`
: Be silent. No output is produced, and the exit value indicates whether or not the pattern was matched.

`-v`
: Invert the sense of the test. `egrep` prints the lines that do *not* match the pattern, and exits successfully if the pattern was not matched.

`-i`
: Ignore case distinctions in both the pattern and the input data.

`-l`
: Only print the names of the files that matched, not the lines that matched.

`-e pattern`

Use pattern as the regexp to match. The purpose of the `-e' option is to allow patterns that start with a `-'.

This version uses the `getopt` library function (see section Processing Command Line Options), and the file transition library program (see section Noting Data File Boundaries).

The program begins with a descriptive comment, and then a `BEGIN` rule that processes the command line arguments with `getopt`. The `-i' (ignore case) option is particularly easy with `gawk`; we just use the `IGNORECASE` built in variable (see section Built-in Variables).

```
# egrep.awk -- simulate egrep in awk
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

# Options:
#    -c    count of lines
#    -s    silent - use exit value
#    -v    invert test, success if no match
#    -i    ignore case
#    -l    print filenames only
#    -e    argument is pattern

BEGIN {
    while ((c = getopt(ARGC, ARGV, "ce:svil")) != -1) {
        if (c == "c")
            count_only++
        else if (c == "s")
            no_print++
        else if (c == "v")
            invert++
        else if (c == "i")
            IGNORECASE = 1
        else if (c == "l")
            filenames_only++
        else if (c == "e")
            pattern = Optarg
        else
            usage()
    }
```

Next comes the code that handles the `egrep` specific behavior. If no pattern was supplied with `-e', the first non-option on the command line is used. The `awk` command line arguments up to `ARGV[Optind]` are cleared, so that `awk` won't try to process them as files. If no files were specified, the standard input is used, and if multiple files were specified, we make sure to note this so that the file names can precede the matched lines in the output.

The last two lines are commented out, since they are not needed in `gawk`. They should be uncommented if you have to use another version of `awk`.

```
    if (pattern == "")
        pattern = ARGV[Optind++]

    for (i = 1; i < Optind; i++)
        ARGV[i] = ""
    if (Optind >= ARGC) {
        ARGV[1] = "-"
        ARGC = 2
    } else if (ARGC - Optind > 1)
        do_filenames++

#    if (IGNORECASE)
#        pattern = tolower(pattern)
}
```

The next set of lines should be uncommented if you are not using `gawk`. This rule translates all the characters in the input line into lower-case if the `-i' option was specified. The rule is commented out since it is not necessary with `gawk`.

```
#{
#    if (IGNORECASE)
#        $0 = tolower($0)
#}
```

The `beginfile` function is called by the rule in `` `ftrans.awk' `` when each new file is processed. In this case, it is very simple; all it does is initialize a variable `fcount` to zero. `fcount` tracks how many lines in the current file matched the pattern.

```
function beginfile(junk)
{
    fcount = 0
}
```

The `endfile` function is called after each file has been processed. It is used only when the user wants a count of the number of lines that matched. `no_print` will be true only if the exit status is desired. `count_only` will be true if line counts are desired. `egrep` will therefore only print line counts if printing and counting are enabled. The output format must be adjusted depending upon the number of files to be processed. Finally, `fcount` is added to `total`, so that we know how many lines altogether matched the pattern.

```
function endfile(file)
{
```

```
    if (! no_print && count_only)
        if (do_filenames)
            print file ":" fcount
        else
            print fcount

    total += fcount
}
```

This rule does most of the work of matching lines. The variable `matches` will be true if the line matched the pattern. If the user wants lines that did not match, the sense of the `matches` is inverted using the `!' operator. `fcount` is incremented with the value of `matches`, which will be either one or zero, depending upon a successful or unsuccessful match. If the line did not match, the `next` statement just moves on to the next record.

There are several optimizations for performance in the following few lines of code. If the user only wants exit status (`no_print` is true), and we don't have to count lines, then it is enough to know that one line in this file matched, and we can skip on to the next file with `nextfile`. Along similar lines, if we are only printing file names, and we don't need to count lines, we can print the file name, and then skip to the next file with `nextfile`.

Finally, each line is printed, with a leading filename and colon if necessary.

```
{
    matches = ($0 ~ pattern)
    if (invert)
        matches = ! matches

    fcount += matches    # 1 or 0

    if (! matches)
        next

    if (no_print && ! count_only)
        nextfile

    if (filenames_only && ! count_only) {
        print FILENAME
        nextfile
    }

    if (do_filenames && ! count_only)
        print FILENAME ":" $0
    else if (! count_only)
        print
}
```

The END rule takes care of producing the correct exit status. If there were no matches, the exit status is one, otherwise it is zero.

```
END    \
{
    if (total == 0)
        exit 1
    exit 0
}
```

The usage function prints a usage message in case of invalid options and then exits.

```
function usage(    e)
{
    e = "Usage: egrep [-csvil] [-e pat] [files ...]"
    print e > "/dev/stderr"
    exit 1
}
```

The variable e is used so that the function fits nicely on the printed page.

Printing Out User Information

The id utility lists a user's real and effective user-id numbers, real and effective group-id numbers, and the user's group set, if any. id will only print the effective user-id and group-id if they are different from the real ones. If possible, id will also supply the corresponding user and group names. The output might look like this:

```
$ id
-| uid=2076(arnold) gid=10(staff) groups=10(staff),4(tty)
```

This information is exactly what is provided by gawk's `/dev/user' special file (see section Special File Names in gawk). However, the id utility provides a more palatable output than just a string of numbers.

Here is a simple version of id written in awk. It uses the user database library functions (see section Reading the User Database), and the group database library functions (see section Reading the Group Database).

The program is fairly straightforward. All the work is done in the BEGIN rule. The user and group id numbers are obtained from `/dev/user'. If there is no support for `/dev/user', the program gives up.

The code is repetitive. The entry in the user database for the real user-id number is split into parts at the `:'. The name is the first field. Similar code is used for the effective user-id number, and the group numbers.

```
# id.awk -- implement id in awk
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

# output is:
# uid=12(foo) euid=34(bar) gid=3(baz) \
#             egid=5(blat) groups=9(nine),2(two),1(one)

BEGIN    \
{
    if ((getline < "/dev/user") < 0) {
        err = "id: no /dev/user support - cannot run"
        print err > "/dev/stderr"
        exit 1
    }
    close("/dev/user")

    uid = $1
    euid = $2
    gid = $3
    egid = $4

    printf("uid=%d", uid)
    pw = getpwuid(uid)
    if (pw != "") {
        split(pw, a, ":")
        printf("(%s)", a[1])
    }

    if (euid != uid) {
        printf(" euid=%d", euid)
        pw = getpwuid(euid)
        if (pw != "") {
            split(pw, a, ":")
            printf("(%s)", a[1])
        }
    }

    printf(" gid=%d", gid)
    pw = getgrgid(gid)
    if (pw != "") {
        split(pw, a, ":")
        printf("(%s)", a[1])
    }
```

```
    if (egid != gid) {
        printf(" egid=%d", egid)
        pw = getgrgid(egid)
        if (pw != "") {
            split(pw, a, ":")
            printf("(%s)", a[1])
        }
    }

    if (NF > 4) {
        printf(" groups=");
        for (i = 5; i <= NF; i++) {
            printf("%d", $i)
            pw = getgrgid($i)
            if (pw != "") {
                split(pw, a, ":")
                printf("(%s)", a[1])
            }
            if (i < NF)
                printf(",")
        }
    }
    print ""
}
```

Splitting a Large File Into Pieces

The `split` program splits large text files into smaller pieces. By default, the output files are named `` `xaa' ``, `` `xab' ``, and so on. Each file has 1000 lines in it, with the likely exception of the last file. To change the number of lines in each file, you supply a number on the command line preceded with a minus, e.g., `-500' for files with 500 lines in them instead of 1000. To change the name of the output files to something like `` `myfileaa' ``, `` `myfileab' ``, and so on, you supply an additional argument that specifies the filename.

Here is a version of `split` in `awk`. It uses the `ord` and `chr` functions presented in section Translating Between Characters and Numbers.

The program first sets its defaults, and then tests to make sure there are not too many arguments. It then looks at each argument in turn. The first argument could be a minus followed by a number. If it is, this happens to look like a negative number, so it is made positive, and that is the count of lines. The data file name is skipped over, and the final argument is used as the prefix for the output file names.

```
# split.awk -- do split in awk
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993
```

```
# usage: split [-num] [file] [outname]

BEGIN    \
{
    outfile = "x"    # default
    count = 1000
    if (ARGC > 4)
        usage()

    i = 1
    if (ARGV[i] ~ /^-[0-9]+$/) {
        count = -ARGV[i]
        ARGV[i] = ""
        i++
    }
    # test argv in case reading from stdin instead of file
    if (i in ARGV)
        i++    # skip data file name
    if (i in ARGV) {
        outfile = ARGV[i]
        ARGV[i] = ""
    }

    s1 = s2 = "a"
    out = (outfile s1 s2)
}
```

The next rule does most of the work. `tcount` (temporary count) tracks how many lines have been printed to the output file so far. If it is greater than `count`, it is time to close the current file and start a new one. `s1` and `s2` track the current suffixes for the file name. If they are both `z', the file is just too big. Otherwise, `s1` moves to the next letter in the alphabet and `s2` starts over again at `a'.

```
{
    if (++tcount > count) {
        close(out)
        if (s2 == "z") {
            if (s1 == "z") {
                printf("split: %s is too large to split\n", \
                       FILENAME) > "/dev/stderr"
                exit 1
            }
            s1 = chr(ord(s1) + 1)
            s2 = "a"
        } else
            s2 = chr(ord(s2) + 1)
        out = (outfile s1 s2)
```

```
        tcount = 1
    }
    print > out
}
```

The `usage` function simply prints an error message and exits.

```
function usage(   e)
{
    e = "usage: split [-num] [file] [outname]"
    print e > "/dev/stderr"
    exit 1
}
```

The variable `e` is used so that the function fits nicely on the page.

This program is a bit sloppy; it relies on `awk` to close the last file for it automatically, instead of doing it in an `END` rule.

Duplicating Output Into Multiple Files

The `tee` program is known as a "pipe fitting." `tee` copies its standard input to its standard output, and also duplicates it to the files named on the command line. Its usage is:

```
tee [-a] file ...
```

The `-a' option tells `tee` to append to the named files, instead of truncating them and starting over.

The `BEGIN` rule first makes a copy of all the command line arguments, into an array named `copy`. `ARGV[0]` is not copied, since it is not needed. `tee` cannot use `ARGV` directly, since `awk` will attempt to process each file named in `ARGV` as input data.

If the first argument is `-a', then the flag variable `append` is set to true, and both `ARGV[1]` and `copy[1]` are deleted. If `ARGC` is less than two, then no file names were supplied, and `tee` prints a usage message and exits. Finally, `awk` is forced to read the standard input by setting `ARGV[1]` to `"-"`, and `ARGC` to two.

```
# tee.awk -- tee in awk
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993
# Revised December 1995

BEGIN    \
{
    for (i = 1; i < ARGC; i++)
        copy[i] = ARGV[i]
```

```
    if (ARGV[1] == "-a") {
        append = 1
        delete ARGV[1]
        delete copy[1]
        ARGC--
    }
    if (ARGC < 2) {
        print "usage: tee [-a] file ..." > "/dev/stderr"
        exit 1
    }
    ARGV[1] = "-"
    ARGC = 2
}
```

The single rule does all the work. Since there is no pattern, it is executed for each line of input. The body of the rule simply prints the line into each file on the command line, and then to the standard output.

```
{
    # moving the if outside the loop makes it run faster
    if (append)
        for (i in copy)
            print >> copy[i]
    else
        for (i in copy)
            print > copy[i]
    print
}
```

It would have been possible to code the loop this way:

```
for (i in copy)
    if (append)
        print >> copy[i]
    else
        print > copy[i]
```

This is more concise, but it is also less efficient. The `if' is tested for each record and for each output file. By duplicating the loop body, the `if' is only tested once for each input record. If there are N input records and M input files, the first method only executes N `if' statements, while the second would execute N*M `if' statements.

Finally, the `END' rule cleans up, by closing all the output files.

```
END    \
{
    for (i in copy)
```

```
        close(copy[i])
}
```

Printing Non-duplicated Lines of Text

The `uniq` utility reads sorted lines of data on its standard input, and (by default) removes duplicate lines. In other words, only unique lines are printed, hence the name. `uniq` has a number of options. The usage is:

```
uniq [-udc [-n]] [+n] [ input file [ output file ]]
```

The option meanings are:

`-d`
: Only print repeated lines.

`-u`
: Only print non-repeated lines.

`-c`
: Count lines. This option overrides `-d' and `-u'. Both repeated and non-repeated lines are counted.

`-n`
: Skip n fields before comparing lines. The definition of fields is the same as `awk`'s default: non-whitespace characters separated by runs of spaces and/or tabs.

`+n`
: Skip n characters before comparing lines. Any fields specified with `-n' are skipped first.

`input file`
: Data is read from the input file named on the command line, instead of from the standard input.

`output file`
: The generated output is sent to the named output file, instead of to the standard output.

Normally `uniq` behaves as if both the `-d' and `-u' options had been provided.

Here is an `awk` implementation of `uniq`. It uses the `getopt` library function (see section Processing Command Line Options), and the `join` library function (see section Merging an Array Into a String).

The program begins with a `usage` function and then a brief outline of the options and their meanings in a comment.

The `BEGIN` rule deals with the command line arguments and options. It uses a trick to get `getopt` to handle options of the form `-25', treating such an option as the option letter `2' with an argument of `5'. If indeed two or more digits were supplied (`Optarg` looks like a number), `Optarg` is concatenated with the option digit, and then result is added to zero to make it into a number. If there is only one digit in the option, then `Optarg` is not needed, and `Optind` must be decremented so that `getopt` will process it next time. This code is admittedly a bit tricky.

If no options were supplied, then the default is taken, to print both repeated and non-repeated lines. The

output file, if provided, is assigned to `outputfile`. Earlier, `outputfile` was initialized to the standard output, `` `/dev/stdout' ``.

```
# uniq.awk -- do uniq in awk
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

function usage(    e)
{
    e = "Usage: uniq [-udc [-n]] [+n] [ in [ out ]]"
    print e > "/dev/stderr"
    exit 1
}

# -c    count lines. overrides -d and -u
# -d    only repeated lines
# -u    only non-repeated lines
# -n    skip n fields
# +n    skip n characters, skip fields first

BEGIN    \
{
    count = 1
    outputfile = "/dev/stdout"
    opts = "udc0:1:2:3:4:5:6:7:8:9:"
    while ((c = getopt(ARGC, ARGV, opts)) != -1) {
        if (c == "u")
            non_repeated_only++
        else if (c == "d")
            repeated_only++
        else if (c == "c")
            do_count++
        else if (index("0123456789", c) != 0) {
            # getopt requires args to options
            # this messes us up for things like -5
            if (Optarg ~ /^[0-9]+$/)
                fcount = (c Optarg) + 0
            else {
                fcount = c + 0
                Optind--
            }
        } else
            usage()
    }
```

```
    if (ARGV[Optind] ~ /^\+[0-9]+$/) {
        charcount = substr(ARGV[Optind], 2) + 0
        Optind++
    }

    for (i = 1; i < Optind; i++)
        ARGV[i] = ""

    if (repeated_only == 0 && non_repeated_only == 0)
        repeated_only = non_repeated_only = 1

    if (ARGC - Optind == 2) {
        outputfile = ARGV[ARGC - 1]
        ARGV[ARGC - 1] = ""
    }
}
```

The following function, `are_equal`, compares the current line, `$0`, to the previous line, `last`. It handles skipping fields and characters.

If no field count and no character count were specified, `are_equal` simply returns one or zero depending upon the result of a simple string comparison of `last` and `$0`. Otherwise, things get more complicated.

If fields have to be skipped, each line is broken into an array using `split` (see section Built-in Functions for String Manipulation), and then the desired fields are joined back into a line using `join`. The joined lines are stored in `clast` and `cline`. If no fields are skipped, `clast` and `cline` are set to `last` and `$0` respectively.

Finally, if characters are skipped, `substr` is used to strip off the leading `charcount` characters in `clast` and `cline`. The two strings are then compared, and `are_equal` returns the result.

```
function are_equal(    n, m, clast, cline, alast, aline)
{
    if (fcount == 0 && charcount == 0)
        return (last == $0)

    if (fcount > 0) {
        n = split(last, alast)
        m = split($0, aline)
        clast = join(alast, fcount+1, n)
        cline = join(aline, fcount+1, m)
    } else {
        clast = last
        cline = $0
    }
```

```
    if (charcount) {
        clast = substr(clast, charcount + 1)
        cline = substr(cline, charcount + 1)
    }

    return (clast == cline)
}
```

The following two rules are the body of the program. The first one is executed only for the very first line of data. It sets `last` equal to `$0`, so that subsequent lines of text have something to be compared to.

The second rule does the work. The variable `equal` will be one or zero depending upon the results of `are_equal`'s comparison. If `uniq` is counting repeated lines, then the `count` variable is incremented if the lines are equal. Otherwise the line is printed and `count` is reset, since the two lines are not equal.

If `uniq` is not counting, `count` is incremented if the lines are equal. Otherwise, if `uniq` is counting repeated lines, and more than one line has been seen, or if `uniq` is counting non-repeated lines, and only one line has been seen, then the line is printed, and `count` is reset.

Finally, similar logic is used in the `END` rule to print the final line of input data.

```
NR == 1 {
    last = $0
    next
}

{
    equal = are_equal()

    if (do_count) {    # overrides -d and -u
        if (equal)
            count++
        else {
            printf("%4d %s\n", count, last) > outputfile
            last = $0
            count = 1    # reset
        }
        next
    }

    if (equal)
        count++
    else {
        if ((repeated_only && count > 1) ||
            (non_repeated_only && count == 1))
                print last > outputfile
        last = $0
```

```
        count = 1
    }
}

END {
    if (do_count)
        printf("%4d %s\n", count, last) > outputfile
    else if ((repeated_only && count > 1) ||
             (non_repeated_only && count == 1))
        print last > outputfile
}
```

Counting Things

The `wc` (word count) utility counts lines, words, and characters in one or more input files. Its usage is:

```
wc [-lwc] [ files ... ]
```

If no files are specified on the command line, `wc` reads its standard input. If there are multiple files, it will also print total counts for all the files. The options and their meanings are:

`-l`

Only count lines.

`-w`

Only count words. A "word" is a contiguous sequence of non-whitespace characters, separated by spaces and/or tabs. Happily, this is the normal way `awk` separates fields in its input data.

`-c`

Only count characters.

Implementing `wc` in `awk` is particularly elegant, since `awk` does a lot of the work for us; it splits lines into words (i.e. fields) and counts them, it counts lines (i.e. records) for us, and it can easily tell us how long a line is.

This version uses the `getopt` library function (see section Processing Command Line Options), and the file transition functions (see section Noting Data File Boundaries).

This version has one major difference from traditional versions of `wc`. Our version always prints the counts in the order lines, words, and characters. Traditional versions note the order of the `-l', `-w', and `-c' options on the command line, and print the counts in that order.

The `BEGIN` rule does the argument processing. The variable `print_total` will be true if more than one file was named on the command line.

```
# wc.awk -- count lines, words, characters
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993
```

```
# Options:
#    -l    only count lines
#    -w    only count words
#    -c    only count characters
#
# Default is to count lines, words, characters

BEGIN {
    # let getopt print a message about
    # invalid options. we ignore them
    while ((c = getopt(ARGC, ARGV, "lwc")) != -1) {
        if (c == "l")
            do_lines = 1
        else if (c == "w")
            do_words = 1
        else if (c == "c")
            do_chars = 1
    }
    for (i = 1; i < Optind; i++)
        ARGV[i] = ""

    # if no options, do all
    if (! do_lines && ! do_words && ! do_chars)
        do_lines = do_words = do_chars = 1

    print_total = (ARC - i > 2)
}
```

The `beginfile` function is simple; it just resets the counts of lines, words, and characters to zero, and saves the current file name in `fname`.

The `endfile` function adds the current file's numbers to the running totals of lines, words, and characters. It then prints out those numbers for the file that was just read. It relies on `beginfile` to reset the numbers for the following data file.

```
function beginfile(file)
{
    chars = lines = words = 0
    fname = FILENAME
}

function endfile(file)
{
    tchars += chars
    tlines += lines
```

```
    twords += words
    if (do_lines)
        printf "\t%d", lines
    if (do_words)
        printf "\t%d", words
    if (do_chars)
        printf "\t%d", chars
    printf "\t%s\n", fname
}
```

There is one rule that is executed for each line. It adds the length of the record to `chars`. It has to add one, since the newline character separating records (the value of `RS`) is not part of the record itself. `lines` is incremented for each line read, and `words` is incremented by the value of `NF`, the number of "words" on this line.(19)

Finally, the `END` rule simply prints the totals for all the files.

```
# do per line
{
    chars += length($0) + 1    # get newline
    lines++
    words += NF
}

END {
    if (print_total) {
        if (do_lines)
            printf "\t%d", tlines
        if (do_words)
            printf "\t%d", twords
        if (do_chars)
            printf "\t%d", tchars
        print "\ttotal"
    }
}
```

A Grab Bag of awk Programs

This section is a large "grab bag" of miscellaneous programs. We hope you find them both interesting and enjoyable.

Finding Duplicated Words in a Document

A common error when writing large amounts of prose is to accidentally duplicate words. Often you will see this in text as something like "the the program does the following ...." When the text is on-line, often the duplicated words occur at the end of one line and the beginning of another, making them very difficult to spot.

This program, `dupword.awk', scans through a file one line at a time, and looks for adjacent occurrences of the same word. It also saves the last word on a line (in the variable `prev`) for comparison with the first word on the next line.

The first two statements make sure that the line is all lower-case, so that, for example, "The" and "the" compare equal to each other. The second statement removes all non-alphanumeric and non-whitespace characters from the line, so that punctuation does not affect the comparison either. This sometimes leads to reports of duplicated words that really are different, but this is unusual.

```
# dupword -- find duplicate words in text
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# December 1991

{
    $0 = tolower($0)
    gsub(/[^A-Za-z0-9 \t]/, "");
    if ($1 == prev)
        printf("%s:%d: duplicate %s\n",
            FILENAME, FNR, $1)
    for (i = 2; i <= NF; i++)
        if ($i == $(i-1))
            printf("%s:%d: duplicate %s\n",
                FILENAME, FNR, $i)
    prev = $NF
}
```

An Alarm Clock Program

The following program is a simple "alarm clock" program. You give it a time of day, and an optional message. At the given time, it prints the message on the standard output. In addition, you can give it the number of times to repeat the message, and also a delay between repetitions.

This program uses the `gettimeofday` function from section Managing the Time of Day.

All the work is done in the `BEGIN` rule. The first part is argument checking and setting of defaults; the delay, the count, and the message to print. If the user supplied a message, but it does not contain the ASCII BEL character (known as the "alert" character, `\a'), then it is added to the message. (On many systems, printing the ASCII BEL generates some sort of audible alert. Thus, when the alarm goes off, the system calls attention to itself, in case the user is not looking at their computer or terminal.)

```
# alarm -- set an alarm
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

# usage: alarm time [ "message" [ count [ delay ] ] ]

BEGIN    \
{
    # Initial argument sanity checking
    usage1 = "usage: alarm time ['message' [count [delay]]]"
    usage2 = sprintf("\t(%s) time ::= hh:mm", ARGV[1])

    if (ARGC < 2) {
        print usage > "/dev/stderr"
        exit 1
    } else if (ARGC == 5) {
        delay = ARGV[4] + 0
        count = ARGV[3] + 0
        message = ARGV[2]
    } else if (ARGC == 4) {
        count = ARGV[3] + 0
        message = ARGV[2]
    } else if (ARGC == 3) {
        message = ARGV[2]
    } else if (ARGV[1] !~ /[0-9]?[0-9]:[0-9][0-9]/) {
        print usage1 > "/dev/stderr"
        print usage2 > "/dev/stderr"
        exit 1
    }

    # set defaults for once we reach the desired time
    if (delay == 0)
        delay = 180    # 3 minutes
    if (count == 0)
        count = 5
    if (message == "")
        message = sprintf("\aIt is now %s!\a", ARGV[1])
    else if (index(message, "\a") == 0)
        message = "\a" message "\a"
```

The next section of code turns the alarm time into hours and minutes, and converts it if necessary to a 24-hour clock. Then it turns that time into a count of the seconds since midnight. Next it turns the current time into a count of seconds since midnight. The difference between the two is how long to wait before setting off the alarm.

```
    # split up dest time
    split(ARGV[1], atime, ":")
    hour = atime[1] + 0    # force numeric
    minute = atime[2] + 0  # force numeric

    # get current broken down time
    gettimeofday(now)

    # if time given is 12-hour hours and it's after that
    # hour, e.g., `alarm 5:30' at 9 a.m. means 5:30 p.m.,
    # then add 12 to real hour
    if (hour < 12 && now["hour"] > hour)
        hour += 12

    # set target time in seconds since midnight
    target = (hour * 60 * 60) + (minute * 60)

    # get current time in seconds since midnight
    current = (now["hour"] * 60 * 60) + \
              (now["minute"] * 60) + now["second"]

    # how long to sleep for
    naptime = target - current
    if (naptime <= 0) {
        print "time is in the past!" > "/dev/stderr"
        exit 1
    }
```

Finally, the program uses the `system` function (see section Built-in Functions for Input/Output) to call the `sleep` utility. The `sleep` utility simply pauses for the given number of seconds. If the exit status is not zero, the program assumes that `sleep` was interrupted, and exits. If `sleep` exited with an OK status (zero), then the program prints the message in a loop, again using `sleep` to delay for however many seconds are necessary.

```
    # zzzzzz..... go away if interrupted
    if (system(sprintf("sleep %d", naptime)) != 0)
        exit 1

    # time to notify!
    command = sprintf("sleep %d", delay)
    for (i = 1; i <= count; i++) {
        print message
        # if sleep command interrupted, go away
        if (system(command) != 0)
            break
```

```
    }

    exit 0
}
```

Transliterating Characters

The system `tr` utility transliterates characters. For example, it is often used to map upper-case letters into lower-case, for further processing.

```
generate data | tr '[A-Z]' '[a-z]' | process data ...
```

You give `tr` two lists of characters enclosed in square brackets. Usually, the lists are quoted to keep the shell from attempting to do a filename expansion.(20) When processing the input, the first character in the first list is replaced with the first character in the second list, the second character in the first list is replaced with the second character in the second list, and so on. If there are more characters in the "from" list than in the "to" list, the last character of the "to" list is used for the remaining characters in the "from" list.

Some time ago, a user proposed to us that we add a transliteration function to `gawk`. Being opposed to "creeping featurism," I wrote the following program to prove that character transliteration could be done with a user-level function. This program is not as complete as the system `tr` utility, but it will do most of the job.

The `translate` program demonstrates one of the few weaknesses of standard `awk`: dealing with individual characters is very painful, requiring repeated use of the `substr`, `index`, and `gsub` built-in functions (see section Built-in Functions for String Manipulation).(21)

There are two functions. The first, `stranslate`, takes three arguments.

`from`
: A list of characters to translate from.

`to`
: A list of characters to translate to.

`target`
: The string to do the translation on.

Associative arrays make the translation part fairly easy. `t_ar` holds the "to" characters, indexed by the "from" characters. Then a simple loop goes through `from`, one character at a time. For each character in `from`, if the character appears in `target`, `gsub` is used to change it to the corresponding `to` character.

The `translate` function simply calls `stranslate` using `$0` as the target. The main program sets two global variables, `FROM` and `TO`, from the command line, and then changes `ARGV` so that `awk` will read from the standard input.

Finally, the processing rule simply calls `translate` for each record.

```
# translate -- do tr like stuff
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# August 1989

# bugs: does not handle things like: tr A-Z a-z, it has
# to be spelled out. However, if `to' is shorter than `from',
# the last character in `to' is used for the rest of `from'.

function stranslate(from, to, target,     lf, lt, t_ar, i, c)
{
    lf = length(from)
    lt = length(to)
    for (i = 1; i <= lt; i++)
        t_ar[substr(from, i, 1)] = substr(to, i, 1)
    if (lt < lf)
        for (; i <= lf; i++)
            t_ar[substr(from, i, 1)] = substr(to, lt, 1)
    for (i = 1; i <= lf; i++) {
        c = substr(from, i, 1)
        if (index(target, c) > 0)
            gsub(c, t_ar[c], target)
    }
    return target
}

function translate(from, to)
{
    return $0 = stranslate(from, to, $0)
}

# main program
BEGIN {
    if (ARGC < 3) {
        print "usage: translate from to" > "/dev/stderr"
        exit
    }
    FROM = ARGV[1]
    TO = ARGV[2]
    ARGC = 2
    ARGV[1] = "-"
}

{
    translate(FROM, TO)
    print
}
```

While it is possible to do character transliteration in a user-level function, it is not necessarily efficie and we started to consider adding a built-in function. However, shortly after writing this program, w learned that the System V Release 4 `awk` had added the `toupper` and `tolower` functions. These functions handle the vast majority of the cases where character transliteration is necessary, and so we chose to simply add those functions to `gawk` as well, and then leave well enough alone.

An obvious improvement to this program would be to set up the `t_ar` array only once, in a `BEGIN` rule. However, this assumes that the "from" and "to" lists will never change throughout the lifetime of the program.

Printing Mailing Labels

Here is a "real world"(22) program. This script reads lists of names and addresses, and generates mailing labels. Each page of labels has 20 labels on it, two across and ten down. The addresses are guaranteed to be no more than five lines of data. Each address is separated from the next by a blank line.

The basic idea is to read 20 labels worth of data. Each line of each label is stored in the `line` array. The single rule takes care of filling the `line` array and printing the page when 20 labels have been read.

The `BEGIN` rule simply sets `RS` to the empty string, so that `awk` will split records at blank lines (see section How Input is Split into Records). It sets `MAXLINES` to 100, since `MAXLINE` is the maximum number of lines on the page (20 * 5 = 100).

Most of the work is done in the `printpage` function. The label lines are stored sequentially in the `line` array. But they have to be printed horizontally; `line[1]` next to `line[6]`, `line[2]` next to `line[7]`, and so on. Two loops are used to accomplish this. The outer loop, controlled by `i`, steps through every 10 lines of data; this is each row of labels. The inner loop, controlled by `j`, goes through the lines within the row. As `j` goes from zero to four, `i+j' is the `j`'th line in the row, and `i+j+5' is the entry next to it. The output ends up looking something like this:

```
line 1          line 6
line 2          line 7
line 3          line 8
line 4          line 9
line 5          line 10
```

As a final note, at lines 21 and 61, an extra blank line is printed, to keep the output lined up on the labels. This is dependent on the particular brand of labels in use when the program was written. You will also note that there are two blank lines at the top and two blank lines at the bottom.

The `END` rule arranges to flush the final page of labels; there may not have been an even multiple of 20 labels in the data.

```
# labels.awk
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# June 1992
```

TOC

```
# Program to print labels.  Each label is 5 lines of data
# that may have blank lines.  The label sheets have 2
# blank lines at the top and 2 at the bottom.

BEGIN    { RS = "" ; MAXLINES = 100 }

function printpage(    i, j)
{
    if (Nlines <= 0)
        return

    printf "\n\n"        # header

    for (i = 1; i <= Nlines; i += 10) {
        if (i == 21 || i == 61)
            print ""
        for (j = 0; j < 5; j++) {
            if (i + j > MAXLINES)
                break
            printf "   %-41s %s\n", line[i+j], line[i+j+5]
        }
        print ""
    }

    printf "\n\n"        # footer

    for (i in line)
        line[i] = ""
}

# main rule
{
    if (Count >= 20) {
        printpage()
        Count = 0
        Nlines = 0
    }
    n = split($0, a, "\n")
    for (i = 1; i <= n; i++)
        line[++Nlines] = a[i]
    for (; i <= 5; i++)
        line[++Nlines] = ""
    Count++
}

END    \
```

```
{
    printpage()
}
```

Generating Word Usage Counts

The following `awk` program prints the number of occurrences of each word in its input. It illustrates the associative nature of `awk` arrays by using strings as subscripts. It also demonstrates the `for x in array' construction. Finally, it shows how `awk` can be used in conjunction with other utility programs to do a useful task of some complexity with a minimum of effort. Some explanations follow the program listing.

```
awk '
# Print list of word frequencies
{
    for (i = 1; i <= NF; i++)
        freq[$i]++
}

END {
    for (word in freq)
        printf "%s\t%d\n", word, freq[word]
}'
```

The first thing to notice about this program is that it has two rules. The first rule, because it has an empty pattern, is executed on every line of the input. It uses `awk`'s field-accessing mechanism (see section Examining Fields) to pick out the individual words from the line, and the built-in variable `NF` (see section Built-in Variables) to know how many fields are available.

For each input word, an element of the array `freq` is incremented to reflect that the word has been seen an additional time.

The second rule, because it has the pattern `END`, is not executed until the input has been exhausted. It prints out the contents of the `freq` table that has been built up inside the first action.

This program has several problems that would prevent it from being useful by itself on real text files:

- Words are detected using the `awk` convention that fields are separated by whitespace and that other characters in the input (except newlines) don't have any special meaning to `awk`. This means that punctuation characters count as part of words.
- The `awk` language considers upper- and lower-case characters to be distinct. Therefore, `bartender' and `Bartender' are not treated as the same word. This is undesirable since, in normal text, words are capitalized if they begin sentences, and a frequency analyzer should not be sensitive to capitalization.
- The output does not come out in any useful order. You're more likely to be interested in which words occur most frequently, or having an alphabetized table of how frequently each word occurs.

The way to solve these problems is to use some of the more advanced features of the `awk` language.

First, we use `tolower` to remove case distinctions. Next, we use `gsub` to remove punctuation characters. Finally, we use the system `sort` utility to process the output of the `awk` script. Here is the new version of the program:

```
# Print list of word frequencies
{
    $0 = tolower($0)    # remove case distinctions
    gsub(/[^a-z0-9_ \t]/, "", $0)  # remove punctuation
    for (i = 1; i <= NF; i++)
        freq[$i]++
}

END {
    for (word in freq)
        printf "%s\t%d\n", word, freq[word]
}
```

Assuming we have saved this program in a file named `` `wordfreq.awk' ``, and that the data is in `` `file1' ``, the following pipeline

```
awk -f wordfreq.awk file1 | sort +1 -nr
```

produces a table of the words appearing in `` `file1' `` in order of decreasing frequency.

The `awk` program suitably massages the data and produces a word frequency table, which is not ordered.

The `awk` script's output is then sorted by the `sort` utility and printed on the terminal. The options given to `sort` in this example specify to sort using the second field of each input line (skipping one field), that the sort keys should be treated as numeric quantities (otherwise `15' would come before `5'), and that the sorting should be done in descending (reverse) order.

We could have even done the `sort` from within the program, by changing the `END` action to:

```
END {
    sort = "sort +1 -nr"
    for (word in freq)
        printf "%s\t%d\n", word, freq[word] | sort
    close(sort)
}
```

You would have to use this way of sorting on systems that do not have true pipes.

See the general operating system documentation for more information on how to use the `sort` program.

Removing Duplicates from Unsorted Text

The `uniq` program (see section Printing Non-duplicated Lines of Text), removes duplicate lines from *sorted* data.

Suppose, however, you need to remove duplicate lines from a data file, but that you wish to preserve the order the lines are in? A good example of this might be a shell history file. The history file keeps a copy of all the commands you have entered, and it is not unusual to repeat a command several times in a row. Occasionally you might wish to compact the history by removing duplicate entries. Yet it is desirable to maintain the order of the original commands.

This simple program does the job. It uses two arrays. The `data` array is indexed by the text of each line. For each line, `data[$0]` is incremented.

If a particular line has not been seen before, then `data[$0]` will be zero. In that case, the text of the line is stored in `lines[count]`. Each element of `lines` is a unique command, and the indices of `lines` indicate the order in which those lines were encountered. The `END` rule simply prints out the lines, in order.

```
# histsort.awk -- compact a shell history file
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

# Thanks to Byron Rakitzis for the general idea
{
    if (data[$0]++ == 0)
        lines[++count] = $0
}

END {
    for (i = 1; i <= count; i++)
        print lines[i]
}
```

This program also provides a foundation for generating other useful information. For example, using the following `print` satement in the `END` rule would indicate how often a particular command was used.

```
print data[lines[i]], lines[i]
```

This works because `data[$0]` was incremented each time a line was seen.

Extracting Programs from Texinfo Source Files

Both this chapter and the previous chapter (section A Library of `awk` Functions), present a large number of `awk` programs. If you wish to experiment with these programs, it is tedious to have to type them in by hand. Here we present a program that can extract parts of a Texinfo input file into separate files.

This book is written in Texinfo, the GNU project's document formatting language. A single Texinfo source file can be used to produce both printed and on-line documentation. Texinfo is fully documented in Texinfo--The GNU Documentation Format, available from the Free Software Foundation.

For our purposes, it is enough to know three things about Texinfo input files.

- The "at" symbol, `@', is special in Texinfo, much like `\' in C or `awk'. Literal `@' symbols are represented in Texinfo source files as `@@'.
- Comments start with either `@c' or `@comment'. The file extraction program will work by using special comments that start at the beginning of a line.
- Example text that should not be split across a page boundary is bracketed between lines containing `@group' and `@end group' commands.

The following program, `extract.awk', reads through a Texinfo source file, and does two things, based on the special comments. Upon seeing `@c system ...', it runs a command, by extracting the command text from the control line and passing it on to the `system' function (see section Built-in Functions for Input/Output). Upon seeing `@c file filename', each subsequent line is sent to the file filename, until `@c endfile' is encountered. The rules in `extract.awk' will match either `@c' or `@comment' by letting the `omment' part be optional. Lines containing `@group' and `@end group' are simply removed. `extract.awk' uses the `join' library function (see section Merging an Array Into a String).

The example programs in the on-line Texinfo source for AWK Language Programming (`gawk.texi') have all been bracketed inside `file', and `endfile' lines. The `gawk' distribution uses a copy of `extract.awk' to extract the sample programs and install many of them in a standard directory, where `gawk' can find them.

`extract.awk' begins by setting `IGNORECASE' to one, so that mixed upper-case and lower-case letters in the directives won't matter.

The first rule handles calling `system', checking that a command was given (`NF' is at least three), and also checking that the command exited with a zero exit status, signifying OK.

```
# extract.awk -- extract files and run programs
#                from texinfo files
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# May 1993

BEGIN    { IGNORECASE = 1 }

/^@c(omment)?[ \t]+system/    \
{
    if (NF < 3) {
        e = (FILENAME ":" FNR)
        e = (e  ": badly formed `system' line")
        print e > "/dev/stderr"
        next
```

```
    }
    $1 = ""
    $2 = ""
    stat = system($0)
    if (stat != 0) {
        e = (FILENAME ":" FNR)
        e = (e ": warning: system returned " stat)
        print e > "/dev/stderr"
    }
}
```

The variable `e` is used so that the function fits nicely on the page.

The second rule handles moving data into files. It verifies that a file name was given in the directive. If the file named is not the current file, then the current file is closed. This means that an `@c endfile' was not given for that file. (We should probably print a diagnostic in this case, although at the moment we do not.)

The `for' loop does the work. It reads lines using `getline` (see section Explicit Input with `getline`). For an unexpected end of file, it calls the `unexpected_eof` function. If the line is an "endfile" line, then it breaks out of the loop. If the line is an `@group' or `@end group' line, then it ignores it, and goes on to the next line.

Most of the work is in the following few lines. If the line has no `@' symbols, it can be printed directly. Otherwise, each leading `@' must be stripped off.

To remove the `@' symbols, the line is split into separate elements of the array `a`, using the `split` function (see section Built-in Functions for String Manipulation). Each element of `a` that is empty indicates two successive `@' symbols in the original line. For each two empty elements (`@@' in the original file), we have to add back in a single `@' symbol.

When the processing of the array is finished, `join` is called with the value of SUBSEP, to rejoin the pieces back into a single line. That line is then printed to the output file.

```
/^@c(omment)?[ \t]+file/    \
{
    if (NF != 3) {
        e = (FILENAME ":" FNR ": badly formed `file' line")
        print e > "/dev/stderr"
        next
    }
    if ($3 != curfile) {
        if (curfile != "")
            close(curfile)
        curfile = $3
    }
```

```
    for (;;) {
        if ((getline line) <= 0)
            unexpected_eof()
        if (line ~ /^@c(omment)?[ \t]+endfile/)
            break
        else if (line ~ /^@(end[ \t]+)?group/)
            continue
        if (index(line, "@") == 0) {
            print line > curfile
            continue
        }
        n = split(line, a, "@")
        # if a[1] == "", means leading @,
        # don't add one back in.
        for (i = 2; i <= n; i++) {
            if (a[i] == "") { # was an @@
                a[i] = "@"
                if (a[i+1] == "")
                    i++
            }
        }
        print join(a, 1, n, SUBSEP) > curfile
    }
}
```

An important thing to note is the use of the `>' redirection. Output done with `>' only opens the file once; it stays open and subsequent output is appended to the file (see section Redirecting Output of `print' and `printf'). This allows us to easily mix program text and explanatory prose for the same sample source file (as has been done here!) without any hassle. The file is only closed when a new data file name is encountered, or at the end of the input file.

Finally, the function `unexpected_eof' prints an appropriate error message and then exits.

The `END' rule handles the final cleanup, closing the open file.

```
function unexpected_eof()
{
    printf("%s:%d: unexpected EOF or error\n", \
        FILENAME, FNR) > "/dev/stderr"
    exit 1
}

END {
    if (curfile)
        close(curfile)
}
```

A Simple Stream Editor

The `sed` utility is a "stream editor," a program that reads a stream of data, makes changes to it, and passes the modified data on. It is often used to make global changes to a large file, or to a stream of data generated by a pipeline of commands.

While `sed` is a complicated program in its own right, its most common use is to perform global substitutions in the middle of a pipeline:

```
command1 < orig.data | sed 's/old/new/g' | command2 > result
```

Here, the `s/old/new/g' tells `sed` to look for the regexp `old' on each input line, and replace it with the text `new', globally (i.e. all the occurrences on a line). This is similar to `awk`'s `gsub` function (see section Built-in Functions for String Manipulation).

The following program, `` `awksed.awk' ``, accepts at least two command line arguments; the pattern to look for and the text to replace it with. Any additional arguments are treated as data file names to process. If none are provided, the standard input is used.

```
# awksed.awk -- do s/foo/bar/g using just print
#    Thanks to Michael Brennan for the idea

# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# August 1995

function usage()
{
    print "usage: awksed pat repl [files...]" > "/dev/stderr"
    exit 1
}

BEGIN {
    # validate arguments
    if (ARGC < 3)
        usage()

    RS = ARGV[1]
    ORS = ARGV[2]

    # don't use arguments as files
    ARGV[1] = ARGV[2] = ""
}

# look ma, no hands!
{
```

```
    if (RT == "")
        printf "%s", $0
    else
        print
}
```

The program relies on `gawk`'s ability to have `RS` be a regexp and on the setting of `RT` to the actual text that terminated the record (see section How Input is Split into Records).

The idea is to have `RS` be the pattern to look for. `gawk` will automatically set `$0` to the text between matches of the pattern. This is text that we wish to keep, unmodified. Then, by setting `ORS` to the replacement text, a simple `print` statement will output the text we wish to keep, followed by the replacement text.

There is one wrinkle to this scheme, which is what to do if the last record doesn't end with text that matches `RS`? Using a `print` statement unconditionally prints the replacement text, which is not correct.

However, if the file did not end in text that matches `RS`, `RT` will be set to the null string. In this case, we can print `$0` using `printf` (see section Using `printf` Statements for Fancier Printing).

The `BEGIN` rule handles the setup, checking for the right number of arguments, and calling `usage` if there is a problem. Then it sets `RS` and `ORS` from the command line arguments, and sets `ARGV[1]` and `ARGV[2]` to the null string, so that they will not be treated as file names (see section Using ARGC and ARGV).

The `usage` function prints an error message and exits.

Finally, the single rule handles the printing scheme outlined above, using `print` or `printf` as appropriate, depending upon the value of `RT`.

An Easy Way to Use Library Functions

Using library functions in `awk` can be very beneficial. It encourages code re-use and the writing of general functions. Programs are smaller, and therefore clearer. However, using library functions is only easy when writing `awk` programs; it is painful when running them, requiring multiple `-f' options. If `gawk` is unavailable, then so too is the `AWKPATH` environment variable and the ability to put `awk` functions into a library directory (see section Command Line Options).

It would be nice to be able to write programs like so:

```
# library functions
@include getopt.awk
@include join.awk
...

# main program
BEGIN {
```

```
    while ((c = getopt(ARGC, ARGV, "a:b:cde")) != -1)
        ...
    ...
}
```

The following program, `igawk.sh', provides this service. It simulates `gawk`'s searching of the `AWKPATH` variable, and also allows nested includes; i.e. a file that has been included with `@include' can contain further `@include' statements. `igawk` will make an effort to only include files once, so that nested includes don't accidentally include a library function twice.

`igawk` should behave externally just like `gawk`. This means it should accept all of `gawk`'s command line arguments, including the ability to have multiple source files specified via `-f', and the ability to mix command line and library source files.

The program is written using the POSIX Shell (`sh`) command language. The way the program works is as follows:

1. Loop through the arguments, saving anything that doesn't represent `awk` source code for later, when the expanded program is run.
2. For any arguments that do represent `awk` text, put the arguments into a temporary file that will be expanded. There are two cases.
    1. Literal text, provided with `--source' or `--source='. This text is just echoed directly. The `echo` program will automatically supply a trailing newline.
    2. File names provided with `-f'. We use a neat trick, and echo `@include filename' into the temporary file. Since the file inclusion program will work the way `gawk` does, this will get the text of the file included into the program at the correct point.
3. Run an `awk` program (naturally) over the temporary file to expand `@include' statements. The expanded program is placed in a second temporary file.
4. Run the expanded program with `gawk` and any other original command line arguments that the user supplied (such as the data file names).

The initial part of the program turns on shell tracing if the first argument was `debug'. Otherwise, a shell `trap` statement arranges to clean up any temporary files on program exit or upon an interrupt.

The next part loops through all the command line arguments. There are several cases of interest.

`--`

This ends the arguments to `igawk`. Anything else should be passed on to the user's `awk` program without being evaluated.

`-W`

This indicates that the next option is specific to `gawk`. To make argument processing easier, the `-W' is appended to the front of the remaining arguments and the loop continues. (This is an `sh` programming trick. Don't worry about it if you are not familiar with `sh`.)

`-v`

`-F`

These are saved and passed on to `gawk`.

`-f`
`--file`
`--file=`
`-Wfile=`

The file name is saved to the temporary file `` `/tmp/ig.s.$$' `` with an `@include' statement. The `sed` utility is used to remove the leading option part of the argument (e.g., `--file=').

`--source`
`--source=`
`-Wsource=`

The source text is echoed into `` `/tmp/ig.s.$$' ``.

`--version`
`--version`
`-Wversion`

`igawk` prints its version number, and runs `gawk --version' to get the `gawk` version information, and then exits.

If none of `-f', `--file', `-Wfile', `--source', or `-Wsource', were supplied, then the first non-option argument should be the `awk` program. If there are no command line arguments left, `igawk` prints an error message and exits. Otherwise, the first argument is echoed into `` `/tmp/ig.s.$$' ``.

In any case, after the arguments have been processed, `` `/tmp/ig.s.$$' `` contains the complete text of the original `awk` program.

The `$$' in `sh` represents the current process ID number. It is often used in shell programs to generate unique temporary file names. This allows multiple users to run `igawk` without worrying that the temporary file names will clash.

Here's the program:

```
#! /bin/sh

# igawk -- like gawk but do @include processing
# Arnold Robbins, arnold@gnu.ai.mit.edu, Public Domain
# July 1993

if [ "$1" = debug ]
then
    set -x
    shift
else
    # cleanup on exit, hangup, interrupt, quit, termination
    trap 'rm -f /tmp/ig.[se].$$' 0 1 2 3 15
fi
```

```
while [ $# -ne 0 ] # loop over arguments
do
    case $1 in
    --)     shift; break;;

    -W)     shift
            set -- -W"$@"
            continue;;

    -[vF])  opts="$opts $1 '$2'"
            shift;;

    -[vF]*) opts="$opts '$1'" ;;

    -f)     echo @include "$2" >> /tmp/ig.s.$$
            shift;;

    -f*)    f=`echo "$1" | sed 's/-f//'`
            echo @include "$f" >> /tmp/ig.s.$$ ;;

    -?file=*)    # -Wfile or --file
            f=`echo "$1" | sed 's/-.file=//'`
            echo @include "$f" >> /tmp/ig.s.$$ ;;

    -?file)    # get arg, $2
            echo @include "$2" >> /tmp/ig.s.$$
            shift;;

    -?source=*)    # -Wsource or --source
            t=`echo "$1" | sed 's/-.source=//'`
            echo "$t" >> /tmp/ig.s.$$ ;;

    -?source)  # get arg, $2
            echo "$2" >> /tmp/ig.s.$$
            shift;;

    -?version)
            echo igawk: version 1.0 1>&2
            gawk --version
            exit 0 ;;

    -[W-]*)    opts="$opts '$1'" ;;

    *)      break;;
    esac
    shift
```

```
done

if [ ! -s /tmp/ig.s.$$ ]
then
    if [ -z "$1" ]
    then
         echo igawk: no program! 1>&2
         exit 1
    else
        echo "$1" > /tmp/ig.s.$$
        shift
    fi
fi

# at this point, /tmp/ig.s.$$ has the program
```

The `awk` program to process `@include' directives reads through the program, one line at a time using `getline` (see section Explicit Input with `getline`). The input file names and `@include' statements are managed using a stack. As each `@include' is encountered, the current file name is "pushed" onto the stack, and the file named in the `@include' directive becomes the current file name. As each file is finished, the stack is "popped," and the previous input file becomes the current input file again. The process is started by making the original file the first one on the stack.

The `pathto` function does the work of finding the full path to a file. It simulates `gawk`'s behavior when searching the `AWKPATH` environment variable (see section The `AWKPATH` Environment Variable). If a file name has a `/' in it, no path search is done. Otherwise, the file name is concatenated with the name of each directory in the path, and an attempt is made to open the generated file name. The only way in `awk` to test if a file can be read is to go ahead and try to read it with `getline`; that is what `pathto` does. If the file can be read, it is closed, and the file name is returned.

```
gawk -- '
# process @include directives

function pathto(file,    i, t, junk)
{
    if (index(file, "/") != 0)
        return file

    for (i = 1; i <= ndirs; i++) {
        t = (pathlist[i] "/" file)
        if ((getline junk < t) > 0) {
            # found it
            close(t)
            return t
        }
    }
```

```
    return ""
}
```

The main program is contained inside one `BEGIN` rule. The first thing it does is set up the `pathlist` array that `pathto` uses. After splitting the path on `:', null elements are replaced with `"."', which represents the current directory.

```
BEGIN {
    path = ENVIRON["AWKPATH"]
    ndirs = split(path, pathlist, ":")
    for (i = 1; i <= ndirs; i++) {
        if (pathlist[i] == "")
            pathlist[i] = "."
    }
```

The stack is initialized with `ARGV[1]`, which will be `` `/tmp/ig.s.$$' ``. The main loop comes next. Input lines are read in succession. Lines that do not start with `@include' are printed verbatim.

If the line does start with `@include', the file name is in `$2`. `pathto` is called to generate the full path. If it could not, then we print an error message and continue.

The next thing to check is if the file has been included already. The `processed` array is indexed by the full file name of each included file, and it tracks this information for us. If the file has been seen, a warning message is printed. Otherwise, the new file name is pushed onto the stack and processing continues.

Finally, when `getline` encounters the end of the input file, the file is closed and the stack is popped. When `stackptr` is less than zero, the program is done.

```
    stackptr = 0
    input[stackptr] = ARGV[1] # ARGV[1] is first file

    for (; stackptr >= 0; stackptr--) {
        while ((getline < input[stackptr]) > 0) {
            if (tolower($1) != "@include") {
                print
                continue
            }
            fpath = pathto($2)
            if (fpath == "") {
                printf("igawk:%s:%d: cannot find %s\n", \
                    input[stackptr], FNR, $2) > "/dev/stderr"
                continue
            }
            if (! (fpath in processed)) {
                processed[fpath] = input[stackptr]
                input[++stackptr] = fpath
```

```
            } else
                print $2, "included in", input[stackptr], \
                    "already included in", \
                    processed[fpath] > "/dev/stderr"
        }
        close(input[stackptr])
    }
}' /tmp/ig.s.$$ > /tmp/ig.e.$$
```

The last step is to call `gawk` with the expanded program and the original options and command line arguments that the user supplied. `gawk`'s exit status is passed back on to `igawk`'s calling program.

```
eval gawk -f /tmp/ig.e.$$ $opts -- "$@"

exit $?
```

This version of `igawk` represents my third attempt at this program. There are three key simplifications that made the program work better.

1. Using `@include' even for the files named with `-f' makes building the initial collected `awk` program much simpler; all the `@include' processing can be done once.
2. The `pathto` function doesn't try to save the line read with `getline` when testing for the file's accessibility. Trying to save this line for use with the main program complicates things considerably.
3. Using a `getline` loop in the `BEGIN` rule does it all in one place. It is not necessary to call out to a separate loop for processing nested `@include' statements.

Also, this program illustrates that it is often worthwhile to combine `sh` and `awk` programming together. You can usually accomplish quite a lot, without having to resort to low-level programming in C or C++, and it is frequently easier to do certain kinds of string and argument manipulation using the shell than it is in `awk`.

Finally, `igawk` shows that it is not always necessary to add new features to a program; they can often be layered on top. With `igawk`, there is no real reason to build `@include' processing into `gawk` itself.

As an additional example of this, consider the idea of having two files in a directory in the search path.

`default.awk'`
: This file would contain a set of default library functions, such as `getopt` and `assert`.

`site.awk'`
: This file would contain library functions that are specific to a site or installation, i.e. locally developed functions. Having a separate file allows `default.awk' to change with new `gawk` releases, without requiring the system administrator to update it each time by adding the local functions.

One user suggested that `gawk` be modified to automatically read these files upon startup. Instead, it would be very simple to modify `igawk` to do this. Since `igawk` can process nested `@include' directives, `default.awk' could simply contain `@include' statements for the desired library

TOC

functions.

Go to the previous, next section.

The Evolution of the awk Language

This book describes the GNU implementation of `awk`, which follows the POSIX specification. Many `awk` users are only familiar with the original `awk` implementation in Version 7 Unix. (This implementation was the basis for `awk` in Berkeley Unix, through 4.3--Reno. The 4.4 release of Berkeley Unix uses `gawk` 2.15.2 for its version of `awk`.) This chapter briefly describes the evolution of the `awk` language, with cross references to other parts of the book where you can find more information.

Major Changes between V7 and SVR3.1

The `awk` language evolved considerably between the release of Version 7 Unix (1978) and the new version first made generally available in System V Release 3.1 (1987). This section summarizes the changes, with cross-references to further details.

- The requirement for `;' to separate rules on a line (see section `awk` Statements Versus Lines).
- User-defined functions, and the `return` statement (see section User-defined Functions).
- The `delete` statement (see section The `delete` Statement).
- The `do-while` statement (see section The `do-while` Statement).
- The built-in functions `atan2`, `cos`, `sin`, `rand` and `srand` (see section Numeric Built-in Functions).
- The built-in functions `gsub`, `sub`, and `match` (see section Built-in Functions for String Manipulation).
- The built-in functions `close`, and `system` (see section Built-in Functions for Input/Output).
- The `ARGC`, `ARGV`, `FNR`, `RLENGTH`, `RSTART`, and `SUBSEP` built-in variables (see section Built-in Variables).
- The conditional expression using the ternary operator `?:' (see section Conditional Expressions).
- The exponentiation operator `^' (see section Arithmetic Operators) and its assignment operator form `^=' (see section Assignment Expressions).
- C-compatible operator precedence, which breaks some old `awk` programs (see section Operator Precedence (How Operators Nest)).
- Regexps as the value of `FS` (see section Specifying How Fields are Separated), and as the third argument to the `split` function (see section Built-in Functions for String Manipulation).
- Dynamic regexps as operands of the `~' and `!~' operators (see section How to Use Regular Expressions).
- The escape sequences `\b', `\f', and `\r' (see section Escape Sequences). (Some vendors have updated their old versions of `awk` to recognize `\r', `\b', and `\f', but this is not something you can

rely on.)

- Redirection of input for the `getline` function (see section Explicit Input with `getline`).
- Multiple `BEGIN` and `END` rules (see section The `BEGIN` and `END` Special Patterns).
- Multi-dimensional arrays (see section Multi-dimensional Arrays).

Changes between SVR3.1 and SVR4

The System V Release 4 version of Unix `awk` added these features (some of which originated in `gawk`):

- The `ENVIRON` variable (see section Built-in Variables).
- Multiple `-f' options on the command line (see section Command Line Options).
- The `-v' option for assigning variables before program execution begins (see section Command Line Options).
- The `--' option for terminating command line options.
- The `\a', `\v', and `\x' escape sequences (see section Escape Sequences).
- A defined return value for the `srand` built-in function (see section Numeric Built-in Functions).
- The `toupper` and `tolower` built-in string functions for case translation (see section Built-in Functions for String Manipulation).
- A cleaner specification for the `%c' format-control letter in the `printf` function (see section Format-Control Letters).
- The ability to dynamically pass the field width and precision (`"%*.*d"`) in the argument list of the `printf` function (see section Format-Control Letters).
- The use of regexp constants such as `/foo/` as expressions, where they are equivalent to using the matching operator, as in `$0 ~ /foo/' (see section Using Regular Expression Constants).

Changes between SVR4 and POSIX `awk`

The POSIX Command Language and Utilities standard for `awk` introduced the following changes into the language:

- The use of `-W' for implementation-specific options.
- The use of `CONVFMT` for controlling the conversion of numbers to strings (see section Conversion of Strings and Numbers).
- The concept of a numeric string, and tighter comparison rules to go with it (see section Variable Typing and Comparison Expressions).
- More complete documentation of many of the previously undocumented features of the language.

The following common extensions are not permitted by the POSIX standard:

- `\x` escape sequences are not recognized (see section Escape Sequences).

- The synonym `func` for the keyword `function` is not recognized (see section Function Definition Syntax).
- The operators `**' and `**=' cannot be used in place of `^' and `^=' (see section Arithmetic Operators, and also see section Assignment Expressions).
- Specifying `-Ft' on the command line does not set the value of `FS` to be a single tab character (see section Specifying How Fields are Separated).
- The `fflush` built-in function is not supported (see section Built-in Functions for Input/Output).

Extensions in the AT&T Bell Laboratories awk

Brian Kernighan, one of the original designers of Unix `awk`, has made his version available via anonymous `ftp` (see section Other Freely Available `awk` Implementations). This section describes extensions in his version of `awk` that are not in POSIX `awk`.

- The `-mf=NNN' and `-mr=NNN' command line options to set the maximum number of fields, and the maximum record size, respectively (see section Command Line Options).
- The `fflush` built-in function for flushing buffered output (see section Built-in Functions for Input/Output).

Extensions in gawk Not in POSIX awk

The GNU implementation, `gawk`, adds a number of features. This sections lists them in the order they were added to `gawk`. They can all be disabled with either the `--traditional' or `--posix' options (see section Command Line Options).

Version 2.10 of `gawk` introduced these features:

- The `AWKPATH` environment variable for specifying a path search for the `-f' command line option (see section Command Line Options).
- The `IGNORECASE` variable and its effects (see section Case-sensitivity in Matching).
- The `/dev/stdin', `/dev/stdout', `/dev/stderr', and `/dev/fd/n' file name interpretation (see section Special File Names in `gawk`).

Version 2.13 of `gawk` introduced these features:

- The `FIELDWIDTHS` variable and its effects (see section Reading Fixed-width Data).
- The `systime` and `strftime` built-in functions for obtaining and printing time stamps (see section Functions for Dealing with Time Stamps).
- The `-W lint' option to provide source code and run time error and portability checking (see section Command Line Options).
- The `-W compat' option to turn off these extensions (see section Command Line Options).
- The `-W posix' option for full POSIX compliance (see section Command Line Options).

Version 2.14 of `gawk` introduced these features:

- The `next file` statement for skipping to the next data file (see section The `nextfile` Statement).

Version 2.15 of `gawk` introduced these features:

- The `ARGIND` variable, that tracks the movement of `FILENAME` through `ARGV` (see section Built-in Variables).
- The `ERRNO` variable, that contains the system error message when `getline` returns -1, or when `close` fails (see section Built-in Variables).
- The ability to use GNU-style long named options that start with `--' (see section Command Line Options).
- The `--source' option for mixing command line and library file source code (see section Command Line Options).
- The `/dev/pid', `/dev/ppid', `/dev/pgrpid', and `/dev/user' file name interpretation (see section Special File Names in `gawk`).

Version 3.0 of `gawk` introduced these features:

- The `next file` statement became `nextfile` (see section The `nextfile` Statement).
- The `--lint-old' option to warn about constructs that are not available in the original Version 7 Unix version of `awk` (see section Major Changes between V7 and SVR3.1).
- The `--traditional' option was added as a better name for `--compat' (see section Command Line Options).
- The ability for `FS` to be a null string, and for the third argument to `split` to be the null string (see section Making Each Character a Separate Field).
- The ability for `RS` to be a regexp (see section How Input is Split into Records).
- The `RT` variable (see section How Input is Split into Records).
- The `gensub` function for more powerful text manipulation (see section Built-in Functions for String Manipulation).
- The `strftime` function acquired a default time format, allowing it to be called with no arguments (see section Functions for Dealing with Time Stamps).
- Full support for both POSIX and GNU regexps (see section Regular Expressions).
- The `--re-interval' option to provide interval expressions in regexps (see section Regular Expression Operators).
- `IGNORECASE` changed, now applying to string comparison as well as regexp operations (see section Case-sensitivity in Matching).
- The `-m' option and the `fflush` function from the Bell Labs research version of `awk` (see section Command Line Options; also see section Built-in Functions for Input/Output).
- The use of GNU Autoconf to control the configuration process (see section Compiling `gawk` for

Unix).

- Amiga support (see section Installing gawk on an Amiga).

Go to the previous, next section.

Go to the previous, next section.

gawk Summary

This appendix provides a brief summary of the `gawk` command line and the `awk` language. It is designed to serve as "quick reference." It is therefore terse, but complete.

Command Line Options Summary

The command line consists of options to `gawk` itself, the `awk` program text (if not supplied via the `-f' option), and values to be made available in the `ARGC` and `ARGV` predefined `awk` variables:

```
gawk [POSIX or GNU style options] -f source-file [--] file ...
gawk [POSIX or GNU style options] [--] 'program' file ...
```

The options that `gawk` accepts are:

`-F fs`

`--field-separator fs`

Use fs for the input field separator (the value of the `FS` predefined variable).

`-f program-file`

`--file program-file`

Read the `awk` program source from the file program-file, instead of from the first command line argument.

`-mf=NNN`

`-mr=NNN`

The `f' flag sets the maximum number of fields, and the `r' flag sets the maximum record size. These options are ignored by `gawk`, since `gawk` has no predefined limits; they are only for compatibility with the Bell Labs research version of Unix `awk`.

`-v var=val`

`--assign var=val`

Assign the variable var the value val before program execution begins.

`-W traditional`

`-W compat`

`--traditional`

`--compat`

Use compatibility mode, in which `gawk` extensions are turned off.

`-W copyleft`

`-W copyright`

`--copyleft`

`--copyright`

Print the short version of the General Public License on the error output. This option may disappear in a future version of `gawk`.

`-W help`

`-W usage`

`--help`

`--usage`

Print a relatively short summary of the available options on the error output.

`-W lint`

`--lint`

Give warnings about dubious or non-portable `awk` constructs.

`-W lint-old`

`--lint-old`

Warn about constructs that are not available in the original Version 7 Unix version of `awk`.

`-W posix`

`--posix`

Use POSIX compatibility mode, in which `gawk` extensions are turned off and additional restrictions apply.

`-W re-interval`

`--re-interval`

Allow interval expressions (see section Regular Expression Operators), in regexps.

`-W source=program-text`

`--source program-text`

Use program-text as `awk` program source code. This option allows mixing command line source code with source code from files, and is particularly useful for mixing command line programs with library functions.

`-W version`

`--version`

Print version information for this particular copy of `gawk` on the error output.

`--`

Signal the end of options. This is useful to allow further arguments to the `awk` program itself to start with a `-'. This is mainly for consistency with POSIX argument parsing conventions.

Any other options are flagged as invalid, but are otherwise ignored. See section Command Line Options, for more details.

Language Summary

An awk program consists of a sequence of zero or more pattern-action statements and optional function definitions. One or the other of the pattern and action may be omitted.

```
pattern    { action statements }
pattern
          { action statements }

function name(parameter list)     { action statements }
```

gawk first reads the program source from the program-file(s), if specified, or from the first non-option argument on the command line. The `-f' option may be used multiple times on the command line. gawk reads the program text from all the program-file files, effectively concatenating them in the order they are specified. This is useful for building libraries of awk functions, without having to include them in each new awk program that uses them. To use a library function in a file from a program typed in on the command line, specify `--source 'program", and type your program in between the single quotes. See section Command Line Options.

The environment variable AWKPATH specifies a search path to use when finding source files named with the `-f' option. The default path, which is `.:/usr/local/share/awk'(23) is used if AWKPATH is not set. If a file name given to the `-f' option contains a `/' character, no path search is performed. See section The AWKPATH Environment Variable.

gawk compiles the program into an internal form, and then proceeds to read each file named in the ARGV array. The initial values of ARGV come from the command line arguments. If there are no files named on the command line, gawk reads the standard input.

If a "file" named on the command line has the form `var=val', it is treated as a variable assignment: the variable var is assigned the value val. If any of the files have a value that is the null string, that element in the list is skipped.

For each record in the input, gawk tests to see if it matches any pattern in the awk program. For each pattern that the record matches, the associated action is executed.

Variables and Fields

awk variables are not declared; they come into existence when they are first used. Their values are either floating-point numbers or strings. awk also has one-dimensional arrays; multiple-dimensional arrays may be simulated. There are several predefined variables that awk sets as a program runs; these are summarized below.

Fields

As each input line is read, `gawk` splits the line into fields, using the value of the `FS` variable as the field separator. If `FS` is a single character, fields are separated by that character. Otherwise, `FS` is expected to be a full regular expression. In the special case that `FS` is a single space, fields are separated by runs of spaces and/or tabs. If `FS` is the null string (`""`), then each individual character in the record becomes a separate field. Note that the value of `IGNORECASE` (see section Case-sensitivity in Matching) also affects how fields are split when `FS` is a regular expression.

Each field in the input line may be referenced by its position, `$1`, `$2`, and so on. `$0` is the whole line. The value of a field may be assigned to as well. Field numbers need not be constants:

```
n = 5
print $n
```

prints the fifth field in the input line. The variable `NF` is set to the total number of fields in the input line.

References to non-existent fields (i.e. fields after `$NF`) return the null string. However, assigning to a non-existent field (e.g., `$(NF+2) = 5`) increases the value of `NF`, creates any intervening fields with the null string as their value, and causes the value of `$0` to be recomputed, with the fields being separated by the value of `OFS`. See section Reading Input Files.

Built-in Variables

`gawk`'s built-in variables are:

`ARGC`
: The number of elements in `ARGV`. See below for what is actually included in `ARGV`.

`ARGIND`
: The index in `ARGV` of the current file being processed. When `gawk` is processing the input data files, it is always true that `FILENAME == ARGV[ARGIND]'.

`ARGV`
: The array of command line arguments. The array is indexed from zero to `ARGC - 1`. Dynamically changing `ARGC` and the contents of `ARGV` can control the files used for data. A null-valued element in `ARGV` is ignored. `ARGV` does not include the options to `awk` or the text of the `awk` program itself.

`CONVFMT`
: The conversion format to use when converting numbers to strings.

`FIELDWIDTHS`
: A space separated list of numbers describing the fixed-width input data.

`ENVIRON`
: An array of environment variable values. The array is indexed by variable name, each element being the value of that variable. Thus, the environment variable `HOME` is `ENVIRON["HOME"]`. One possible value might be `` `/home/arnold' ``.

Changing this array does not affect the environment seen by programs which `gawk` spawns via redirection or the `system` function. (This may change in a future version of `gawk`.)

Some operating systems do not have environment variables. The `ENVIRON` array is empty when running on these systems.

`ERRNO`

The system error message when an error occurs using `getline` or `close`.

`FILENAME`

The name of the current input file. If no files are specified on the command line, the value of `FILENAME` is the null string.

`FNR`

The input record number in the current input file.

`FS`

The input field separator, a space by default.

`IGNORECASE`

The case-sensitivity flag for string comparisons and regular expression operations. If `IGNORECASE` has a non-zero value, then pattern matching in rules, record separating with `RS`, field splitting with `FS`, regular expression matching with `~' and `!~', and the `gensub`, `gsub`, `index`, `match`, `split` and `sub` built-in functions all ignore case when doing regular expression operations, and all string comparisons are done ignoring case.

`NF`

The number of fields in the current input record.

`NR`

The total number of input records seen so far.

`OFMT`

The output format for numbers for the `print` statement, `"%.6g"` by default.

`OFS`

The output field separator, a space by default.

`ORS`

The output record separator, by default a newline.

`RS`

The input record separator, by default a newline. If `RS` is set to the null string, then records are separated by blank lines. When `RS` is set to the null string, then the newline character always acts as a field separator, in addition to whatever value `FS` may have. If `RS` is set to a multi-character string, it denotes a regexp; input text matching the regexp separates records.

`RT`

The input text that matched the text denoted by `RS`, the record separator.

`RSTART`

The index of the first character last matched by `match`; zero if no match.

RLENGTH
: The length of the string last matched by `match`; -1 if no match.

SUBSEP
: The string used to separate multiple subscripts in array elements, by default `"\034"`.

See section Built-in Variables, for more information.

Arrays

Arrays are subscripted with an expression between square brackets (`[' and `]'). Array subscripts are *always* strings; numbers are converted to strings as necessary, following the standard conversion rules (see section Conversion of Strings and Numbers).

If you use multiple expressions separated by commas inside the square brackets, then the array subscript is a string consisting of the concatenation of the individual subscript values, converted to strings, separated by the subscript separator (the value of SUBSEP).

The special operator `in` may be used in a conditional context to see if an array has an index consisting of a particular value.

```
if (val in array)
        print array[val]
```

If the array has multiple subscripts, use `(i, j, ...) in array' to test for existence of an element.

The `in` construct may also be used in a `for` loop to iterate over all the elements of an array. See section Scanning All Elements of an Array.

You can remove an element from an array using the `delete` statement.

You can clear an entire array using `delete array'.

See section Arrays in `awk`.

Data Types

The value of an `awk` expression is always either a number or a string.

Some contexts (such as arithmetic operators) require numeric values. They convert strings to numbers by interpreting the text of the string as a number. If the string does not look like a number, it converts to zero.

Other contexts (such as concatenation) require string values. They convert numbers to strings by effectively printing them with `sprintf`. See section Conversion of Strings and Numbers, for the details.

To force conversion of a string value to a number, simply add zero to it. If the value you start with is already a number, this does not change it.

To force conversion of a numeric value to a string, concatenate it with the null string.

Comparisons are done numerically if both operands are numeric, or if one is numeric and the other is a numeric string. Otherwise one or both operands are converted to strings and a string comparison is performed. Fields, `getline` input, `FILENAME`, `ARGV` elements, `ENVIRON` elements and the elements of an array created by `split` are the only items that can be numeric strings. String constants, such as `"3.1415927"` are not numeric strings, they are string constants. The full rules for comparisons are described in section Variable Typing and Comparison Expressions.

Uninitialized variables have the string value `""` (the null, or empty, string). In contexts where a number is required, this is equivalent to zero.

See section Variables, for more information on variable naming and initialization; see section Conversion of Strings and Numbers, for more information on how variable values are interpreted.

Patterns

An `awk` program is mostly composed of rules, each consisting of a pattern followed by an action. The action is enclosed in `{' and `}'. Either the pattern may be missing, or the action may be missing, but not both. If the pattern is missing, the action is executed for every input record. A missing action is equivalent to `{ print }', which prints the entire line.

Comments begin with the `#' character, and continue until the end of the line. Blank lines may be used to separate statements. Statements normally end with a newline; however, this is not the case for lines ending in a `,', `{', `?', `:', `&&', or `||'. Lines ending in `do` or `else` also have their statements automatically continued on the following line. In other cases, a line can be continued by ending it with a `\', in which case the newline is ignored.

Multiple statements may be put on one line by separating each one with a `;'. This applies to both the statements within the action part of a rule (the usual case), and to the rule statements.

See section Comments in `awk` Programs, for information on `awk`'s commenting convention; see section `awk` Statements Versus Lines, for a description of the line continuation mechanism in `awk`.

Pattern Summary

`awk` patterns may be one of the following:

```
/regular expression/
relational expression
pattern && pattern
pattern || pattern
pattern ? pattern : pattern
(pattern)
! pattern
```

```
pattern1, pattern2
BEGIN
END
```

`BEGIN` and `END` are two special kinds of patterns that are not tested against the input. The action parts of all `BEGIN` rules are concatenated as if all the statements had been written in a single `BEGIN` rule. They are executed before any of the input is read. Similarly, all the `END` rules are concatenated, and executed when all the input is exhausted (or when an `exit` statement is executed). `BEGIN` and `END` patterns cannot be combined with other patterns in pattern expressions. `BEGIN` and `END` rules cannot have missing action parts.

For `/regular-expression/` patterns, the associated statement is executed for each input record that matches the regular expression. Regular expressions are summarized below.

A relational expression may use any of the operators defined below in the section on actions. These generally test whether certain fields match certain regular expressions.

The `&&', `||', and `!' operators are logical "and," logical "or," and logical "not," respectively, as in C. They do short-circuit evaluation, also as in C, and are used for combining more primitive pattern expressions. As in most languages, parentheses may be used to change the order of evaluation.

The `?:' operator is like the same operator in C. If the first pattern matches, then the second pattern is matched against the input record; otherwise, the third is matched. Only one of the second and third patterns is matched.

The `pattern1, pattern2' form of a pattern is called a range pattern. It matches all input lines starting with a line that matches pattern1, and continuing until a line that matches pattern2, inclusive. A range pattern cannot be used as an operand of any of the pattern operators.

See section Pattern Elements.

Regular Expressions

Regular expressions are based on POSIX EREs (extended regular expressions). The escape sequences allowed in string constants are also valid in regular expressions (see section Escape Sequences). Regexps are composed of characters as follows:

`c`

matches the character c (assuming c is none of the characters listed below).

`\c`

matches the literal character c.

`.`

matches any character, *including* newline. In strict POSIX mode, `.' does not match the NUL character, which is a character with all bits equal to zero.

`^`

matches the beginning of a string.

`$`

matches the end of a string.

`[abc...]`

matches any of the characters abc... (character list).

`[[:class:]]`

matches any character in the character class class. Allowable classes are `alnum`, `alpha`, `blank`, `cntrl`, `digit`, `graph`, `lower`, `print`, `punct`, `space`, `upper`, and `xdigit`.

`[[.symbol.]]`

matches the multi-character collating symbol symbol. `gawk` does not currently support collating symbols.

`[[=chars=]]`

matches any of the equivalent characters in chars. `gawk` does not currently support equivalence classes.

`[^abc...]`

matches any character except abc... and newline (negated character list).

`r1|r2`

matches either r1 or r2 (alternation).

`r1r2`

matches r1, and then r2 (concatenation).

`r+`

matches one or more r's.

`r*`

matches zero or more r's.

`r?`

matches zero or one r's.

`(r)`

matches r (grouping).

`r{n}`
`r{n,}`
`r{n,m}`

matches at least n, n to any number, or n to m occurrences of r (interval expressions).

`\y`

matches the empty string at either the beginning or the end of a word.

`\B`

matches the empty string within a word.

`\<`

matches the empty string at the beginning of a word.

`\>`
: matches the empty string at the end of a word.

`\w`
: matches any word-constituent character (alphanumeric characters and the underscore).

`\W`
: matches any character that is not word-constituent.

`\``
: matches the empty string at the beginning of a buffer (same as a string in `gawk`).

`\'`
: matches the empty string at the end of a buffer.

The various command line options control how `gawk` interprets characters in regexps.

No options
: In the default case, `gawk` provide all the facilities of POSIX regexps and the GNU regexp operators described above. However, interval expressions are not supported.

`--posix`
: Only POSIX regexps are supported, the GNU operators are not special (e.g., `\w' matches a literal `w'). Interval expressions are allowed.

`--traditional`
: Traditional Unix `awk` regexps are matched. The GNU operators are not special, interval expressions are not available, and neither are the POSIX character classes (`[[:alnum:]]` and so on). Characters described by octal and hexadecimal escape sequences are treated literally, even if they represent regexp metacharacters.

`--re-interval`
: Allow interval expressions in regexps, even if `--traditional' has been provided.

See section Regular Expressions.

Actions

Action statements are enclosed in braces, `{' and `}'. A missing action statement is equivalent to `{ print }'.

Action statements consist of the usual assignment, conditional, and looping statements found in most languages. The operators, control statements, and Input/Output statements available are similar to those in C.

Comments begin with the `#' character, and continue until the end of the line. Blank lines may be used to separate statements. Statements normally end with a newline; however, this is not the case for lines ending in a `,', `{', `?', `:', `&&', or `||'. Lines ending in `do` or `else` also have their statements automatically continued on the following line. In other cases, a line can be continued by ending it with a `\', in which case the newline is ignored.

Multiple statements may be put on one line by separating each one with a `;'. This applies to both the statements within the action part of a rule (the usual case), and to the rule statements.

See section Comments in awk Programs, for information on awk's commenting convention; see section awk Statements Versus Lines, for a description of the line continuation mechanism in awk.

Operators

The operators in awk, in order of decreasing precedence, are:

`(...)`
: Grouping.

`$`
: Field reference.

`++ --`
: Increment and decrement, both prefix and postfix.

`^`
: Exponentiation (`**' may also be used, and `**=' for the assignment operator, but they are not specified in the POSIX standard).

`+ - !`
: Unary plus, unary minus, and logical negation.

`* / %`
: Multiplication, division, and modulus.

`+ -`
: Addition and subtraction.

`space`
: String concatenation.

`< <= > >= != ==`
: The usual relational operators.

`~ !~`
: Regular expression match, negated match.

`in`
: Array membership.

`&&`
: Logical "and".

`||`
: Logical "or".

`?:`
: A conditional expression. This has the form `expr1 ? expr2 : expr3'. If expr1 is true, the value of

the expression is expr2; otherwise it is expr3. Only one of expr2 and expr3 is evaluated.

`= += -= *= /= %= ^=`

Assignment. Both absolute assignment (`var=value`) and operator assignment (the other forms) are supported.

See section Expressions.

Control Statements

The control statements are as follows:

```
if (condition) statement [ else statement ]
while (condition) statement
do statement while (condition)
for (expr1; expr2; expr3) statement
for (var in array) statement
break
continue
delete array[index]
delete array
exit [ expression ]
{ statements }
```

See section Control Statements in Actions.

I/O Statements

The Input/Output statements are as follows:

`getline`

Set `$0` from next input record; set `NF`, `NR`, `FNR`. See section Explicit Input with `getline`.

`getline <file`

Set `$0` from next record of file; set `NF`.

`getline var`

Set var from next input record; set `NF`, `FNR`.

`getline var <file`

Set var from next record of file.

`command | getline`

Run command, piping its output into `getline`; sets `$0`, `NF`, `NR`.

`command | getline var`

Run command, piping its output into `getline`; sets var.

`next`

Stop processing the current input record. The next input record is read and processing starts over with the first pattern in the `awk` program. If the end of the input data is reached, the `END` rule(s), if any, are executed. See section The `next` Statement.

`nextfile`

Stop processing the current input file. The next input record read comes from the next input file. `FILENAME` is updated, `FNR` is set to one, `ARGIND` is incremented, and processing starts over with the first pattern in the `awk` program. If the end of the input data is reached, the `END` rule(s), if any, are executed. Earlier versions of `gawk` used `next file'; this usage is still supported, but is considered to be deprecated. See section The `nextfile` Statement.

`print`

Prints the current record. See section Printing Output.

`print expr-list`

Prints expressions.

`print expr-list > file`

Prints expressions to file. If file does not exist, it is created. If it does exist, its contents are deleted the first time the `print` is executed.

`print expr-list >> file`

Prints expressions to file. The previous contents of file are retained, and the output of `print` is appended to the file.

`print expr-list | command`

Prints expressions, sending the output down a pipe to command. The pipeline to the command stays open until the `close` function is called.

`printf fmt, expr-list`

Format and print.

`printf fmt, expr-list > file`

Format and print to file. If file does not exist, it is created. If it does exist, its contents are deleted the first time the `printf` is executed.

`printf fmt, expr-list >> file`

Format and print to file. The previous contents of file are retained, and the output of `printf` is appended to the file.

`printf fmt, expr-list | command`

Format and print, sending the output down a pipe to command. The pipeline to the command stays open until the `close` function is called.

`getline` returns zero on end of file, and -1 on an error. In the event of an error, `getline` will set `ERRNO` to the value of a system-dependent string that describes the error.

`printf` Summary

Conversion specification have the form %[flag][width][.prec]format. Items in brackets are optional.

The `awk` `printf` statement and `sprintf` function accept the following conversion specification formats:

`%c`

An ASCII character. If the argument used for `%c' is numeric, it is treated as a character and printed. Otherwise, the argument is assumed to be a string, and the only first character of that string is printed.

`%d`

`%i`

A decimal number (the integer part).

`%e`

`%E`

A floating point number of the form `[-]d.dddddde[+-]dd'. The `%E' format uses `E' instead of `e'.

`%f`

A floating point number of the form `[-]ddd.dddddd`.

`%g`

`%G`

Use either the `%e' or `%f' formats, whichever produces a shorter string, with non-significant zeros suppressed. `%G' will use `%E' instead of `%e'.

`%o`

An unsigned octal number (again, an integer).

`%s`

A character string.

`%x`

`%X`

An unsigned hexadecimal number (an integer). The `%X' format uses `A' through `F' instead of `a' through `f' for decimal 10 through 15.

`%%`

A single `%' character; no argument is converted.

There are optional, additional parameters that may lie between the `%' and the control letter:

`-`

The expression should be left-justified within its field.

`space`

For numeric conversions, prefix positive values with a space, and negative values with a minus sign.

`+`

The plus sign, used before the width modifier (see below), says to always supply a sign for numeric conversions, even if the data to be formatted is positive. The `+' overrides the space modifier.

`#`

Use an "alternate form" for certain control letters. For `o', supply a leading zero. For `x', and `X', supply a leading `0x' or `0X' for a non-zero result. For `e', `E', and `f', the result will always contain a decimal point. For `g', and `G', trailing zeros are not removed from the result.

`0`

A leading `0' (zero) acts as a flag, that indicates output should be padded with zeros instead of spaces. This applies even to non-numeric output formats. This flag only has an effect when the field width is wider than the value to be printed.

`width`

The field should be padded to this width. The field is normally padded with spaces. If the `0' flag has been used, it is padded with zeros.

`.prec`

A number that specifies the precision to use when printing. For the `e', `E', and `f' formats, this specifies the number of digits you want printed to the right of the decimal point. For the `g', and `G' formats, it specifies the maximum number of significant digits. For the `d', `o', `i', `u', `x', and `X' formats, it specifies the minimum number of digits to print. For the `s' format, it specifies the maximum number of characters from the string that should be printed.

Either or both of the width and prec values may be specified as `*'. In that case, the particular value is taken from the argument list.

See section Using `printf` Statements for Fancier Printing.

Special File Names

When doing I/O redirection from either `print` or `printf` into a file, or via `getline` from a file, `gawk` recognizes certain special file names internally. These file names allow access to open file descriptors inherited from `gawk`'s parent process (usually the shell). The file names are:

`` `/dev/stdin' ``

The standard input.

`` `/dev/stdout' ``

The standard output.

`` `/dev/stderr' ``

The standard error output.

`` `/dev/fd/n' ``

The file denoted by the open file descriptor n.

In addition, reading the following files provides process related information about the running `gawk`

program. All returned records are terminated with a newline.

`/dev/pid'
: Returns the process ID of the current process.

`/dev/ppid'
: Returns the parent process ID of the current process.

`/dev/pgrpid'
: Returns the process group ID of the current process.

`/dev/user'
: At least four space-separated fields, containing the return values of the `getuid`, `geteuid`, `getgid`, and `getegid` system calls. If there are any additional fields, they are the group IDs returned by `getgroups` system call. (Multiple groups may not be supported on all systems.)

These file names may also be used on the command line to name data files. These file names are only recognized internally if you do not actually have files with these names on your system.

See section Special File Names in `gawk`, for a longer description that provides the motivation for this feature.

Built-in Functions

`awk` provides a number of built-in functions for performing numeric operations, string related operations, and I/O related operations.

The built-in arithmetic functions are:

`atan2(y, x)`
: the arctangent of y/x in radians.

`cos(expr)`
: the cosine in radians.

`exp(expr)`
: the exponential function (`e ^ expr`).

`int(expr)`
: truncates to integer.

`log(expr)`
: the natural logarithm of `expr`.

`rand()`
: a random number between zero and one.

`sin(expr)`
: the sine in radians.

`sqrt(expr)`
: the square root function.

`srand([expr])`

use expr as a new seed for the random number generator. If no expr is provided, the time of day is used. The return value is the previous seed for the random number generator.

`awk` has the following built-in string functions:

`gensub(regex, subst, how [, target])`

If how is a string beginning with `g' or `G', then replace each match of regex in target with subst. Otherwise, replace the how'th occurrence. If target is not supplied, use `$0`. The return value is the changed string; the original target is not modified. Within subst, `\n', where n is a digit from one to nine, can be used to indicate the text that matched the n'th parenthesized subexpression.

`gsub(regex, subst [, target])`

for each substring matching the regular expression regex in the string target, substitute the string subst, and return the number of substitutions. If target is not supplied, use `$0`.

`index(str, search)`

returns the index of the string search in the string str, or zero if search is not present.

`length([str])`

returns the length of the string str. The length of `$0` is returned if no argument is supplied.

`match(str, regex)`

returns the position in str where the regular expression regex occurs, or zero if regex is not present, and sets the values of `RSTART` and `RLENGTH`.

`split(str, arr [, regex])`

splits the string str into the array arr on the regular expression regex, and returns the number of elements. If regex is omitted, `FS` is used instead. regex can be the null string, causing each character to be placed into its own array element. The array arr is cleared first.

`sprintf(fmt, expr-list)`

prints expr-list according to fmt, and returns the resulting string.

`sub(regex, subst [, target])`

just like `gsub`, but only the first matching substring is replaced.

`substr(str, index [, len])`

returns the len-character substring of str starting at index. If len is omitted, the rest of str is used.

`tolower(str)`

returns a copy of the string str, with all the upper-case characters in str translated to their corresponding lower-case counterparts. Non-alphabetic characters are left unchanged.

`toupper(str)`

returns a copy of the string str, with all the lower-case characters in str translated to their corresponding upper-case counterparts. Non-alphabetic characters are left unchanged.

The I/O related functions are:

`close(expr)`

Close the open file or pipe denoted by expr.

`fflush([expr])`

Flush any buffered output for the output file or pipe denoted by expr. If expr is omitted, standard output is flushed. If expr is the null string (""), all output buffers are flushed.

`system(cmd-line)`

Execute the command cmd-line, and return the exit status. If your operating system does not support `system`, calling it will generate a fatal error.

`system("")' can be used to force `awk` to flush any pending output. This is more portable, but less obvious, than calling `fflush`.

Time Functions

The following two functions are available for getting the current time of day, and for formatting time stamps.

`systime()`

returns the current time of day as the number of seconds since a particular epoch (Midnight, January 1, 1970 UTC, on POSIX systems).

`strftime([format[, timestamp]])`

formats timestamp according to the specification in format. The current time of day is used if no timestamp is supplied. A default format equivalent to the output of the `date` utility is used if no format is supplied. See section Functions for Dealing with Time Stamps, for the details on the conversion specifiers that `strftime` accepts.

See section Built-in Functions, for a description of all of `awk`'s built-in functions.

String Constants

String constants in `awk` are sequences of characters enclosed in double quotes ("). Within strings, certain escape sequences are recognized, as in C. These are:

`\\`

A literal backslash.

`\a`

The "alert" character; usually the ASCII BEL character.

`\b`

Backspace.

`\f`

Formfeed.

`\n`

Newline.

`\r`

Carriage return.

`\t`

Horizontal tab.

`\v`

Vertical tab.

`\xhex digits`

The character represented by the string of hexadecimal digits following the `\x'. As in ANSI C, all following hexadecimal digits are considered part of the escape sequence. E.g., `"\x1B"` is a string containing the ASCII ESC (escape) character. (The `\x' escape sequence is not in POSIX `awk`.)

`\ddd`

The character represented by the one, two, or three digit sequence of octal digits. Thus, `"\033"` is also a string containing the ASCII ESC (escape) character.

`\c`

The literal character c, if c is not one of the above.

The escape sequences may also be used inside constant regular expressions (e.g., the regexp `/[ \t\f\n\r\v]/` matches whitespace characters).

See section Escape Sequences.

User-defined Functions

Functions in `awk` are defined as follows:

```
function name(parameter list) { statements }
```

Actual parameters supplied in the function call are used to instantiate the formal parameters declared in the function. Arrays are passed by reference, other variables are passed by value.

If there are fewer arguments passed than there are names in parameter-list, the extra names are given the null string as their value. Extra names have the effect of local variables.

The open-parenthesis in a function call of a user-defined function must immediately follow the function name, without any intervening white space. This is to avoid a syntactic ambiguity with the concatenation operator.

The word `func` may be used in place of `function` (but not in POSIX `awk`).

Use the `return` statement to return a value from a function.

See section User-defined Functions.

Historical Features

There are two features of historical `awk` implementations that `gawk` supports.

First, it is possible to call the `length` built-in function not only with no arguments, but even without parentheses!

```
a = length
```

is the same as either of

```
a = length()
a = length($0)
```

For example:

```
$ echo abcdef | awk '{ print length }'
-| 6
```

This feature is marked as "deprecated" in the POSIX standard, and `gawk` will issue a warning about its use if `--lint' is specified on the command line. (The ability to use `length` this way was actually an accident of the original Unix `awk` implementation. If any built-in function used `$0` as its default argument, it was possible to call that function without the parentheses. In particular, it was common practice to use the `length` function in this fashion, and this usage was documented in the `awk` manual page.)

The other historical feature is the use of either the `break` statement, or the `continue` statement outside the body of a `while`, `for`, or `do` loop. Traditional `awk` implementations have treated such usage as equivalent to the `next` statement. More recent versions of Unix `awk` do not allow it. `gawk` supports this usage if `--traditional' has been specified.

See section Command Line Options, for more information about the `--posix' and `--lint' options.

Go to the previous, next section.

Go to the previous, next section.

Installing gawk

This appendix provides instructions for installing `gawk` on the various platforms that are supported by the developers. The primary developers support Unix (and one day, GNU), while the other ports were contributed. The file `` `ACKNOWLEDGMENT' `` in the `gawk` distribution lists the electronic mail addresses of the people who did the respective ports, and they are also provided in section Reporting Problems and Bugs.

The gawk Distribution

This section first describes how to get the `gawk` distribution, how to extract it, and then what is in the various files and subdirectories.

Getting the gawk Distribution

There are three ways you can get GNU software.

1. You can copy it from someone else who already has it.
2. You can order `gawk` directly from the Free Software Foundation. Software distributions are available for Unix, MS-DOS, and VMS, on tape, CD-ROM, or floppies (MS-DOS only). The address is:

   Free Software Foundation
   59 Temple Place--Suite 330
   Boston, MA 02111-1307 USA
   Phone: +1-617-542-5942
   Fax (including Japan): +1-617-542-2652
   E-mail: `gnu@prep.ai.mit.edu`

   Ordering from the FSF directly contributes to the support of the foundation and to the production of more free software.
3. You can get `gawk` by using anonymous `ftp` to the Internet host `ftp.gnu.ai.mit.edu`, in the directory `` `/pub/gnu' ``.

   Here is a list of alternate `ftp` sites from which you can obtain GNU software. When a site is listed as "site`:`directory" the directory indicates the directory where GNU software is kept. You should use a site that is geographically close to you.

   Asia:

   ```
   cair-archive.kaist.ac.kr:/pub/gnu
   ftp.cs.titech.ac.jp
   ftp.nectec.or.th:/pub/mirrors/gnu
   ```

`utsun.s.u-tokyo.ac.jp:/ftpsync/prep`

- Australia:

`archie.au:/gnu`

(`archie.oz` or `archie.oz.au` for ACSnet)

- Africa:

`ftp.sun.ac.za:/pub/gnu`

- Middle East:

`ftp.technion.ac.il:/pub/unsupported/gnu`

- Europe:

`archive.eu.net`
`ftp.denet.dk`
`ftp.eunet.ch`
`ftp.funet.fi:/pub/gnu`
`ftp.ieunet.ie:pub/gnu`
`ftp.informatik.rwth-aachen.de:/pub/gnu`
`ftp.informatik.tu-muenchen.de`
`ftp.luth.se:/pub/unix/gnu`
`ftp.mcc.ac.uk`
`ftp.stacken.kth.se`
`ftp.sunet.se:/pub/gnu`
`ftp.univ-lyon1.fr:pub/gnu`
`ftp.win.tue.nl:/pub/gnu`
`irisa.irisa.fr:/pub/gnu`
`isy.liu.se`
`nic.switch.ch:/mirror/gnu`
`src.doc.ic.ac.uk:/gnu`
`unix.hensa.ac.uk:/pub/uunet/systems/gnu`

- South America:

`ftp.inf.utfsm.cl:/pub/gnu`
`ftp.unicamp.br:/pub/gnu`

- Western Canada:

`ftp.cs.ubc.ca:/mirror2/gnu`

- USA:

`col.hp.com:/mirrors/gnu`
`f.ms.uky.edu:/pub3/gnu`
`ftp.cc.gatech.edu:/pub/gnu`

`ftp.cs.columbia.edu:/archives/gnu/prep`
`ftp.digex.net:/pub/gnu`
`ftp.hawaii.edu:/mirrors/gnu`
`ftp.kpc.com:/pub/mirror/gnu`

- USA (continued):

`ftp.uu.net:/systems/gnu`
`gatekeeper.dec.com:/pub/GNU`
`jaguar.utah.edu:/gnustuff`
`labrea.stanford.edu`
`mrcnext.cso.uiuc.edu:/pub/gnu`
`vixen.cso.uiuc.edu:/gnu`
`wuarchive.wustl.edu:/systems/gnu`

Extracting the Distribution

`gawk` is distributed as a `tar` file compressed with the GNU Zip program, `gzip`.

Once you have the distribution (for example, `` `gawk-3.0.0.tar.gz' ``), first use `gzip` to expand the file, and then use `tar` to extract it. You can use the following pipeline to produce the `gawk` distribution:

```
# Under System V, add 'o' to the tar flags
gzip -d -c gawk-3.0.0.tar.gz | tar -xvpf -
```

This will create a directory named `` `gawk-3.0.0' `` in the current directory.

The distribution file name is of the form `` `gawk-V.R.n.tar.gz' ``. The V represents the major version of `gawk`, the R represents the current release of version V, and the n represents a patch level, meaning that minor bugs have been fixed in the release. The current patch level is 0, but when retrieving distributions, you should get the version with the highest version, release, and patch level. (Note that release levels greater than or equal to 90 denote "beta," or non-production software; you may not wish to retrieve such a version unless you don't mind experimenting.)

If you are not on a Unix system, you will need to make other arrangements for getting and extracting the `gawk` distribution. You should consult a local expert.

Contents of the gawk Distribution

The `gawk` distribution has a number of C source files, documentation files, subdirectories and files related to the configuration process (see section Compiling and Installing `gawk` on Unix), and several subdirectories related to different, non-Unix, operating systems.

various `.c', `.y', and `.h' files

These files are the actual `gawk` source code.

`` `README' ``

`README_d/README.*'

Descriptive files: `README' for gawk under Unix, and the rest for the various hardware and software combinations.

`INSTALL'

A file providing an overview of the configuration and installation process.

`PORTS'

A list of systems to which gawk has been ported, and which have successfully run the test suite.

`ACKNOWLEDGMENT'

A list of the people who contributed major parts of the code or documentation.

`ChangeLog'

A detailed list of source code changes as bugs are fixed or improvements made.

`NEWS'

A list of changes to gawk since the last release or patch.

`COPYING'

The GNU General Public License.

`FUTURES'

A brief list of features and/or changes being contemplated for future releases, with some indication of the time frame for the feature, based on its difficulty.

`LIMITATIONS'

A list of those factors that limit gawk's performance. Most of these depend on the hardware or operating system software, and are not limits in gawk itself.

`POSIX.STD'

A description of one area where the POSIX standard for awk is incorrect, and how gawk handles the problem.

`PROBLEMS'

A file describing known problems with the current release.

`doc/gawk.1'

The troff source for a manual page describing gawk. This is distributed for the convenience of Unix users.

`doc/gawk.texi'

The Texinfo source file for this book. It should be processed with TeX to produce a printed document, and with makeinfo to produce an Info file.

`doc/gawk.info'

The generated Info file for this book.

`doc/igawk.1'

The troff source for a manual page describing the igawk program presented in section An Easy Way to Use Library Functions.

`doc/Makefile.in'

The input file used during the configuration process to generate the actual `Makefile' for creating the documentation.

`Makefile.in'

`acconfig.h'

`aclocal.m4'

`configh.in'

`configure.in'

`configure'

`custom.h'

`missing/*'

These files and subdirectory are used when configuring gawk for various Unix systems. They are explained in detail in section Compiling and Installing gawk on Unix.

`awklib/extract.awk'

`awklib/Makefile.in'

The `awklib' directory contains a copy of `extract.awk' (see section Extracting Programs from Texinfo Source Files), which can be used to extract the sample programs from the Texinfo source file for this book, and a `Makefile.in' file, which configure uses to generate a `Makefile'. As part of the process of building gawk, the library functions from section A Library of awk Functions, and the igawk program from section An Easy Way to Use Library Functions, are extracted into ready to use files. They are installed as part of the installation process.

`amiga/*'

Files needed for building gawk on an Amiga. See section Installing gawk on an Amiga, for details.

`atari/*'

Files needed for building gawk on an Atari ST. See section Installing gawk on the Atari ST, for details.

`pc/*'

Files needed for building gawk under MS-DOS and OS/2. See section MS-DOS and OS/2 Installation and Compilation, for details.

`vms/*'

Files needed for building gawk under VMS. See section How to Compile and Install gawk on VMS, for details.

`test/*'

A test suite for gawk. You can use `make check' from the top level gawk directory to run your version of gawk against the test suite. If gawk successfully passes `make check' then you can be confident of a successful port.

Compiling and Installing gawk on Unix

Usually, you can compile and install `gawk` by typing only two commands. However, if you do use an unusual system, you may need to configure `gawk` for your system yourself.

Compiling gawk for Unix

After you have extracted the `gawk` distribution, `cd` to `` `gawk-3.0.0' ``. Like most GNU software, `gawk` is configured automatically for your Unix system by running the `configure` program. This program is a Bourne shell script that was generated automatically using GNU `autoconf`. (The `autoconf` software is described fully in Autoconf--Generating Automatic Configuration Scripts, which is available from the Free Software Foundation.)

To configure `gawk`, simply run `configure`:

```
sh ./configure
```

This produces a `` `Makefile' `` and `` `config.h' `` tailored to your system. The `` `config.h' `` file describes various facts about your system. You may wish to edit the `` `Makefile' `` to change the `CFLAGS` variable, which controls the command line options that are passed to the C compiler (such as optimization levels, or compiling for debugging).

Alternatively, you can add your own values for most `make` variables, such as `CC` and `CFLAGS`, on the command line when running `configure`:

```
CC=cc CFLAGS=-g sh ./configure
```

See the file `` `INSTALL' `` in the `gawk` distribution for all the details.

After you have run `configure`, and possibly edited the `` `Makefile' ``, type:

```
make
```

and shortly thereafter, you should have an executable version of `gawk`. That's all there is to it! (If these steps do not work, please send in a bug report; see section Reporting Problems and Bugs.)

The Configuration Process

(This section is of interest only if you know something about using the C language and the Unix operating system.)

The source code for `gawk` generally attempts to adhere to formal standards wherever possible. This means that `gawk` uses library routines that are specified by the ANSI C standard and by the POSIX operating system interface standard. When using an ANSI C compiler, function prototypes are used to help improve the compile-time checking.

Many Unix systems do not support all of either the ANSI or the POSIX standards. The `` `missing' ``

subdirectory in the gawk distribution contains replacement versions of those subroutines that are most likely to be missing.

The `config.h' file that is created by the configure program contains definitions that describe features of the particular operating system where you are attempting to compile gawk. The three things described by this file are what header files are available, so that they can be correctly included, what (supposedly) standard functions are actually available in your C libraries, and other miscellaneous facts about your variant of Unix. For example, there may not be an st_blksize element in the stat structure. In this case `HAVE_ST_BLKSIZE' would be undefined.

It is possible for your C compiler to lie to configure. It may do so by not exiting with an error when a library function is not available. To get around this, you can edit the file `custom.h'. Use an `#ifdef' that is appropriate for your system, and either #define any constants that configure should have defined but didn't, or #undef any constants that configure defined and should not have. `custom.h' is automatically included by `config.h'.

It is also possible that the configure program generated by autoconf will not work on your system in some other fashion. If you do have a problem, the file `configure.in' is the input for autoconf. You may be able to change this file, and generate a new version of configure that will work on your system. See section Reporting Problems and Bugs, for information on how to report problems in configuring gawk. The same mechanism may be used to send in updates to `configure.in' and/or `custom.h'.

How to Compile and Install gawk on VMS

This section describes how to compile and install gawk under VMS.

Compiling gawk on VMS

To compile gawk under VMS, there is a DCL command procedure that will issue all the necessary CC and LINK commands, and there is also a `Makefile' for use with the MMS utility. From the source directory, use either

```
$ @[.VMS]VMSBUILD.COM
```

or

```
$ MMS/DESCRIPTION=[.VMS]DESCRIP.MMS GAWK
```

Depending upon which C compiler you are using, follow one of the sets of instructions in this table:

VAX C V3.x

> Use either `vmsbuild.com' or `descrip.mms' as is. These use CC/OPTIMIZE=NOLINE, which is essential for Version 3.0.

VAX C V2.x

> You must have Version 2.3 or 2.4; older ones won't work. Edit either `vmsbuild.com' or

`descrip.mms' according to the comments in them. For `vmsbuild.com', this just entails removing two `!' delimiters. Also edit `config.h' (which is a copy of file `[.config]vms-conf.h') and comment out or delete the two lines `#define __STDC__ 0' and `#define VAXC_BUILTINS' near the end.

GNU C

Edit `vmsbuild.com' or `descrip.mms'; the changes are different from those for VAX C V2.x, but equally straightforward. No changes to `config.h' should be needed.

DEC C

Edit `vmsbuild.com' or `descrip.mms' according to their comments. No changes to `config.h' should be needed.

gawk has been tested under VAX/VMS 5.5-1 using VAX C V3.2, GNU C 1.40 and 2.3. It should work without modifications for VMS V4.6 and up.

Installing gawk on VMS

To install gawk, all you need is a "foreign" command, which is a DCL symbol whose value begins with a dollar sign. For example:

```
$ GAWK :== $disk1:[gnubin]GAWK
```

(Substitute the actual location of gawk.exe for `$disk1:[gnubin]'.) The symbol should be placed in the `login.com' of any user who wishes to run gawk, so that it will be defined every time the user logs on. Alternatively, the symbol may be placed in the system-wide `sylogin.com' procedure, which will allow all users to run gawk.

Optionally, the help entry can be loaded into a VMS help library:

```
$ LIBRARY/HELP SYS$HELP:HELPLIB [.VMS]GAWK.HLP
```

(You may want to substitute a site-specific help library rather than the standard VMS library `HELPLIB'.) After loading the help text,

```
$ HELP GAWK
```

will provide information about both the gawk implementation and the awk programming language.

The logical name `AWK_LIBRARY' can designate a default location for awk program files. For the `-f' option, if the specified filename has no device or directory path information in it, gawk will look in the current directory first, then in the directory specified by the translation of `AWK_LIBRARY' if the file was not found. If after searching in both directories, the file still is not found, then gawk appends the suffix `.awk' to the filename and the file search will be re-tried. If `AWK_LIBRARY' is not defined, that portion of the file search will fail benignly.

Running gawk on VMS

Command line parsing and quoting conventions are significantly different on VMS, so examples in this book or from other sources often need minor changes. They *are* minor though, and all `awk` programs should run correctly.

Here are a couple of trivial tests:

```
$ gawk -- "BEGIN {print ""Hello, World!""}"
$ gawk -"W" version
! could also be -"W version" or "-W version"
```

Note that upper-case and mixed-case text must be quoted.

The VMS port of `gawk` includes a `DCL`-style interface in addition to the original shell-style interface (see the help entry for details). One side-effect of dual command line parsing is that if there is only a single parameter (as in the quoted string program above), the command becomes ambiguous. To work around this, the normally optional `--' flag is required to force Unix style rather than `DCL` parsing. If any other dash-type options (or multiple parameters such as data files to be processed) are present, there is no ambiguity and `--' can be omitted.

The default search path when looking for `awk` program files specified by the `-f' option is `"SYS$DISK:[],AWK_LIBRARY:"`. The logical name `AWKPATH' can be used to override this default. The format of `AWKPATH' is a comma-separated list of directory specifications. When defining it, the value should be quoted so that it retains a single translation, and not a multi-translation `RMS` searchlist.

Building and Using gawk on VMS POSIX

Ignore the instructions above, although `` `vms/gawk.hlp' `` should still be made available in a help library. Make sure that the `configure` script is executable; use `chmod +x' on it if necessary. Then execute the following commands:

```
$ POSIX
psx> CC=vms/posix-cc.sh configure
psx> CC=c89 make gawk
```

The first command will construct files `` `config.h' `` and `` `Makefile' `` out of templates. The second command will compile and link `gawk`. Ignore the warning `"Could not find lib m in lib list"`; it is harmless, caused by the explicit use of `-lm' as a linker option which is not needed under VMS POSIX. Under V1.1 (but not V1.0) a problem with the `yacc` skeleton `` `/etc/yyparse.c' `` will cause a compiler warning for `` `awktab.c' ``, followed by a linker warning about compilation warnings in the resulting object module. These warnings can be ignored.

Once built, `gawk` will work like any other shell utility. Unlike the normal VMS port of `gawk`, no special command line manipulation is needed in the VMS POSIX environment.

MS-DOS and OS/2 Installation and Compilation

If you have received a binary distribution prepared by the DOS maintainers, then `gawk` and the necessary support files will appear under the `` `gnu' `` directory, with executables in `` `gnu/bin' ``, libraries in `` `gnu/lib/awk' ``, and manual pages under `` `gnu/man' ``. This is designed for easy installation to a `` `/gnu' `` directory on your drive, but the files can be installed anywhere provided `AWKPATH` is set properly. Regardless of the installation directory, the first line of `` `igawk.cmd' `` and `` `igawk.bat' `` (in `` `gnu/bin' ``) may need to be edited.

The binary distribution will contain a separate file describing the contents. In particular, it may include more than one version of the `gawk` executable. OS/2 binary distributions may have a different arrangement, but installation is similar.

The OS/2 and MS-DOS versions of `gawk` search for program files as described in section The `AWKPATH` Environment Variable. However, semicolons (rather than colons) separate elements in the `AWKPATH` variable. If `AWKPATH` is not set or is empty, then the default search path is `".;c:/lib/awk;c:/gnu/lib/awk"`.

An `sh`-like shell (as opposed to `command.com` under MS-DOS or `cmd.exe` under OS/2) may be useful for `awk` programming. Ian Stewartson has written an excellent shell for MS-DOS and OS/2, and a `ksh` clone and GNU Bash are available for OS/2. The file `` `README_d/README.pc' `` in the `gawk` distribution contains information on these shells. Users of Stewartson's shell on DOS should examine its documentation on handling of command-lines. In particular, the setting for `gawk` in the shell configuration may need to be changed, and the `ignoretype` option may also be of interest.

`gawk` can be compiled for MS-DOS and OS/2 using the GNU development tools from DJ Delorie (DJGPP, MS-DOS-only) or Eberhard Mattes (EMX, MS-DOS and OS/2). Microsoft C can be used to build 16-bit versions for MS-DOS and OS/2. The file `` `README_d/README.pc' `` in the `gawk` distribution contains additional notes, and `` `pc/Makefile' `` contains important notes on compilation options.

To build `gawk`, copy the files in the `` `pc' `` directory to the directory with the rest of the `gawk` sources. The `` `Makefile' `` contains a configuration section with comments, and may need to be edited in order to work with your `make` utility.

The `` `Makefile' `` contains a number of targets for building various MS-DOS and OS/2 versions. A list of targets will be printed if the `make` command is given without a target. As an example, to build `gawk` using the DJGPP tools, enter `make djgpp'.

Using `make` to run the standard tests and to install `gawk` requires additional Unix-like tools, including `sh`, `sed`, and `cp`. In order to run the tests, the `` `test/*.ok' `` files may need to be converted so that they have the usual DOS-style end-of-line markers. Most of the tests will work properly with Stewartson's shell along with the companion utilities or appropriate GNU utilities. However, some editing of `` `test/Makefile' `` is required. It is recommended that the file `` `pc/Makefile.tst' `` be copied to `` `test/Makefile' `` as a replacement. Details can be found in `` `README_d/README.pc' ``.

TOC

Installing gawk on the Atari ST

There are no substantial differences when installing `gawk` on various Atari models. Compiled `gawk` executables do not require a large amount of memory with most `awk` programs and should run on all Motorola processor based models (called further ST, even if that is not exactly right).

In order to use `gawk`, you need to have a shell, either text or graphics, that does not map all the characters of a command line to upper-case. Maintaining case distinction in option flags is very important (see section Command Line Options). These days this is the default, and it may only be a problem for some very old machines. If your system does not preserve the case of option flags, you will need to upgrade your tools. Support for I/O redirection is necessary to make it easy to import `awk` programs from other environments. Pipes are nice to have, but not vital.

Compiling gawk on the Atari ST

A proper compilation of `gawk` sources when `sizeof(int)` differs from `sizeof(void *)` requires an ANSI C compiler. An initial port was done with `gcc`. You may actually prefer executables where `int`s are four bytes wide, but the other variant works as well.

You may need quite a bit of memory when trying to recompile the `gawk` sources, as some source files (`` `regex.c' `` in particular) are quite big. If you run out of memory compiling such a file, try reducing the optimization level for this particular file; this may help.

With a reasonable shell (Bash will do), and in particular if you run Linux, MiNT or a similar operating system, you have a pretty good chance that the `configure` utility will succeed. Otherwise sample versions of `` `config.h' `` and `` `Makefile.st' `` are given in the `` `atari' `` subdirectory and can be edited and copied to the corresponding files in the main source directory. Even if `configure` produced something, it might be advisable to compare its results with the sample versions and possibly make adjustments.

Some `gawk` source code fragments depend on a preprocessor define `atarist'. This basically assumes the TOS environment with `gcc`. Modify these sections as appropriate if they are not right for your environment. Also see the remarks about `AWKPATH` and `envsep` in section Running `gawk` on the Atari ST.

As shipped, the sample `` `config.h' `` claims that the `system` function is missing from the libraries, which is not true, and an alternative implementation of this function is provided in `` `atari/system.c' ``. Depending upon your particular combination of shell and operating system, you may wish to change the file to indicate that `system` is available.

Running gawk on the Atari ST

An executable version of `gawk` should be placed, as usual, anywhere in your `PATH` where your shell can find it.

While executing, `gawk` creates a number of temporary files. When using `gcc` libraries for TOS, `gawk`

looks for either of the environment variables `TEMP` or `TMPDIR`, in that order. If either one is found, its value is assumed to be a directory for temporary files. This directory must exist, and if you can spare the memory, it is a good idea to put it on a RAM drive. If neither `TEMP` nor `TMPDIR` are found, then `gawk` uses the current directory for its temporary files.

The ST version of `gawk` searches for its program files as described in section The `AWKPATH` Environment Variable. The default value for the `AWKPATH` variable is taken from `DEFPATH` defined in `` `Makefile' ``. The sample `gcc`/TOS `` `Makefile' `` for the ST in the distribution sets `DEFPATH` to `".,c:\lib\awk,c:\gnu\lib\awk"`. The search path can be modified by explicitly setting `AWKPATH` to whatever you wish. Note that colons cannot be used on the ST to separate elements in the `AWKPATH` variable, since they have another, reserved, meaning. Instead, you must use a comma to separate elements in the path. When recompiling, the separating character can be modified by initializing the `envsep` variable in `` `atari/gawkmisc.atr' `` to another value.

Although `awk` allows great flexibility in doing I/O redirections from within a program, this facility should be used with care on the ST running under TOS. In some circumstances the OS routines for file handle pool processing lose track of certain events, causing the computer to crash, and requiring a reboot. Often a warm reboot is sufficient. Fortunately, this happens infrequently, and in rather esoteric situations. In particular, avoid having one part of an `awk` program using `print` statements explicitly redirected to `"/dev/stdout"`, while other `print` statements use the default standard output, and a calling shell has redirected standard output to a file.

When `gawk` is compiled with the ST version of `gcc` and its usual libraries, it will accept both `/' and `\' as path separators. While this is convenient, it should be remembered that this removes one, technically valid, character (`/') from your file names, and that it may create problems for external programs, called via the `system` function, which may not support this convention. Whenever it is possible that a file created by `gawk` will be used by some other program, use only backslashes. Also remember that in `awk`, backslashes in strings have to be doubled in order to get literal backslashes (see section Escape Sequences).

Installing gawk on an Amiga

You can install `gawk` on an Amiga system using a Unix emulation environment available via anonymous `ftp` from `wuarchive.wustl.edu` in the directory `` `pub/aminet/dev/gcc' ``. This includes a shell based on `pdksh`. The primary component of this environment is a Unix emulation library, `` `ixemul.lib' ``.

A more complete distribution for the Amiga is available on the FreshFish CD-ROM from:

> Amiga Library Services
> 610 North Alma School Road, Suite 18
> Chandler, AZ 85224 USA
> Phone: +1-602-491-0048
> FAX: +1-602-491-0048
> E-mail: `orders@amigalib.com`

Once you have the distribution, you can configure `gawk` simply by running `configure`:

```
configure -v m68k-cbm-amigados
```

Then run `make`, and you should be all set! (If these steps do not work, please send in a bug report; see section Reporting Problems and Bugs.)

Reporting Problems and Bugs

If you have problems with `gawk` or think that you have found a bug, please report it to the developers; we cannot promise to do anything but we might well want to fix it.

Before reporting a bug, make sure you have actually found a real bug. Carefully reread the documentation and see if it really says you can do what you're trying to do. If it's not clear whether you should be able to do something or not, report that too; it's a bug in the documentation!

Before reporting a bug or trying to fix it yourself, try to isolate it to the smallest possible `awk` program and input data file that reproduces the problem. Then send us the program and data file, some idea of what kind of Unix system you're using, and the exact results `gawk` gave you. Also say what you expected to occur; this will help us decide whether the problem was really in the documentation.

Once you have a precise problem, there are two e-mail addresses you can send mail to.

Internet:

`bug-gnu-utils@prep.ai.mit.edu'

UUCP:

`uunet!prep.ai.mit.edu!bug-gnu-utils'

Please include the version number of `gawk` you are using. You can get this information with the command `gawk --version'. You should send a carbon copy of your mail to Arnold Robbins, who can be reached at `arnold@gnu.ai.mit.edu'.

Important! Do *not* try to report bugs in `gawk` by posting to the Usenet/Internet newsgroup `comp.lang.awk`. While the `gawk` developers do occasionally read this newsgroup, there is no guarantee that we will see your posting. The steps described above are the official, recognized ways for reporting bugs.

Non-bug suggestions are always welcome as well. If you have questions about things that are unclear in the documentation or are just obscure features, ask Arnold Robbins; he will try to help you out, although he may not have the time to fix the problem. You can send him electronic mail at the Internet address above.

If you find bugs in one of the non-Unix ports of `gawk`, please send an electronic mail message to the person who maintains that port. They are listed below, and also in the `README' file in the `gawk` distribution. Information in the `README` file should be considered authoritative if it conflicts with this book.

The people maintaining the non-Unix ports of `gawk` are:

MS-DOS

Scott Deifik, `scottd@amgen.com', and Darrel Hankerson, `hankedr@mail.auburn.edu'.

OS/2

Kai Uwe Rommel, `rommel@ars.de'.

VMS

Pat Rankin, `rankin@eql.caltech.edu'.

Atari ST

Michal Jaegermann, `michal@gortel.phys.ualberta.ca'.

Amiga

Fred Fish, `fnf@amigalib.com'.

If your bug is also reproducible under Unix, please send copies of your report to the general GNU bug list, as well as to Arnold Robbins, at the addresses listed above.

Other Freely Available `awk` Implementations

There are two other freely available `awk` implementations. This section briefly describes where to get them.

Unix `awk`

Brian Kernighan has been able to make his implementation of `awk` freely available. You can get it via anonymous `ftp` to the host `netlib.att.com`. Change directory to `` `/netlib/research' ``. Use "binary" or "image" mode, and retrieve `` `awk.bundle.Z' ``.

This is a shell archive that has been compressed with the `compress` utility. It can be uncompressed with either `uncompress` or the GNU `gunzip` utility.

This version requires an ANSI C compiler; GCC (the GNU C compiler) works quite nicely.

`mawk`

Michael Brennan has written an independent implementation of `awk`, called `mawk`. It is available under the GPL (see section GNU GENERAL PUBLIC LICENSE), just as `gawk` is.

You can get it via anonymous `ftp` to the host `oxy.edu`. Change directory to `` `/public' ``. Use "binary" or "image" mode, and retrieve `` `mawk1.2.1.tar.gz' `` (or the latest version that is there).

`gunzip` may be used to decompress this file. Installation is similar to `gawk`'s (see section Compiling and Installing `gawk` on Unix).

Go to the previous, next section.

Go to the previous, next section.

Implementation Notes

This appendix contains information mainly of interest to implementors and maintainers of gawk. Everything in it applies specifically to gawk, and not to other implementations.

Downward Compatibility and Debugging

See section Extensions in gawk Not in POSIX awk, for a summary of the GNU extensions to the awk language and program. All of these features can be turned off by invoking gawk with the `--traditional' option, or with the `--posix' option.

If gawk is compiled for debugging with `-DDEBUG', then there is one more option available on the command line:

`-W parsedebug`

`--parsedebug`

Print out the parse stack information as the program is being parsed.

This option is intended only for serious gawk developers, and not for the casual user. It probably has not even been compiled into your version of gawk, since it slows down execution.

Making Additions to gawk

If you should find that you wish to enhance gawk in a significant fashion, you are perfectly free to do so. That is the point of having free software; the source code is available, and you are free to change it as you wish (see section GNU GENERAL PUBLIC LICENSE).

This section discusses the ways you might wish to change gawk, and any considerations you should bear in mind.

Adding New Features

You are free to add any new features you like to gawk. However, if you want your changes to be incorporated into the gawk distribution, there are several steps that you need to take in order to make it possible for me to include to your changes.

1. Get the latest version. It is much easier for me to integrate changes if they are relative to the most recent distributed version of gawk. If your version of gawk is very old, I may not be able to integrate them at all. See section Getting the gawk Distribution, for information on getting the latest version of gawk.
2. Follow the GNU Coding Standards. This document describes how GNU software should be written. If you haven't read it, please do so, preferably *before* starting to modify gawk. (The GNU

Coding Standards are available as part of the Autoconf distribution, from the FSF.)

3. Use the `gawk` coding style. The C code for `gawk` follows the instructions in the GNU Coding Standards, with minor exceptions. The code is formatted using the traditional "K&R" style, particularly as regards the placement of braces and the use of tabs. In brief, the coding rules for `gawk` are:
   - Use old style (non-prototype) function headers when defining functions.
   - Put the name of the function at the beginning of its own line.
   - Put the return type of the function, even if it is `int`, on the line above the line with the name and arguments of the function.
   - The declarations for the function arguments should not be indented.
   - Put spaces around parentheses used in control structures (`if`, `while`, `for`, `do`, `switch` and `return`).
   - Do not put spaces in front of parentheses used in function calls.
   - Put spaces around all C operators, and after commas in function calls.
   - Do not use the comma operator to produce multiple side-effects, except in `for` loop initialization and increment parts, and in macro bodies.
   - Use real tabs for indenting, not spaces.
   - Use the "K&R" brace layout style.
   - Use comparisons against `NULL` and `'\0'` in the conditions of `if`, `while` and `for` statements, and in the `case`s of `switch` statements, instead of just the plain pointer or character value.
   - Use the `TRUE`, `FALSE`, and `NULL` symbolic constants, and the character constant `'\0'` where appropriate, instead of `1` and `0`.
   - Provide one-line descriptive comments for each function.
   - Do not use `#elif'. Many older Unix C compilers cannot handle it.

   If I have to reformat your code to follow the coding style used in `gawk`, I may not bother.
4. Be prepared to sign the appropriate paperwork. In order for the FSF to distribute your changes, you must either place those changes in the public domain, and submit a signed statement to that effect, or assign the copyright in your changes to the FSF. Both of these actions are easy to do, and *many* people have done so already. If you have questions, please contact me (see section Reporting Problems and Bugs), or `gnu@prep.ai.mit.edu`.
5. Update the documentation. Along with your new code, please supply new sections and or chapters for this book. If at all possible, please use real Texinfo, instead of just supplying unformatted ASCII text (although even that is better than no documentation at all). Conventions to be followed in AWK Language Programming are provided after the `@bye' at the end of the Texinfo source file. If possible, please update the man page as well.

   You will also have to sign paperwork for your documentation changes.
6. Submit changes as context diffs or unified diffs. Use `diff -c -r -N' or `diff -u -r -N' to compare the original `gawk` source tree with your version. (I find context diffs to be more readable, but unified

diffs are more compact.) I recommend using the GNU version of `diff`. Send the output produ by either run of `diff` to me when you submit your changes. See section Reporting Problems a Bugs, for the electronic mail information.

Using this format makes it easy for me to apply your changes to the master version of the `gawk` source code (using `patch`). If I have to apply the changes manually, using a text editor, I may not do so, particularly if there are lots of changes.

Although this sounds like a lot of work, please remember that while you may write the new code, I have to maintain it and support it, and if it isn't possible for me to do that with a minimum of extra work, then I probably will not.

Porting gawk to a New Operating System

If you wish to port `gawk` to a new operating system, there are several steps to follow.

1. Follow the guidelines in section Adding New Features, concerning coding style, submission of diffs, and so on.
2. When doing a port, bear in mind that your code must co-exist peacefully with the rest of `gawk`, and the other ports. Avoid gratuitous changes to the system-independent parts of the code. If at all possible, avoid sprinkling `#ifdef's just for your port throughout the code.

   If the changes needed for a particular system affect too much of the code, I probably will not accept them. In such a case, you will, of course, be able to distribute your changes on your own, as long as you comply with the GPL (see section GNU GENERAL PUBLIC LICENSE).
3. A number of the files that come with `gawk` are maintained by other people at the Free Software Foundation. Thus, you should not change them unless it is for a very good reason. I.e. changes are not out of the question, but changes to these files will be scrutinized extra carefully. The files are `` `alloca.c' ``, `` `getopt.h' ``, `` `getopt.c' ``, `` `getopt1.c' ``, `` `regex.h' ``, `` `regex.c' ``, `` `dfa.h' ``, `` `dfa.c' ``, `` `install-sh' ``, and `` `mkinstalldirs' ``.
4. Be willing to continue to maintain the port. Non-Unix operating systems are supported by volunteers who maintain the code needed to compile and run `gawk` on their systems. If no-one volunteers to maintain a port, that port becomes unsupported, and it may be necessary to remove it from the distribution.
5. Supply an appropriate `` `gawkmisc.???' `` file. Each port has its own `` `gawkmisc.???' `` that implements certain operating system specific functions. This is cleaner than a plethora of `#ifdef's scattered throughout the code. The `` `gawkmisc.c' `` in the main source directory includes the appropriate `` `gawkmisc.???' `` file from each subdirectory. Be sure to update it as well.

   Each port's `` `gawkmisc.???' `` file has a suffix reminiscent of the machine or operating system for the port. For example, `` `pc/gawkmisc.pc' `` and `` `vms/gawkmisc.vms' ``. The use of separate suffixes, instead of plain `` `gawkmisc.c' ``, makes it possible to move files from a port's subdirectory into the main subdirectory, without accidentally destroying the real `` `gawkmisc.c' `` file. (Currently, this is only an issue for the MS-DOS and OS/2 ports.)
6. Supply a `` `Makefile' `` and any other C source and header files that are necessary for your operating system. All your code should be in a separate subdirectory, with a name that is the same

as, or reminiscent of, either your operating system or the computer system. If possible, try to structure things so that it is not necessary to move files out of the subdirectory into the main source directory. If that is not possible, then be sure to avoid using names for your files that duplicate the names of files in the main source directory.

7. Update the documentation. Please write a section (or sections) for this book describing the installation and compilation steps needed to install and/or compile `gawk` for your system.
8. Be prepared to sign the appropriate paperwork. In order for the FSF to distribute your code, you must either place your code in the public domain, and submit a signed statement to that effect, or assign the copyright in your code to the FSF.

Following these steps will make it much easier to integrate your changes into `gawk`, and have them co-exist happily with the code for other operating systems that is already there.

In the code that you supply, and that you maintain, feel free to use a coding style and brace layout that suits your taste.

Probable Future Extensions

`AWK is a language similar to PERL, only considerably more elegant.`
`Arnold Robbins`

`Hey!`
`Larry Wall`

This section briefly lists extensions and possible improvements that indicate the directions we are currently considering for `gawk`. The file `` `FUTURES' `` in the `gawk` distributions lists these extensions as well.

This is a list of probable future changes that will be usable by the `awk` language programmer.

Localization

The GNU project is starting to support multiple languages. It will at least be possible to make `gawk` print its warnings and error messages in languages other than English. It may be possible for `awk` programs to also use the multiple language facilities, separate from `gawk` itself.

Databases

It may be possible to map a GDBM/NDBM/SDBM file into an `awk` array.

A `PROCINFO` Array

The special files that provide process-related information (see section Special File Names in gawk) may be superseded by a `PROCINFO` array that would provide the same information, in an easier to access fashion.

More `lint` warnings

There are more things that could be checked for portability.

Control of subprocess environment

Changes made in `gawk` to the array `ENVIRON` may be propagated to subprocesses run by `gaw`

This is a list of probable improvements that will make `gawk` perform better.

An Improved Version of `dfa`

The `dfa` pattern matcher from GNU `grep` has some problems. Either a new version or a fixed one will deal with some important regexp matching issues.

Use of `mmap`

On systems that support the `mmap` system call, its use would provide much faster file input, and considerably simplified input buffer management.

Use of GNU `malloc`

The GNU version of `malloc` could potentially speed up `gawk`, since it relies heavily on the use of dynamic memory allocation.

Use of the `rx` regexp library

The `rx` regular expression library could potentially speed up all regexp operations that require knowing the exact location of matches. This includes record termination, field and array splitting, and the `sub`, `gsub`, `gensub` and `match` functions.

Suggestions for Improvements

Here are some projects that would-be `gawk` hackers might like to take on. They vary in size from a few days to a few weeks of programming, depending on which one you choose and how fast a programmer you are. Please send any improvements you write to the maintainers at the GNU project. See section Adding New Features, for guidelines to follow when adding new features to `gawk`. See section Reporting Problems and Bugs, for information on contacting the maintainers.

1. Compilation of `awk` programs: `gawk` uses a Bison (YACC-like) parser to convert the script given it into a syntax tree; the syntax tree is then executed by a simple recursive evaluator. This method incurs a lot of overhead, since the recursive evaluator performs many procedure calls to do even the simplest things.

   It should be possible for `gawk` to convert the script's parse tree into a C program which the user would then compile, using the normal C compiler and a special `gawk` library to provide all the needed functions (regexps, fields, associative arrays, type coercion, and so on).

   An easier possibility might be for an intermediate phase of `awk` to convert the parse tree into a linear byte code form like the one used in GNU Emacs Lisp. The recursive evaluator would then be replaced by a straight line byte code interpreter that would be intermediate in speed between running a compiled program and doing what `gawk` does now.
2. The programs in the test suite could use documenting in this book.
3. See the `` `FUTURES' `` file for more ideas. Contact us if you would seriously like to tackle any of the items listed there.

Go to the previous, next section.

Go to the previous, next section.

Glossary

Action

A series of `awk` statements attached to a rule. If the rule's pattern matches an input record, `awk` executes the rule's action. Actions are always enclosed in curly braces. See section Overview of Actions.

Amazing `awk` Assembler

Henry Spencer at the University of Toronto wrote a retargetable assembler completely as `awk` scripts. It is thousands of lines long, including machine descriptions for several eight-bit microcomputers. It is a good example of a program that would have been better written in another language.

Amazingly Workable Formatter (`awf`)

Henry Spencer at the University of Toronto wrote a formatter that accepts a large subset of the `nroff -ms' and `nroff -man' formatting commands, using `awk` and `sh`.

ANSI

The American National Standards Institute. This organization produces many standards, among them the standards for the C and C++ programming languages.

Assignment

An `awk` expression that changes the value of some `awk` variable or data object. An object that you can assign to is called an lvalue. The assigned values are called rvalues. See section Assignment Expressions.

`awk` Language

The language in which `awk` programs are written.

`awk` Program

An `awk` program consists of a series of patterns and actions, collectively known as rules. For each input record given to the program, the program's rules are all processed in turn. `awk` programs may also contain function definitions.

`awk` Script

Another name for an `awk` program.

Bash

The GNU version of the standard shell (the Bourne-Again shell). See "Bourne Shell."

BBS

See "Bulletin Board System."

Boolean Expression

Named after the English mathematician Boole. See "Logical Expression."

Bourne Shell

The standard shell (`/bin/sh') on Unix and Unix-like systems, originally written by Steven Bourne. Many shells (Bash, ksh, pdksh, zsh) are generally upwardly compatible with the Bourne shell.

Built-in Function

The awk language provides built-in functions that perform various numerical, time stamp related, and string computations. Examples are sqrt (for the square root of a number) and substr (for a substring of a string). See section Built-in Functions.

Built-in Variable

ARGC, ARGIND, ARGV, CONVFMT, ENVIRON, ERRNO, FIELDWIDTHS, FILENAME, FNR, FS, IGNORECASE, NF, NR, OFMT, OFS, ORS, RLENGTH, RSTART, RS, RT, and SUBSEP, are the variables that have special meaning to awk. Changing some of them affects awk's running environment. Several of these variables are specific to gawk. See section Built-in Variables.

Braces

See "Curly Braces."

Bulletin Board System

A computer system allowing users to log in and read and/or leave messages for other users of the system, much like leaving paper notes on a bulletin board.

C

The system programming language that most GNU software is written in. The awk programming language has C-like syntax, and this book points out similarities between awk and C when appropriate.

Character Set

The set of numeric codes used by a computer system to represent the characters (letters, numbers, punctuation, etc.) of a particular country or place. The most common character set in use today is ASCII (American Standard Code for Information Interchange). Many European countries use an extension of ASCII known as ISO-8859-1 (ISO Latin-1).

CHEM

A preprocessor for pic that reads descriptions of molecules and produces pic input for drawing them. It was written in awk by Brian Kernighan and Jon Bentley, and is available from netlib@research.att.com.

Compound Statement

A series of awk statements, enclosed in curly braces. Compound statements may be nested. See section Control Statements in Actions.

Concatenation

Concatenating two strings means sticking them together, one after another, giving a new string. For example, the string `foo' concatenated with the string `bar' gives the string `foobar'. See section String Concatenation.

Conditional Expression

An expression using the `?:' ternary operator, such as `expr1 ? expr2 : expr3'. The expression expr1 is evaluated; if the result is true, the value of the whole expression is the value of expr2, otherwise

the value is expr3. In either case, only one of expr2 and expr3 is evaluated. See section Conditional Expressions.

Comparison Expression

A relation that is either true or false, such as `(a < b)'. Comparison expressions are used in `if`, `while`, `do`, and `for` statements, and in patterns to select which input records to process. See section Variable Typing and Comparison Expressions.

Curly Braces

The characters `{' and `}'. Curly braces are used in `awk` for delimiting actions, compound statements, and function bodies.

Dark Corner

An area in the language where specifications often were (or still are) not clear, leading to unexpected or undesirable behavior. Such areas are marked in this book with "(d.c.)" in the text, and are indexed under the heading "dark corner."

Data Objects

These are numbers and strings of characters. Numbers are converted into strings and vice versa, as needed. See section Conversion of Strings and Numbers.

Double Precision

An internal representation of numbers that can have fractional parts. Double precision numbers keep track of more digits than do single precision numbers, but operations on them are more expensive. This is the way `awk` stores numeric values. It is the C type `double`.

Dynamic Regular Expression

A dynamic regular expression is a regular expression written as an ordinary expression. It could be a string constant, such as `"foo"`, but it may also be an expression whose value can vary. See section Using Dynamic Regexps.

Environment

A collection of strings, of the form name=val, that each program has available to it. Users generally place values into the environment in order to provide information to various programs. Typical examples are the environment variables `HOME` and `PATH`.

Empty String

See "Null String."

Escape Sequences

A special sequence of characters used for describing non-printing characters, such as `\n' for newline, or `\033' for the ASCII ESC (escape) character. See section Escape Sequences.

Field

When `awk` reads an input record, it splits the record into pieces separated by whitespace (or by a separator regexp which you can change by setting the built-in variable `FS`). Such pieces are called fields. If the pieces are of fixed length, you can use the built-in variable `FIELDWIDTHS` to describe their lengths. See section Specifying How Fields are Separated, and also see See section Reading Fixed-width Data.

Floating Point Number

Often referred to in mathematical terms as a "rational" number, this is just a number that can have a fractional part. See "Double Precision" and "Single Precision."

Format

Format strings are used to control the appearance of output in the `printf` statement. Also, data conversions from numbers to strings are controlled by the format string contained in the built-in variable `CONVFMT`. See section Format-Control Letters.

Function

A specialized group of statements used to encapsulate general or program-specific tasks. `awk` has a number of built-in functions, and also allows you to define your own. See section Built-in Functions, and section User-defined Functions.

FSF

See "Free Software Foundation."

Free Software Foundation

A non-profit organization dedicated to the production and distribution of freely distributable software. It was founded by Richard M. Stallman, the author of the original Emacs editor. GNU Emacs is the most widely used version of Emacs today.

`gawk`

The GNU implementation of `awk`.

General Public License

This document describes the terms under which `gawk` and its source code may be distributed. (see section GNU GENERAL PUBLIC LICENSE)

GNU

"GNU's not Unix". An on-going project of the Free Software Foundation to create a complete, freely distributable, POSIX-compliant computing environment.

GPL

See "General Public License."

Hexadecimal

Base 16 notation, where the digits are `0-9` and `A-F`, with `A' representing 10, `B' representing 11, and so on up to `F' for 15. Hexadecimal numbers are written in C using a leading `0x', to indicate their base. Thus, `0x12` is 18 (one times 16 plus 2).

I/O

Abbreviation for "Input/Output," the act of moving data into and/or out of a running program.

Input Record

A single chunk of data read in by `awk`. Usually, an `awk` input record consists of one line of text. See section How Input is Split into Records.

Integer

A whole number, i.e. a number that does not have a fractional part.

Keyword

In the `awk` language, a keyword is a word that has special meaning. Keywords are reserved and may not be used as variable names.

`gawk`'s keywords are: `BEGIN`, `END`, `if`, `else`, `while`, `do...while`, `for`, `for...in`, `break`, `continue`, `delete`, `next`, `nextfile`, `function`, `func`, and `exit`.

Logical Expression

An expression using the operators for logic, AND, OR, and NOT, written `&&', `||', and `!' in `awk`. Often called Boolean expressions, after the mathematician who pioneered this kind of mathematical logic.

Lvalue

An expression that can appear on the left side of an assignment operator. In most languages, lvalues can be variables or array elements. In `awk`, a field designator can also be used as an lvalue.

Null String

A string with no characters in it. It is represented explicitly in `awk` programs by placing two double-quote characters next to each other (`""`). It can appear in input data by having two successive occurrences of the field separator appear next to each other.

Number

A numeric valued data object. The `gawk` implementation uses double precision floating point to represent numbers. Very old `awk` implementations use single precision floating point.

Octal

Base-eight notation, where the digits are `0-7`. Octal numbers are written in C using a leading `0', to indicate their base. Thus, `013` is 11 (one times 8 plus 3).

Pattern

Patterns tell `awk` which input records are interesting to which rules.

A pattern is an arbitrary conditional expression against which input is tested. If the condition is satisfied, the pattern is said to match the input record. A typical pattern might compare the input record against a regular expression. See section Pattern Elements.

POSIX

The name for a series of standards being developed by the IEEE that specify a Portable Operating System interface. The "IX" denotes the Unix heritage of these standards. The main standard of interest for `awk` users is IEEE Standard for Information Technology, Standard 1003.2-1992, Portable Operating System Interface (POSIX) Part 2: Shell and Utilities. Informally, this standard is often referred to as simply "P1003.2."

Private

Variables and/or functions that are meant for use exclusively by library functions, and not for the main `awk` program. Special care must be taken when naming such variables and functions. See section Naming Library Function Global Variables.

Range (of input lines)

A sequence of consecutive lines from the input file. A pattern can specify ranges of input lines for

awk to process, or it can specify single lines. See section Pattern Elements.

Recursion

When a function calls itself, either directly or indirectly. If this isn't clear, refer to the entry for "recursion."

Redirection

Redirection means performing input from other than the standard input stream, or output to other than the standard output stream.

You can redirect the output of the `print` and `printf` statements to a file or a system command, using the `>', `>>', and `|' operators. You can redirect input to the `getline` statement using the `<' and `|' operators. See section Redirecting Output of `print` and `printf`, and section Explicit Input with `getline`.

Regexp

Short for regular expression. A regexp is a pattern that denotes a set of strings, possibly an infinite set. For example, the regexp `R.*xp' matches any string starting with the letter `R' and ending with the letters `xp'. In awk, regexps are used in patterns and in conditional expressions. Regexps may contain escape sequences. See section Regular Expressions.

Regular Expression

See "regexp."

Regular Expression Constant

A regular expression constant is a regular expression written within slashes, such as `/foo/`. This regular expression is chosen when you write the awk program, and cannot be changed doing its execution. See section How to Use Regular Expressions.

Rule

A segment of an awk program that specifies how to process single input records. A rule consists of a pattern and an action. awk reads an input record; then, for each rule, if the input record satisfies the rule's pattern, awk executes the rule's action. Otherwise, the rule does nothing for that input record.

Rvalue

A value that can appear on the right side of an assignment operator. In awk, essentially every expression has a value. These values are rvalues.

`sed`

See "Stream Editor."

Short-Circuit

The nature of the awk logical operators `&&' and `||'. If the value of the entire expression can be deduced from evaluating just the left-hand side of these operators, the right-hand side will not be evaluated (see section Boolean Expressions).

Side Effect

A side effect occurs when an expression has an effect aside from merely producing a value. Assignment expressions, increment and decrement expressions and function calls have side

effects. See section Assignment Expressions.

Single Precision

An internal representation of numbers that can have fractional parts. Single precision numbers keep track of fewer digits than do double precision numbers, but operations on them are less expensive in terms of CPU time. This is the type used by some very old versions of `awk` to store numeric values. It is the C type `float`.

Space

The character generated by hitting the space bar on the keyboard.

Special File

A file name interpreted internally by `gawk`, instead of being handed directly to the underlying operating system. For example, `` `/dev/stderr' ``. See section Special File Names in `gawk`.

Stream Editor

A program that reads records from an input stream and processes them one or more at a time. This is in contrast with batch programs, which may expect to read their input files in entirety before starting to do anything, and with interactive programs, which require input from the user.

String

A datum consisting of a sequence of characters, such as `I am a string'. Constant strings are written with double-quotes in the `awk` language, and may contain escape sequences. See section Escape Sequences.

Tab

The character generated by hitting the TAB key on the keyboard. It usually expands to up to eight spaces upon output.

Unix

A computer operating system originally developed in the early 1970's at AT&T Bell Laboratories. It initially became popular in universities around the world, and later moved into commercial evnironments as a software development system and network server system. There are many commercial versions of Unix, as well as several work-alike systems whose source code is freely available (such as Linux, NetBSD, and FreeBSD).

Whitespace

A sequence of space or tab characters occurring inside an input record or a string.

Go to the previous, next section.

Go to the previous, next section.

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.

2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

   You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

3. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:

   1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
   2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
   3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

   These requirements apply to the modified work as a whole. If identifiable sections of that work are not derived from the Program, and can be reasonably considered independent and separate works in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

   Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works

based on the Program.

In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for non-commercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

    The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

    If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.
5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.
6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on it.
7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other

pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.

9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.
11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING,

REPAIR OR CORRECTION.

13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and an idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or
modify it under the terms of the GNU General Public License
as published by the Free Software Foundation; either version 2
of the License, or (at your option) any later version.

This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 59 Temple Place -- Suite 330, Boston, MA 02111-1307, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details
type `show w'.  This is free software, and you are welcome
to redistribute it under certain conditions; type `show c'
```

```
for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright
interest in the program `Gnomovision'
(which makes passes at compilers) written
by James Hacker.

signature of Ty Coon, 1 April 1989
Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License instead of this License.

Go to the previous section.

AWK Language Programming

(1)

These commands are available on POSIX compliant systems, as well as on traditional Unix based systems. If you are using some other operating system, you still need to be familiar with the ideas of I/O redirection and pipes

(2)

Often, these systems use `gawk` for their `awk` implementation!

(3)

The `#!' mechanism works on Linux systems, Unix systems derived from Berkeley Unix, System V Release 4, and some System V Release 3 systems.

(4)

The line beginning with `#!' lists the full file name of an interpreter to be run, and an optional initial command line argument to pass to that interpreter. The operating system then runs the interpreter with the given argument and the full argument list of the executed program. The first argument in the list is the full file name of the `awk` program. The rest of the argument list will either be options to `awk`, or data files, or both.

(5)

The `sed` utility is a "stream editor." Its behavior is also defined by the POSIX standard.

(6)

The internal representation uses double-precision floating point numbers. If you don't know what that means, then don't worry about it.

(7)

Some early implementations of Unix `awk` initialized `FILENAME` to `"-"`, even if there were data files to be processed. This behavior was incorrect, and should not be relied upon in your programs.

(8)

Computer generated random numbers really are not truly random. They are technically known as "pseudo-random." This means that while the numbers in a sequence appear to be random, you can in fact generate the same sequence of random numbers over and over again.

(9)

This consequence was certainly unintended.

(10)

As of December 1995, with final approval and publication hopefully sometime in 1996.

(11)

Occasionally there are minutes in a year with one or two leap seconds, which is why the seconds can go up to 61.

(12)

This is because ANSI C leaves the behavior of the C version of `strftime` undefined, and `gawk` will use the system's version of `strftime` if it's there. Typically, the conversion specifier will either not appear in the returned string, or it will appear literally.

(13)

If you don't understand any of this, don't worry about it; these facilities are meant to make it easier to "internationalize" programs.

(14)

Not recommended.

(15)

Your version of `gawk` may use a directory that is different than `` `/usr/local/share/awk' ``; it will depend upon how `gawk` was built and installed. The actual directory will be the value of `$(datadir)' generated when `gawk` was configured. You probably don't need to worry about this though.

(16)

Some implementations of `awk` do not allow you to execute `next` from within a function body. Some other work-around will be necessary if you use such a version.

(17)

ASCII has been extended in many countries to use the values from 128 to 255 for country-specific characters. If your system uses these extensions, you can simplify `_ord_init` to simply loop from zero to 255.

(18)

This is the Epoch on POSIX systems. It may be different on other systems.

(19)

Examine the code in section Noting Data File Boundaries. Why must `wc` use a separate `lines` variable, instead of using the value of `FNR` in `endfile`?

(20)

On older, non-POSIX systems, `tr` often does not require that the lists be enclosed in square brackets and quoted. This is a feature.

(21)

This program was written before `gawk` acquired the ability to split each character in a string into separate array elements. How might this ability simplify the program?

(22)

"Real world" is defined as "a program actually used to get something done."

(23)

The path may use a directory other than `` `/usr/local/share/awk' ``, depending upon how `gawk` was built and installed.

Using and Porting GNU CC

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it.

(Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.
2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate

copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License a to the absence of any warranty; and give any other recipients of the Program a copy of this Licer along with the Program.

You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

3. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:
    1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
    2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
    3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

    These requirements apply to the modified work as a whole. If identifiable sections of that work are not derived from the Program, and can be reasonably considered independent and separate works in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

    Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

    In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of

Sections 1 and 2 above on a medium customarily used for software interchange; or,

3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for noncommercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.

5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.
6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on it.
7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

   If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting th integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.

9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.
11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM

(INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and a brief idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or modify
it under the terms of the GNU General Public License as published by
the Free Software Foundation; either version 2 of the License, or
(at your option) any later version.

This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details
type `show w'.
This is free software, and you are welcome to redistribute it
under certain conditions; type `show c' for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright interest in the program
`Gnomovision' (which makes passes at compilers) written by James Hacker.

signature of Ty Coon, 1 April 1989
Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License instead of this License.

Contributors to GNU CC

In addition to Richard Stallman, several people have written parts of GNU CC.

- The idea of using RTL and some of the optimization ideas came from the program PO written at the University of Arizona by Jack Davidson and Christopher Fraser. See "Register Allocation and Exhaustive Peephole Optimization", Software Practice and Experience 14 (9), Sept. 1984, 857-866.
- Paul Rubin wrote most of the preprocessor.
- Leonard Tower wrote parts of the parser, RTL generator, and RTL definitions, and of the Vax machine description.
- Ted Lemon wrote parts of the RTL reader and printer.
- Jim Wilson implemented loop strength reduction and some other loop optimizations.
- Nobuyuki Hikichi of Software Research Associates, Tokyo, contributed the support for the Sony NEWS machine.
- Charles LaBrec contributed the support for the Integrated Solutions 68020 system.
- Michael Tiemann of Cygnus Support wrote the front end for C++, as well as the support for inline functions and instruction scheduling. Also the descriptions of the National Semiconductor 32000 series cpu, the SPARC cpu and part of the Motorola 88000 cpu.
- Gerald Baumgartner added the signature extension to the C++ front-end.
- Jan Stein of the Chalmers Computer Society provided support for Genix, as well as part of the 32000 machine description.
- Randy Smith finished the Sun FPA support.
- Robert Brown implemented the support for Encore 32000 systems.
- David Kashtan of SRI adapted GNU CC to VMS.
- Alex Crain provided changes for the 3b1.
- Greg Satz and Chris Hanson assisted in making GNU CC work on HP-UX for the 9000 series 300.
- William Schelter did most of the work on the Intel 80386 support.
- Christopher Smith did the port for Convex machines.
- Paul Petersen wrote the machine description for the Alliant FX/8.
- Dario Dariol contributed the four varieties of sample programs that print a copy of their source.
- Alain Lichnewsky ported GNU CC to the Mips cpu.
- Devon Bowen, Dale Wiles and Kevin Zachmann ported GNU CC to the Tahoe.
- Jonathan Stone wrote the machine description for the Pyramid computer.
- Gary Miller ported GNU CC to Charles River Data Systems machines.
- Richard Kenner of the New York University Ultracomputer Research Laboratory wrote the machine descriptions for the AMD 29000, the DEC Alpha, the IBM RT PC, and the IBM RS/6000

as well as the support for instruction attributes. He also made changes to better support RISC processors including changes to common subexpression elimination, strength reduction, functi calling sequence handling, and condition code support, in addition to generalizing the code for frame pointer elimination.

- Richard Kenner and Michael Tiemann jointly developed reorg.c, the delay slot scheduler.
- Mike Meissner and Tom Wood of Data General finished the port to the Motorola 88000.
- Masanobu Yuhara of Fujitsu Laboratories implemented the machine description for the Tron architecture (specifically, the Gmicro).
- NeXT, Inc. donated the front end that supports the Objective C language.
- James van Artsdalen wrote the code that makes efficient use of the Intel 80387 register stack.
- Mike Meissner at the Open Software Foundation finished the port to the MIPS cpu, including adding ECOFF debug support, and worked on the Intel port for the Intel 80386 cpu.
- Ron Guilmette implemented the `protoize` and `unprotoize` tools, the support for Dwarf symbolic debugging information, and much of the support for System V Release 4. He has also worked heavily on the Intel 386 and 860 support.
- Torbjorn Granlund of the Swedish Institute of Computer Science implemented multiply-by-constant optimization and better long long support, and improved leaf function register allocation.
- Mike Stump implemented the support for Elxsi 64 bit CPU.
- John Wehle added the machine description for the Western Electric 32000 processor used in several 3b series machines (no relation to the National Semiconductor 32000 processor).
- Holger Teutsch provided the support for the Clipper cpu.
- Kresten Krab Thorup wrote the run time support for the Objective C language.
- Stephen Moshier contributed the floating point emulator that assists in cross-compilation and permits support for floating point numbers wider than 64 bits.
- David Edelsohn contributed the changes to RS/6000 port to make it support the PowerPC and POWER2 architectures.
- Steve Chamberlain wrote the support for the Hitachi SH processor.
- Peter Schauer wrote the code to allow debugging to work on the Alpha.
- Oliver M. Kellogg of Deutsche Aerospace contributed the port to the MIL-STD-1750A.

Funding Free Software

If you want to have more free software a few years from now, it makes sense for you to help encourage people to contribute funds for its development. The most effective approach known is to encourage commercial redistributors to donate.

Users of free software systems can boost the pace of development by encouraging for-a-fee distributors to donate part of their selling price to free software developers--the Free Software Foundation, and others.

The way to convince distributors to do this is to demand it and expect it from them. So when you compare distributors, judge them partly by how much they give to free software development. Show distributors they must compete to be the one who gives the most.

To make this approach work, you must insist on numbers that you can compare, such as, "We will donate ten dollars to the Frobnitz project for each disk sold." Don't be satisfied with a vague promise, such as "A portion of the profits are donated," since it doesn't give a basis for comparison.

Even a precise fraction "of the profits from this disk" is not very meaningful, since creative accounting and unrelated business decisions can greatly alter what fraction of the sales price counts as profit. If the price you pay is $50, ten percent of the profit is probably less than a dollar; it might be a few cents, or nothing at all.

Some redistributors do development work themselves. This is useful too; but to keep everyone honest, you need to inquire how much they do, and what kind. Some kinds of development make much more long-term difference than others. For example, maintaining a separate version of a program contributes very little; maintaining the standard version of a program for the whole community contributes much. Easy new ports contribute little, since someone else would surely do them; difficult ports such as adding a new CPU to the GNU C compiler contribute more; major new features or packages contribute the most.

By establishing the idea that supporting further development is "the proper thing to do" when distributing free software for a fee, we can assure a steady flow of resources into making more free software.

Protect Your Freedom--Fight "Look And Feel"

This section is a political message from the League for Programming Freedom to the users of GNU CC. We have included it here because the issue of interface copyright is important to the GNU project.

Apple and Lotus have tried to create a new form of legal monopoly: a copyright on a user interface.

An interface is a kind of language--a set of conventions for communication between two entities, human or machine. Until a few years ago, the law seemed clear: interfaces were outside the domain of copyright, so programmers could program freely and implement whatever interface the users demanded. Imitating de-facto standard interfaces, sometimes with improvements, was standard practice in the computer field. These improvements, if accepted by the users, caught on and became the norm; in this way, much progress took place.

Computer users, and most software developers, were happy with this state of affairs. However, large companies such as Apple and Lotus would prefer a different system--one in which they can own interfaces and thereby rid themselves of all serious competitors. They hope that interface copyright will give them, in effect, monopolies on major classes of software.

Other large companies such as IBM and Digital also favor interface monopolies, for the same reason: if languages become property, they expect to own many de-facto standard languages. But Apple and Lotus are the ones who have actually sued. Lotus has won lawsuits against two small companies, which were thus put out of business. Then they sued Borland; this case is now before the court of appeals. Apple's lawsuit against HP and Microsoft is also being decided by an appeals court. Widespread rumors that Apple had lost the case are untrue; as of July 1994, the final outcome is unknown.

If the monopolists get their way, they will hobble the software field:

- Gratuitous incompatibilities will burden users. Imagine if each car manufacturer had to design a different way to start, stop, and steer a car.
- Users will be "locked in" to whichever interface they learn; then they will be prisoners of one supplier, who will charge a monopolistic price.
- Large companies have an unfair advantage wherever lawsuits become commonplace. Since they can afford to sue, they can intimidate smaller developers with threats even when they don't really have a case.
- Interface improvements will come slower, since incremental evolution through creative partial imitation will no longer occur.

If interface monopolies are accepted, other large companies are waiting to grab theirs:

- Adobe is expected to claim a monopoly on the interfaces of various popular application programs, if Borland's appeal against Lotus fails.

- Open Computing magazine reported a Microsoft vice president as threatening to sue people w copy the interface of Windows.

Users invest a great deal of time and money in learning to use computer interfaces. Far more, in fact, than software developers invest in developing *and even implementing* the interfaces. Whoever can own an interface, has made its users into captives, and misappropriated their investment.

To protect our freedom from monopolies like these, a group of programmers and users have formed a grass-roots political organization, the League for Programming Freedom.

The purpose of the League is to oppose monopolistic practices such as interface copyright and software patents. The League calls for a return to the legal policies of the recent past, in which programmers could program freely. The League is not concerned with free software as an issue, and is not affiliated with the Free Software Foundation.

The League's activities include publicizing the issue, as is being done here, and filing friend-of-the-court briefs on behalf of defendants sued by monopolists. Recently the League filed a friend-of-the-court brief for Borland in its appeal against Lotus.

The League's membership rolls include John McCarthy, inventor of Lisp, Marvin Minsky, founder of the MIT Artificial Intelligence lab, Guy L. Steele, Jr., author of well-known books on Lisp and C, as well as Richard Stallman, the developer of GNU CC. Please join and add your name to the list. Membership dues in the League are $42 per year for programmers, managers and professionals; $10.50 for students; $21 for others.

Activist members are especially important, but members who have no time to give are also important. Surveys at major ACM conferences have indicated a vast majority of attendees agree with the League. If just ten percent of the programmers who agree with the League join the League, we will probably triumph.

To join, or for more information, phone (617) 243-4091 or write to:

```
League for Programming Freedom
1 Kendall Square #143
P.O. Box 9171
Cambridge, MA 02139
```

You can also send electronic mail to `lpf@uunet.uu.net`.

In addition to joining the League, here are some suggestions from the League for other things you can do to protect your freedom to write programs:

- Tell your friends and colleagues about this issue and how it threatens to ruin the computer industry.
- Mention that you are a League member in your `` `.signature' ``, and mention the League's email address for inquiries.
- Ask the companies you consider working for or working with to make statements against software monopolies, and give preference to those that do.

- When employers ask you to sign contracts giving them copyright or patent rights, insist on cla saying they can use these rights only defensively. Don't rely on "company policy," since that c change at any time; don't rely on an individual executive's private word, since that person may be replaced. Get a commitment just as binding as the commitment they get from you.
- Write to Congress to explain the importance of this issue.

```
House Subcommittee on Intellectual Property
2137 Rayburn Bldg
Washington, DC 20515

Senate Subcommittee on Patents, Trademarks and Copyrights
United States Senate
Washington, DC 20510
```

(These committees have received lots of mail already; let's give them even more.)

Democracy means nothing if you don't use it. Stand up and be counted!

Compile C, C++, or Objective C

The C, C++, and Objective C versions of the compiler are integrated; the GNU C compiler can compile programs written in C, C++, or Objective C.

"GCC" is a common shorthand term for the GNU C compiler. This is both the most general name for the compiler, and the name used when the emphasis is on compiling C programs.

When referring to C++ compilation, it is usual to call the compiler "G++". Since there is only one compiler, it is also accurate to call it "GCC" no matter what the language context; however, the term "G++" is more useful when the emphasis is on compiling C++ programs.

We use the name "GNU CC" to refer to the compilation system as a whole, and more specifically to the language-independent part of the compiler. For example, we refer to the optimization options as affecting the behavior of "GNU CC" or sometimes just "the compiler".

Front ends for other languages, such as Ada 9X, Fortran, Modula-3, and Pascal, are under development. These front-ends, like that for C++, are built in subdirectories of GNU CC and link to it. The result is an integrated compiler that can compile programs written in C, C++, Objective C, or any of the languages for which you have installed front ends.

In this manual, we only discuss the options for the C, Objective-C, and C++ compilers and those of the GNU CC core. Consult the documentation of the other front ends for the options to use when compiling programs written in other languages.

G++ is a *compiler*, not merely a preprocessor. G++ builds object code directly from your C++ program source. There is no intermediate C version of the program. (By contrast, for example, some other implementations use a program that generates a C program from your C++ source.) Avoiding an intermediate C representation of the program means that you get better object code, and better debugging information. The GNU debugger, GDB, works with this information in the object code to give you comprehensive C++ source-level editing capabilities (see section 'C and C++' in Debugging with GDB).

Go to the previous, next section.

Go to the previous, next section.

GNU CC Command Options

When you invoke GNU CC, it normally does preprocessing, compilation, assembly and linking. The "overall options" allow you to stop this process at an intermediate stage. For example, the `-c' option says not to run the linker. Then the output consists of object files output by the assembler.

Other options are passed on to one stage of processing. Some options control the preprocessor and others the compiler itself. Yet other options control the assembler and linker; most of these are not documented here, since you rarely need to use any of them.

Most of the command line options that you can use with GNU CC are useful for C programs; when an option is only useful with another language (usually C++), the explanation says so explicitly. If the description for a particular option does not mention a source language, you can use that option with all supported languages.

See section Compiling C++ Programs, for a summary of special options for compiling C++ programs.

The `gcc` program accepts options and file names as operands. Many options have multiletter names; therefore multiple single-letter options may *not* be grouped: `-dr' is very different from `-d -r'.

You can mix options and other arguments. For the most part, the order you use doesn't matter. Order does matter when you use several options of the same kind; for example, if you specify `-L' more than once, the directories are searched in the order specified.

Many options have long names starting with `-f' or with `-W'---for example, `-fforce-mem', `-fstrength-reduce', `-Wformat' and so on. Most of these have both positive and negative forms; the negative form of `-ffoo' would be `-fno-foo'. This manual documents only one of these two forms, whichever one is not the default.

Option Summary

Here is a summary of all the options, grouped by type. Explanations are in the following sections.

Overall Options

See section Options Controlling the Kind of Output.

```
-c  -S  -E  -o file  -pipe  -v  -x language
```

C Language Options

See section Options Controlling C Dialect.

```
-ansi  -fallow-single-precision -fcond-mismatch  -fno-asm
-fno-builtin  -fsigned-bitfields  -fsigned-char
-funsigned-bitfields  -funsigned-char  -fwritable-strings
```

```
-traditional  -traditional-cpp  -trigraphs
```

C++ Language Options

See section Options Controlling C++ Dialect.

```
-fall-virtual  -fdollars-in-identifiers  -felide-constructors
-fenum-int-equiv -fexternal-templates  -fhandle-signatures
-fmemoize-lookups  -fno-default-inline -fno-gnu-keywords
-fnonnull-objects  -foperator-names  -fstrict-prototype
-fthis-is-variable -nostdinc++ -traditional  +en
```

Warning Options

See section Options to Request or Suppress Warnings.

```
-fsyntax-only  -pedantic  -pedantic-errors
-w  -W  -Wall  -Waggregate-return  -Wbad-function-cast
-Wcast-align -Wcast-qual  -Wchar-subscript  -Wcomment
-Wconversion -Wenum-clash  -Werror  -Wformat
-Wid-clash-len  -Wimplicit  -Wimport  -Winline
-Wlarger-than-len  -Wmissing-declarations
-Wmissing-prototypes  -Wnested-externs
-Wno-import  -Woverloaded-virtual -Wparentheses
-Wpointer-arith  -Wredundant-decls -Wreorder -Wreturn-type -Wshadow
-Wstrict-prototypes  -Wswitch  -Wsynth  -Wtemplate-debugging
-Wtraditional  -Wtrigraphs -Wuninitialized  -Wunused
-Wwrite-strings
```

Debugging Options

See section Options for Debugging Your Program or GNU CC.

```
-a  -dletters  -fpretend-float
-g  -glevel -gcoff  -gdwarf  -gdwarf+
-ggdb  -gstabs  -gstabs+  -gxcoff  -gxcoff+
-p  -pg  -print-file-name=library  -print-libgcc-file-name
-print-prog-name=program  -print-search-dirs  -save-temps
```

Optimization Options

See section Options That Control Optimization.

```
-fcaller-saves  -fcse-follow-jumps  -fcse-skip-blocks
-fdelayed-branch  -fexpensive-optimizations
-ffast-math  -ffloat-store  -fforce-addr  -fforce-mem
-finline-functions  -fkeep-inline-functions
-fno-default-inline  -fno-defer-pop  -fno-function-cse
-fno-inline  -fno-peephole  -fomit-frame-pointer
-frerun-cse-after-loop  -fschedule-insns
-fschedule-insns2  -fstrength-reduce  -fthread-jumps
```

```
-funroll-all-loops  -funroll-loops
-O  -O0  -O1  -O2  -O3
```

Preprocessor Options

See section Options Controlling the Preprocessor.

```
-Aquestion(answer)  -C  -dD  -dM  -dN
-Dmacro[=defn]  -E  -H
-idirafter dir
-include file  -imacros file
-iprefix file  -iwithprefix dir
-iwithprefixbefore dir  -isystem dir
-M  -MD  -MM  -MMD  -MG  -nostdinc  -P  -trigraphs
-undef  -Umacro  -Wp,option
```

Assembler Option

See section Passing Options to the Assembler.

```
-Wa,option
```

Linker Options

See section Options for Linking.

```
object-file-name  -llibrary
-nostartfiles  -nodefaultlibs  -nostdlib
-s  -static  -shared  -symbolic
-Wl,option  -Xlinker option
-u symbol
```

Directory Options

See section Options for Directory Search.

```
-Bprefix  -Idir  -I-  -Ldir
```

Target Options

See section Specifying Target Machine and Compiler Version.

```
-b machine  -V version
```

Machine Dependent Options

See section Hardware Models and Configurations.

```
M680x0 Options
-m68000  -m68020  -m68020-40  -m68030  -m68040  -m68881
-mbitfield  -mc68000  -mc68020  -mfpa  -mnobitfield
-mrtd  -mshort  -msoft-float
```

VAX Options

```
-mg  -mgnu  -munix
```

SPARC Options

```
-mapp-regs  -mcypress  -mepilogue  -mflat  -mfpu  -mhard-float
-mhard-quad-float  -mno-app-regs  -mno-flat  -mno-fpu
-mno-epilogue  -mno-unaligned-doubles
-msoft-float  -msoft-quad-float
-msparclite  -msupersparc  -munaligned-doubles  -mv8
```

SPARC V9 compilers support the following options in addition to the above:

```
-mmedlow  -mmedany
-mint32  -mint64  -mlong32  -mlong64
-mno-stack-bias  -mstack-bias
```

Convex Options

```
-mc1  -mc2  -mc32  -mc34  -mc38
-margcount  -mnoargcount
-mlong32  -mlong64
-mvolatile-cache  -mvolatile-nocache
```

AMD29K Options

```
-m29000  -m29050  -mbw  -mnbw  -mdw  -mndw
-mlarge  -mnormal  -msmall
-mkernel-registers  -mno-reuse-arg-regs
-mno-stack-check  -mno-storem-bug
-mreuse-arg-regs  -msoft-float  -mstack-check
-mstorem-bug  -muser-registers
```

ARM Options

```
-mapcs -m2 -m3 -m6 -mbsd -mxopen -mno-symrename
```

M88K Options

```
-m88000  -m88100  -m88110  -mbig-pic
-mcheck-zero-division  -mhandle-large-shift
-midentify-revision  -mno-check-zero-division
-mno-ocs-debug-info  -mno-ocs-frame-position
-mno-optimize-arg-area  -mno-serialize-volatile
-mno-underscores  -mocs-debug-info
-mocs-frame-position  -moptimize-arg-area
-mserialize-volatile  -mshort-data-num  -msvr3
-msvr4  -mtrap-large-shift  -muse-div-instruction
-mversion-03.00  -mwarn-passed-structs
```

RS/6000 and PowerPC Options

```
-mcpu=cpu  type
-mpower  -mno-power  -mpower2  -mno-power2
-mpowerpc  -mno-powerpc
-mpowerpc-gpopt  -mno-powerpc-gpopt
-mpowerpc-gfxopt  -mno-powerpc-gfxopt
-mnew-mnemonics  -mno-new-mnemonics
-mfull-toc   -mminimal-toc  -mno-fop-in-toc  -mno-sum-in-toc
-msoft-float  -mhard-float -mmultiple -mno-multiple
-mstring -mno-string -mbit-align -mno-bit-align
-mstrict-align -mno-strict-align -mrelocatable -mno-relocatable
-mtoc -mno-toc -mtraceback -mno-traceback
-mlittle -mlittle-endian -mbig -mbig-endian
```

RT Options

```
-mcall-lib-mul  -mfp-arg-in-fpregs  -mfp-arg-in-gregs
-mfull-fp-blocks  -mhc-struct-return  -min-line-mul
-mminimum-fp-blocks  -mnohc-struct-return
```

MIPS Options

```
-mabicalls  -mcpu=cpu  type  -membedded-data
-membedded-pic  -mfp32  -mfp64  -mgas  -mgp32  -mgp64
-mgpopt  -mhalf-pic  -mhard-float  -mint64 -mips1

```

DEC Alpha Options

```
-mfp-regs  -mno-fp-regs  -mno-soft-float
-msoft-float
```

Clipper Options

```
-mc300 -mc400
```

H8/300 Options

```
-mrelax  -mh
```

System V Options

```
-Qy  -Qn  -YP,paths  -Ym,dir
```

Code Generation Options

See section Options for Code Generation Conventions.

```
-fcall-saved-reg  -fcall-used-reg
-ffixed-reg  -finhibit-size-directive
-fno-common  -fno-ident  -fno-gnu-linker
-fpcc-struct-return  -fpic  -fPIC
-freg-struct-return  -fshared-data  -fshort-enums
-fshort-double  -fvolatile  -fvolatile-global
-fverbose-asm -fpack-struct +e0  +e1
```

Options Controlling the Kind of Output

Compilation can involve up to four stages: preprocessing, compilation proper, assembly and linking, always in that order. The first three stages apply to an individual source file, and end by producing an object file; linking combines all the object files (those newly compiled, and those specified as input) into an executable file.

For any given input file, the file name suffix determines what kind of compilation is done:

`file.c`

C source code which must be preprocessed.

`file.i`

C source code which should not be preprocessed.

`file.ii`

C++ source code which should not be preprocessed.

`file.m`

Objective-C source code. Note that you must link with the library `` `libobjc.a' `` to make an Objective-C program work.

`file.h`

C header file (not to be compiled or linked).

`file.cc`

`file.cxx`

`file.cpp`

`file.C`

C++ source code which must be preprocessed. Note that in `.cxx', the last two letters must both be literally `x'. Likewise, `.C' refers to a literal capital C.

`file.s`

Assembler code.

`file.S`

Assembler code which must be preprocessed.

`other`

An object file to be fed straight into linking. Any file name with no recognized suffix is treated this way.

You can specify the input language explicitly with the `-x' option:

`-x language`

Specify explicitly the language for the following input files (rather than letting the compiler choose a default based on the file name suffix). This option applies to all following input files until the next `-x' option. Possible values for language are:

```
c  objective-c  c++
c-header  cpp-output  c++-cpp-output
assembler  assembler-with-cpp
```

`-x none`

Turn off any specification of a language, so that subsequent files are handled according to their file name suffixes (as they are if `-x' has not been used at all).

If you only want some of the stages of compilation, you can use `-x' (or filename suffixes) to tell `gcc` where to start, and one of the options `-c', `-S', or `-E' to say where `gcc` is to stop. Note that some combinations (for example, `-x cpp-output -E' instruct `gcc` to do nothing at all.

`-c`

Compile or assemble the source files, but do not link. The linking stage simply is not done. The ultimate output is in the form of an object file for each source file.

By default, the object file name for a source file is made by replacing the suffix `.c', `.i', `.s', etc., with `.o'.

Unrecognized input files, not requiring compilation or assembly, are ignored.

`-S`

Stop after the stage of compilation proper; do not assemble. The output is in the form of an assembler code file for each non-assembler input file specified.

By default, the assembler file name for a source file is made by replacing the suffix `.c', `.i', etc., with `.s'.

Input files that don't require compilation are ignored.

`-E`

Stop after the preprocessing stage; do not run the compiler proper. The output is in the form of preprocessed source code, which is sent to the standard output.

Input files which don't require preprocessing are ignored.

`-o file`

Place output in file file. This applies regardless to whatever sort of output is being produced, whether it be an executable file, an object file, an assembler file or preprocessed C code.

Since only one output file can be specified, it does not make sense to use `-o' when compiling more than one input file, unless you are producing an executable file as output.

If `-o' is not specified, the default is to put an executable file in `a.out', the object file for `source.suffix' in `source.o', its assembler file in `source.s', and all preprocessed C source on standard output.

`-v`

Print (on standard error output) the commands executed to run the stages of compilation. Also print the version number of the compiler driver program and of the preprocessor and the compiler proper.

`-pipe`

Use pipes rather than temporary files for communication between the various stages of compilation. This fails to work on some systems where the assembler is unable to read from a pipe; but the GNU assembler has no trouble.

Compiling C++ Programs

C++ source files conventionally use one of the suffixes `.C', `.cc', `cpp', or `.cxx'; preprocessed C++ files use the suffix `.ii'. GNU CC recognizes files with these names and compiles them as C++ programs even if you call the compiler the same way as for compiling C programs (usually with the name `gcc').

However, C++ programs often require class libraries as well as a compiler that understands the C++

language--and under some circumstances, you might want to compile programs from standard input, c otherwise without a suffix that flags them as C++ programs. `g++` is a program that calls GNU CC wit default language set to C++, and automatically specifies linking against the GNU class library libg++. (1) On many systems, the script `g++` is also installed with the name `c++`.

When you compile C++ programs, you may specify many of the same command-line options that you use for compiling programs in any language; or command-line options meaningful for C and related languages; or options that are meaningful only for C++ programs. See section Options Controlling C Dialect, for explanations of options for languages related to C. See section Options Controlling C++ Dialect, for explanations of options that are meaningful only for C++ programs.

Options Controlling C Dialect

The following options control the dialect of C (or languages derived from C, such as C++ and Objective C) that the compiler accepts:

`-ansi`

Support all ANSI standard C programs.

This turns off certain features of GNU C that are incompatible with ANSI C, such as the `asm`, `inline` and `typeof` keywords, and predefined macros such as `unix` and `vax` that identify the type of system you are using. It also enables the undesirable and rarely used ANSI trigraph feature, and disallows `$' as part of identifiers.

The alternate keywords `__asm__`, `__extension__`, `__inline__` and `__typeof__` continue to work despite `-ansi'. You would not want to use them in an ANSI C program, of course, but it is useful to put them in header files that might be included in compilations done with `-ansi'. Alternate predefined macros such as `__unix__` and `__vax__` are also available, with or without `-ansi'.

The `-ansi' option does not cause non-ANSI programs to be rejected gratuitously. For that, `-pedantic' is required in addition to `-ansi'. See section Options to Request or Suppress Warnings.

The macro `__STRICT_ANSI__` is predefined when the `-ansi' option is used. Some header files may notice this macro and refrain from declaring certain functions or defining certain macros that the ANSI standard doesn't call for; this is to avoid interfering with any programs that might use these names for other things.

The functions `alloca`, `abort`, `exit`, and `_exit` are not builtin functions when `-ansi' is used.

`-fno-asm`

Do not recognize `asm`, `inline` or `typeof` as a keyword, so that code can use these words as identifiers. You can use the keywords `__asm__`, `__inline__` and `__typeof__` instead. `-ansi' implies `-fno-asm'.

In C++, this switch only affects the `typeof` keyword, since `asm` and `inline` are standard keywords. You may want to use the `-fno-gnu-keywords' flag instead, as it also disables the other, C++-specific, extension keywords such as `headof`.

`-fno-builtin`

Don't recognize builtin functions that do not begin with two leading underscores. Currently, the functions affected include `abort`, `abs`, `alloca`, `cos`, `exit`, `fabs`, `ffs`, `labs`, `memcmp`, `memcpy`, `sin`, `sqrt`, `strcmp`, `strcpy`, and `strlen`.

GCC normally generates special code to handle certain builtin functions more efficiently; for instance, calls to `alloca` may become single instructions that adjust the stack directly, and calls to `memcpy` may become inline copy loops. The resulting code is often both smaller and faster, but since the function calls no longer appear as such, you cannot set a breakpoint on those calls, nor can you change the behavior of the functions by linking with a different library.

The `-ansi' option prevents `alloca` and `ffs` from being builtin functions, since these functions do not have an ANSI standard meaning.

`-trigraphs`

Support ANSI C trigraphs. You don't want to know about this brain-damage. The `-ansi' option implies `-trigraphs'.

`-traditional`

Attempt to support some aspects of traditional C compilers. Specifically:

All `extern` declarations take effect globally even if they are written inside of a function definition. This includes implicit declarations of functions.

The newer keywords `typeof`, `inline`, `signed`, `const` and `volatile` are not recognized. (You can still use the alternative keywords such as `__typeof__`, `__inline__`, and so on.)

Comparisons between pointers and integers are always allowed.

Integer types `unsigned short` and `unsigned char` promote to `unsigned int`.

Out-of-range floating point literals are not an error.

Certain constructs which ANSI regards as a single invalid preprocessing number, such as `0xe-0xd', are treated as expressions instead.

String "constants" are not necessarily constant; they are stored in writable space, and identical looking constants are allocated separately. (This is the same as the effect of `-fwritable-strings'.)

All automatic variables not declared `register` are preserved by `longjmp`. Ordinarily, GNU C follows ANSI C: automatic variables not declared `volatile` may be clobbered.

The character escape sequences `\x' and `\a' evaluate as the literal characters `x' and `a' respectively. Without `-traditional', `\x' is a prefix for the hexadecimal representation of a character, and `\a' produces a bell.

In C++ programs, assignment to `this` is permitted with `-traditional'. (The option `-fthis-is-variable' also has this effect.)

You may wish to use `-fno-builtin' as well as `-traditional' if your program uses names that are normally GNU C builtin functions for other purposes of its own.

You cannot use `-traditional' if you include any header files that rely on ANSI C features. Some vendors are starting to ship systems with ANSI C header files and you cannot use `-traditional' on such systems to compile files that include any system headers.

In the preprocessor, comments convert to nothing at all, rather than to a space. This allows traditional token concatenation.

In preprocessing directive, the `#' symbol must appear as the first character of a line.

In the preprocessor, macro arguments are recognized within string constants in a macro definition (and their values are stringified, though without additional quote marks, when they appear in such a context). The preprocessor always considers a string constant to end at a newline.

The predefined macro `__STDC__` is not defined when you use `-traditional', but `__GNUC__` is (since the GNU extensions which `__GNUC__` indicates are not affected by `-traditional'). If you need to write header files that work differently depending on whether `-traditional' is in use, by testing both of these predefined macros you can distinguish four situations: GNU C, traditional GNU C, other ANSI C compilers, and other old C compilers. The predefined macro `__STDC_VERSION__` is also not defined when you use `-traditional'. See section 'Standard Predefined Macros' in The C Preprocessor, for more discussion of these and other predefined macros.

The preprocessor considers a string constant to end at a newline (unless the newline is escaped with `\'). (Without `-traditional', string constants can contain the newline character as typed.)

`-traditional-cpp`

Attempt to support some aspects of traditional C preprocessors. This includes the last five items in the table immediately above, but none of the other effects of `-traditional'.

`-fcond-mismatch`

Allow conditional expressions with mismatched types in the second and third arguments. The value of such an expression is void.

`-funsigned-char`

Let the type `char` be unsigned, like `unsigned char`.

Each kind of machine has a default for what `char` should be. It is either like `unsigned char` by default or like `signed char` by default.

Ideally, a portable program should always use `signed char` or `unsigned char` when it depends on the signedness of an object. But many programs have been written to use plain `char` and expect it to be signed, or expect it to be unsigned, depending on the machines they were written for. This option, and its inverse, let you make such a program work with the opposite default.

The type `char` is always a distinct type from each of `signed char` or `unsigned char`, even though its behavior is always just like one of those two.

`-fsigned-char`

Let the type `char` be signed, like `signed char`.

Note that this is equivalent to `-fno-unsigned-char', which is the negative form of `-funsigned-char'. Likewise, the option `-fno-signed-char' is equivalent to `-funsigned-char'.

`-fsigned-bitfields`

`-funsigned-bitfields`
`-fno-signed-bitfields`
`-fno-unsigned-bitfields`

These options control whether a bitfield is signed or unsigned, when the declaration does not use either `signed` or `unsigned`. By default, such a bitfield is signed, because this is consistent: the basic integer types such as `int` are signed types.

However, when `-traditional' is used, bitfields are all unsigned no matter what.

`-fwritable-strings`

Store string constants in the writable data segment and don't uniquize them. This is for compatibility with old programs which assume they can write into string constants. The option `-traditional' also has this effect.

Writing into string constants is a very bad idea; "constants" should be constant.

`-fallow-single-precision`

Do not promote single precision math operations to double precision, even when compiling with `-traditional'.

Traditional K&R C promotes all floating point operations to double precision, regardless of the sizes of the operands. On the architecture for which you are compiling, single precision may be faster than double precision. If you must use `-traditional', but want to use single precision operations when the operands are single precision, use this option. This option has no effect when compiling with ANSI or GNU C conventions (the default).

Options Controlling C++ Dialect

This section describes the command-line options that are only meaningful for C++ programs; but you can also use most of the GNU compiler options regardless of what language your program is in. For example, you might compile a file `firstClass.C` like this:

```
g++ -g -felide-constructors -O -c firstClass.C
```

In this example, only `-felide-constructors' is an option meant only for C++ programs; you can use the other options with any language supported by GNU CC.

Here is a list of options that are *only* for compiling C++ programs:

`-fno-access-control`

Turn off all access checking. This switch is mainly useful for working around bugs in the access control code.

`-fall-virtual`

Treat all possible member functions as virtual, implicitly. All member functions (except for constructor functions and `new` or `delete` member operators) are treated as virtual functions of the class where they appear.

This does not mean that all calls to these member functions will be made through the internal table

of virtual functions. Under some circumstances, the compiler can determine that a call to a given virtual function can be made directly; in these cases the calls are direct in any case.

`-fcheck-new`

Check that the pointer returned by `operator new` is non-null before attempting to modify the storage allocated. The current Working Paper requires that `operator new` never return a null pointer, so this check is normally unnecessary.

`-fconserve-space`

Put uninitialized or runtime-initialized global variables into the common segment, as C does. This saves space in the executable at the cost of not diagnosing duplicate definitions. If you compile with this flag and your program mysteriously crashes after `main()` has completed, you may have an object that is being destroyed twice because two definitions were merged.

`-fdollars-in-identifiers`

Accept `$' in identifiers. You can also explicitly prohibit use of `$' with the option `-fno-dollars-in-identifiers'. (GNU C++ allows `$' by default on some target systems but not others.) Traditional C allowed the character `$' to form part of identifiers. However, ANSI C and C++ forbid `$' in identifiers.

`-fenum-int-equiv`

Anachronistically permit implicit conversion of `int` to enumeration types. Current C++ allows conversion of `enum` to `int`, but not the other way around.

`-fexternal-templates`

Cause template instantiations to obey `#pragma interface' and `implementation'; template instances are emitted or not according to the location of the template definition. See section Where's the Template?, for more information.

`-falt-external-templates`

Similar to -fexternal-templates, but template instances are emitted or not according to the place where they are first instantiated. See section Where's the Template?, for more information.

`-fno-gnu-keywords`

Do not recognize `classof`, `headof`, `signature`, `sigof` or `typeof` as a keyword, so that code can use these words as identifiers. You can use the keywords `__classof__`, `__headof__`, `__signature__`, `__sigof__`, and `__typeof__` instead. `-ansi' implies `-fno-gnu-keywords'.

`-fno-implicit-templates`

Never emit code for templates which are instantiated implicitly (i.e. by use); only emit code for explicit instantiations. See section Where's the Template?, for more information.

`-fhandle-signatures`

Recognize the `signature` and `sigof` keywords for specifying abstract types. The default (`-fno-handle-signatures') is not to recognize them. See section Type Abstraction using Signatures.

`-fhuge-objects`

Support virtual function calls for objects that exceed the size representable by a `short int'. Users should not use this flag by default; if you need to use it, the compiler will tell you so. If you compile any of your code with this flag, you must compile *all* of your code with this flag (including libg++,

if you use it).

This flag is not useful when compiling with -fvtable-thunks.

`-fno-implement-inlines`

To save space, do not emit out-of-line copies of inline functions controlled by `#pragma implementation'. This will cause linker errors if these functions are not inlined everywhere they are called.

`-fmemoize-lookups`

`-fsave-memoized`

Use heuristics to compile faster. These heuristics are not enabled by default, since they are only effective for certain input files. Other input files compile more slowly.

The first time the compiler must build a call to a member function (or reference to a data member), it must (1) determine whether the class implements member functions of that name; (2) resolve which member function to call (which involves figuring out what sorts of type conversions need to be made); and (3) check the visibility of the member function to the caller. All of this adds up to slower compilation. Normally, the second time a call is made to that member function (or reference to that data member), it must go through the same lengthy process again. This means that code like this:

```
cout << "This " << p << " has " << n << " legs.\n";
```

makes six passes through all three steps. By using a software cache, a "hit" significantly reduces this cost. Unfortunately, using the cache introduces another layer of mechanisms which must be implemented, and so incurs its own overhead. `-fmemoize-lookups' enables the software cache.

Because access privileges (visibility) to members and member functions may differ from one function context to the next, G++ may need to flush the cache. With the `-fmemoize-lookups' flag, the cache is flushed after every function that is compiled. The `-fsave-memoized' flag enables the same software cache, but when the compiler determines that the context of the last function compiled would yield the same access privileges of the next function to compile, it preserves the cache. This is most helpful when defining many member functions for the same class: with the exception of member functions which are friends of other classes, each member function has exactly the same access privileges as every other, and the cache need not be flushed.

The code that implements these flags has rotted; you should probably avoid using them.

`-fstrict-prototype`

Within an `extern "C"' linkage specification, treat a function declaration with no arguments, such as `int foo ();', as declaring the function to take no arguments. Normally, such a declaration means that the function `foo` can take any combination of arguments, as in C. `-pedantic' implies `-fstrict-prototype' unless overridden with `-fno-strict-prototype'.

This flag no longer affects declarations with C++ linkage.

`-fno-nonnull-objects`

Don't assume that a reference is initialized to refer to a valid object. Although the current C++ Working Paper prohibits null references, some old code may rely on them, and you can use

`-fno-nonnull-objects' to turn on checking.

At the moment, the compiler only does this checking for conversions to virtual base classes.

`-foperator-names`

Recognize the operator name keywords `and`, `bitand`, `bitor`, `compl`, `not`, `or` and `xor` as synonyms for the symbols they refer to. `-ansi' implies `-foperator-names'.

`-fthis-is-variable`

Permit assignment to `this`. The incorporation of user-defined free store management into C++ has made assignment to `this' an anachronism. Therefore, by default it is invalid to assign to `this` within a class member function; that is, GNU C++ treats `this' in a member function of class `X` as a non-lvalue of type `X *'. However, for backwards compatibility, you can make it valid with `-fthis-is-variable'.

`-fvtable-thunks`

Use `thunks' to implement the virtual function dispatch table (`vtable'). The traditional (cfront-style) approach to implementing vtables was to store a pointer to the function and two offsets for adjusting the `this' pointer at the call site. Newer implementations store a single pointer to a `thunk' function which does any necessary adjustment and then calls the target function.

This option also enables a heuristic for controlling emission of vtables; if a class has any non-inline virtual functions, the vtable will be emitted in the translation unit containing the first one of those.

`-nostdinc++`

Do not search for header files in the standard directories specific to C++, but do still search the other standard directories. (This option is used when building libg++.)

`-traditional`

For C++ programs (in addition to the effects that apply to both C and C++), this has the same effect as `-fthis-is-variable'. See section Options Controlling C Dialect.

In addition, these optimization, warning, and code generation options have meanings only for C++ programs:

`-fno-default-inline`

Do not assume `inline' for functions defined inside a class scope. See section Options That Control Optimization.

`-Wenum-clash`

`-Woverloaded-virtual`

`-Wtemplate-debugging`

Warnings that apply only to C++ programs. See section Options to Request or Suppress Warnings.

`+en`

Control how virtual function definitions are used, in a fashion compatible with `cfront` 1.x. See section Options for Code Generation Conventions.

Options to Request or Suppress Warnings

Warnings are diagnostic messages that report constructions which are not inherently erroneous but which are risky or suggest there may have been an error.

You can request many specific warnings with options beginning `-W', for example `-Wimplicit' to request warnings on implicit declarations. Each of these specific warning options also has a negative form beginning `-Wno-' to turn off warnings; for example, `-Wno-implicit'. This manual lists only one of the two forms, whichever is not the default.

These options control the amount and kinds of warnings produced by GNU CC:

`-fsyntax-only`

Check the code for syntax errors, but don't do anything beyond that.

`-pedantic`

Issue all the warnings demanded by strict ANSI standard C; reject all programs that use forbidden extensions.

Valid ANSI standard C programs should compile properly with or without this option (though a rare few will require `-ansi'). However, without this option, certain GNU extensions and traditional C features are supported as well. With this option, they are rejected.

`-pedantic' does not cause warning messages for use of the alternate keywords whose names begin and end with `__'. Pedantic warnings are also disabled in the expression that follows `__extension__`. However, only system header files should use these escape routes; application programs should avoid them. See section Alternate Keywords.

This option is not intended to be *useful*; it exists only to satisfy pedants who would otherwise claim that GNU CC fails to support the ANSI standard.

Some users try to use `-pedantic' to check programs for strict ANSI C conformance. They soon find that it does not do quite what they want: it finds some non-ANSI practices, but not all--only those for which ANSI C *requires* a diagnostic.

A feature to report any failure to conform to ANSI C might be useful in some instances, but would require considerable additional work and would be quite different from `-pedantic'. We recommend, rather, that users take advantage of the extensions of GNU C and disregard the limitations of other compilers. Aside from certain supercomputers and obsolete small machines, there is less and less reason ever to use any other C compiler other than for bootstrapping GNU CC.

`-pedantic-errors`

Like `-pedantic', except that errors are produced rather than warnings.

`-w`

Inhibit all warning messages.

`-Wno-import`

Inhibit warning messages about the use of `#import'.

`-Wchar-subscripts`

Warn if an array subscript has type `char`. This is a common cause of error, as programmers often forget that this type is signed on some machines.

`-Wcomment`

Warn whenever a comment-start sequence `/*' appears in a comment.

`-Wformat`

Check calls to `printf` and `scanf`, etc., to make sure that the arguments supplied have types appropriate to the format string specified.

`-Wimplicit`

Warn whenever a function or parameter is implicitly declared.

`-Wparentheses`

Warn if parentheses are omitted in certain contexts, such as when there is an assignment in a context where a truth value is expected, or when operators are nested whose precedence people often get confused about.

`-Wreturn-type`

Warn whenever a function is defined with a return-type that defaults to `int`. Also warn about any `return` statement with no return-value in a function whose return-type is not `void`.

`-Wswitch`

Warn whenever a `switch` statement has an index of enumeral type and lacks a `case` for one or more of the named codes of that enumeration. (The presence of a `default` label prevents this warning.) `case` labels outside the enumeration range also provoke warnings when this option is used.

`-Wtrigraphs`

Warn if any trigraphs are encountered (assuming they are enabled).

`-Wunused`

Warn whenever a variable is unused aside from its declaration, whenever a function is declared static but never defined, whenever a label is declared but not used, and whenever a statement computes a result that is explicitly not used.

To suppress this warning for an expression, simply cast it to void. For unused variables and parameters, use the `unused' attribute (see section Specifying Attributes of Variables).

`-Wuninitialized`

An automatic variable is used without first being initialized.

These warnings are possible only in optimizing compilation, because they require data flow information that is computed only when optimizing. If you don't specify `-O', you simply won't get these warnings.

These warnings occur only for variables that are candidates for register allocation. Therefore, they do not occur for a variable that is declared `volatile`, or whose address is taken, or whose size is other than 1, 2, 4 or 8 bytes. Also, they do not occur for structures, unions or arrays, even when they are in registers.

Note that there may be no warning about a variable that is used only to compute a value that itself is

never used, because such computations may be deleted by data flow analysis before the warnings are printed.

These warnings are made optional because GNU CC is not smart enough to see all the reasons why the code might be correct despite appearing to have an error. Here is one example of how this can happen:

```
{
  int x;
  switch (y)
    {
    case 1: x = 1;
      break;
    case 2: x = 4;
      break;
    case 3: x = 5;
    }
  foo (x);
}
```

If the value of `y` is always 1, 2 or 3, then `x` is always initialized, but GNU CC doesn't know this. Here is another common case:

```
{
  int save_y;
  if (change_y) save_y = y, y = new_y;
  ...
  if (change_y) y = save_y;
}
```

This has no bug because `save_y` is used only if it is set.

Some spurious warnings can be avoided if you declare all the functions you use that never return as `noreturn`. See section Declaring Attributes of Functions.

`-Wenum-clash`

Warn about conversion between different enumeration types. (C++ only).

`-Wreorder (C++ only)`

Warn when the order of member initializers given in the code does not match the order in which they must be executed. For instance:

```
struct A {
  int i;
  int j;
  A(): j (0), i (1) { }
};
```

Here the compiler will warn that the member initializers for `i' and `j' will be rearranged to mat the declaration order of the members.

`-Wtemplate-debugging`

When using templates in a C++ program, warn if debugging is not yet fully available (C++ only).

`-Wall`

All of the above `-W' options combined. These are all the options which pertain to usage that we recommend avoiding and that we believe is easy to avoid, even in conjunction with macros.

The remaining `-W...' options are not implied by `-Wall' because they warn about constructions that we consider reasonable to use, on occasion, in clean programs.

`-W`

Print extra warning messages for these events:

A nonvolatile automatic variable might be changed by a call to `longjmp`. These warnings as well are possible only in optimizing compilation.

The compiler sees only the calls to `setjmp`. It cannot know where `longjmp` will be called; in fact, a signal handler could call it at any point in the code. As a result, you may get a warning even when there is in fact no problem because `longjmp` cannot in fact be called at the place which would cause a problem.

A function can return either with or without a value. (Falling off the end of the function body is considered returning without a value.) For example, this function would evoke such a warning:

```
foo (a)
{
  if (a > 0)
    return a;
}
```

An expression-statement contains no side effects.

An unsigned value is compared against zero with `<' or `<='.

A comparison like `x<=y<=z' appears; this is equivalent to `(x<=y ? 1 : 0) <= z', which is a different interpretation from that of ordinary mathematical notation.

Storage-class specifiers like `static` are not the first things in a declaration. According to the C Standard, this usage is obsolescent.

If `-Wall' or `-Wunused' is also specified, warn about unused arguments.

An aggregate has a partly bracketed initializer. For example, the following code would evoke such a warning, because braces are missing around the initializer for `x.h`:

```
struct s { int f, g; };
struct t { struct s h; int i; };
struct t x = { 1, 2, 3 };
```

`-Wtraditional`

Warn about certain constructs that behave differently in traditional and ANSI C.

Macro arguments occurring within string constants in the macro body. These would substitute the argument in traditional C, but are part of the constant in ANSI C.

A function declared external in one block and then used after the end of the block.

A `switch` statement has an operand of type `long`.

`-Wshadow`

Warn whenever a local variable shadows another local variable.

`-Wid-clash-len`

Warn whenever two distinct identifiers match in the first len characters. This may help you prepare a program that will compile with certain obsolete, brain-damaged compilers.

`-Wlarger-than-len`

Warn whenever an object of larger than len bytes is defined.

`-Wpointer-arith`

Warn about anything that depends on the "size of" a function type or of `void`. GNU C assigns these types a size of 1, for convenience in calculations with `void *` pointers and pointers to functions.

`-Wbad-function-cast`

Warn whenever a function call is cast to a non-matching type. For example, warn if `int malloc()` is cast to `anything *`.

`-Wcast-qual`

Warn whenever a pointer is cast so as to remove a type qualifier from the target type. For example, warn if a `const char *` is cast to an ordinary `char *`.

`-Wcast-align`

Warn whenever a pointer is cast such that the required alignment of the target is increased. For example, warn if a `char *` is cast to an `int *` on machines where integers can only be accessed at two- or four-byte boundaries.

`-Wwrite-strings`

Give string constants the type `const char[length]` so that copying the address of one into a non-`const` `char *` pointer will get a warning. These warnings will help you find at compile time code that can try to write into a string constant, but only if you have been very careful about using `const` in declarations and prototypes. Otherwise, it will just be a nuisance; this is why we did not make `-Wall' request these warnings.

`-Wconversion`

Warn if a prototype causes a type conversion that is different from what would happen to the same argument in the absence of a prototype. This includes conversions of fixed point to floating and vice versa, and conversions changing the width or signedness of a fixed point argument except when the same as the default promotion.

Also, warn if a negative integer constant expression is implicitly converted to an unsigned type. For example, warn about the assignment `x = -1` if `x` is unsigned. But do not warn about explicit casts like `(unsigned) -1`.

`-Waggregate-return`

Warn if any functions that return structures or unions are defined or called. (In languages where you can return an array, this also elicits a warning.)

`-Wstrict-prototypes`

Warn if a function is declared or defined without specifying the argument types. (An old-style function definition is permitted without a warning if preceded by a declaration which specifies the argument types.)

`-Wmissing-prototypes`

Warn if a global function is defined without a previous prototype declaration. This warning is issued even if the definition itself provides a prototype. The aim is to detect global functions that fail to be declared in header files.

`-Wmissing-declarations`

Warn if a global function is defined without a previous declaration. Do so even if the definition itself provides a prototype. Use this option to detect global functions that are not declared in header files.

`-Wredundant-decls`

Warn if anything is declared more than once in the same scope, even in cases where multiple declaration is valid and changes nothing.

`-Wnested-externs`

Warn if an `extern` declaration is encountered within an function.

`-Winline`

Warn if a function can not be inlined, and either it was declared as inline, or else the `-finline-functions' option was given.

`-Woverloaded-virtual`

Warn when a derived class function declaration may be an error in defining a virtual function (C++ only). In a derived class, the definitions of virtual functions must match the type signature of a virtual function declared in the base class. With this option, the compiler warns when you define a function with the same name as a virtual function, but with a type signature that does not match any declarations from the base class.

`-Wsynth (C++ only)`

Warn when g++'s synthesis behavior does not match that of cfront. For instance:

```
struct A {
  operator int ();
  A& operator = (int);
};

main ()
{
  A a,b;
  a = b;
}
```

In this example, g++ will synthesize a default `A& operator = (const A&);', while cfront will us user-defined `operator ='.

`-Werror`

Make all warnings into errors.

Options for Debugging Your Program or GNU CC

GNU CC has various special options that are used for debugging either your program or GCC:

`-g`

Produce debugging information in the operating system's native format (stabs, COFF, XCOFF, or DWARF). GDB can work with this debugging information.

On most systems that use stabs format, `-g' enables use of extra debugging information that only GDB can use; this extra information makes debugging work better in GDB but will probably make other debuggers crash or refuse to read the program. If you want to control for certain whether to generate the extra information, use `-gstabs+', `-gstabs', `-gxcoff+', `-gxcoff', `-gdwarf+', or `-gdwarf' (see below).

Unlike most other C compilers, GNU CC allows you to use `-g' with `-O'. The shortcuts taken by optimized code may occasionally produce surprising results: some variables you declared may not exist at all; flow of control may briefly move where you did not expect it; some statements may not be executed because they compute constant results or their values were already at hand; some statements may execute in different places because they were moved out of loops.

Nevertheless it proves possible to debug optimized output. This makes it reasonable to use the optimizer for programs that might have bugs.

The following options are useful when GNU CC is generated with the capability for more than one debugging format.

`-ggdb`

Produce debugging information in the native format (if that is supported), including GDB extensions if at all possible.

`-gstabs`

Produce debugging information in stabs format (if that is supported), without GDB extensions. This is the format used by DBX on most BSD systems. On MIPS, Alpha and System V Release 4 systems this option produces stabs debugging output which is not understood by DBX or SDB. On System V Release 4 systems this option requires the GNU assembler.

`-gstabs+`

Produce debugging information in stabs format (if that is supported), using GNU extensions understood only by the GNU debugger (GDB). The use of these extensions is likely to make other debuggers crash or refuse to read the program.

`-gcoff`

Produce debugging information in COFF format (if that is supported). This is the format used by

SDB on most System V systems prior to System V Release 4.

`-gxcoff`

Produce debugging information in XCOFF format (if that is supported). This is the format used by the DBX debugger on IBM RS/6000 systems.

`-gxcoff+`

Produce debugging information in XCOFF format (if that is supported), using GNU extensions understood only by the GNU debugger (GDB). The use of these extensions is likely to make other debuggers crash or refuse to read the program, and may cause assemblers other than the GNU assembler (GAS) to fail with an error.

`-gdwarf`

Produce debugging information in DWARF format (if that is supported). This is the format used by SDB on most System V Release 4 systems.

`-gdwarf+`

Produce debugging information in DWARF format (if that is supported), using GNU extensions understood only by the GNU debugger (GDB). The use of these extensions is likely to make other debuggers crash or refuse to read the program.

`-glevel`

`-ggdblevel`

`-gstabslevel`

`-gcofflevel`

`-gxcofflevel`

`-gdwarflevel`

Request debugging information and also use level to specify how much information. The default level is 2.

Level 1 produces minimal information, enough for making backtraces in parts of the program that you don't plan to debug. This includes descriptions of functions and external variables, but no information about local variables and no line numbers.

Level 3 includes extra information, such as all the macro definitions present in the program. Some debuggers support macro expansion when you use `-g3'.

`-p`

Generate extra code to write profile information suitable for the analysis program `prof`. You must use this option when compiling the source files you want data about, and you must also use it when linking.

`-pg`

Generate extra code to write profile information suitable for the analysis program `gprof`. You must use this option when compiling the source files you want data about, and you must also use it when linking.

`-a`

Generate extra code to write profile information for basic blocks, which will record the number of times each basic block is executed, the basic block start address, and the function name containing

the basic block. If `-g' is used, the line number and filename of the start of the basic block will also be recorded. If not overridden by the machine description, the default action is to append to the file `bb.out'.

This data could be analyzed by a program like `tcov`. Note, however, that the format of the data is not what `tcov` expects. Eventually GNU `gprof` should be extended to process this data.

`-dletters`

Says to make debugging dumps during compilation at times specified by letters. This is used for debugging the compiler. The file names for most of the dumps are made by appending a word to the source file name (e.g. `foo.c.rtl' or `foo.c.jump'). Here are the possible letters for use in letters, and their meanings:

`M'

Dump all macro definitions, at the end of preprocessing, and write no output.

`N'

Dump all macro names, at the end of preprocessing.

`D'

Dump all macro definitions, at the end of preprocessing, in addition to normal output.

`y'

Dump debugging information during parsing, to standard error.

`r'

Dump after RTL generation, to `file.rtl'.

`x'

Just generate RTL for a function instead of compiling it. Usually used with `r'.

`j'

Dump after first jump optimization, to `file.jump'.

`s'

Dump after CSE (including the jump optimization that sometimes follows CSE), to `file.cse'.

`L'

Dump after loop optimization, to `file.loop'.

`t'

Dump after the second CSE pass (including the jump optimization that sometimes follows CSE), to `file.cse2'.

`f'

Dump after flow analysis, to `file.flow'.

`c'

Dump after instruction combination, to the file `file.combine'.

`S'

Dump after the first instruction scheduling pass, to `file.sched'.

`l'

Dump after local register allocation, to `file.lreg'.

`g'

Dump after global register allocation, to `file.greg'.

`R'

Dump after the second instruction scheduling pass, to `file.sched2'.

`J'

Dump after last jump optimization, to `file.jump2'.

`d'

Dump after delayed branch scheduling, to `file.dbr'.

`k'

Dump after conversion from registers to stack, to `file.stack'.

`a'

Produce all the dumps listed above.

`m'

Print statistics on memory usage, at the end of the run, to standard error.

`p'

Annotate the assembler output with a comment indicating which pattern and alternative was used.

- -fpretend-float When running a cross-compiler, pretend that the target machine uses the same floating point format as the host machine. This causes incorrect output of the actual floating constants, but the actual instruction sequence will probably be the same as GNU CC would make when running on the target machine.
- -save-temps Store the usual "temporary" intermediate files permanently; place them in the current directory and name them based on the source file. Thus, compiling `foo.c' with `-c -save-temps' would produce files `foo.i' and `foo.s', as well as `foo.o'.
- -print-file-name=library Print the full absolute name of the library file library that would be used when linking--and don't do anything else. With this option, GNU CC does not compile or link anything; it just prints the file name.
- -print-prog-name=program Like `-print-file-name', but searches for a program such as `cpp'.
- -print-libgcc-file-name Same as `-print-file-name=libgcc.a'.

This is useful when you use `-nostdlib' or `-nodefaultlibs' but you do want to link with `libgcc.a'. You can do

```
gcc -nostdlib files... `gcc -print-libgcc-file-name`
```

- -print-search-dirs Print the name of the configured installation directory and a list of program and library directories gcc will search--and don't do anything else.

This is useful when gcc prints the error message `installation problem, cannot exec cpp: No such file or directory'. To resolve this you either need to put `cpp' and the other compiler components where gcc

expects to find them, or you can set the environment variable `GCC_EXEC_PREFIX` to the directory you installed them. Don't forget the trailing '/'. See section Environment Variables Affecting GNU CC

Options That Control Optimization

These options control various sorts of optimizations:

`-O`

`-O1`

Optimize. Optimizing compilation takes somewhat more time, and a lot more memory for a large function.

Without `-O', the compiler's goal is to reduce the cost of compilation and to make debugging produce the expected results. Statements are independent: if you stop the program with a breakpoint between statements, you can then assign a new value to any variable or change the program counter to any other statement in the function and get exactly the results you would expect from the source code.

Without `-O', the compiler only allocates variables declared `register` in registers. The resulting compiled code is a little worse than produced by PCC without `-O'.

With `-O', the compiler tries to reduce code size and execution time.

When you specify `-O', the compiler turns on `-fthread-jumps' and `-fdefer-pop' on all machines. The compiler turns on `-fdelayed-branch' on machines that have delay slots, and `-fomit-frame-pointer' on machines that can support debugging even without a frame pointer. On some machines the compiler also turns on other flags.

`-O2`

Optimize even more. GNU CC performs nearly all supported optimizations that do not involve a space-speed tradeoff. The compiler does not perform loop unrolling or function inlining when you specify `-O2'. As compared to `-O', this option increases both compilation time and the performance of the generated code.

`-O2' turns on all optional optimizations except for loop unrolling and function inlining. It also turns on frame pointer elimination on machines where doing so does not interfere with debugging.

`-O3`

Optimize yet more. `-O3' turns on all optimizations specified by `-O2' and also turns on the `inline-functions' option.

`-O0`

Do not optimize.

If you use multiple `-O' options, with or without level numbers, the last such option is the one that is effective.

Options of the form `-fflag' specify machine-independent flags. Most flags have both positive and negative forms; the negative form of `-ffoo' would be `-fno-foo'. In the table below, only one of the forms is listed--the one which is not the default. You can figure out the other form by either removing `no-' or

adding it.

`-ffloat-store`

Do not store floating point variables in registers, and inhibit other options that might change whether a floating point value is taken from a register or memory.

This option prevents undesirable excess precision on machines such as the 68000 where the floating registers (of the 68881) keep more precision than a `double` is supposed to have. For most programs, the excess precision does only good, but a few programs rely on the precise definition of IEEE floating point. Use `-ffloat-store' for such programs.

`-fno-default-inline`

Do not make member functions inline by default merely because they are defined inside the class scope (C++ only). Otherwise, when you specify `-O', member functions defined inside class scope are compiled inline by default; i.e., you don't need to add `inline' in front of the member function name.

`-fno-defer-pop`

Always pop the arguments to each function call as soon as that function returns. For machines which must pop arguments after a function call, the compiler normally lets arguments accumulate on the stack for several function calls and pops them all at once.

`-fforce-mem`

Force memory operands to be copied into registers before doing arithmetic on them. This may produce better code by making all memory references potential common subexpressions. When they are not common subexpressions, instruction combination should eliminate the separate register-load. I am interested in hearing about the difference this makes.

`-fforce-addr`

Force memory address constants to be copied into registers before doing arithmetic on them. This may produce better code just as `-fforce-mem' may. I am interested in hearing about the difference this makes.

`-fomit-frame-pointer`

Don't keep the frame pointer in a register for functions that don't need one. This avoids the instructions to save, set up and restore frame pointers; it also makes an extra register available in many functions. **It also makes debugging impossible on some machines.**

On some machines, such as the Vax, this flag has no effect, because the standard calling sequence automatically handles the frame pointer and nothing is saved by pretending it doesn't exist. The machine-description macro `FRAME_POINTER_REQUIRED` controls whether a target machine supports this flag. See section Register Usage.

`-fno-inline`

Don't pay attention to the `inline` keyword. Normally this option is used to keep the compiler from expanding any functions inline. Note that if you are not optimizing, no functions can be expanded inline.

`-finline-functions`

Integrate all simple functions into their callers. The compiler heuristically decides which functions are simple enough to be worth integrating in this way.

If all calls to a given function are integrated, and the function is declared `static`, then the function is normally not output as assembler code in its own right.

`-fkeep-inline-functions`

Even if all calls to a given function are integrated, and the function is declared `static`, nevertheless output a separate run-time callable version of the function.

`-fno-function-cse`

Do not put function addresses in registers; make each instruction that calls a constant function contain the function's address explicitly.

This option results in less efficient code, but some strange hacks that alter the assembler output may be confused by the optimizations performed when this option is not used.

`-ffast-math`

This option allows GCC to violate some ANSI or IEEE rules and/or specifications in the interest of optimizing code for speed. For example, it allows the compiler to assume arguments to the `sqrt` function are non-negative numbers and that no floating-point values are NaNs.

This option should never be turned on by any `-O' option since it can result in incorrect output for programs which depend on an exact implementation of IEEE or ANSI rules/specifications for math functions.

The following options control specific optimizations. The `-O2' option turns on all of these optimizations except `-funroll-loops' and `-funroll-all-loops'. On most machines, the `-O' option turns on the `-fthread-jumps' and `-fdelayed-branch' options, but specific machines may handle it differently.

You can use the following flags in the rare cases when "fine-tuning" of optimizations to be performed is desired.

`-fstrength-reduce`

Perform the optimizations of loop strength reduction and elimination of iteration variables.

`-fthread-jumps`

Perform optimizations where we check to see if a jump branches to a location where another comparison subsumed by the first is found. If so, the first branch is redirected to either the destination of the second branch or a point immediately following it, depending on whether the condition is known to be true or false.

`-fcse-follow-jumps`

In common subexpression elimination, scan through jump instructions when the target of the jump is not reached by any other path. For example, when CSE encounters an `if` statement with an `else` clause, CSE will follow the jump when the condition tested is false.

`-fcse-skip-blocks`

This is similar to `-fcse-follow-jumps', but causes CSE to follow jumps which conditionally skip over blocks. When CSE encounters a simple `if` statement with no else clause, `-fcse-skip-blocks' causes CSE to follow the jump around the body of the `if`.

`-frerun-cse-after-loop`

Re-run common subexpression elimination after loop optimizations has been performed.

`-fexpensive-optimizations`

Perform a number of minor optimizations that are relatively expensive.

`-fdelayed-branch`

If supported for the target machine, attempt to reorder instructions to exploit instruction slots available after delayed branch instructions.

`-fschedule-insns`

If supported for the target machine, attempt to reorder instructions to eliminate execution stalls due to required data being unavailable. This helps machines that have slow floating point or memory load instructions by allowing other instructions to be issued until the result of the load or floating point instruction is required.

`-fschedule-insns2`

Similar to `-fschedule-insns', but requests an additional pass of instruction scheduling after register allocation has been done. This is especially useful on machines with a relatively small number of registers and where memory load instructions take more than one cycle.

`-fcaller-saves`

Enable values to be allocated in registers that will be clobbered by function calls, by emitting extra instructions to save and restore the registers around such calls. Such allocation is done only when it seems to result in better code than would otherwise be produced.

This option is enabled by default on certain machines, usually those which have no call-preserved registers to use instead.

`-funroll-loops`

Perform the optimization of loop unrolling. This is only done for loops whose number of iterations can be determined at compile time or run time. `-funroll-loop' implies both `-fstrength-reduce' and `-frerun-cse-after-loop'.

`-funroll-all-loops`

Perform the optimization of loop unrolling. This is done for all loops and usually makes programs run more slowly. `-funroll-all-loops' implies `-fstrength-reduce' as well as `-frerun-cse-after-loop'.

`-fno-peephole`

Disable any machine-specific peephole optimizations.

Options Controlling the Preprocessor

These options control the C preprocessor, which is run on each C source file before actual compilation.

If you use the `-E' option, nothing is done except preprocessing. Some of these options make sense only together with `-E' because they cause the preprocessor output to be unsuitable for actual compilation.

`-include file`

Process file as input before processing the regular input file. In effect, the contents of file are compiled first. Any `-D' and `-U' options on the command line are always processed before `-include file', regardless of the order in which they are written. All the `-include' and `-imacros' options are processed in the order in which they are written.

`-imacros file`

Process file as input, discarding the resulting output, before processing the regular input file. Because the output generated from file is discarded, the only effect of `-imacros file' is to make the macros defined in file available for use in the main input.

Any `-D' and `-U' options on the command line are always processed before `-imacros file', regardless of the order in which they are written. All the `-include' and `-imacros' options are processed in the order in which they are written.

`-idirafter dir`

Add the directory dir to the second include path. The directories on the second include path are searched when a header file is not found in any of the directories in the main include path (the one that `-I' adds to).

`-iprefix prefix`

Specify prefix as the prefix for subsequent `-iwithprefix' options.

`-iwithprefix dir`

Add a directory to the second include path. The directory's name is made by concatenating prefix and dir, where prefix was specified previously with `-iprefix'. If you have not specified a prefix yet, the directory containing the installed passes of the compiler is used as the default.

`-iwithprefixbefore dir`

Add a directory to the main include path. The directory's name is made by concatenating prefix and dir, as in the case of `-iwithprefix'.

`-isystem dir`

Add a directory to the beginning of the second include path, marking it as a system directory, so that it gets the same special treatment as is applied to the standard system directories.

`-nostdinc`

Do not search the standard system directories for header files. Only the directories you have specified with `-I' options (and the current directory, if appropriate) are searched. See section Options for Directory Search, for information on `-I'.

By using both `-nostdinc' and `-I-', you can limit the include-file search path to only those directories you specify explicitly.

`-undef`

Do not predefine any nonstandard macros. (Including architecture flags).

`-E`

Run only the C preprocessor. Preprocess all the C source files specified and output the results to standard output or to the specified output file.

`-C`

Tell the preprocessor not to discard comments. Used with the `-E' option.

`-P`

Tell the preprocessor not to generate `#line' directives. Used with the `-E' option.

`-M`

Tell the preprocessor to output a rule suitable for `make` describing the dependencies of each ob file. For each source file, the preprocessor outputs one `make`-rule whose target is the object file name for that source file and whose dependencies are all the `#include` header files it uses. This rule may be a single line or may be continued with `\'-newline if it is long. The list of rules is printed on standard output instead of the preprocessed C program.

`-M' implies `-E'.

Another way to specify output of a `make` rule is by setting the environment variable `DEPENDENCIES_OUTPUT` (see section Environment Variables Affecting GNU CC).

`-MM`

Like `-M' but the output mentions only the user header files included with `#include "file"'. System header files included with `#include <file>' are omitted.

`-MD`

Like `-M' but the dependency information is written to a file made by replacing ".c" with ".d" at the end of the input file names. This is in addition to compiling the file as specified---`-MD' does not inhibit ordinary compilation the way `-M' does.

In Mach, you can use the utility `md` to merge multiple dependency files into a single dependency file suitable for using with the `make' command.

`-MMD`

Like `-MD' except mention only user header files, not system header files.

`-MG`

Treat missing header files as generated files and assume they live in the same directory as the source file. If you specify `-MG', you must also specify either `-M' or `-MM'. `-MG' is not supported with `-MD' or `-MMD'.

`-H`

Print the name of each header file used, in addition to other normal activities.

`-Aquestion(answer)`

Assert the answer answer for question, in case it is tested with a preprocessing conditional such as `#if #question(answer)'. `-A-' disables the standard assertions that normally describe the target machine.

`-Dmacro`

Define macro macro with the string `1' as its definition.

`-Dmacro=defn`

Define macro macro as defn. All instances of `-D' on the command line are processed before any `-U' options.

`-Umacro`

Undefine macro macro. `-U' options are evaluated after all `-D' options, but before any `-include' and `-imacros' options.

`-dM`

Tell the preprocessor to output only a list of the macro definitions that are in effect at the end of

preprocessing. Used with the `-E' option.

`-dD`

Tell the preprocessing to pass all macro definitions into the output, in their proper sequence in the rest of the output.

`-dN`

Like `-dD' except that the macro arguments and contents are omitted. Only `#define name' is included in the output.

`-trigraphs`

Support ANSI C trigraphs. The `-ansi' option also has this effect.

`-Wp,option`

Pass option as an option to the preprocessor. If option contains commas, it is split into multiple options at the commas.

Passing Options to the Assembler

You can pass options to the assembler.

`-Wa,option`

Pass option as an option to the assembler. If option contains commas, it is split into multiple options at the commas.

Options for Linking

These options come into play when the compiler links object files into an executable output file. They are meaningless if the compiler is not doing a link step.

`object-file-name`

A file name that does not end in a special recognized suffix is considered to name an object file or library. (Object files are distinguished from libraries by the linker according to the file contents.) If linking is done, these object files are used as input to the linker.

`-c`

`-S`

`-E`

If any of these options is used, then the linker is not run, and object file names should not be used as arguments. See section Options Controlling the Kind of Output.

`-llibrary`

Search the library named library when linking.

It makes a difference where in the command you write this option; the linker searches processes libraries and object files in the order they are specified. Thus, `foo.o -lz bar.o' searches library `z' after file `foo.o' but before `bar.o'. If `bar.o' refers to functions in `z', those functions may not be loaded.

The linker searches a standard list of directories for the library, which is actually a file named `liblibrary.a'. The linker then uses this file as if it had been specified precisely by name.

The directories searched include several standard system directories plus any that you specify with `-L'.

Normally the files found this way are library files--archive files whose members are object files. The linker handles an archive file by scanning through it for members which define symbols that have so far been referenced but not defined. But if the file that is found is an ordinary object file, it is linked in the usual fashion. The only difference between using an `-l' option and specifying a file name is that `-l' surrounds library with `lib' and `.a' and searches several directories.

`-lobjc`

You need this special case of the `-l' option in order to link an Objective C program.

`-nostartfiles`

Do not use the standard system startup files when linking. The standard system libraries are used normally, unless `-nostdlib` or `-nodefaultlibs` is used.

`-nodefaultlibs`

Do not use the standard system libraries when linking. Only the libraries you specify will be passed to the linker. The standard startup files are used normally, unless `-nostartfiles` is used.

`-nostdlib`

Do not use the standard system startup files or libraries when linking. No startup files and only the libraries you specify will be passed to the linker.

One of the standard libraries bypassed by `-nostdlib' and `-nodefaultlibs' is `libgcc.a', a library of internal subroutines that GNU CC uses to overcome shortcomings of particular machines, or special needs for some languages. (See section Interfacing to GNU CC Output, for more discussion of `libgcc.a'.) In most cases, you need `libgcc.a' even when you want to avoid other standard libraries. In other words, when you specify `-nostdlib' or `-nodefaultlibs' you should usually specify `-lgcc' as well. This ensures that you have no unresolved references to internal GNU CC library subroutines. (For example, `__main', used to ensure C++ constructors will be called; see section `collect2`.)

`-s`

Remove all symbol table and relocation information from the executable.

`-static`

On systems that support dynamic linking, this prevents linking with the shared libraries. On other systems, this option has no effect.

`-shared`

Produce a shared object which can then be linked with other objects to form an executable. Only a few systems support this option.

`-symbolic`

Bind references to global symbols when building a shared object. Warn about any unresolved references (unless overridden by the link editor option `-Xlinker -z -Xlinker defs'). Only a few systems support this option.

`-Xlinker option`

Pass option as an option to the linker. You can use this to supply system-specific linker options which GNU CC does not know how to recognize.

If you want to pass an option that takes an argument, you must use `-Xlinker' twice, once for the option and once for the argument. For example, to pass `-assert definitions', you must write `-Xlinker -assert -Xlinker definitions'. It does not work to write `-Xlinker "-assert definitions"', because this passes the entire string as a single argument, which is not what the linker expects.

`-Wl,option`

Pass option as an option to the linker. If option contains commas, it is split into multiple options at the commas.

`-u symbol`

Pretend the symbol symbol is undefined, to force linking of library modules to define it. You can use `-u' multiple times with different symbols to force loading of additional library modules.

Options for Directory Search

These options specify directories to search for header files, for libraries and for parts of the compiler:

`-Idir`

Add the directory directory to the head of the list of directories to be searched for header files. This can be used to override a system header file, substituting your own version, since these directories are searched before the system header file directories. If you use more than one `-I' option, the directories are scanned in left-to-right order; the standard system directories come after.

`-I-`

Any directories you specify with `-I' options before the `-I-' option are searched only for the case of `#include "file"'; they are not searched for `#include <file>'.

If additional directories are specified with `-I' options after the `-I-', these directories are searched for all `#include' directives. (Ordinarily *all* `-I' directories are used this way.)

In addition, the `-I-' option inhibits the use of the current directory (where the current input file came from) as the first search directory for `#include "file"'. There is no way to override this effect of `-I-'. With `-I.' you can specify searching the directory which was current when the compiler was invoked. That is not exactly the same as what the preprocessor does by default, but it is often satisfactory.

`-I-' does not inhibit the use of the standard system directories for header files. Thus, `-I-' and `-nostdinc' are independent.

`-Ldir`

Add directory dir to the list of directories to be searched for `-l'.

`-Bprefix`

This option specifies where to find the executables, libraries, include files, and data files of the compiler itself.

The compiler driver program runs one or more of the subprograms `cpp', `cc1', `as' and `ld'. It tries prefix as a prefix for each program it tries to run, both with and without `machine/version/' (see section Specifying Target Machine and Compiler Version).

For each subprogram to be run, the compiler driver first tries the `-B' prefix, if any. If that name is not found, or if `-B' was not specified, the driver tries two standard prefixes, which are `/usr/lib/gcc/' and `/usr/local/lib/gcc-lib/'. If neither of those results in a file name that is found, the unmodified program name is searched for using the directories specified in your `PATH' environment variable.

`-B' prefixes that effectively specify directory names also apply to libraries in the linker, because the compiler translates these options into `-L' options for the linker. They also apply to includes files in the preprocessor, because the compiler translates these options into `-isystem' options for the preprocessor. In this case, the compiler appends `include' to the prefix.

The run-time support file `libgcc.a' can also be searched for using the `-B' prefix, if needed. If it is not found there, the two standard prefixes above are tried, and that is all. The file is left out of the link if it is not found by those means.

Another way to specify a prefix much like the `-B' prefix is to use the environment variable `GCC_EXEC_PREFIX`. See section Environment Variables Affecting GNU CC.

Specifying Target Machine and Compiler Version

By default, GNU CC compiles code for the same type of machine that you are using. However, it can also be installed as a cross-compiler, to compile for some other type of machine. In fact, several different configurations of GNU CC, for different target machines, can be installed side by side. Then you specify which one to use with the `-b' option.

In addition, older and newer versions of GNU CC can be installed side by side. One of them (probably the newest) will be the default, but you may sometimes wish to use another.

`-b machine`

The argument machine specifies the target machine for compilation. This is useful when you have installed GNU CC as a cross-compiler.

The value to use for machine is the same as was specified as the machine type when configuring GNU CC as a cross-compiler. For example, if a cross-compiler was configured with `configure i386v', meaning to compile for an 80386 running System V, then you would specify `-b i386v' to run that cross compiler.

When you do not specify `-b', it normally means to compile for the same type of machine that you are using.

`-V version`

The argument version specifies which version of GNU CC to run. This is useful when multiple versions are installed. For example, version might be `2.0', meaning to run GNU CC version 2.0.

The default version, when you do not specify `-V', is the last version of GNU CC that you installed.

The `-b' and `-V' options actually work by controlling part of the file name used for the executable files and libraries used for compilation. A given version of GNU CC, for a given target machine, is normally kept in the directory `/usr/local/lib/gcc-lib/machine/version'.

Thus, sites can customize the effect of `-b' or `-V' either by changing the names of these directories or adding alternate names (or symbolic links). If in directory `/usr/local/lib/gcc-lib/' the file `80386' is a link to the file `i386v', then `-b 80386' becomes an alias for `-b i386v'.

In one respect, the `-b' or `-V' do not completely change to a different compiler: the top-level driver program `gcc' that you originally invoked continues to run and invoke the other executables (preprocessor, compiler per se, assembler and linker) that do the real work. However, since no real work is done in the driver program, it usually does not matter that the driver program in use is not the one for the specified target and version.

The only way that the driver program depends on the target machine is in the parsing and handling of special machine-specific options. However, this is controlled by a file which is found, along with the other executables, in the directory for the specified version and target machine. As a result, a single installed driver program adapts to any specified target machine and compiler version.

The driver program executable does control one significant thing, however: the default version and target machine. Therefore, you can install different instances of the driver program, compiled for different targets or versions, under different names.

For example, if the driver for version 2.0 is installed as `ogcc' and that for version 2.1 is installed as `gcc', then the command `gcc' will use version 2.1 by default, while `ogcc' will use 2.0 by default. However, you can choose either version with either command with the `-V' option.

Hardware Models and Configurations

Earlier we discussed the standard option `-b' which chooses among different installed compilers for completely different target machines, such as Vax vs. 68000 vs. 80386.

In addition, each of these target machine types can have its own special options, starting with `-m', to choose among various hardware models or configurations--for example, 68010 vs 68020, floating coprocessor or none. A single installed version of the compiler can compile for any model or configuration, according to the options specified.

Some configurations of the compiler also support additional special options, usually for compatibility with other compilers on the same platform.

These options are defined by the macro `TARGET_SWITCHES' in the machine description. The default for the options is also defined by that macro, which enables you to change the defaults.

M680x0 Options

These are the `-m' options defined for the 68000 series. The default values for these options depends on which style of 68000 was selected when the compiler was configured; the defaults for the most common choices are given below.

`-m68000`

`-mc68000`

Generate output for a 68000. This is the default when the compiler is configured for 68000-based systems.

`-m68020`

`-mc68020`

Generate output for a 68020. This is the default when the compiler is configured for 68020-based systems.

`-m68881`

Generate output containing 68881 instructions for floating point. This is the default for most 68020 systems unless `-nfp' was specified when the compiler was configured.

`-m68030`

Generate output for a 68030. This is the default when the compiler is configured for 68030-based systems.

`-m68040`

Generate output for a 68040. This is the default when the compiler is configured for 68040-based systems.

This option inhibits the use of 68881/68882 instructions that have to be emulated by software on the 68040. If your 68040 does not have code to emulate those instructions, use `-m68040'.

`-m68020-40`

Generate output for a 68040, without using any of the new instructions. This results in code which can run relatively efficiently on either a 68020/68881 or a 68030 or a 68040. The generated code does use the 68881 instructions that are emulated on the 68040.

`-mfpa`

Generate output containing Sun FPA instructions for floating point.

`-msoft-float`

Generate output containing library calls for floating point. **Warning:** the requisite libraries are not available for all m68k targets. Normally the facilities of the machine's usual C compiler are used, but this can't be done directly in cross-compilation. You must make your own arrangements to provide suitable library functions for cross-compilation. The embedded targets `m68k-*-aout' and `m68k-*-coff' do provide software floating point support.

`-mshort`

Consider type `int` to be 16 bits wide, like `short int`.

`-mnobitfield`

Do not use the bit-field instructions. The `-m68000' option implies `-mnobitfield'.

`-mbitfield`

Do use the bit-field instructions. The `-m68020' option implies `-mbitfield'. This is the default if you use a configuration designed for a 68020.

`-mrtd`

Use a different function-calling convention, in which functions that take a fixed number of arguments return with the `rtd` instruction, which pops their arguments while returning. This sa one instruction in the caller since there is no need to pop the arguments there.

This calling convention is incompatible with the one normally used on Unix, so you cannot use it if you need to call libraries compiled with the Unix compiler.

Also, you must provide function prototypes for all functions that take variable numbers of arguments (including `printf`); otherwise incorrect code will be generated for calls to those functions.

In addition, seriously incorrect code will result if you call a function with too many arguments. (Normally, extra arguments are harmlessly ignored.)

The `rtd` instruction is supported by the 68010 and 68020 processors, but not by the 68000.

VAX Options

These `-m' options are defined for the Vax:

`-munix`

Do not output certain jump instructions (`aobleq` and so on) that the Unix assembler for the Vax cannot handle across long ranges.

`-mgnu`

Do output those jump instructions, on the assumption that you will assemble with the GNU assembler.

`-mg`

Output code for g-format floating point numbers instead of d-format.

SPARC Options

These `-m' switches are supported on the SPARC:

`-mno-app-regs`

`-mapp-regs`

Specify `-mapp-regs' to generate output using the global registers 2 through 4, which the SPARC SVR4 ABI reserves for applications. This is the default.

To be fully SVR4 ABI compliant at the cost of some performance loss, specify `-mno-app-regs'. You should compile libraries and system software with this option.

`-mfpu`

`-mhard-float`

Generate output containing floating point instructions. This is the default.

`-mno-fpu`

`-msoft-float`

Generate output containing library calls for floating point. **Warning:** the requisite libraries are not

available for all SPARC targets. Normally the facilities of the machine's usual C compiler are u
but this cannot be done directly in cross-compilation. You must make your own arrangements t
provide suitable library functions for cross-compilation. The embedded targets `sparc-*-aout' and
`sparclite-*-*' do provide software floating point support.

`-msoft-float' changes the calling convention in the output file; therefore, it is only useful if you compile *all* of a program with this option. In particular, you need to compile `libgcc.a', the library that comes with GNU CC, with `-msoft-float' in order for this to work.

`-mhard-quad-float`

Generate output containing quad-word (long double) floating point instructions.

`-msoft-quad-float`

Generate output containing library calls for quad-word (long double) floating point instructions. The functions called are those specified in the SPARC ABI. This is the default.

As of this writing, there are no sparc implementations that have hardware support for the quad-word floating point instructions. They all invoke a trap handler for one of these instructions, and then the trap handler emulates the effect of the instruction. Because of the trap handler overhead, this is much slower than calling the ABI library routines. Thus the `-msoft-quad-float' option is the default.

`-mno-epilogue`

`-mepilogue`

With `-mepilogue' (the default), the compiler always emits code for function exit at the end of each function. Any function exit in the middle of the function (such as a return statement in C) will generate a jump to the exit code at the end of the function.

With `-mno-epilogue', the compiler tries to emit exit code inline at every function exit.

`-mno-flat`

`-mflat`

With `-mflat', the compiler does not generate save/restore instructions and will use a "flat" or single register window calling convention. This model uses %i7 as the frame pointer and is compatible with the normal register window model. Code from either may be intermixed although debugger support is still incomplete. The local registers and the input registers (0-5) are still treated as "call saved" registers and will be saved on the stack as necessary.

With `-mno-flat' (the default), the compiler emits save/restore instructions (except for leaf functions) and is the normal mode of operation.

`-mno-unaligned-doubles`

`-munaligned-doubles`

Assume that doubles have 8 byte alignment. This is the default.

With `-munaligned-doubles', GNU CC assumes that doubles have 8 byte alignment only if they are contained in another type, or if they have an absolute address. Otherwise, it assumes they have 4 byte alignment. Specifying this option avoids some rare compatibility problems with code generated by other compilers. It is not the default because it results in a performance loss, especially for floating point code.

`-mv8`

`-msparclite`

These two options select variations on the SPARC architecture.

By default (unless specifically configured for the Fujitsu SPARClite), GCC generates code for the v7 variant of the SPARC architecture.

`-mv8' will give you SPARC v8 code. The only difference from v7 code is that the compiler emits the integer multiply and integer divide instructions which exist in SPARC v8 but not in SPARC v7.

`-msparclite' will give you SPARClite code. This adds the integer multiply, integer divide step and scan (`ffs`) instructions which exist in SPARClite but not in SPARC v7.

`-mcypress`

`-msupersparc`

These two options select the processor for which the code is optimised.

With `-mcypress' (the default), the compiler optimizes code for the Cypress CY7C602 chip, as used in the SparcStation/SparcServer 3xx series. This is also appropriate for the older SparcStation 1, 2, IPX etc.

With `-msupersparc' the compiler optimizes code for the SuperSparc cpu, as used in the SparcStation 10, 1000 and 2000 series. This flag also enables use of the full SPARC v8 instruction set.

In a future version of GCC, these options will very likely be renamed to `-mcpu=cypress' and `-mcpu=supersparc'.

These `-m' switches are supported in addition to the above on SPARC V9 processors:

`-mmedlow`

Generate code for the Medium/Low code model: assume a 32 bit address space. Programs are statically linked, PIC is not supported. Pointers are still 64 bits.

It is very likely that a future version of GCC will rename this option.

`-mmedany`

Generate code for the Medium/Anywhere code model: assume a 32 bit text segment starting at offset 0, and a 32 bit data segment starting anywhere (determined at link time). Programs are statically linked, PIC is not supported. Pointers are still 64 bits.

It is very likely that a future version of GCC will rename this option.

`-mint64`

Types long and int are 64 bits.

`-mlong32`

Types long and int are 32 bits.

`-mlong64`

`-mint32`

Type long is 64 bits, and type int is 32 bits.

`-mstack-bias`

`-mno-stack-bias`

With `-mstack-bias', GNU CC assumes that the stack pointer, and frame pointer if present, are offset by -2047 which must be added back when making stack frame references. Otherwise, assume no such offset is present.

Convex Options

These `-m' options are defined for Convex:

`-mc1`

Generate output for C1. The code will run on any Convex machine. The preprocessor symbol `__convex__c1__` is defined.

`-mc2`

Generate output for C2. Uses instructions not available on C1. Scheduling and other optimizations are chosen for max performance on C2. The preprocessor symbol `__convex_c2__` is defined.

`-mc32`

Generate output for C32xx. Uses instructions not available on C1. Scheduling and other optimizations are chosen for max performance on C32. The preprocessor symbol `__convex_c32__` is defined.

`-mc34`

Generate output for C34xx. Uses instructions not available on C1. Scheduling and other optimizations are chosen for max performance on C34. The preprocessor symbol `__convex_c34__` is defined.

`-mc38`

Generate output for C38xx. Uses instructions not available on C1. Scheduling and other optimizations are chosen for max performance on C38. The preprocessor symbol `__convex_c38__` is defined.

`-margcount`

Generate code which puts an argument count in the word preceding each argument list. This is compatible with regular CC, and a few programs may need the argument count word. GDB and other source-level debuggers do not need it; this info is in the symbol table.

`-mnoargcount`

Omit the argument count word. This is the default.

`-mvolatile-cache`

Allow volatile references to be cached. This is the default.

`-mvolatile-nocache`

Volatile references bypass the data cache, going all the way to memory. This is only needed for multi-processor code that does not use standard synchronization instructions. Making non-volatile references to volatile locations will not necessarily work.

`-mlong32`

Type long is 32 bits, the same as type int. This is the default.

`-mlong64`

Type long is 64 bits, the same as type long long. This option is useless, because no library support exists for it.

AMD29K Options

These `-m' options are defined for the AMD Am29000:

`-mdw`

Generate code that assumes the `DW` bit is set, i.e., that byte and halfword operations are directly supported by the hardware. This is the default.

`-mndw`

Generate code that assumes the `DW` bit is not set.

`-mbw`

Generate code that assumes the system supports byte and halfword write operations. This is the default.

`-mnbw`

Generate code that assumes the systems does not support byte and halfword write operations. `-mnbw' implies `-mndw'.

`-msmall`

Use a small memory model that assumes that all function addresses are either within a single 256 KB segment or at an absolute address of less than 256k. This allows the `call` instruction to be used instead of a `const`, `consth`, `calli` sequence.

`-mnormal`

Use the normal memory model: Generate `call` instructions only when calling functions in the same file and `calli` instructions otherwise. This works if each file occupies less than 256 KB but allows the entire executable to be larger than 256 KB. This is the default.

`-mlarge`

Always use `calli` instructions. Specify this option if you expect a single file to compile into more than 256 KB of code.

`-m29050`

Generate code for the Am29050.

`-m29000`

Generate code for the Am29000. This is the default.

`-mkernel-registers`

Generate references to registers `gr64-gr95` instead of to registers `gr96-gr127`. This option can be used when compiling kernel code that wants a set of global registers disjoint from that used by user-mode code.

Note that when this option is used, register names in `-f' flags must use the normal, user-mode, names.

`-muser-registers`

Use the normal set of global registers, `gr96-gr127`. This is the default.

`-mstack-check`

`-mno-stack-check`

Insert (or do not insert) a call to `__msp_check` after each stack adjustment. This is often used for kernel code.

`-mstorem-bug`

`-mno-storem-bug`

`-mstorem-bug' handles 29k processors which cannot handle the separation of a mtsrim insn and a storem instruction (most 29000 chips to date, but not the 29050).

`-mno-reuse-arg-regs`

`-mreuse-arg-regs`

`-mno-reuse-arg-regs' tells the compiler to only use incoming argument registers for copying out arguments. This helps detect calling a function with fewer arguments than it was declared with.

`-msoft-float`

Generate output containing library calls for floating point. **Warning:** the requisite libraries are not part of GNU CC. Normally the facilities of the machine's usual C compiler are used, but this can't be done directly in cross-compilation. You must make your own arrangements to provide suitable library functions for cross-compilation.

ARM Options

These `-m' options are defined for Advanced RISC Machines (ARM) architectures:

`-m2`

`-m3`

These options are identical. Generate code for the ARM2 and ARM3 processors. This option is the default. You should also use this option to generate code for ARM6 processors that are running with a 26-bit program counter.

`-m6`

Generate code for the ARM6 processor when running with a 32-bit program counter.

`-mapcs`

Generate a stack frame that is compliant with the ARM Procedure Call Standard for all functions, even if this is not strictly necessary for correct execution of the code.

`-mbsd`

This option only applies to RISC iX. Emulate the native BSD-mode compiler. This is the default if `-ansi' is not specified.

`-mxopen`

This option only applies to RISC iX. Emulate the native X/Open-mode compiler.

`-mno-symrename`

This option only applies to RISC iX. Do not run the assembler post-processor, `symrename', after code has been assembled. Normally it is necessary to modify some of the standard symbols in preparation for linking with the RISC iX C library; this option suppresses this pass. The post-processor is never run when the compiler is built for cross-compilation.

M88K Options

These `-m' options are defined for Motorola 88k architectures:

`-m88000`

Generate code that works well on both the m88100 and the m88110.

`-m88100`

Generate code that works best for the m88100, but that also runs on the m88110.

`-m88110`

Generate code that works best for the m88110, and may not run on the m88100.

`-mbig-pic`

Obsolete option to be removed from the next revision. Use `-fPIC'.

`-midentify-revision`

Include an `ident` directive in the assembler output recording the source file name, compiler name and version, timestamp, and compilation flags used.

`-mno-underscores`

In assembler output, emit symbol names without adding an underscore character at the beginning of each name. The default is to use an underscore as prefix on each name.

`-mocs-debug-info`

`-mno-ocs-debug-info`

Include (or omit) additional debugging information (about registers used in each stack frame) as specified in the 88open Object Compatibility Standard, "OCS". This extra information allows debugging of code that has had the frame pointer eliminated. The default for DG/UX, SVr4, and Delta 88 SVr3.2 is to include this information; other 88k configurations omit this information by default.

`-mocs-frame-position`

When emitting COFF debugging information for automatic variables and parameters stored on the stack, use the offset from the canonical frame address, which is the stack pointer (register 31) on entry to the function. The DG/UX, SVr4, Delta88 SVr3.2, and BCS configurations use `-mocs-frame-position'; other 88k configurations have the default `-mno-ocs-frame-position'.

`-mno-ocs-frame-position`

When emitting COFF debugging information for automatic variables and parameters stored on the stack, use the offset from the frame pointer register (register 30). When this option is in effect, the frame pointer is not eliminated when debugging information is selected by the -g switch.

`-moptimize-arg-area`

`-mno-optimize-arg-area`

Control how function arguments are stored in stack frames. `-moptimize-arg-area' saves space by optimizing them, but this conflicts with the 88open specifications. The opposite alternative, `-mno-optimize-arg-area', agrees with 88open standards. By default GNU CC does not optimize the argument area.

`-mshort-data-num`

Generate smaller data references by making them relative to `r0`, which allows loading a value using a single instruction (rather than the usual two). You control which data references are affected by specifying num with this option. For example, if you specify `-mshort-data-512', then the data references affected are those involving displacements of less than 512 bytes. `-mshort-data-num' is not effective for num greater than 64k.

`-mserialize-volatile`

`-mno-serialize-volatile`

Do, or don't, generate code to guarantee sequential consistency of volatile memory references. By default, consistency is guaranteed.

The order of memory references made by the MC88110 processor does not always match the order of the instructions requesting those references. In particular, a load instruction may execute before a preceding store instruction. Such reordering violates sequential consistency of volatile memory references, when there are multiple processors. When consistency must be guaranteed, GNU C generates special instructions, as needed, to force execution in the proper order.

The MC88100 processor does not reorder memory references and so always provides sequential consistency. However, by default, GNU C generates the special instructions to guarantee consistency even when you use `-m88100', so that the code may be run on an MC88110 processor. If you intend to run your code only on the MC88100 processor, you may use `-mno-serialize-volatile'.

The extra code generated to guarantee consistency may affect the performance of your application. If you know that you can safely forgo this guarantee, you may use `-mno-serialize-volatile'.

`-msvr4`

`-msvr3`

Turn on (`-msvr4') or off (`-msvr3') compiler extensions related to System V release 4 (SVr4). This controls the following:

Which variant of the assembler syntax to emit.

`-msvr4' makes the C preprocessor recognize `#pragma weak' that is used on System V release 4.

`-msvr4' makes GNU CC issue additional declaration directives used in SVr4.

`-msvr4' is the default for the m88k-motorola-sysv4 and m88k-dg-dgux m88k configurations. `-msvr3' is the default for all other m88k configurations.

`-mversion-03.00`

This option is obsolete, and is ignored.

`-mno-check-zero-division`

`-mcheck-zero-division`

Do, or don't, generate code to guarantee that integer division by zero will be detected. By default detection is guaranteed.

Some models of the MC88100 processor fail to trap upon integer division by zero under certain conditions. By default, when compiling code that might be run on such a processor, GNU C generates code that explicitly checks for zero-valued divisors and traps with exception number 503 when one is detected. Use of mno-check-zero-division suppresses such checking for code generated to run on an MC88100 processor.

GNU C assumes that the MC88110 processor correctly detects all instances of integer division by zero. When `-m88110' is specified, both `-mcheck-zero-division' and `-mno-check-zero-division' are ignored, and no explicit checks for zero-valued divisors are generated.

`-muse-div-instruction`

Use the div instruction for signed integer division on the MC88100 processor. By default, the div instruction is not used.

On the MC88100 processor the signed integer division instruction div) traps to the operating system on a negative operand. The operating system transparently completes the operation, but at a large cost in execution time. By default, when compiling code that might be run on an MC88100 processor, GNU C emulates signed integer division using the unsigned integer division instruction divu), thereby avoiding the large penalty of a trap to the operating system. Such emulation has its own, smaller, execution cost in both time and space. To the extent that your code's important signed integer division operations are performed on two nonnegative operands, it may be desirable to use the div instruction directly.

On the MC88110 processor the div instruction (also known as the divs instruction) processes negative operands without trapping to the operating system. When `-m88110' is specified, `-muse-div-instruction' is ignored, and the div instruction is used for signed integer division.

Note that the result of dividing INT_MIN by -1 is undefined. In particular, the behavior of such a division with and without `-muse-div-instruction' may differ.

`-mtrap-large-shift`

`-mhandle-large-shift`

Include code to detect bit-shifts of more than 31 bits; respectively, trap such shifts or emit code to handle them properly. By default GNU CC makes no special provision for large bit shifts.

`-mwarn-passed-structs`

Warn when a function passes a struct as an argument or result. Structure-passing conventions have changed during the evolution of the C language, and are often the source of portability problems. By default, GNU CC issues no such warning.

IBM RS/6000 and PowerPC Options

These `-m' options are defined for the IBM RS/6000 and PowerPC:

`-mpower`

`-mno-power`
`-mpower2`
`-mno-power2`
`-mpowerpc`
`-mno-powerpc`
`-mpowerpc-gpopt`
`-mno-powerpc-gpopt`
`-mpowerpc-gfxopt`
`-mno-powerpc-gfxopt`

GNU CC supports two related instruction set architectures for the RS/6000 and PowerPC. The POWER instruction set are those instructions supported by the `rios' chip set used in the original RS/6000 systems and the PowerPC instruction set is the architecture of the Motorola MPC6xx microprocessors. The PowerPC architecture defines 64-bit instructions, but they are not supported by any current processors.

Neither architecture is a subset of the other. However there is a large common subset of instructions supported by both. An MQ register is included in processors supporting the POWER architecture.

You use these options to specify which instructions are available on the processor you are using. The default value of these options is determined when configuring GNU CC. Specifying the `-mcpu=cpu_type' overrides the specification of these options. We recommend you use that option rather than these.

The `-mpower' option allows GNU CC to generate instructions that are found only in the POWER architecture and to use the MQ register. Specifying `-mpower2' implies `-power' and also allows GNU CC to generate instructions that are present in the POWER2 architecture but not the original POWER architecture.

The `-mpowerpc' option allows GNU CC to generate instructions that are found only in the 32-bit subset of the PowerPC architecture. Specifying `-mpowerpc-gpopt' implies `-mpowerpc' and also allows GNU CC to use the optional PowerPC architecture instructions in the General Purpose group, including floating-point square root. Specifying `-mpowerpc-gfxopt' implies `-mpowerpc' and also allows GNU CC to use the optional PowerPC architecture instructions in the Graphics group, including floating-point select.

If you specify both `-mno-power' and `-mno-powerpc', GNU CC will use only the instructions in the common subset of both architectures plus some special AIX common-mode calls, and will not use the MQ register. Specifying both `-mpower' and `-mpowerpc' permits GNU CC to use any instruction from either architecture and to allow use of the MQ register; specify this for the Motorola MPC601.

`-mnew-mnemonics`
`-mold-mnemonics`

Select which mnemonics to use in the generated assembler code. `-mnew-mnemonics' requests output that uses the assembler mnemonics defined for the PowerPC architecture, while `-mold-mnemonics' requests the assembler mnemonics defined for the POWER architecture.

Instructions defined in only one architecture have only one mnemonic; GNU CC uses that mnemonic irrespective of which of thse options is specified.

PowerPC assemblers support both the old and new mnemonics, as will later POWER assemblers. Current POWER assemblers only support the old mnemonics. Specify `-mnew-mnemonics' if you have an assembler that supports them, otherwise specify `-mold-mnemonics'.

The default value of these options depends on how GNU CC was configured. Specifying `-mcpu=cpu_type' sometimes overrides the value of these option. Unless you are building a cross-compiler, you should normally not specify either `-mnew-mnemonics' or `-mold-mnemonics', but should instead accept the default.

`-mcpu=cpu_type`

Set architecture type, register usage, choice of mnemonics, and instruction scheduling parameters for machine type cpu_type. By default, cpu_type is the target system defined when GNU CC was configured. Supported values for cpu_type are `rios1', `rios2', `rsc', `601', `603', `604', `power', `powerpc', `403', and `common'. `-mcpu=power' and `-mcpu=powerpc' specify generic POWER and pure PowerPC (i.e., not MPC601) architecture machine types, with an appropriate, generic processor model assumed for scheduling purposes.

Specifying `-mcpu=rios1', `-mcpu=rios2', `-mcpu=rsc', or `-mcpu=power' enables the `-mpower' option and disables the `-mpowerpc' option; `-mcpu=601' enables both the `-mpower' and `-mpowerpc' options; `-mcpu=603', `-mcpu=604', `-mcpu=403', and `-mcpu=powerpc' enable the `-mpowerpc' option and disable the `-mpower' option; `-mcpu=common' disables both the `-mpower' and `-mpowerpc' options.

To generate code that will operate on all members of the RS/6000 and PowerPC families, specify `-mcpu=common'. In that case, GNU CC will use only the instructions in the common subset of both architectures plus some special AIX common-mode calls, and will not use the MQ register. GNU CC assumes a generic processor model for scheduling purposes.

Specifying `-mcpu=rios1', `-mcpu=rios2', `-mcpu=rsc', or `-mcpu=power' also disables the `new-mnemonics' option. Specifying `-mcpu=601', `-mcpu=603', `-mcpu=604', `403', or `-mcpu=powerpc' also enables the `new-mnemonics' option.

`-mfull-toc`

`-mno-fp-in-toc`

`-mno-sum-in-toc`

`-mminimal-toc`

Modify generation of the TOC (Table Of Contents), which is created for every executable file. The `-mfull-toc' option is selected by default. In that case, GNU CC will allocate at least one TOC entry for each unique non-automatic variable reference in your program. GNU CC will also place floating-point constants in the TOC. However, only 16,384 entries are available in the TOC.

If you receive a linker error message that saying you have overflowed the available TOC space, you can reduce the amount of TOC space used with the `-mno-fp-in-toc' and `-mno-sum-in-toc' options. `-mno-fp-in-toc' prevents GNU CC from putting floating-point constants in the TOC and `-mno-sum-in-toc' forces GNU CC to generate code to calculate the sum of an address and a constant at run-time instead of putting that sum into the TOC. You may specify one or both of these

options. Each causes GNU CC to produce very slightly slower and larger code at the expense of conserving TOC space.

If you still run out of space in the TOC even when you specify both of these options, specify `-mminimal-toc' instead. This option causes GNU CC to make only one TOC entry for every file. When you specify this option, GNU CC will produce code that is slower and larger but which uses extremely little TOC space. You may wish to use this option only on files that contain less frequently executed code.

`-msoft-float`

`-mhard-float`

Generate code that does not use (uses) the floating-point register set. Software floating point emulation is provided if you use the `-msoft-float' option, and pass the option to GNU CC when linking.

`-mmultiple`

`-mno-multiple`

Generate code that uses (does not use) the load multiple word instructions and the store multiple word instructions. These instructions are generated by default on POWER systems, and not generated on PowerPC systems. Do not use `-mmultiple' on little endian PowerPC systems, since those instructions do not work when the processor is in little endian mode.

`-mstring`

`-mno-string`

Generate code that uses (does not use) the load string instructions and the store string word instructions to save multiple registers and do small block moves. These instructions are generated by default on POWER systems, anod not generated on PowerPC systems. Do not use `-mstring' on little endian PowerPC systems, since those instructions do not work when the processor is in little endian mode.

`-mno-bit-align`

`-mbit-align`

On System V.4 and embedded PowerPC systems do not (do) force structures and unions that contain bit fields to be aligned to the base type of the bit field.

For example, by default a structure containing nothing but 8 `unsigned` bitfields of length 1 would be aligned to a 4 byte boundary and have a size of 4 bytes. By using `-mno-bit-align', the structure would be aligned to a 1 byte boundary and be one byte in size.

`-mno-strict-align`

`-mstrict-align`

On System V.4 and embedded PowerPC systems do not (do) assume that unaligned memory references will be handled by the system.

`-mrelocatable`

`-mno-relocatable`

On embedded PowerPC systems generate code that allows (does not allow) the program to be relocated to a different address at runtime.

`-mno-toc`
`-mtoc`

On System V.4 and embedded PowerPC systems do not (do) assume that register 2 contains a pointer to a global area pointing to the addresses used in the program.

`-mno-traceback`
`-mtraceback`

On embedded PowerPC systems do not (do) generate a traceback tag before the start of the function. This tag can be used by the debugger to identify where the start of a function is.

`-mlittle`
`-mlittle-endian`

On System V.4 and embedded PowerPC systems compile code for the processor in little endian mode. The `-mlittle-endian' option is the same as `-mlittle'.

`-mbig`
`-mbig-endian`

On System V.4 and embedded PowerPC systems compile code for the processor in big endian mode. The `-mbig-endian' option is the same as `-mbig'.

IBM RT Options

These `-m' options are defined for the IBM RT PC:

`-min-line-mul`

Use an in-line code sequence for integer multiplies. This is the default.

`-mcall-lib-mul`

Call `lmul$$` for integer multiples.

`-mfull-fp-blocks`

Generate full-size floating point data blocks, including the minimum amount of scratch space recommended by IBM. This is the default.

`-mminimum-fp-blocks`

Do not include extra scratch space in floating point data blocks. This results in smaller code, but slower execution, since scratch space must be allocated dynamically.

`-mfp-arg-in-fpregs`

Use a calling sequence incompatible with the IBM calling convention in which floating point arguments are passed in floating point registers. Note that `varargs.h` and `stdargs.h` will not work with floating point operands if this option is specified.

`-mfp-arg-in-gregs`

Use the normal calling convention for floating point arguments. This is the default.

`-mhc-struct-return`

Return structures of more than one word in memory, rather than in a register. This provides compatibility with the MetaWare HighC (hc) compiler. Use the option `-fpcc-struct-return' for compatibility with the Portable C Compiler (pcc).

`-mnohc-struct-return`

Return some structures of more than one word in registers, when convenient. This is the default. For compatibility with the IBM-supplied compilers, use the option `-fpcc-struct-return' or the option `-mhc-struct-return'.

MIPS Options

These `-m' options are defined for the MIPS family of computers:

`-mcpu=cpu type`

Assume the defaults for the machine type cpu type when scheduling instructions. The choices for cpu type are `r2000', `r3000', `r4000', `r4400', `r4600', and `r6000'. While picking a specific cpu type will schedule things appropriately for that particular chip, the compiler will not generate any code that does not meet level 1 of the MIPS ISA (instruction set architecture) without the `-mips2' or `-mips3' switches being used.

`-mips1`

Issue instructions from level 1 of the MIPS ISA. This is the default. `r3000' is the default cpu type at this ISA level.

`-mips2`

Issue instructions from level 2 of the MIPS ISA (branch likely, square root instructions). `r6000' is the default cpu type at this ISA level.

`-mips3`

Issue instructions from level 3 of the MIPS ISA (64 bit instructions). `r4000' is the default cpu type at this ISA level. This option does not change the sizes of any of the C data types.

`-mfp32`

Assume that 32 32-bit floating point registers are available. This is the default.

`-mfp64`

Assume that 32 64-bit floating point registers are available. This is the default when the `-mips3' option is used.

`-mgp32`

Assume that 32 32-bit general purpose registers are available. This is the default.

`-mgp64`

Assume that 32 64-bit general purpose registers are available. This is the default when the `-mips3' option is used.

`-mint64`

Types long, int, and pointer are 64 bits. This works only if `-mips3' is also specified.

`-mlong64`

Types long and pointer are 64 bits, and type int is 32 bits. This works only if `-mips3' is also specified.

`-mmips-as`

Generate code for the MIPS assembler, and invoke `mips-tfile' to add normal debug

information. This is the default for all platforms except for the OSF/1 reference platform, using OSF/rose object format. If the either of the `-gstabs' or `-gstabs+' switches are used, the `mips-tfile' program will encapsulate the stabs within MIPS ECOFF.

`-mgas`

Generate code for the GNU assembler. This is the default on the OSF/1 reference platform, using the OSF/rose object format.

`-mrnames`

`-mno-rnames`

The `-mrnames' switch says to output code using the MIPS software names for the registers, instead of the hardware names (ie, a0 instead of $4). The only known assembler that supports this option is the Algorithmics assembler.

`-mgpopt`

`-mno-gpopt`

The `-mgpopt' switch says to write all of the data declarations before the instructions in the text section, this allows the MIPS assembler to generate one word memory references instead of using two words for short global or static data items. This is on by default if optimization is selected.

`-mstats`

`-mno-stats`

For each non-inline function processed, the `-mstats' switch causes the compiler to emit one line to the standard error file to print statistics about the program (number of registers saved, stack size, etc.).

`-mmemcpy`

`-mno-memcpy`

The `-mmemcpy' switch makes all block moves call the appropriate string function (`memcpy' or `bcopy') instead of possibly generating inline code.

`-mmips-tfile`

`-mno-mips-tfile`

The `-mno-mips-tfile' switch causes the compiler not postprocess the object file with the `mips-tfile' program, after the MIPS assembler has generated it to add debug support. If `mips-tfile' is not run, then no local variables will be available to the debugger. In addition, `stage2' and `stage3' objects will have the temporary file names passed to the assembler embedded in the object file, which means the objects will not compare the same. The `-mno-mips-tfile' switch should only be used when there are bugs in the `mips-tfile' program that prevents compilation.

`-msoft-float`

Generate output containing library calls for floating point. **Warning:** the requisite libraries are not part of GNU CC. Normally the facilities of the machine's usual C compiler are used, but this can't be done directly in cross-compilation. You must make your own arrangements to provide suitable library functions for cross-compilation.

`-mhard-float`

Generate output containing floating point instructions. This is the default if you use the unmodified

sources.

`-mabicalls`

`-mno-abicalls`

Emit (or do not emit) the pseudo operations `.abicalls', `.cpload', and `.cprestore' that some System V.4 ports use for position independent code.

`-mlong-calls`

`-mno-long-calls`

Do all calls with the `JALR' instruction, which requires loading up a function's address into a register before the call. You need to use this switch, if you call outside of the current 512 megabyte segment to functions that are not through pointers.

`-mhalf-pic`

`-mno-half-pic`

Put pointers to extern references into the data section and load them up, rather than put the references in the text section.

`-membedded-pic`

`-mno-embedded-pic`

Generate PIC code suitable for some embedded systems. All calls are made using PC relative address, and all data is addressed using the $gp register. This requires GNU as and GNU ld which do most of the work.

`-membedded-data`

`-mno-embedded-data`

Allocate variables to the read-only data section first if possible, then next in the small data section if possible, otherwise in data. This gives slightly slower code than the default, but reduces the amount of RAM required when executing, and thus may be preferred for some embedded systems.

`-msingle-float`

`-mdouble-float`

The `-msingle-float' switch tells gcc to assume that the floating point coprocessor only supports single precision operations, as on the `r4650' chip. The `-mdouble-float' switch permits gcc to use double precision operations. This is the default.

`-mmad`

`-mno-mad`

Permit use of the `mad', `madu' and `mul' instructions, as on the `r4650' chip.

`-m4650`

Turns on `-msingle-float', `-mmad', and, at least for now, `-mcpu=r4650'.

`-EL`

Compile code for the processor in little endian mode. The requisite libraries are assumed to exist.

`-EB`

Compile code for the processor in big endian mode. The requisite libraries are assumed to exist.

`-G num`

Put global and static items less than or equal to num bytes into the small data or bss sections instead of the normal data or bss section. This allows the assembler to emit one word memory reference instructions based on the global pointer (gp or $28), instead of the normal two words used. By default, num is 8 when the MIPS assembler is used, and 0 when the GNU assembler is used. The `-G num' switch is also passed to the assembler and linker. All modules should be compiled with the same `-G num' value.

`-nocpp`

Tell the MIPS assembler to not run it's preprocessor over user assembler files (with a `.s' suffix) when assembling them.

These options are defined by the macro `TARGET_SWITCHES` in the machine description. The default for the options is also defined by that macro, which enables you to change the defaults.

Intel 386 Options

These `-m' options are defined for the i386 family of computers:

`-m486`

`-m386`

Control whether or not code is optimized for a 486 instead of an 386. Code generated for an 486 will run on a 386 and vice versa.

`-mieee-fp`

`-mno-ieee-fp`

Control whether or not the compiler uses IEEE floating point comparisons. These handle correctly the case where the result of a comparison is unordered.

`-msoft-float`

Generate output containing library calls for floating point. **Warning:** the requisite libraries are not part of GNU CC. Normally the facilities of the machine's usual C compiler are used, but this can't be done directly in cross-compilation. You must make your own arrangements to provide suitable library functions for cross-compilation.

On machines where a function returns floating point results in the 80387 register stack, some floating point opcodes may be emitted even if `-msoft-float' is used.

`-mno-fp-ret-in-387`

Do not use the FPU registers for return values of functions.

The usual calling convention has functions return values of types `float` and `double` in an FPU register, even if there is no FPU. The idea is that the operating system should emulate an FPU.

The option `-mno-fp-ret-in-387' causes such values to be returned in ordinary CPU registers instead.

`-mno-fancy-math-387`

Some 387 emulators do not support the `sin`, `cos` and `sqrt` instructions for the 387. Specify this option to avoid generating those instructions. This option is the default on FreeBSD. As of revision 2.6.1, these instructions are not generated unless you also use the `-ffast-math' switch.

`-malign-double`

`-mno-align-double`

Control whether GNU CC aligns `double`, `long double`, and `long long` variables on a two word boundary or a one word boundary. Aligning `double` variables on a two word boundary will produce code that runs somewhat faster on a `Pentium' at the expense of more memory.

Warning: if you use the `-malign-double' switch, structures containing the above types will be aligned differently than the published application binary interface specifications for the 386.

`-msvr3-shlib`

`-mno-svr3-shlib`

Control whether GNU CC places uninitialized locals into `bss` or `data`. `-msvr3-shlib' places these locals into `bss`. These options are meaningful only on System V Release 3.

`-mno-wide-multiply`

`-mwide-multiply`

Control whether GNU CC uses the `mul` and `imul` that produce 64 bit results in `eax:edx` from 32 bit operands to do `long long` multiplies and 32-bit division by constants.

`-mrtd`

Use a different function-calling convention, in which functions that take a fixed number of arguments return with the `ret` num instruction, which pops their arguments while returning. This saves one instruction in the caller since there is no need to pop the arguments there.

You can specify that an individual function is called with this calling sequence with the function attribute `stdcall'. You can also override the `-mrtd' option by using the function attribute `cdecl'. See section Declaring Attributes of Functions

Warning: this calling convention is incompatible with the one normally used on Unix, so you cannot use it if you need to call libraries compiled with the Unix compiler.

Also, you must provide function prototypes for all functions that take variable numbers of arguments (including `printf`); otherwise incorrect code will be generated for calls to those functions.

In addition, seriously incorrect code will result if you call a function with too many arguments. (Normally, extra arguments are harmlessly ignored.)

`-mreg-alloc=regs`

Control the default allocation order of integer registers. The string regs is a series of letters specifying a register. The supported letters are: `a` allocate EAX; `b` allocate EBX; `c` allocate ECX; `d` allocate EDX; `S` allocate ESI; `D` allocate EDI; `B` allocate EBP.

`-mregparm=num`

Control how many registers are used to pass integer arguments. By default, no registers are used to pass arguments, and at most 3 registers can be used. You can control this behavior for a specific function by using the function attribute `regparm'. See section Declaring Attributes of Functions

Warning: if you use this switch, and num is nonzero, then you must build all modules with the same value, including any libraries. This includes the system libraries and startup modules.

`-malign-loops=num`

Align loops to a 2 raised to a num byte boundary. If `-malign-loops' is not specified, the default is 2.

`-malign-jumps=num`

Align instructions that are only jumped to to a 2 raised to a num byte boundary. If `-malign-jumps' is not specified, the default is 2 if optimizing for a 386, and 4 if optimizing for a 486.

`-malign-functions=num`

Align the start of functions to a 2 raised to num byte boundary. If `-malign-jumps' is not specified, the default is 2 if optimizing for a 386, and 4 if optimizing for a 486.

HPPA Options

These `-m' options are defined for the HPPA family of computers:

`-mpa-risc-1-0`

Generate code for a PA 1.0 processor.

`-mpa-risc-1-1`

Generate code for a PA 1.1 processor.

`-mjump-in-delay`

Fill delay slots of function calls with unconditional jump instructions by modifying the return pointer for the function call to be the target of the conditional jump.

`-mmillicode-long-calls`

Generate code which assumes millicode routines can not be reached by the standard millicode call sequence, linker-generated long-calls, or linker-modified millicode calls. In practice this should only be needed for dynamicly linked executables with extremely large SHLIB_INFO sections.

`-mdisable-fpregs`

Prevent floating point registers from being used in any manner. This is necessary for compiling kernels which perform lazy context switching of floating point registers. If you use this option and attempt to perform floating point operations, the compiler will abort.

`-mdisable-indexing`

Prevent the compiler from using indexing address modes. This avoids some rather obscure problems when compiling MIG generated code under MACH.

`-mfast-indirect-calls`

Generate code which performs faster indirect calls. Such code is suitable for kernels and for static linking. The fast indirect call code will fail miserably if it's part of a dynamically linked executable and in the presense of nested functions.

`-mportable-runtime`

Use the portable calling conventions proposed by HP for ELF systems.

`-mgas`

Enable the use of assembler directives only GAS understands.

`-mschedule=cpu type`

Schedule code according to the constraints for the machine type cpu type. The choices for cpu type

are `700' for 7n0 machines, `7100' for 7n5 machines, and `7100' for 7n2 machines. `700' is the default for cpu type.

Note the `7100LC' scheduling information is incomplete and using `7100LC' often leads to bad schedules. For now it's probably best to use `7100' instead of `7100LC' for the 7n2 machines.

`-msoft-float`

Generate output containing library calls for floating point. **Warning:** the requisite libraries are not available for all HPPA targets. Normally the facilities of the machine's usual C compiler are used, but this cannot be done directly in cross-compilation. You must make your own arrangements to provide suitable library functions for cross-compilation. The embedded target `hppa1.1-*-pro' does provide software floating point support.

`-msoft-float' changes the calling convention in the output file; therefore, it is only useful if you compile *all* of a program with this option. In particular, you need to compile `libgcc.a', the library that comes with GNU CC, with `-msoft-float' in order for this to work.

Intel 960 Options

These `-m' options are defined for the Intel 960 implementations:

`-mcpu type`

Assume the defaults for the machine type cpu type for some of the other options, including instruction scheduling, floating point support, and addressing modes. The choices for cpu type are `ka', `kb', `mc', `ca', `cf', `sa', and `sb'. The default is `kb'.

`-mnumerics`

`-msoft-float`

The `-mnumerics' option indicates that the processor does support floating-point instructions. The `-msoft-float' option indicates that floating-point support should not be assumed.

`-mleaf-procedures`

`-mno-leaf-procedures`

Do (or do not) attempt to alter leaf procedures to be callable with the `bal` instruction as well as `call`. This will result in more efficient code for explicit calls when the `bal` instruction can be substituted by the assembler or linker, but less efficient code in other cases, such as calls via function pointers, or using a linker that doesn't support this optimization.

`-mtail-call`

`-mno-tail-call`

Do (or do not) make additional attempts (beyond those of the machine-independent portions of the compiler) to optimize tail-recursive calls into branches. You may not want to do this because the detection of cases where this is not valid is not totally complete. The default is `-mno-tail-call'.

`-mcomplex-addr`

`-mno-complex-addr`

Assume (or do not assume) that the use of a complex addressing mode is a win on this implementation of the i960. Complex addressing modes may not be worthwhile on the K-series, but they definitely are on the C-series. The default is currently `-mcomplex-addr' for all processors

except the CB and CC.

`-mcode-align`

`-mno-code-align`

Align code to 8-byte boundaries for faster fetching (or don't bother). Currently turned on by default for C-series implementations only.

`-mic-compat`

`-mic2.0-compat`

`-mic3.0-compat`

Enable compatibility with iC960 v2.0 or v3.0.

`-masm-compat`

`-mintel-asm`

Enable compatibility with the iC960 assembler.

`-mstrict-align`

`-mno-strict-align`

Do not permit (do permit) unaligned accesses.

`-mold-align`

Enable structure-alignment compatibility with Intel's gcc release version 1.3 (based on gcc 1.37). Currently this is buggy in that `#pragma align 1' is always assumed as well, and cannot be turned off.

DEC Alpha Options

These `-m' options are defined for the DEC Alpha implementations:

`-mno-soft-float`

`-msoft-float`

Use (do not use) the hardware floating-point instructions for floating-point operations. When `-msoft-float` is specified, functions in `` `libgcc1.c' `` will be used to perform floating-point operations. Unless they are replaced by routines that emulate the floating-point operations, or compiled in such a way as to call such emulations routines, these routines will issue floating-point operations. If you are compiling for an Alpha without floating-point operations, you must ensure that the library is built so as not to call them.

Note that Alpha implementations without floating-point operations are required to have floating-point registers.

`-mfp-reg`

`-mno-fp-regs`

Generate code that uses (does not use) the floating-point register set. `-mno-fp-regs` implies `-msoft-float`. If the floating-point register set is not used, floating point operands are passed in integer registers as if they were integers and floating-point results are passed in $0 instead of $f0. This is a non-standard calling sequence, so any function with a floating-point argument or return value called by code compiled with `-mno-fp-regs` must also be compiled with that option.

A typical use of this option is building a kernel that does not use, and hence need not save and restore, any floating-point registers.

Clipper Options

These `-m' options are defined for the Clipper implementations:

`-mc300`

Produce code for a C300 Clipper processor. This is the default.

`-mc400`

Produce code for a C400 Clipper processor i.e. use floating point registers f8..f15.

H8/300 Options

These `-m' options are defined for the H8/300 implementations:

`-mrelax`

Shorten some address references at link time, when possible; uses the linker option `-relax'. See section '`ld` and the H8/300' in Using ld, for a fuller description.

`-mh`

Generate code for the H8/300H.

Options for System V

These additional options are available on System V Release 4 for compatibility with other compilers on those systems:

`-Qy`

Identify the versions of each tool used by the compiler, in a `.ident` assembler directive in the output.

`-Qn`

Refrain from adding `.ident` directives to the output file (this is the default).

`-YP,dirs`

Search the directories dirs, and no others, for libraries specified with `-l'.

`-Ym,dir`

Look in the directory dir to find the M4 preprocessor. The assembler uses this option.

Options for Code Generation Conventions

These machine-independent options control the interface conventions used in code generation.

Most of them have both positive and negative forms; the negative form of `-ffoo' would be `-fno-foo'. In the table below, only one of the forms is listed--the one which is not the default. You can figure out the other form by either removing `no-' or adding it.

`-fpcc-struct-return`

Return "short" `struct` and `union` values in memory like longer ones, rather than in registers. This convention is less efficient, but it has the advantage of allowing intercallability between GNU CC-compiled files and files compiled with other compilers.

The precise convention for returning structures in memory depends on the target configuration macros.

Short structures and unions are those whose size and alignment match that of some integer type.

`-freg-struct-return`

Use the convention that `struct` and `union` values are returned in registers when possible. This is more efficient for small structures than `-fpcc-struct-return'.

If you specify neither `-fpcc-struct-return' nor its contrary `-freg-struct-return', GNU CC defaults to whichever convention is standard for the target. If there is no standard convention, GNU CC defaults to `-fpcc-struct-return', except on targets where GNU CC is the principal compiler. In those cases, we can choose the standard, and we chose the more efficient register return alternative.

`-fshort-enums`

Allocate to an `enum` type only as many bytes as it needs for the declared range of possible values. Specifically, the `enum` type will be equivalent to the smallest integer type which has enough room.

`-fshort-double`

Use the same size for `double` as for `float`.

`-fshared-data`

Requests that the data and non-`const` variables of this compilation be shared data rather than private data. The distinction makes sense only on certain operating systems, where shared data is shared between processes running the same program, while private data exists in one copy per process.

`-fno-common`

Allocate even uninitialized global variables in the bss section of the object file, rather than generating them as common blocks. This has the effect that if the same variable is declared (without `extern`) in two different compilations, you will get an error when you link them. The only reason this might be useful is if you wish to verify that the program will work on other systems which always work this way.

`-fno-ident`

Ignore the `#ident' directive.

`-fno-gnu-linker`

Do not output global initializations (such as C++ constructors and destructors) in the form used by the GNU linker (on systems where the GNU linker is the standard method of handling them). Use this option when you want to use a non-GNU linker, which also requires using the `collect2` program to make sure the system linker includes constructors and destructors. (`collect2` is included in the GNU CC distribution.) For systems which *must* use `collect2`, the compiler driver `gcc` is configured to do this automatically.

`-finhibit-size-directive`

Don't output a `.size` assembler directive, or anything else that would cause trouble if the func is split in the middle, and the two halves are placed at locations far apart in memory. This optio used when compiling `` `crtstuff.c' ``; you should not need to use it for anything else.

`-fverbose-asm`

Put extra commentary information in the generated assembly code to make it more readable. This option is generally only of use to those who actually need to read the generated assembly code (perhaps while debugging the compiler itself).

`-fvolatile`

Consider all memory references through pointers to be volatile.

`-fvolatile-global`

Consider all memory references to extern and global data items to be volatile.

`-fpic`

Generate position-independent code (PIC) suitable for use in a shared library, if supported for the target machine. Such code accesses all constant addresses through a global offset table (GOT). If the GOT size for the linked executable exceeds a machine-specific maximum size, you get an error message from the linker indicating that `-fpic' does not work; in that case, recompile with `-fPIC' instead. (These maximums are 16k on the m88k, 8k on the Sparc, and 32k on the m68k and RS/6000. The 386 has no such limit.)

Position-independent code requires special support, and therefore works only on certain machines. For the 386, GNU CC supports PIC for System V but not for the Sun 386i. Code generated for the IBM RS/6000 is always position-independent.

The GNU assembler does not fully support PIC. Currently, you must use some other assembler in order for PIC to work. We would welcome volunteers to upgrade GAS to handle this; the first part of the job is to figure out what the assembler must do differently.

`-fPIC`

If supported for the target machine, emit position-independent code, suitable for dynamic linking and avoiding any limit on the size of the global offset table. This option makes a difference on the m68k, m88k and the Sparc.

Position-independent code requires special support, and therefore works only on certain machines.

`-ffixed-reg`

Treat the register named reg as a fixed register; generated code should never refer to it (except perhaps as a stack pointer, frame pointer or in some other fixed role).

reg must be the name of a register. The register names accepted are machine-specific and are defined in the `REGISTER_NAMES` macro in the machine description macro file.

This flag does not have a negative form, because it specifies a three-way choice.

`-fcall-used-reg`

Treat the register named reg as an allocatable register that is clobbered by function calls. It may be allocated for temporaries or variables that do not live across a call. Functions compiled this way will not save and restore the register reg.

Use of this flag for a register that has a fixed pervasive role in the machine's execution model, s as the stack pointer or frame pointer, will produce disastrous results.

This flag does not have a negative form, because it specifies a three-way choice.

`-fcall-saved-reg`

Treat the register named reg as an allocatable register saved by functions. It may be allocated even for temporaries or variables that live across a call. Functions compiled this way will save and restore the register reg if they use it.

Use of this flag for a register that has a fixed pervasive role in the machine's execution model, such as the stack pointer or frame pointer, will produce disastrous results.

A different sort of disaster will result from the use of this flag for a register in which function values may be returned.

This flag does not have a negative form, because it specifies a three-way choice.

`-fpack-struct`

Pack all structure members together without holes. Usually you would not want to use this option, since it makes the code suboptimal, and the offsets of structure members won't agree with system libraries.

`+e0`

`+e1`

Control whether virtual function definitions in classes are used to generate code, or only to define interfaces for their callers. (C++ only).

These options are provided for compatibility with `cfront` 1.x usage; the recommended alternative GNU C++ usage is in flux. See section Declarations and Definitions in One Header.

With `+e0', virtual function definitions in classes are declared `extern`; the declaration is used only as an interface specification, not to generate code for the virtual functions (in this compilation).

With `+e1', G++ actually generates the code implementing virtual functions defined in the code, and makes them publicly visible.

Environment Variables Affecting GNU CC

This section describes several environment variables that affect how GNU CC operates. They work by specifying directories or prefixes to use when searching for various kinds of files.

Note that you can also specify places to search using options such as `-B', `-I' and `-L' (see section Options for Directory Search). These take precedence over places specified using environment variables, which in turn take precedence over those specified by the configuration of GNU CC. See section Controlling the Compilation Driver, `gcc'.

`TMPDIR`

If `TMPDIR` is set, it specifies the directory to use for temporary files. GNU CC uses temporary files

to hold the output of one stage of compilation which is to be used as input to the next stage: for example, the output of the preprocessor, which is the input to the compiler proper.

`GCC_EXEC_PREFIX`

If `GCC_EXEC_PREFIX` is set, it specifies a prefix to use in the names of the subprograms executed by the compiler. No slash is added when this prefix is combined with the name of a subprogram, but you can specify a prefix that ends with a slash if you wish.

If GNU CC cannot find the subprogram using the specified prefix, it tries looking in the usual places for the subprogram.

The default value of `GCC_EXEC_PREFIX` is `` `prefix/lib/gcc-lib/' `` where prefix is the value of `prefix` when you ran the `` `configure' `` script.

Other prefixes specified with `-B' take precedence over this prefix.

This prefix is also used for finding files such as `` `crt0.o' `` that are used for linking.

In addition, the prefix is used in an unusual way in finding the directories to search for header files. For each of the standard directories whose name normally begins with `/usr/local/lib/gcc-lib' (more precisely, with the value of `GCC_INCLUDE_DIR`), GNU CC tries replacing that beginning with the specified prefix to produce an alternate directory name. Thus, with `-Bfoo/', GNU CC will search `` `foo/bar' `` where it would normally search `` `/usr/local/lib/bar' ``. These alternate directories are searched first; the standard directories come next.

`COMPILER_PATH`

The value of `COMPILER_PATH` is a colon-separated list of directories, much like `PATH`. GNU CC tries the directories thus specified when searching for subprograms, if it can't find the subprograms using `GCC_EXEC_PREFIX`.

`LIBRARY_PATH`

The value of `LIBRARY_PATH` is a colon-separated list of directories, much like `PATH`. When configured as a native compiler, GNU CC tries the directories thus specified when searching for special linker files, if it can't find them using `GCC_EXEC_PREFIX`. Linking using GNU CC also uses these directories when searching for ordinary libraries for the `-l' option (but directories specified with `-L' come first).

`C_INCLUDE_PATH`

`CPLUS_INCLUDE_PATH`

`OBJC_INCLUDE_PATH`

These environment variables pertain to particular languages. Each variable's value is a colon-separated list of directories, much like `PATH`. When GNU CC searches for header files, it tries the directories listed in the variable for the language you are using, after the directories specified with `-I' but before the standard header file directories.

`DEPENDENCIES_OUTPUT`

If this variable is set, its value specifies how to output dependencies for Make based on the header files processed by the compiler. This output looks much like the output from the `-M' option (see section Options Controlling the Preprocessor), but it goes to a separate file, and is in addition to the usual results of compilation.

The value of `DEPENDENCIES_OUTPUT` can be just a file name, in which case the Make rules are written to that file, guessing the target name from the source file name. Or the value can have the form `file target', in which case the rules are written to file file using target as the target name.

Running Protoize

The program `protoize` is an optional part of GNU C. You can use it to add prototypes to a program, thus converting the program to ANSI C in one respect. The companion program `unprotoize` does the reverse: it removes argument types from any prototypes that are found.

When you run these programs, you must specify a set of source files as command line arguments. The conversion programs start out by compiling these files to see what functions they define. The information gathered about a file foo is saved in a file named `` `foo.X' ``.

After scanning comes actual conversion. The specified files are all eligible to be converted; any files they include (whether sources or just headers) are eligible as well.

But not all the eligible files are converted. By default, `protoize` and `unprotoize` convert only source and header files in the current directory. You can specify additional directories whose files should be converted with the `-d directory' option. You can also specify particular files to exclude with the `-x file' option. A file is converted if it is eligible, its directory name matches one of the specified directory names, and its name within the directory has not been excluded.

Basic conversion with `protoize` consists of rewriting most function definitions and function declarations to specify the types of the arguments. The only ones not rewritten are those for varargs functions.

`protoize` optionally inserts prototype declarations at the beginning of the source file, to make them available for any calls that precede the function's definition. Or it can insert prototype declarations with block scope in the blocks where undeclared functions are called.

Basic conversion with `unprotoize` consists of rewriting most function declarations to remove any argument types, and rewriting function definitions to the old-style pre-ANSI form.

Both conversion programs print a warning for any function declaration or definition that they can't convert. You can suppress these warnings with `-q'.

The output from `protoize` or `unprotoize` replaces the original source file. The original file is renamed to a name ending with `.save'. If the `.save' file already exists, then the source file is simply discarded.

`protoize` and `unprotoize` both depend on GNU CC itself to scan the program and collect information about the functions it uses. So neither of these programs will work until GNU CC is installed.

Here is a table of the options you can use with `protoize` and `unprotoize`. Each option works with both programs unless otherwise stated.

`-B directory`

Look for the file `` `SYSCALLS.c.X' `` in directory, instead of the usual directory (normally

`/usr/local/lib'). This file contains prototype information about standard system functi
This option applies only to `protoize`.

`-c compilation-options`

Use compilation-options as the options when running `gcc` to produce the `.X' files. The special option `-aux-info' is always passed in addition, to tell `gcc` to write a `.X' file.

Note that the compilation options must be given as a single argument to `protoize` or `unprotoize`. If you want to specify several `gcc` options, you must quote the entire set of compilation options to make them a single word in the shell.

There are certain `gcc` arguments that you cannot use, because they would produce the wrong kind of output. These include `-g', `-O', `-c', `-S', and `-o' If you include these in the compilation-options, they are ignored.

`-C`

Rename files to end in `.C' instead of `.c'. This is convenient if you are converting a C program to C++. This option applies only to `protoize`.

`-g`

Add explicit global declarations. This means inserting explicit declarations at the beginning of each source file for each function that is called in the file and was not declared. These declarations precede the first function definition that contains a call to an undeclared function. This option applies only to `protoize`.

`-i string`

Indent old-style parameter declarations with the string string. This option applies only to `protoize`.

`unprotoize` converts prototyped function definitions to old-style function definitions, where the arguments are declared between the argument list and the initial `{'. By default, `unprotoize` uses five spaces as the indentation. If you want to indent with just one space instead, use `-i " "'.

`-k`

Keep the `.X' files. Normally, they are deleted after conversion is finished.

`-l`

Add explicit local declarations. `protoize` with `-l' inserts a prototype declaration for each function in each block which calls the function without any declaration. This option applies only to `protoize`.

`-n`

Make no real changes. This mode just prints information about the conversions that would have been done without `-n'.

`-N`

Make no `.save' files. The original files are simply deleted. Use this option with caution.

`-p program`

Use the program program as the compiler. Normally, the name `gcc' is used.

`-q`

Work quietly. Most warnings are suppressed.

`-v`

Print the version number, just like `-v' for `gcc`.

If you need special compiler options to compile one of your program's source files, then you should generate that file's `.X' file specially, by running `gcc` on that source file with the appropriate options and the option `-aux-info'. Then run `protoize` on the entire set of files. `protoize` will use the existing `.X' file because it is newer than the source file. For example:

```
gcc -Dfoo=bar file1.c -aux-info
protoize *.c
```

You need to include the special files along with the rest in the `protoize` command, even though their `.X' files already exist, because otherwise they won't get converted.

See section Caveats of using `protoize`, for more information on how to use `protoize` successfully.

Go to the previous, next section.

Go to the previous, next section.

Installing GNU CC

Here is the procedure for installing GNU CC on a Unix system. See section Installing GNU CC on VMS, for VMS systems. In this section we assume you compile in the same directory that contains the source files; see section Compilation in a Separate Directory, to find out how to compile in a separate directory on Unix systems.

You cannot install GNU C by itself on MSDOS; it will not compile under any MSDOS compiler except itself. You need to get the complete compilation package DJGPP, which includes binaries as well as sources, and includes all the necessary compilation tools and libraries.

1. If you have built GNU CC previously in the same directory for a different target machine, do `make distclean' to delete all files that might be invalid. One of the files this deletes is `Makefile'; if `make distclean' complains that `Makefile' does not exist, it probably means that the directory is already suitably clean.
2. On a System V release 4 system, make sure `/usr/bin' precedes `/usr/ucb' in PATH. The cc command in `/usr/ucb' uses libraries which have bugs.
3. Specify the host, build and target machine configurations. You do this by running the file `configure'.

   The build machine is the system which you are using, the host machine is the system where you want to run the resulting compiler (normally the build machine), and the target machine is the system for which you want the compiler to generate code.

   If you are building a compiler to produce code for the machine it runs on (a native compiler), you normally do not need to specify any operands to `configure'; it will try to guess the type of machine you are on and use that as the build, host and target machines. So you don't need to specify a configuration when building a native compiler unless `configure' cannot figure out what your configuration is or guesses wrong.

   In those cases, specify the build machine's configuration name with the `--build' option; the host and target will default to be the same as the build machine. (If you are building a cross-compiler, see section Building and Installing a Cross-Compiler.)

   Here is an example:

   from an MSDOS console window or from the program manager dialog box. Configure.bat assumes that you have already installed and in your path a Unix-like sed program which is used to modify Makefile.in to create a working Makefile.@smallexample ./configure --build=sparc-sun-sunos4.1

   A configuration name may be canonical or it may be more or less abbreviated.

   A canonical configuration name has three parts, separated by dashes. It looks like this: `cpu-company-system'. (The three parts may themselves contain dashes; `configure' can figure out which dashes serve which purpose.) For example, `m68k-sun-sunos4.1' specifies a Sun 3.

   You can also replace parts of the configuration by nicknames or aliases. For example, `sun3' stands for `m68k-sun', so `sun3-sunos4.1' is another way to specify a Sun 3. You can also use simply `sun3-sunos', since the version of SunOS is assumed by default to be version 4. `sun3-bsd' also works, since

`configure' knows that the only BSD variant on a Sun 3 is SunOS.

You can specify a version number after any of the system types, and some of the CPU types. In most cases, the version is irrelevant, and will be ignored. So you might as well specify the version if you know it.

See section Configurations Supported by GNU CC, for a list of supported configuration names and notes on many of the configurations. You should check the notes in that section before proceeding any further with the installation of GNU CC.

There are four additional options you can specify independently to describe variant hardware and software configurations. These are `--with-gnu-as', `--with-gnu-ld', `--with-stabs' and `--nfp'.

`--with-gnu-as'

If you will use GNU CC with the GNU assembler (GAS), you should declare this by using the `--with-gnu-as' option when you run `configure'.

Using this option does not install GAS. It only modifies the output of GNU CC to work with GAS. Building and installing GAS is up to you.

Conversely, if you *do not* wish to use GAS and do not specify `--with-gnu-as' when building GNU CC, it is up to you to make sure that GAS is not installed. GNU CC searches for a program named `as` in various directories; if the program it finds is GAS, then it runs GAS. If you are not sure where GNU CC finds the assembler it is using, try specifying `-v' when you run it.

The systems where it makes a difference whether you use GAS are `hppa1.0-any-any', `hppa1.1-any-any', `i386-any-sysv', `i386-any-isc', `i860-any-bsd', `m68k-bull-sysv', `m68k-hp-hpux', `m68k-sony-bsd', `m68k-altos-sysv', `m68000-hp-hpux', `m68000-att-sysv', `any-lynx-lynxos', and `mips-any'). On any other system, `--with-gnu-as' has no effect.

On the systems listed above (except for the HP-PA, for ISC on the 386, and for `mips-sgi-irix5.*'), if you use GAS, you should also use the GNU linker (and specify `--with-gnu-ld').

`--with-gnu-ld'

Specify the option `--with-gnu-ld' if you plan to use the GNU linker with GNU CC.

This option does not cause the GNU linker to be installed; it just modifies the behavior of GNU CC to work with the GNU linker. Specifically, it inhibits the installation of `collect2`, a program which otherwise serves as a front-end for the system's linker on most configurations.

`--with-stabs'

On MIPS based systems and on Alphas, you must specify whether you want GNU CC to create the normal ECOFF debugging format, or to use BSD-style stabs passed through the ECOFF symbol table. The normal ECOFF debug format cannot fully handle languages other than C. BSD stabs format can handle other languages, but it only works with the GNU debugger GDB.

Normally, GNU CC uses the ECOFF debugging format by default; if you prefer BSD stabs, specify `--with-stabs' when you configure GNU CC.

No matter which default you choose when you configure GNU CC, the user can use the `-gcoff' and `-gstabs+' options to specify explicitly the debug format for a particular compilation.

`--with-stabs' is meaningful on the ISC system on the 386, also, if `--with-gas' is used. It selects use

of stabs debugging information embedded in COFF output. This kind of debugging information supports C++ well; ordinary COFF debugging information does not.

`--with-stabs' is also meaningful on 386 systems running SVR4. It selects use of stabs debugging information embedded in ELF output. The C++ compiler currently (2.6.0) does not support the DWARF debugging information normally used on 386 SVR4 platforms; stabs provide a workable alternative. This requires gas and gdb, as the normal SVR4 tools can not generate or interpret stabs.

`--nfp'

On certain systems, you must specify whether the machine has a floating point unit. These systems include `m68k-sun-sunosn' and `m68k-isi-bsd'. On any other system, `--nfp' currently has no effect, though perhaps there are other systems where it could usefully make a difference.

The `configure' script searches subdirectories of the source directory for other compilers that are to be integrated into GNU CC. The GNU compiler for C++, called G++ is in a subdirectory named `cp'. `configure' inserts rules into `Makefile' to build all of those compilers.

Here we spell out what files will be set up by `configure`. Normally you need not be concerned with these files.

- A symbolic link named `config.h' is made to the top-level config file for the machine you will run the compiler on (see section The Configuration File). This file is responsible for defining information about the host machine. It includes `tm.h'.

  The top-level config file is located in the subdirectory `config'. Its name is always `xm-something.h'; usually `xm-machine.h', but there are some exceptions.

  If your system does not support symbolic links, you might want to set up `config.h' to contain a `#include' command which refers to the appropriate file.
- A symbolic link named `tconfig.h' is made to the top-level config file for your target machine. This is used for compiling certain programs to run on that machine.
- A symbolic link named `tm.h' is made to the machine-description macro file for your target machine. It should be in the subdirectory `config' and its name is often `machine.h'.
- A symbolic link named `md' will be made to the machine description pattern file. It should be in the `config' subdirectory and its name should be `machine.md'; but machine is often not the same as the name used in the `tm.h' file because the `md' files are more general.
- A symbolic link named `aux-output.c' will be made to the output subroutine file for your machine. It should be in the `config' subdirectory and its name should be `machine.c'.
- The command file `configure' also constructs the file `Makefile' by adding some text to the template file `Makefile.in'. The additional text comes from files in the `config' directory, named `t-target' and `x-host'. If these files do not exist, it means nothing needs to be added for a given target or host.

4. The standard directory for installing GNU CC is `/usr/local/lib'. If you want to install its files somewhere else, specify `--prefix=dir' when you run `configure'. Here dir is a directory name to use instead of `/usr/local' for all purposes with one exception: the directory `/usr/local/include' is searched for header files no matter where you install the compiler. To override this name, use the `--local-prefix` option below.
5. Specify `--local-prefix=dir' if you want the compiler to search directory `dir/include' for locally installed header files *instead* of `/usr/local/include'.

You should specify `--local-prefix' **only** if your site has a different convention (not `/usr/local' where to put site-specific files.

Do not specify `/usr' as the `--local-prefix'! The directory you use for `--local-prefix' **must not** contain any of the system's standard header files. If it did contain them, certain programs would be miscompiled (including GNU Emacs, on certain targets), because this would override and nullify the header file corrections made by the `fixincludes` script.

6. Make sure the Bison parser generator is installed. (This is unnecessary if the Bison output files `c-parse.c' and `cexp.c' are more recent than `c-parse.y' and `cexp.y' and you do not plan to change the `.y' files.)

   Bison versions older than Sept 8, 1988 will produce incorrect output for `c-parse.c'.

7. If you have chosen a configuration for GNU CC which requires other GNU tools (such as GAS or the GNU linker) instead of the standard system tools, install the required tools in the build directory under the names `as', `ld' or whatever is appropriate. This will enable the compiler to find the proper tools for compilation of the program `enquire'.

   Alternatively, you can do subsequent compilation using a value of the `PATH` environment variable such that the necessary GNU tools come before the standard system tools.

8. Build the compiler. Just type `make LANGUAGES=c' in the compiler directory.

   `LANGUAGES=c' specifies that only the C compiler should be compiled. The makefile normally builds compilers for all the supported languages; currently, C, C++ and Objective C. However, C is the only language that is sure to work when you build with other non-GNU C compilers. In addition, building anything but C at this stage is a waste of time.

   In general, you can specify the languages to build by typing the argument `LANGUAGES="list"', where list is one or more words from the list `c', `c++', and `objective-c'. If you have any additional GNU compilers as subdirectories of the GNU CC source directory, you may also specify their names in this list.

   Ignore any warnings you may see about "statement not reached" in `insn-emit.c'; they are normal. Also, warnings about "unknown escape sequence" are normal in `genopinit.c' and perhaps some other files. Likewise, you should ignore warnings about "constant is so large that it is unsigned" in `insn-emit.c' and `insn-recog.c'. Any other compilation errors may represent bugs in the port to your machine or operating system, and should be investigated and reported (see section Reporting Bugs).

   Some commercial compilers fail to compile GNU CC because they have bugs or limitations. For example, the Microsoft compiler is said to run out of macro space. Some Ultrix compilers run out of expression space; then you need to break up the statement where the problem happens.

9. If you are building a cross-compiler, stop here. See section Building and Installing a Cross-Compiler.

10. Move the first-stage object files and executables into a subdirectory with this command:

    ```
    make stage1
    ```

    The files are moved into a subdirectory named `stage1'. Once installation is complete, you may wish to delete these files with `rm -r stage1`.

11. If you have chosen a configuration for GNU CC which requires other GNU tools (such as GAS or the GNU linker) instead of the standard system tools, install the required tools in the `stage1' subdirectory

under the names `as', `ld' or whatever is appropriate. This will enable the stage 1 compiler to find the proper tools in the following stage.

Alternatively, you can do subsequent compilation using a value of the PATH environment variable such that the necessary GNU tools come before the standard system tools.

12. Recompile the compiler with itself, with this command:

```
make CC="stage1/xgcc -Bstage1/" CFLAGS="-g -O"
```

This is called making the stage 2 compiler.

The command shown above builds compilers for all the supported languages. If you don't want them all, you can specify the languages to build by typing the argument `LANGUAGES="list"'. list should contain one or more words from the list `c', `c++', `objective-c', and `proto'. Separate the words with spaces. `proto' stands for the programs protoize and unprotoize; they are not a separate language, but you use LANGUAGES to enable or disable their installation.

If you are going to build the stage 3 compiler, then you might want to build only the C language in stage 2.

Once you have built the stage 2 compiler, if you are short of disk space, you can delete the subdirectory `stage1'.

On a 68000 or 68020 system lacking floating point hardware, unless you have selected a `tm.h' file that expects by default that there is no such hardware, do this instead:

```
make CC="stage1/xgcc -Bstage1/" CFLAGS="-g -O -msoft-float"
```

13. If you wish to test the compiler by compiling it with itself one more time, install any other necessary GNU tools (such as GAS or the GNU linker) in the `stage2' subdirectory as you did in the `stage1' subdirectory, then do this:

```
make stage2
make CC="stage2/xgcc -Bstage2/" CFLAGS="-g -O2"
```

This is called making the stage 3 compiler. Aside from the `-B' option, the compiler options should be the same as when you made the stage 2 compiler. But the LANGUAGES option need not be the same. The command shown above builds compilers for all the supported languages; if you don't want them all, you can specify the languages to build by typing the argument `LANGUAGES="list"', as described above.

If you do not have to install any additional GNU tools, you may use the command

```
make bootstrap LANGUAGES=language-list BOOT_CFLAGS=option-list
```

instead of making `stage1', `stage2', and performing the two compiler builds.

14. Then compare the latest object files with the stage 2 object files--they ought to be identical, aside from time stamps (if any).

On some systems, meaningful comparison of object files is impossible; they always appear "different." This is currently true on Solaris and probably on all systems that use ELF object file format. On some versions of Irix on SGI machines and OSF/1 on Alpha systems, you will not be able to compare the files without specifying `-save-temps'; see the description of individual systems above to see if you get

comparison failures. You may have similar problems on other systems.

Use this command to compare the files:

```
make compare
```

This will mention any object files that differ between stage 2 and stage 3. Any difference, no matter how innocuous, indicates that the stage 2 compiler has compiled GNU CC incorrectly, and is therefore a potentially serious bug which you should investigate and report (see section Reporting Bugs).

If your system does not put time stamps in the object files, then this is a faster way to compare them (using the Bourne shell):

```
for file in *.o; do
cmp $file stage2/$file
done
```

If you have built the compiler with the `-mno-mips-tfile' option on MIPS machines, you will not be able to compare the files.

15. Build the Objective C library (if you have built the Objective C compiler). Here is the command to do this:

    ```
    make objc-runtime CC="stage2/xgcc -Bstage2/" CFLAGS="-g -O"
    ```

16. Install the compiler driver, the compiler's passes and run-time support with `make install'. Use the same value for `CC`, `CFLAGS` and `LANGUAGES` that you used when compiling the files that are being installed. One reason this is necessary is that some versions of Make have bugs and recompile files gratuitously when you do this step. If you use the same variable values, those files will be recompiled properly.

    For example, if you have built the stage 2 compiler, you can use the following command:

    ```
    make install CC="stage2/xgcc -Bstage2/" CFLAGS="-g -O" LANGUAGES="list"
    ```

    This copies the files `cc1', `cpp' and `libgcc.a' to files `cc1', `cpp' and `libgcc.a' in the directory `/usr/local/lib/gcc-lib/target/version', which is where the compiler driver program looks for them. Here target is the target machine type specified when you ran `configure', and version is the version number of GNU CC. This naming scheme permits various versions and/or cross-compilers to coexist.

    This also copies the driver program `xgcc' into `/usr/local/bin/gcc', so that it appears in typical execution search paths.

    On some systems, this command causes recompilation of some files. This is usually due to bugs in `make`. You should either ignore this problem, or use GNU Make.

    Warning: there is a bug in `alloca` in the Sun library. To avoid this bug, be sure to install the executables of GNU CC that were compiled by GNU CC. (That is, the executables from stage 2 or 3, not stage 1.) They use `alloca` as a built-in function and never the one in the library.

    (It is usually better to install GNU CC executables from stage 2 or 3, since they usually run faster than the ones compiled with some other compiler.)

17. Install the Objective C library (if you are installing the Objective C compiler). Here is the command to do this:

    ```
    make install-libobjc CC="stage2/xgcc -Bstage2/" CFLAGS="-g -O"
    ```

18. If you're going to use C++, it's likely that you need to also install the libg++ distribution. It should be available from the same place where you got the GNU C distribution. Just as GNU C does not distribute a C runtime library, it also does not include a C++ run-time library. All I/O functionality, special class libraries, etc., are available in the libg++ distribution.

Configurations Supported by GNU CC

Here are the possible CPU types:

> 1750a, a29k, alpha, arm, cn, clipper, dsp16xx, elxsi, h8300, hppa1.0, hppa1.1, i370, i386, i486, i586, i860, i960, m68000, m68k, m88k, mips, mipsel, mips64, mips64el, ns32k, powerpc, powerpcle, pyramid, romp, rs6000, sh, sparc, sparclite, sparc64, vax, we32k.

Here are the recognized company names. As you can see, customary abbreviations are used rather than the longer official names.

> acorn, alliant, altos, apollo, att, bull, cbm, convergent, convex, crds, dec, dg, dolphin, elxsi, encore, harris, hitachi, hp, ibm, intergraph, isi, mips, motorola, ncr, next, ns, omron, plexus, sequent, sgi, sony, sun, tti, unicom, wrs.

The company name is meaningful only to disambiguate when the rest of the information supplied is insufficient. You can omit it, writing just `cpu-system', if it is not needed. For example, `vax-ultrix4.2' is equivalent to `vax-dec-ultrix4.2'.

Here is a list of system types:

> 386bsd, aix, acis, amigados, aos, aout, bosx, bsd, clix, coff, ctix, cxux, dgux, dynix, ebmon, ecoff, elf, esix, freebsd, hms, genix, gnu, gnu/linux, hiux, hpux, iris, irix, isc, luna, lynxos, mach, minix, msdos, mvs, netbsd, newsos, nindy, ns, osf, osfrose, ptx, riscix, riscos, rtu, sco, sim, solaris, sunos, sym, sysv, udi, ultrix, unicos, uniplus, unos, vms, vsta, vxworks, winnt, xenix.

You can omit the system type; then `configure' guesses the operating system from the CPU and company.

You can add a version number to the system type; this may or may not make a difference. For example, you can write `bsd4.3' or `bsd4.4' to distinguish versions of BSD. In practice, the version number is most needed for `sysv3' and `sysv4', which are often treated differently.

If you specify an impossible combination such as `i860-dg-vms', then you may get an error message from `configure', or it may ignore part of the information and do the best it can with the rest. `configure' always prints the canonical name for the alternative that it used. GNU CC does not support all possible alternatives.

Often a particular model of machine has a name. Many machine names are recognized as aliases for CPU/company combinations. Thus, the machine name `sun3', mentioned above, is an alias for `m68k-sun'. Sometimes we accept a company name as a machine name, when the name is popularly used for a particular machine. Here is a table of the known machine names:

> 3300, 3b1, 3bn, 7300, altos3068, altos, apollo68, att-7300, balance, convex-cn, crds, decstation-3100, decstation, delta, encore, fx2800, gmicro, hp7nn, hp8nn, hp9k2nn, hp9k3nn,

hp9k7nn, hp9k8nn, iris4d, iris, isi68, m3230, magnum, merlin, miniframe, mmax, news-3600, news800, news, next, pbd, pc532, pmax, powerpc, powerpcle, ps2, risc-news, rtpc, sun2, sun386i, sun386, sun3, sun4, symmetry, tower-32, tower.

Remember that a machine name specifies both the cpu type and the company name. If you want to install your own homemade configuration files, you can use `local' as the company name to access them. If you use configuration `cpu-local', the configuration name without the cpu prefix is used to form the configuration file names.

Thus, if you specify `m68k-local', configuration uses files `m68k.md', `local.h', `m68k.c', `xm-local.h', `t-local', and `x-local', all in the directory `config/m68k'.

Here is a list of configurations that have special treatment or special things you must know:

`1750a-*-*'

MIL-STD-1750A processors.

Starting with GCC 2.6.1, the MIL-STD-1750A cross configuration no longer supports the Tektronix Assembler, but instead produces output for `as1750`, an assembler/linker available under the GNU Public License for the 1750A. Contact *okellogg@salyko.cube.net* for more details on obtaining `as1750'. A similarly licensed simulator for the 1750A is available from same address.

You should ignore a fatal error during the building of libgcc (libgcc is not yet implemented for the 1750A.)

The `as1750` assembler requires the file `ms1750.inc', which is found in the directory `config/1750a'.

GNU CC produced the same sections as the Fairchild F9450 C Compiler, namely:

`NREL`
: The program code section.

`SREL`
: The read/write (RAM) data section.

`KREL`
: The read-only (ROM) constants section.

`IREL`
: Initialization section (code to copy KREL to SREL).

The smallest addressable unit is 16 bits (BITS_PER_UNIT is 16). This means that type `char' is represented with a 16-bit word per character. The 1750A's "Load/Store Upper/Lower Byte" instructions are not used by GNU CC.

There is a problem with long argument lists to functions. The compiler aborts if the sum of space needed by all arguments exceeds 14 words. This is because the arguments are passed in registers (R0..R13) not on the stack, and there is a problem with passing further arguments (i.e. beyond those in R0..R13) via the stack.

If efficiency is less important than using long argument lists, you can change the definition of the `FUNCTION_ARG` macro in `config/1750/1750a.h' to always return zero. If you do that, GNU CC will pass all parameters on the stack.

- alpha-*-osf1 Systems using processors that implement the DEC Alpha architecture and are running the OSF/1

operating system, for example the DEC Alpha AXP systems. (VMS on the Alpha is not currently supported GNU CC.)

GNU CC writes a `.verstamp' directive to the assembler output file unless it is built as a cross-compiler. It gets the version to use from the system header file `/usr/include/stamp.h'. If you install a new version of OSF/1, you should rebuild GCC to pick up the new version stamp.

Note that since the Alpha is a 64-bit architecture, cross-compilers from 32-bit machines will not generate code as efficient as that generated when the compiler is running on a 64-bit machine because many optimizations that depend on being able to represent a word on the target in an integral value on the host cannot be performed. Building cross-compilers on the Alpha for 32-bit machines has only been tested in a few cases and may not work properly.

`make compare` may fail on old versions of OSF/1 unless you add `-save-temps' to `CFLAGS`. On these systems, the name of the assembler input file is stored in the object file, and that makes comparison fail if it differs between the `stage1` and `stage2` compilations. The option `-save-temps' forces a fixed name to be used for the assembler input file, instead of a randomly chosen name in `/tmp'. Do not add `-save-temps' unless the comparisons fail without that option. If you add `-save-temps', you will have to manually delete the `.i' and `.s' files after each series of compilations.

GNU CC now supports both the native (ECOFF) debugging format used by DBX and GDB and an encapsulated STABS format for use only with GDB. See the discussion of the `--with-stabs' option of `configure' above for more information on these formats and how to select them.

There is a bug in DEC's assembler that produces incorrect line numbers for ECOFF format when the `.align' directive is used. To work around this problem, GNU CC will not emit such alignment directives while writing ECOFF format debugging information even if optimization is being performed. Unfortunately, this has the very undesirable side-effect that code addresses when `-O' is specified are different depending on whether or not `-g' is also specified.

To avoid this behavior, specify `-gstabs+' and use GDB instead of DBX. DEC is now aware of this problem with the assembler and hopes to provide a fix shortly.

- arm Advanced RISC Machines ARM-family processors. These are often used in embedded applications. There are no standard Unix configurations. This configuration corresponds to the basic instruction sequences and will produce a.out format object modules.

You may need to make a variant of the file `arm.h' for your particular configuration.

- arm-*-riscix The ARM2 or ARM3 processor running RISC iX, Acorn's port of BSD Unix. If you are running a version of RISC iX prior to 1.2 then you must specify the version number during configuration. Note that the assembler shipped with RISC iX does not support stabs debugging information; a new version of the assembler, with stabs support included, is now available from Acorn.
- a29k AMD Am29k-family processors. These are normally used in embedded applications. There are no standard Unix configurations. This configuration corresponds to AMD's standard calling sequence and binary interface and is compatible with other 29k tools.

You may need to make a variant of the file `a29k.h' for your particular configuration.

- a29k-*-bsd AMD Am29050 used in a system running a variant of BSD Unix.
- decstation-* DECstations can support three different personalities: Ultrix, DEC OSF/1, and OSF/rose. To configure GCC for these platforms use the following configurations:

`decstation-ultrix'

Ultrix configuration.

`decstation-osf1'

Dec's version of OSF/1.

`decstation-osfrose'

Open Software Foundation reference port of OSF/1 which uses the OSF/rose object file format instead of ECOFF. Normally, you would not select this configuration.

The MIPS C compiler needs to be told to increase its table size for switch statements with the `-Wf,-XNg1500' option in order to compile `cp/parse.c'. If you use the `-O2' optimization option, you also need to use `-Olimit 3000'. Both of these options are automatically generated in the `Makefile' that the shell script `configure' builds. If you override the CC make variable and use the MIPS compilers, you may need to add `-Wf,-XNg1500 -Olimit 3000'.

- elxsi-elxsi-bsd The Elxsi's C compiler has known limitations that prevent it from compiling GNU C. Please contact mrs@cygnus.com for more details.
- dsp16xx A port to the AT&T DSP1610 family of processors.
- h8300-*-* The calling convention and structure layout has changed in release 2.6. All code must be recompiled. The calling convention now passes the first three arguments in function calls in registers. Structures are no longer a multiple of 2 bytes.
- hppa*-*-* There are two variants of this CPU, called 1.0 and 1.1, which have different machine descriptions. You must use the right one for your machine. All 7nn machines and 8n7 machines use 1.1, while all other 8nn machines use 1.0.

The easiest way to handle this problem is to use `configure hpnnn' or `configure hpnnn-hpux', where nnn is the model number of the machine. Then `configure' will figure out if the machine is a 1.0 or 1.1. Use `uname -a' to find out the model number of your machine.

`-g' does not work on HP-UX, since that system uses a peculiar debugging format which GNU CC does not know about. However, `-g' will work if you also use GAS and GDB in conjunction with GCC. We highly recommend using GAS for all HP-PA configurations.

You should be using GAS-2.3 (or later) along with GDB-4.12 (or later). These can be retrieved from all the traditional GNU ftp archive sites.

Build GAS and install the resulting binary as:

```
/usr/local/lib/gcc-lib/configuration/gccversion/as
```

where configuration is the configuration name (perhaps `hpnnn-hpux') and gccversion is the GNU CC version number. Do this *before* starting the build process, otherwise you will get errors from the HPUX assembler while building `libgcc2.a'. The command

```
make install-dir
```

will create the necessary directory hierarchy so you can install GAS before building GCC.

To enable debugging, configure GNU CC with the `--with-gnu-as' option before building.

It has been reported that GNU CC produces invalid assembly code for 1.1 machines running HP-UX 8.02 when using the HP assembler. Typically the errors look like this:

```
as: bug.s @line#15 [err#1060]
  Argument 0 or 2 in FARG upper
          - lookahead = ARGW1=FR,RTNVAL=GR
as: foo.s @line#28 [err#1060]
  Argument 0 or 2 in FARG upper
          - lookahead = ARGW1=FR
```

You can check the version of HP-UX you are running by executing the command `uname -r'. If you are indeed running HP-UX 8.02 on a PA and using the HP assembler then configure GCC with "hpnnn-hpux8.02".

- i370-*-* This port is very preliminary and has many known bugs. We hope to have a higher-quality port for this machine soon.
- i386-*-linuxoldld Use this configuration to generate a.out binaries on Linux if you do not have gas/binutils version 2.5.2 or later installed. This is an obsolete configuration.
- i386-*-linuxaout Use this configuration to generate a.out binaries on Linux. This is an obsolete configuration. You must use gas/binutils version 2.5.2 or later.
- i386-*-linux Use this configuration to generate ELF binaries on Linux. You must use gas/binutils version 2.5.2 or later.
- i386-*-sco Compilation with RCC is recommended. Also, it may be a good idea to link with GNU malloc instead of the malloc that comes with the system.
- i386-*-sco3.2v4 Use this configuration for SCO release 3.2 version 4.
- i386-*-isc It may be a good idea to link with GNU malloc instead of the malloc that comes with the system.

In ISC version 4.1, `sed' core dumps when building `deduced.h'. Use the version of `sed' from version 4.0.

- i386-*-esix It may be good idea to link with GNU malloc instead of the malloc that comes with the system.
- i386-ibm-aix You need to use GAS version 2.1 or later, and and LD from GNU binutils version 2.2 or later.
- i386-sequent-bsd Go to the Berkeley universe before compiling. In addition, you probably need to create a file named `string.h' containing just one line: `#include <strings.h>'.
- i386-sequent-ptx1* Sequent DYNIX/ptx 1.x.
- i386-sequent-ptx2* Sequent DYNIX/ptx 2.x.
- i386-sun-sunos4 You may find that you need another version of GNU CC to begin bootstrapping with, since the current version when built with the system's own compiler seems to get an infinite loop compiling part of `libgcc2.c'. GNU CC version 2 compiled with GNU CC (any version) seems not to have this problem.

See section Installing GNU CC on the Sun, for information on installing GNU CC on Sun systems.

- i[345]86-*-winnt3.5 This version requires a GAS that has not let been released. Until it is, you can get a prebuilt binary version via anonymous ftp from `cs.washington.edu:pub/gnat' or `cs.nyu.edu:pub/gnat'. You must also use the Microsoft header files from the Windows NT 3.5 SDK. Find these on the CDROM in the `/mstools/h' directory dated 9/4/94. You must use a fixed version of Microsoft linker made especially for NT 3.5, which is also is available on the NT 3.5 SDK CDROM. If you do not have this linker, can you also use the linker from Visual C/C++ 1.0 or 2.0.

Installing GNU CC for NT builds a wrapper linker, called `ld.exe', which mimics the behaviour of Unix `ld' in the specification of libraries (`-L' and `-l'). `ld.exe' looks for both Unix and Microsoft named libraries. For example, if you specify `-lfoo', `ld.exe' will look first for `libfoo.a' and then for

`foo.lib'.

You may install GNU CC for Windows NT in one of two ways, depending on whether or not you have a Unix-like shell and various Unix-like utilities.

1. If you do not have a Unix-like shell and few Unix-like utilities, you will use a DOS style batch script called `configure.bat'. Invoke it as `configure winnt` from an MSDOS console window or from the program manager dialog box. `configure.bat' assumes you have already installed and have in your path a Unix-like `sed' program which is used to create a working `Makefile' from `Makefile.in'.

   `Makefile' uses the Microsoft Nmake program maintenance utility and the Visual C/C++ V8.00 compiler to build GNU CC. You need only have the utilities `sed' and `touch' to use this installation method, which only automatically builds the compiler itself. You must then examine what `fixinc.winnt' does, edit the header files by hand and build `libgcc.a' manually.
2. The second type of installation assumes you are running a Unix-like shell, have a complete suite of Unix-like utilities in your path, and have a previous version of GNU CC already installed, either through building it via the above installation method or acquiring a pre-built binary. In this case, use the `configure' script in the normal fashion.

- i860-intel-osf1 This is the Paragon. If you have version 1.0 of the operating system, see section Installation Problems, for special things you need to do to compensate for peculiarities in the system.
- *-lynx-lynxos LynxOS 2.2 and earlier comes with GNU CC 1.x already installed as `/bin/gcc'. You should compile with this instead of `/bin/cc'. You can tell GNU CC to use the GNU assembler and linker, by specifying `--with-gnu-as --with-gnu-ld' when configuring. These will produce COFF format object files and executables; otherwise GNU CC will use the installed tools, which produce a.out format executables.
- m68000-hp-bsd HP 9000 series 200 running BSD. Note that the C compiler that comes with this system cannot compile GNU CC; contact `law@cs.utah.edu` to get binaries of GNU CC for bootstrapping.
- m68k-altos Altos 3068. You must use the GNU assembler, linker and debugger. Also, you must fix a kernel bug. Details in the file `README.ALTOS'.
- m68k-att-sysv AT&T 3b1, a.k.a. 7300 PC. Special procedures are needed to compile GNU CC with this machine's standard C compiler, due to bugs in that compiler. You can bootstrap it more easily with previous versions of GNU CC if you have them.

Installing GNU CC on the 3b1 is difficult if you do not already have GNU CC running, due to bugs in the installed C compiler. However, the following procedure might work. We are unable to test it.

1. Comment out the `#include "config.h"' line on line 37 of `cccp.c' and do `make cpp'. This makes a preliminary version of GNU cpp.
2. Save the old `/lib/cpp' and copy the preliminary GNU cpp to that file name.
3. Undo your change in `cccp.c', or reinstall the original version, and do `make cpp' again.
4. Copy this final version of GNU cpp into `/lib/cpp'.
5. Replace every occurrence of `obstack_free` in the file `tree.c' with `_obstack_free`.
6. Run `make` to get the first-stage GNU CC.
7. Reinstall the original version of `/lib/cpp'.
8. Now you can compile GNU CC with itself and install it in the normal fashion.

- m68k-bull-sysv Bull DPX/2 series 200 and 300 with BOS-2.00.45 up to BOS-2.01. GNU CC works either with native assembler or GNU assembler. You can use GNU assembler with native coff generation by providing

`--with-gnu-as' to the configure script or use GNU assembler with dbx-in-coff encapsulation by providing `--with-gnu-as --stabs'. For any problem with native assembler or for availability of the DPX/2 port of GAS contact `F.Pierresteguy@frcl.bull.fr'.

- m68k-crds-unox Use `configure unos' for building on Unos.

The Unos assembler is named `casm` instead of `as`. For some strange reason linking `` `/bin/as' `` to `` `/bin/casm' `` changes the behavior, and does not work. So, when installing GNU CC, you should install the following script as `` `as' `` in the subdirectory where the passes of GCC are installed:

```
#!/bin/sh
casm $*
```

The default Unos library is named `` `libunos.a' `` instead of `` `libc.a' ``. To allow GNU CC to function, either change all references to `-lc' in `` `gcc.c' `` to `-lunos' or link `` `/lib/libc.a' `` to `` `/lib/libunos.a' ``.

When compiling GNU CC with the standard compiler, to overcome bugs in the support of `alloca`, do not use `-O' when making stage 2. Then use the stage 2 compiler with `-O' to make the stage 3 compiler. This compiler will have the same characteristics as the usual stage 2 compiler on other systems. Use it to make a stage 4 compiler and compare that with stage 3 to verify proper compilation.

(Perhaps simply defining `ALLOCA` in `` `x-crds' `` as described in the comments there will make the above paragraph superfluous. Please inform us of whether this works.)

Unos uses memory segmentation instead of demand paging, so you will need a lot of memory. 5 Mb is barely enough if no other tasks are running. If linking `` `cc1' `` fails, try putting the object files into a library and linking from that library.

- m68k-hp-hpux HP 9000 series 300 or 400 running HP-UX. HP-UX version 8.0 has a bug in the assembler that prevents compilation of GNU CC. To fix it, get patch PHCO_4484 from HP.

In addition, if you wish to use gas `--with-gnu-as' you must use gas version 2.1 or later, and you must use the GNU linker version 2.1 or later. Earlier versions of gas relied upon a program which converted the gas output into the native HP/UX format, but that program has not been kept up to date. gdb does not understand that native HP/UX format, so you must use gas if you wish to use gdb.

- m68k-sun Sun 3. We do not provide a configuration file to use the Sun FPA by default, because programs that establish signal handlers for floating point traps inherently cannot work with the FPA.

See section Installing GNU CC on the Sun, for information on installing GNU CC on Sun systems.

- m88k-*-svr3 Motorola m88k running the AT&T/Unisoft/Motorola V.3 reference port. These systems tend to use the Green Hills C, revision 1.8.5, as the standard C compiler. There are apparently bugs in this compiler that result in object files differences between stage 2 and stage 3. If this happens, make the stage 4 compiler and compare it to the stage 3 compiler. If the stage 3 and stage 4 object files are identical, this suggests you encountered a problem with the standard C compiler; the stage 3 and 4 compilers may be usable.

It is best, however, to use an older version of GNU CC for bootstrapping if you have one.

- m88k-*-dgux Motorola m88k running DG/UX. To build 88open BCS native or cross compilers on DG/UX, specify the configuration name as `m88k-*-dguxbcs' and build in the 88open BCS software development environment. To build ELF native or cross compilers on DG/UX, specify `m88k-*-dgux' and build in the DG/UX ELF development environment. You set the software development environment by issuing `sde-target' command and specifying either `m88kbcs' or `m88kdguxelf' as the operand.

If you do not specify a configuration name, `configure' guesses the configuration based on the current software development environment.

- m88k-tektronix-sysv3 Tektronix XD88 running UTekV 3.2e. Do not turn on optimization while building stage1 if you bootstrap with the buggy Green Hills compiler. Also, The bundled LAI System V NFS is buggy so if you build in an NFS mounted directory, start from a fresh reboot, or avoid NFS all together. Otherwise you may have trouble getting clean comparisons between stages.
- mips-mips-bsd MIPS machines running the MIPS operating system in BSD mode. It's possible that some old versions of the system lack the functions `memcpy`, `memcmp`, and `memset`. If your system lacks these, you must remove or undo the definition of `TARGET_MEM_FUNCTIONS` in `mips-bsd.h'.

The MIPS C compiler needs to be told to increase its table size for switch statements with the `-Wf,-XNg1500' option in order to compile `cp/parse.c'. If you use the `-O2' optimization option, you also need to use `-Olimit 3000'. Both of these options are automatically generated in the `Makefile' that the shell script `configure' builds. If you override the `CC` make variable and use the MIPS compilers, you may need to add `-Wf,-XNg1500 -Olimit 3000'.

- mips-mips-riscos* The MIPS C compiler needs to be told to increase its table size for switch statements with the `-Wf,-XNg1500' option in order to compile `cp/parse.c'. If you use the `-O2' optimization option, you also need to use `-Olimit 3000'. Both of these options are automatically generated in the `Makefile' that the shell script `configure' builds. If you override the `CC` make variable and use the MIPS compilers, you may need to add `-Wf,-XNg1500 -Olimit 3000'.

MIPS computers running RISC-OS can support four different personalities: default, BSD 4.3, System V.3, and System V.4 (older versions of RISC-OS don't support V.4). To configure GCC for these platforms use the following configurations:

`mips-mips-riscos`rev`'
: Default configuration for RISC-OS, revision `rev`.

`mips-mips-riscos`rev`bsd'
: BSD 4.3 configuration for RISC-OS, revision `rev`.

`mips-mips-riscos`rev`sysv4'
: System V.4 configuration for RISC-OS, revision `rev`.

`mips-mips-riscos`rev`sysv'
: System V.3 configuration for RISC-OS, revision `rev`.

The revision `rev` mentioned above is the revision of RISC-OS to use. You must reconfigure GCC when going from a RISC-OS revision 4 to RISC-OS revision 5. This has the effect of avoiding a linker bug (see section Installation Problems, for more details).

- mips-sgi-* In order to compile GCC on an SGI running IRIX 4, the "c.hdr.lib" option must be installed from the CD-ROM supplied from Silicon Graphics. This is found on the 2nd CD in release 4.0.1.

In order to compile GCC on an SGI running IRIX 5, the "compiler_dev.hdr" subsystem must be installed from the IDO CD-ROM supplied by Silicon Graphics.

`make compare` may fail on version 5 of IRIX unless you add `-save-temps' to `CFLAGS`. On these systems, the name of the assembler input file is stored in the object file, and that makes comparison fail if it differs between the `stage1` and `stage2` compilations. The option `-save-temps' forces a fixed name to be used for the assembler input file, instead of a randomly chosen name in `/tmp'. Do not add `-save-temps' unless the comparisons fail without that option. If you do you `-save-temps', you will have to manually delete the `.i' and

`.s' files after each series of compilations.

The MIPS C compiler needs to be told to increase its table size for switch statements with the `-Wf,-XNg1500' option in order to compile `cp/parse.c'. If you use the `-O2' optimization option, you also need to use `-Olimit 3000'. Both of these options are automatically generated in the `Makefile' that the shell script `configure' builds. If you override the CC make variable and use the MIPS compilers, you may need to add `-Wf,-XNg1500 -Olimit 3000'.

On Irix version 4.0.5F, and perhaps on some other versions as well, there is an assembler bug that reorders instructions incorrectly. To work around it, specify the target configuration `mips-sgi-irix4loser'. This configuration inhibits assembler optimization.

In a compiler configured with target `mips-sgi-irix4', you can turn off assembler optimization by using the `-noasmopt' option. This compiler option passes the option `-O0' to the assembler, to inhibit reordering.

The `-noasmopt' option can be useful for testing whether a problem is due to erroneous assembler reordering. Even if a problem does not go away with `-noasmopt', it may still be due to assembler reordering--perhaps GNU CC itself was miscompiled as a result.

To enable debugging under Irix 5, you must use GNU as 2.5 or later, and use the `--with-gnu-as' configure option when configuring gcc. GNU as is distributed as part of the binutils package.

- mips-sony-sysv Sony MIPS NEWS. This works in NEWSOS 5.0.1, but not in 5.0.2 (which uses ELF instead of COFF). Support for 5.0.2 will probably be provided soon by volunteers. In particular, the linker does not like the code generated by GCC when shared libraries are linked in.
- ns32k-encore Encore ns32000 system. Encore systems are supported only under BSD.
- ns32k-*-genix National Semiconductor ns32000 system. Genix has bugs in alloca and malloc; you must get the compiled versions of these from GNU Emacs.
- ns32k-sequent Go to the Berkeley universe before compiling. In addition, you probably need to create a file named `string.h' containing just one line: `#include <strings.h>'.
- ns32k-utek UTEK ns32000 system ("merlin"). The C compiler that comes with this system cannot compile GNU CC; contact `tektronix!reed!mason' to get binaries of GNU CC for bootstrapping.
- romp-*-aos
- romp-*-mach The only operating systems supported for the IBM RT PC are AOS and MACH. GNU CC does not support AIX running on the RT. We recommend you compile GNU CC with an earlier version of itself; if you compile GNU CC with hc, the Metaware compiler, it will work, but you will get mismatches between the stage 2 and stage 3 compilers in various files. These errors are minor differences in some floating-point constants and can be safely ignored; the stage 3 compiler is correct.
- rs6000-*-aix
- powerpc-*-aix Various early versions of each release of the IBM XLC compiler will not bootstrap GNU CC. Symptoms include differences between the stage2 and stage3 object files, and errors when compiling `libgcc.a' or `enquire'. Known problematic releases include: xlc-1.2.1.8, xlc-1.3.0.0 (distributed with AIX 3.2.5), and xlc-1.3.0.19. Both xlc-1.2.1.28 and xlc-1.3.0.24 (PTF 432238) are known to produce working versions of GNU CC, but most other recent releases correctly bootstrap GNU CC. Also, releases of AIX prior to AIX 3.2.4 include a version of the IBM assembler which does not accept debugging directives: assembler updates are available as PTFs. See the file `README.RS6000' for more details on both of these problems.

Only AIX is supported on the PowerPC. GNU CC does not yet support the 64-bit PowerPC instructions.

Objective C does not work on this architecture.

AIX on the RS/6000 provides support (NLS) for environments outside of the United States. Compilers and assemblers use NLS to support locale-specific representations of various objects including floating-point numbers ("." vs "," for separating decimal fractions). There have been problems reported where the library linked with GNU CC does not produce the same floating-point formats that the assembler accepts. If you have this problem, set the LANG environment variable to "C" or "En_US".

- powerpc-*-elf
- powerpc-*-sysv4 PowerPC system in big endian mode, running System V.4. This system is currently under development.
- powerpc-*-eabi Embedded PowerPC system in big endian mode. This system is currently under development.
- powerpcle-*-elf
- powerpcle-*-eabi PowerPC system in little endian mode, running System V.4. This system is currently under development.
- powerpcle-*-sysv4 Embedded PowerPC system in little endian mode. This system is currently under development.
- vax-dec-ultrix Don't try compiling with Vax C (`vcc`). It produces incorrect code in some cases (for example, when `alloca` is used).

Meanwhile, compiling `` `cp/parse.c' `` with pcc does not work because of an internal table size limitation in that compiler. To avoid this problem, compile just the GNU C compiler first, and use it to recompile building all the languages that you want to run.

- sparc-sun-* See section Installing GNU CC on the Sun, for information on installing GNU CC on Sun systems.
- vax-dec-vms See section Installing GNU CC on VMS, for details on how to install GNU CC on VMS.
- we32k-*-* These computers are also known as the 3b2, 3b5, 3b20 and other similar names. (However, the 3b1 is actually a 68000; see section Configurations Supported by GNU CC.)

Don't use `-g' when compiling with the system's compiler. The system's linker seems to be unable to handle such a large program with debugging information.

The system's compiler runs out of capacity when compiling `` `stmt.c' `` in GNU CC. You can work around this by building `` `cpp' `` in GNU CC first, then use that instead of the system's preprocessor with the system's C compiler to compile `` `stmt.c' ``. Here is how:

```
mv /lib/cpp /lib/cpp.att
cp cpp /lib/cpp.gnu
echo '/lib/cpp.gnu -traditional ${1+"$@"}' > /lib/cpp
chmod +x /lib/cpp
```

The system's compiler produces bad code for some of the GNU CC optimization files. So you must build the stage 2 compiler without optimization. Then build a stage 3 compiler with optimization. That executable should work. Here are the necessary commands:

```
make LANGUAGES=c CC=stage1/xgcc CFLAGS="-Bstage1/ -g"
make stage2
make CC=stage2/xgcc CFLAGS="-Bstage2/ -g -O"
```

You may need to raise the ULIMIT setting to build a C++ compiler, as the file `` `cc1plus' `` is larger than one

megabyte.

Compilation in a Separate Directory

If you wish to build the object files and executables in a directory other than the one containing the source files, here is what you must do differently:

1. Make sure you have a version of Make that supports the `VPATH` feature. (GNU Make supports it, as do Make versions on most BSD systems.)
2. If you have ever run `` `configure' `` in the source directory, you must undo the configuration. Do this by running:

   ```
   make distclean
   ```
3. Go to the directory in which you want to build the compiler before running `` `configure' ``:

   ```
   mkdir gcc-sun3
   cd gcc-sun3
   ```

   On systems that do not support symbolic links, this directory must be on the same file system as the source code directory.
4. Specify where to find `` `configure' `` when you run it:

   ```
   ../gcc/configure ...
   ```

   This also tells `configure` where to find the compiler sources; `configure` takes the directory from the file name that was used to invoke it. But if you want to be sure, you can specify the source directory with the `--srcdir' option, like this:

   ```
   ../gcc/configure --srcdir=../gcc other options
   ```

   The directory you specify with `--srcdir' need not be the same as the one that `configure` is found in.

Now, you can run `make` in that directory. You need not repeat the configuration steps shown above, when ordinary source files change. You must, however, run `configure` again when the configuration files change, if your system does not support symbolic links.

Building and Installing a Cross-Compiler

GNU CC can function as a cross-compiler for many machines, but not all.

- Cross-compilers for the Mips as target using the Mips assembler currently do not work, because the auxiliary programs `` `mips-tdump.c' `` and `` `mips-tfile.c' `` can't be compiled on anything but a Mips. It does work to cross compile for a Mips if you use the GNU assembler and linker.
- Cross-compilers between machines with different floating point formats have not all been made to work. GNU CC now has a floating point emulator with which these can work, but each target machine description needs to be updated to take advantage of it.
- Cross-compilation between machines of different word sizes is somewhat problematic and sometimes does not work.

Since GNU CC generates assembler code, you probably need a cross-assembler that GNU CC can run, in order to produce object files. If you want to link on other than the target machine, you need a cross-linker as well. You also need header files and libraries suitable for the target machine that you can install on the host machine.

Steps of Cross-Compilation

To compile and run a program using a cross-compiler involves several steps:

- Run the cross-compiler on the host machine to produce assembler files for the target machine. This requires header files for the target machine.
- Assemble the files produced by the cross-compiler. You can do this either with an assembler on the target machine, or with a cross-assembler on the host machine.
- Link those files to make an executable. You can do this either with a linker on the target machine, or with a cross-linker on the host machine. Whichever machine you use, you need libraries and certain startup files (typically `` `crt....o' ``) for the target machine.

It is most convenient to do all of these steps on the same host machine, since then you can do it all with a single invocation of GNU CC. This requires a suitable cross-assembler and cross-linker. For some targets, the GNU assembler and linker are available.

Configuring a Cross-Compiler

To build GNU CC as a cross-compiler, you start out by running `` `configure' ``. Use the `--target=target' to specify the target type. If `` `configure' `` was unable to correctly identify the system you are running on, also specify the `--build=build' option. For example, here is how to configure for a cross-compiler that produces code for an HP 68030 system running BSD on a system that `` `configure' `` can correctly identify:

```
./configure --target=m68k-hp-bsd4.3
```

Tools and Libraries for a Cross-Compiler

If you have a cross-assembler and cross-linker available, you should install them now. Put them in the directory `` `/usr/local/target/bin' ``. Here is a table of the tools you should put in this directory:

`` `as' ``
: This should be the cross-assembler.

`` `ld' ``
: This should be the cross-linker.

`` `ar' ``
: This should be the cross-archiver: a program which can manipulate archive files (linker libraries) in the target machine's format.

`` `ranlib' ``
: This should be a program to construct a symbol table in an archive file.

The installation of GNU CC will find these programs in that directory, and copy or link them to the proper place to for the cross-compiler to find them when run later.

The easiest way to provide these files is to build the Binutils package and GAS. Configure them with the same

`--host' and `--target' options that you use for configuring GNU CC, then build and install them. They install their executables automatically into the proper directory. Alas, they do not support all the targets that GNU supports.

If you want to install libraries to use with the cross-compiler, such as a standard C library, put them in the directory `/usr/local/target/lib'; installation of GNU CC copies all all the files in that subdirectory into the proper place for GNU CC to find them and link with them. Here's an example of copying some libraries from a target machine:

```
ftp target-machine
lcd /usr/local/target/lib
cd /lib
get libc.a
cd /usr/lib
get libg.a
get libm.a
quit
```

The precise set of libraries you'll need, and their locations on the target machine, vary depending on its operating system.

Many targets require "start files" such as `crt0.o' and `crtn.o' which are linked into each executable; these too should be placed in `/usr/local/target/lib'. There may be several alternatives for `crt0.o', for use with profiling or other compilation options. Check your target's definition of STARTFILE_SPEC to find out what start files it uses. Here's an example of copying these files from a target machine:

```
ftp target-machine
lcd /usr/local/target/lib
prompt
cd /lib
mget *crt*.o
cd /usr/lib
mget *crt*.o
quit
```

`libgcc.a' and Cross-Compilers

Code compiled by GNU CC uses certain runtime support functions implicitly. Some of these functions can be compiled successfully with GNU CC itself, but a few cannot be. These problem functions are in the source file `libgcc1.c'; the library made from them is called `libgcc1.a'.

When you build a native compiler, these functions are compiled with some other compiler--the one that you use for bootstrapping GNU CC. Presumably it knows how to open code these operations, or else knows how to call the run-time emulation facilities that the machine comes with. But this approach doesn't work for building a cross-compiler. The compiler that you use for building knows about the host system, not the target system.

So, when you build a cross-compiler you have to supply a suitable library `libgcc1.a' that does the job it is expected to do.

To compile `libgcc1.c' with the cross-compiler itself does not work. The functions in this file are supp to implement arithmetic operations that GNU CC does not know how to open code for your target machine. these functions are compiled with GNU CC itself, they will compile into infinite recursion.

On any given target, most of these functions are not needed. If GNU CC can open code an arithmetic operation, it will not call these functions to perform the operation. It is possible that on your target machine, none of these functions is needed. If so, you can supply an empty library as `libgcc1.a'.

Many targets need library support only for multiplication and division. If you are linking with a library that contains functions for multiplication and division, you can tell GNU CC to call them directly by defining the macros `MULSI3_LIBCALL`, and the like. These macros need to be defined in the target description macro file. For some targets, they are defined already. This may be sufficient to avoid the need for libgcc1.a; if so, you can supply an empty library.

Some targets do not have floating point instructions; they need other functions in `libgcc1.a', which do floating arithmetic. Recent versions of GNU CC have a file which emulates floating point. With a certain amount of work, you should be able to construct a floating point emulator that can be used as `libgcc1.a'. Perhaps future versions will contain code to do this automatically and conveniently. That depends on whether someone wants to implement it.

Some embedded targets come with all the necessary `libgcc1.a' routines written in C or assembler. These targets build `libgcc1.a' automatically and you do not need to do anything special for them. Other embedded targets do not need any `libgcc1.a' routines since all the necessary operations are supported by the hardware.

If your target system has another C compiler, you can configure GNU CC as a native compiler on that machine, build just `libgcc1.a' with `make libgcc1.a' on that machine, and use the resulting file with the cross-compiler. To do this, execute the following on the target machine:

```
cd target-build-dir
./configure --host=sparc --target=sun3
make libgcc1.a
```

And then this on the host machine:

```
ftp target-machine
binary
cd target-build-dir
get libgcc1.a
quit
```

Another way to provide the functions you need in `libgcc1.a' is to define the appropriate `perform_...` macros for those functions. If these definitions do not use the C arithmetic operators that they are meant to implement, you should be able to compile them with the cross-compiler you are building. (If these definitions already exist for your target file, then you are all set.)

To build `libgcc1.a' using the perform macros, use `LIBGCC1=libgcc1.a OLDCC=./xgcc' when building the compiler. Otherwise, you should place your replacement library under the name `libgcc1.a' in the directory in which you will build the cross-compiler, before you run `make`.

Cross-Compilers and Header Files

If you are cross-compiling a standalone program or a program for an embedded system, then you may not need any header files except the few that are part of GNU CC (and those of your program). However, if you intend to link your program with a standard C library such as `libc.a', then you probably need to compile with the header files that go with the library you use.

The GNU C compiler does not come with these files, because (1) they are system-specific, and (2) they belong in a C library, not in a compiler.

If the GNU C library supports your target machine, then you can get the header files from there (assuming you actually use the GNU library when you link your program).

If your target machine comes with a C compiler, it probably comes with suitable header files also. If you make these files accessible from the host machine, the cross-compiler can use them also.

Otherwise, you're on your own in finding header files to use when cross-compiling.

When you have found suitable header files, put them in `/usr/local/target/include', before building the cross compiler. Then installation will run fixincludes properly and install the corrected versions of the header files where the compiler will use them.

Provide the header files before you build the cross-compiler, because the build stage actually runs the cross-compiler to produce parts of `libgcc.a'. (These are the parts that *can* be compiled with GNU CC.) Some of them need suitable header files.

Here's an example showing how to copy the header files from a target machine. On the target machine, do this:

```
(cd /usr/include; tar cf - .) > tarfile
```

Then, on the host machine, do this:

```
ftp target-machine
lcd /usr/local/target/include
get tarfile
quit
tar xf tarfile
```

Actually Building the Cross-Compiler

Now you can proceed just as for compiling a single-machine compiler through the step of building stage 1. If you have not provided some sort of `libgcc1.a', then compilation will give up at the point where it needs that file, printing a suitable error message. If you do provide `libgcc1.a', then building the compiler will automatically compile and link a test program called `libgcc1-test'; if you get errors in the linking, it means that not all of the necessary routines in `libgcc1.a' are available.

You must provide the header file `float.h'. One way to do this is to compile `enquire' and run it on your target machine. The job of `enquire' is to run on the target machine and figure out by experiment the nature of its floating point representation. `enquire' records its findings in the header file `float.h'. If you can't produce this file by running `enquire' on the target machine, then you will need to come up with a suitable `float.h' in some other way (or else, avoid using it in your programs).

Do not try to build stage 2 for a cross-compiler. It doesn't work to rebuild GNU CC as a cross-compiler using the cross-compiler, because that would produce a program that runs on the target machine, not on the host. For example, if you compile a 386-to-68030 cross-compiler with itself, the result will not be right either for the 386 (because it was compiled into 68030 code) or for the 68030 (because it was configured for a 386 as the host). If you want to compile GNU CC into 68030 code, whether you compile it on a 68030 or with a cross-compiler on a 386, you must specify a 68030 as the host when you configure it.

To install the cross-compiler, use `make install', as usual.

Installing GNU CC on the Sun

On Solaris (version 2.1), do not use the linker or other tools in `/usr/ucb' to build GNU CC. Use `/usr/ccs/bin`.

Make sure the environment variable `FLOAT_OPTION` is not set when you compile `libgcc.a'. If this option were set to `f68881` when `libgcc.a' is compiled, the resulting code would demand to be linked with a special startup file and would not link properly without special pains.

There is a bug in `alloca` in certain versions of the Sun library. To avoid this bug, install the binaries of GNU CC that were compiled by GNU CC. They use `alloca` as a built-in function and never the one in the library.

Some versions of the Sun compiler crash when compiling GNU CC. The problem is a segmentation fault in cpp. This problem seems to be due to the bulk of data in the environment variables. You may be able to avoid it by using the following command to compile GNU CC with Sun CC:

```
make CC="TERMCAP=x OBJS=x LIBFUNCS=x STAGESTUFF=x cc"
```

Installing GNU CC on VMS

The VMS version of GNU CC is distributed in a backup saveset containing both source code and precompiled binaries.

To install the `gcc' command so you can use the compiler easily, in the same manner as you use the VMS C compiler, you must install the VMS CLD file for GNU CC as follows:

1. Define the VMS logical names `GNU_CC' and `GNU_CC_INCLUDE' to point to the directories where the GNU CC executables (`gcc-cpp.exe', `gcc-cc1.exe', etc.) and the C include files are kept respectively. This should be done with the commands:

   ```
   $ assign /system /translation=concealed -
     disk:[gcc.] gnu_cc
   $ assign /system /translation=concealed -
     disk:[gcc.include.] gnu_cc_include
   ```

   with the appropriate disk and directory names. These commands can be placed in your system startup file so they will be executed whenever the machine is rebooted. You may, if you choose, do this via the `GCC_INSTALL.COM' script in the `[GCC]' directory.
2. Install the `GCC' command with the command line:

```
$ set command /table=sys$common:[syslib]dcltables -
  /output=sys$common:[syslib]dcltables gnu_cc:[000000]gcc
$ install replace sys$common:[syslib]dcltables
```

3. To install the help file, do the following:

   ```
   $ library/help sys$library:helplib.hlb gcc.hlp
   ```

   Now you can invoke the compiler with a command like `gcc /verbose file.c', which is equivalent to the command `gcc -v -c file.c' in Unix.

If you wish to use GNU C++ you must first install GNU CC, and then perform the following steps:

1. Define the VMS logical name `GNU_GXX_INCLUDE' to point to the directory where the preprocessor will search for the C++ header files. This can be done with the command:

   ```
   $ assign /system /translation=concealed -
     disk:[gcc.gxx_include.] gnu_gxx_include
   ```

   with the appropriate disk and directory name. If you are going to be using libg++, this is where the libg++ install procedure will install the libg++ header files.

2. Obtain the file `gcc-cc1plus.exe', and place this in the same directory that `gcc-cc1.exe' is kept.

   The GNU C++ compiler can be invoked with a command like `gcc /plus /verbose file.cc', which is equivalent to the command `g++ -v -c file.cc' in Unix.

We try to put corresponding binaries and sources on the VMS distribution tape. But sometimes the binaries will be from an older version than the sources, because we don't always have time to update them. (Use the `/version' option to determine the version number of the binaries and compare it with the source file `version.c' to tell whether this is so.) In this case, you should use the binaries you get to recompile the sources. If you must recompile, here is how:

1. Execute the command procedure `vmsconfig.com' to set up the files `tm.h', `config.h', `aux-output.c', and `md.', and to create files `tconfig.h' and `hconfig.h'. This procedure also creates several linker option files used by `make-cc1.com' and a data file used by `make-l2.com'.

   ```
   $ @vmsconfig.com
   ```

2. Setup the logical names and command tables as defined above. In addition, define the VMS logical name `GNU_BISON' to point at the to the directories where the Bison executable is kept. This should be done with the command:

   ```
   $ assign /system /translation=concealed -
     disk:[bison.] gnu_bison
   ```

   You may, if you choose, use the `INSTALL_BISON.COM' script in the `[BISON]' directory.

3. Install the `BISON' command with the command line:

   ```
   $ set command /table=sys$common:[syslib]dcltables -
     /output=sys$common:[syslib]dcltables -
   ```

```
  gnu_bison:[000000]bison
$ install replace sys$common:[syslib]dcltables
```

4. Type `@make-gcc' to recompile everything (alternatively, submit the file `make-gcc.com' to a batch queue). If you wish to build the GNU C++ compiler as well as the GNU CC compiler, you must first edit `make-gcc.com' and follow the instructions that appear in the comments.
5. In order to use GCC, you need a library of functions which GCC compiled code will call to perform certain tasks, and these functions are defined in the file `libgcc2.c'. To compile this you should use the command procedure `make-l2.com', which will generate the library `libgcc2.olb'. `libgcc2.olb' should be built using the compiler built from the same distribution that `libgcc2.c' came from, and `make-gcc.com' will automatically do all of this for you.

   To install the library, use the following commands:

   ```
   $ library gnu_cc:[000000]gcclib/delete=(new,eprintf)
   $ library gnu_cc:[000000]gcclib/delete=L_*
   $ library libgcc2/extract=*/output=libgcc2.obj
   $ library gnu_cc:[000000]gcclib libgcc2.obj
   ```

   The first command simply removes old modules that will be replaced with modules from `libgcc2' under different module names. The modules `new` and `eprintf` may not actually be present in your `gcclib.olb'---if the VMS librarian complains about those modules not being present, simply ignore the message and continue on with the next command. The second command removes the modules that came from the previous version of the library `libgcc2.c'.

   Whenever you update the compiler on your system, you should also update the library with the above procedure.
6. You may wish to build GCC in such a way that no files are written to the directory where the source files reside. An example would be the when the source files are on a read-only disk. In these cases, execute the following DCL commands (substituting your actual path names):

   ```
   $ assign dua0:[gcc.build_dir.]/translation=concealed, -
            dua1:[gcc.source_dir.]/translation=concealed  gcc_build
   $ set default gcc_build:[000000]
   ```

   where the directory `dua1:[gcc.source_dir]' contains the source code, and the directory `dua0:[gcc.build_dir]' is meant to contain all of the generated object files and executables. Once you have done this, you can proceed building GCC as described above. (Keep in mind that `gcc_build' is a rooted logical name, and thus the device names in each element of the search list must be an actual physical device name rather than another rooted logical name).
7. **If you are building GNU CC with a previous version of GNU CC, you also should check to see that you have the newest version of the assembler**. In particular, GNU CC version 2 treats global constant variables slightly differently from GNU CC version 1, and GAS version 1.38.1 does not have the patches required to work with GCC version 2. If you use GAS 1.38.1, then `extern const` variables will not have the read-only bit set, and the linker will generate warning messages about mismatched psect attributes for these variables. These warning messages are merely a nuisance, and can safely be ignored.

   If you are compiling with a version of GNU CC older than 1.33, specify `/DEFINE=("inline=")' as an option in all the compilations. This requires editing all the `gcc` commands in `make-cc1.com'. (The older versions had problems supporting `inline`.) Once you have a working 1.33 or newer GNU CC, you

can change this file back.

8. If you want to build GNU CC with the VAX C compiler, you will need to make minor changes in `make-cccp.com' and `make-cc1.com' to choose alternate definitions of CC, CFLAGS, and LIBS. See comments in those files. However, you must also have a working version of the GNU assembler (GNU as, aka GAS) as it is used as the back-end for GNU CC to produce binary object modules and is not included in the GNU CC sources. GAS is also needed to compile `libgcc2' in order to build `gcclib' (see above); `make-l2.com' expects to be able to find it operational in `gnu_cc:[000000]gnu-as.exe'.

   To use GNU CC on VMS, you need the VMS driver programs `gcc.exe', `gcc.com', and `gcc.cld'. They are distributed with the VMS binaries (`gcc-vms') rather than the GNU CC sources. GAS is also included in `gcc-vms', as is Bison.

   Once you have successfully built GNU CC with VAX C, you should use the resulting compiler to rebuild itself. Before doing this, be sure to restore the CC, CFLAGS, and LIBS definitions in `make-cccp.com' and `make-cc1.com'. The second generation compiler will be able to take advantage of many optimizations that must be suppressed when building with other compilers.

Under previous versions of GNU CC, the generated code would occasionally give strange results when linked with the sharable `VAXCRTL' library. Now this should work.

Even with this version, however, GNU CC itself should not be linked with the sharable `VAXCRTL'. The version of `qsort' in `VAXCRTL' has a bug (known to be present in VMS versions V4.6 through V5.5) which causes the compiler to fail.

The executables are generated by `make-cc1.com' and `make-cccp.com' use the object library version of `VAXCRTL' in order to make use of the `qsort' routine in `gcclib.olb'. If you wish to link the compiler executables with the shareable image version of `VAXCRTL', you should edit the file `tm.h' (created by `vmsconfig.com') to define the macro `QSORT_WORKAROUND'.

`QSORT_WORKAROUND' is always defined when GNU CC is compiled with VAX C, to avoid a problem in case `gcclib.olb' is not yet available.

collect2

Many target systems do not have support in the assembler and linker for "constructors"---initialization functions to be called before the official "start" of `main'. On such systems, GNU CC uses a utility called `collect2' to arrange to call these functions at start time.

The program `collect2' works by linking the program once and looking through the linker output file for symbols with particular names indicating they are constructor functions. If it finds any, it creates a new temporary `.c' file containing a table of them, compiles it, and links the program a second time including that file.

The actual calls to the constructors are carried out by a subroutine called `__main', which is called (automatically) at the beginning of the body of `main' (provided `main' was compiled with GNU CC). Calling `__main' is necessary, even when compiling C code, to allow linking C and C++ object code together. (If you use `-nostdlib', you get an unresolved reference to `__main', since it's defined in the standard GCC library. Include `-lgcc' at the end of your compiler command line to resolve this reference.)

The program `collect2' is installed as `ld' in the directory where the passes of the compiler are installed. When

`collect2` needs to find the *real* `ld`, it tries the following file names:

- `` `real-ld' `` in the directories listed in the compiler's search directories.
- `` `real-ld' `` in the directories listed in the environment variable `PATH`.
- The file specified in the `REAL_LD_FILE_NAME` configuration macro, if specified.
- `` `ld' `` in the compiler's search directories, except that `collect2` will not execute itself recursively.
- `` `ld' `` in `PATH`.

"The compiler's search directories" means all the directories where `gcc` searches for passes of the compiler. This includes directories that you specify with `-B'.

Cross-compilers search a little differently:

- `` `real-ld' `` in the compiler's search directories.
- `` `target-real-ld' `` in `PATH`.
- The file specified in the `REAL_LD_FILE_NAME` configuration macro, if specified.
- `` `ld' `` in the compiler's search directories.
- `` `target-ld' `` in `PATH`.

`collect2` explicitly avoids running `ld` using the file name under which `collect2` itself was invoked. In fact, it remembers up a list of such names--in case one copy of `collect2` finds another copy (or version) of `collect2` installed as `ld` in a second place in the search path.

`collect2` searches for the utilities `nm` and `strip` using the same algorithm as above for `ld`.

Standard Header File Directories

`GCC_INCLUDE_DIR` means the same thing for native and cross. It is where GNU CC stores its private include files, and also where GNU CC stores the fixed include files. A cross compiled GNU CC runs `fixincludes` on the header files in `` `$(tooldir)/include' ``. (If the cross compilation header files need to be fixed, they must be installed before GNU CC is built. If the cross compilation header files are already suitable for ANSI C and GNU CC, nothing special need be done).

`GPLUS_INCLUDE_DIR` means the same thing for native and cross. It is where `g++` looks first for header files. `libg++` installs only target independent header files in that directory.

`LOCAL_INCLUDE_DIR` is used only for a native compiler. It is normally `` `/usr/local/include' ``. GNU CC searches this directory so that users can install header files in `` `/usr/local/include' ``.

`CROSS_INCLUDE_DIR` is used only for a cross compiler. GNU CC doesn't install anything there.

`TOOL_INCLUDE_DIR` is used for both native and cross compilers. It is the place for other packages to install header files that GNU CC will use. For a cross-compiler, this is the equivalent of `` `/usr/include' ``. When you build a cross-compiler, `fixincludes` processes any header files in this directory.

Go to the previous, next section.

Go to the previous, next section.

Extensions to the C Language Family

GNU C provides several language features not found in ANSI standard C. (The `-pedantic' option directs GNU CC to print a warning message if any of these features is used.) To test for the availability of these features in conditional compilation, check for a predefined macro `__GNUC__`, which is always defined under GNU CC.

These extensions are available in C and Objective C. Most of them are also available in C++. See section Extensions to the C++ Language, for extensions that apply *only* to C++.

Statements and Declarations in Expressions

A compound statement enclosed in parentheses may appear as an expression in GNU C. This allows you to use loops, switches, and local variables within an expression.

Recall that a compound statement is a sequence of statements surrounded by braces; in this construct, parentheses go around the braces. For example:

```
({ int y = foo (); int z;
   if (y > 0) z = y;
   else z = - y;
   z; })
```

is a valid (though slightly more complex than necessary) expression for the absolute value of `foo ()`.

The last thing in the compound statement should be an expression followed by a semicolon; the value of this subexpression serves as the value of the entire construct. (If you use some other kind of statement last within the braces, the construct has type `void`, and thus effectively no value.)

This feature is especially useful in making macro definitions "safe" (so that they evaluate each operand exactly once). For example, the "maximum" function is commonly defined as a macro in standard C as follows:

```
#define max(a,b) ((a) > (b) ? (a) : (b))
```

But this definition computes either a or b twice, with bad results if the operand has side effects. In GNU C, if you know the type of the operands (here let's assume `int`), you can define the macro safely as follows:

```
#define maxint(a,b) \
  ({int _a = (a), _b = (b); _a > _b ? _a : _b; })
```

Embedded statements are not allowed in constant expressions, such as the value of an enumeration

constant, the width of a bit field, or the initial value of a static variable.

If you don't know the type of the operand, you can still do this, but you must use `typeof` (see section Referring to a Type with `typeof`) or type naming (see section Naming an Expression's Type).

Locally Declared Labels

Each statement expression is a scope in which local labels can be declared. A local label is simply an identifier; you can jump to it with an ordinary `goto` statement, but only from within the statement expression it belongs to.

A local label declaration looks like this:

```
__label__ label;
```

or

```
__label__ label1, label2, ...;
```

Local label declarations must come at the beginning of the statement expression, right after the `({', before any ordinary declarations.

The label declaration defines the label *name*, but does not define the label itself. You must do this in the usual way, with `label:`, within the statements of the statement expression.

The local label feature is useful because statement expressions are often used in macros. If the macro contains nested loops, a `goto` can be useful for breaking out of them. However, an ordinary label whose scope is the whole function cannot be used: if the macro can be expanded several times in one function, the label will be multiply defined in that function. A local label avoids this problem. For example:

```
#define SEARCH(array, target)                     \
({                                                \
  __label__ found;                                \
  typeof (target) _SEARCH_target = (target);      \
  typeof (*(array)) *_SEARCH_array = (array);     \
  int i, j;                                       \
  int value;                                      \
  for (i = 0; i < max; i++)                       \
    for (j = 0; j < max; j++)                     \
      if (_SEARCH_array[i][j] == _SEARCH_target)  \
        { value = i; goto found; }                \
  value = -1;                                     \
 found:                                           \
  value;                                          \
})
```

Labels as Values

You can get the address of a label defined in the current function (or a containing function) with the unary operator `&&'. The value has type `void *`. This value is a constant and can be used wherever a constant of that type is valid. For example:

```
void *ptr;
...
ptr = &&foo;
```

To use these values, you need to be able to jump to one. This is done with the computed goto statement(2), `goto *exp;`. For example,

```
goto *ptr;
```

Any expression of type `void *` is allowed.

One way of using these constants is in initializing a static array that will serve as a jump table:

```
static void *array[] = { &&foo, &&bar, &&hack };
```

Then you can select a label with indexing, like this:

```
goto *array[i];
```

Note that this does not check whether the subscript is in bounds--array indexing in C never does that.

Such an array of label values serves a purpose much like that of the `switch` statement. The `switch` statement is cleaner, so use that rather than an array unless the problem does not fit a `switch` statement very well.

Another use of label values is in an interpreter for threaded code. The labels within the interpreter function can be stored in the threaded code for super-fast dispatching.

You can use this mechanism to jump to code in a different function. If you do that, totally unpredictable things will happen. The best way to avoid this is to store the label address only in automatic variables and never pass it as an argument.

Nested Functions

A nested function is a function defined inside another function. (Nested functions are not supported for GNU C++.) The nested function's name is local to the block where it is defined. For example, here we define a nested function named `square`, and call it twice:

```
foo (double a, double b)
{
```

```
  double square (double z) { return z * z; }

  return square (a) + square (b);
}
```

The nested function can access all the variables of the containing function that are visible at the point of its definition. This is called lexical scoping. For example, here we show a nested function which uses an inherited variable named `offset`:

```
bar (int *array, int offset, int size)
{
  int access (int *array, int index)
    { return array[index + offset]; }
  int i;
  ...
  for (i = 0; i < size; i++)
    ... access (array, i) ...
}
```

Nested function definitions are permitted within functions in the places where variable definitions are allowed; that is, in any block, before the first statement in the block.

It is possible to call the nested function from outside the scope of its name by storing its address or passing the address to another function:

```
hack (int *array, int size)
{
  void store (int index, int value)
    { array[index] = value; }

  intermediate (store, size);
}
```

Here, the function `intermediate` receives the address of `store` as an argument. If `intermediate` calls `store`, the arguments given to `store` are used to store into `array`. But this technique works only so long as the containing function (`hack`, in this example) does not exit.

If you try to call the nested function through its address after the containing function has exited, all hell will break loose. If you try to call it after a containing scope level has exited, and if it refers to some of the variables that are no longer in scope, you may be lucky, but it's not wise to take the risk. If, however, the nested function does not refer to anything that has gone out of scope, you should be safe.

GNU CC implements taking the address of a nested function using a technique called trampolines. A paper describing them is available from `maya.idiap.ch' in directory `pub/tmb', file `usenix88-lexic.ps.Z'.

A nested function can jump to a label inherited from a containing function, provided the label was

explicitly declared in the containing function (see section Locally Declared Labels). Such a jump returns instantly to the containing function, exiting the nested function which did the `goto` and any intermediate functions as well. Here is an example:

```
bar (int *array, int offset, int size)
{
  __label__ failure;
  int access (int *array, int index)
    {
      if (index > size)
        goto failure;
      return array[index + offset];
    }
  int i;
  ...
  for (i = 0; i < size; i++)
    ... access (array, i) ...
  ...
  return 0;

 /* Control comes here from access
    if it detects an error.  */
 failure:
  return -1;
}
```

A nested function always has internal linkage. Declaring one with `extern` is erroneous. If you need to declare the nested function before its definition, use `auto` (which is otherwise meaningless for function declarations).

```
bar (int *array, int offset, int size)
{
  __label__ failure;
  auto int access (int *, int);
  ...
  int access (int *array, int index)
    {
      if (index > size)
        goto failure;
      return array[index + offset];
    }
  ...
}
```

Constructing Function Calls

Using the built-in functions described below, you can record the arguments a function received, and call another function with the same arguments, without knowing the number or types of the arguments.

You can also record the return value of that function call, and later return that value, without knowing what data type the function tried to return (as long as your caller expects that data type).

`__builtin_apply_args ()`

This built-in function returns a pointer of type `void *` to data describing how to perform a call with the same arguments as were passed to the current function.

The function saves the arg pointer register, structure value address, and all registers that might be used to pass arguments to a function into a block of memory allocated on the stack. Then it returns the address of that block.

`__builtin_apply (function, arguments, size)`

This built-in function invokes function (type `void (*)()`) with a copy of the parameters described by arguments (type `void *`) and size (type `int`).

The value of arguments should be the value returned by `__builtin_apply_args`. The argument size specifies the size of the stack argument data, in bytes.

This function returns a pointer of type `void *` to data describing how to return whatever value was returned by function. The data is saved in a block of memory allocated on the stack.

It is not always simple to compute the proper value for size. The value is used by `__builtin_apply` to compute the amount of data that should be pushed on the stack and copied from the incoming argument area.

`__builtin_return (result)`

This built-in function returns the value described by result from the containing function. You should specify, for result, a value returned by `__builtin_apply`.

Naming an Expression's Type

You can give a name to the type of an expression using a `typedef` declaration with an initializer. Here is how to define name as a type name for the type of exp:

```
typedef name = exp;
```

This is useful in conjunction with the statements-within-expressions feature. Here is how the two together can be used to define a safe "maximum" macro that operates on any arithmetic type:

```
#define max(a,b) \
  ({typedef _ta = (a), _tb = (b);  \
    _ta _a = (a); _tb _b = (b);     \
```

```
_a > _b ? _a : _b; })
```

The reason for using names that start with underscores for the local variables is to avoid conflicts with variable names that occur within the expressions that are substituted for `a` and `b`. Eventually we hope to design a new form of declaration syntax that allows you to declare variables whose scopes start only after their initializers; this will be a more reliable way to prevent such conflicts.

Referring to a Type with `typeof`

Another way to refer to the type of an expression is with `typeof`. The syntax of using of this keyword looks like `sizeof`, but the construct acts semantically like a type name defined with `typedef`.

There are two ways of writing the argument to `typeof`: with an expression or with a type. Here is an example with an expression:

```
typeof (x[0](1))
```

This assumes that `x` is an array of functions; the type described is that of the values of the functions.

Here is an example with a typename as the argument:

```
typeof (int *)
```

Here the type described is that of pointers to `int`.

If you are writing a header file that must work when included in ANSI C programs, write `__typeof__` instead of `typeof`. See section Alternate Keywords.

A `typeof`-construct can be used anywhere a typedef name could be used. For example, you can use it in a declaration, in a cast, or inside of `sizeof` or `typeof`.

- This declares `y` with the type of what `x` points to.

  ```
  typeof (*x) y;
  ```

- This declares `y` as an array of such values.

  ```
  typeof (*x) y[4];
  ```

- This declares `y` as an array of pointers to characters:

  ```
  typeof (typeof (char *)[4]) y;
  ```

  It is equivalent to the following traditional C declaration:

  ```
  char *y[4];
  ```

  To see the meaning of the declaration using `typeof`, and why it might be a useful way to write, let's rewrite it with these macros:

```
#define pointer(T)  typeof(T *)
#define array(T, N) typeof(T [N])
```

Now the declaration can be rewritten this way:

```
array (pointer (char), 4) y;
```

Thus, `array (pointer (char), 4)` is the type of arrays of 4 pointers to `char`.

Generalized Lvalues

Compound expressions, conditional expressions and casts are allowed as lvalues provided their operands are lvalues. This means that you can take their addresses or store values into them.

Standard C++ allows compound expressions and conditional expressions as lvalues, and permits casts to reference type, so use of this extension is deprecated for C++ code.

For example, a compound expression can be assigned, provided the last expression in the sequence is an lvalue. These two expressions are equivalent:

```
(a, b) += 5
a, (b += 5)
```

Similarly, the address of the compound expression can be taken. These two expressions are equivalent:

```
&(a, b)
a, &b
```

A conditional expression is a valid lvalue if its type is not void and the true and false branches are both valid lvalues. For example, these two expressions are equivalent:

```
(a ? b : c) = 5
(a ? b = 5 : (c = 5))
```

A cast is a valid lvalue if its operand is an lvalue. A simple assignment whose left-hand side is a cast works by converting the right-hand side first to the specified type, then to the type of the inner left-hand side expression. After this is stored, the value is converted back to the specified type to become the value of the assignment. Thus, if `a` has type `char *`, the following two expressions are equivalent:

```
(int)a = 5
(int)(a = (char *)(int)5)
```

An assignment-with-arithmetic operation such as `+=' applied to a cast performs the arithmetic using the type resulting from the cast, and then continues as in the previous case. Therefore, these two expressions are equivalent:

```
(int)a += 5
(int)(a = (char *)(int) ((int)a + 5))
```

You cannot take the address of an lvalue cast, because the use of its address would not work out coherently. Suppose that `&(int)f` were permitted, where `f` has type `float`. Then the following statement would try to store an integer bit-pattern where a floating point number belongs:

```
*&(int)f = 1;
```

This is quite different from what `(int)f = 1` would do--that would convert 1 to floating point and store it. Rather than cause this inconsistency, we think it is better to prohibit use of `&' on a cast.

If you really do want an `int *` pointer with the address of `f`, you can simply write `(int *)&f`.

Conditionals with Omitted Operands

The middle operand in a conditional expression may be omitted. Then if the first operand is nonzero, its value is the value of the conditional expression.

Therefore, the expression

```
x ? : y
```

has the value of `x` if that is nonzero; otherwise, the value of `y`.

This example is perfectly equivalent to

```
x ? x : y
```

In this simple case, the ability to omit the middle operand is not especially useful. When it becomes useful is when the first operand does, or may (if it is a macro argument), contain a side effect. Then repeating the operand in the middle would perform the side effect twice. Omitting the middle operand uses the value already computed without the undesirable effects of recomputing it.

Double-Word Integers

GNU C supports data types for integers that are twice as long as `long int`. Simply write `long long int` for a signed integer, or `unsigned long long int` for an unsigned integer. To make an integer constant of type `long long int`, add the suffix `LL` to the integer. To make an integer constant of type `unsigned long long int`, add the suffix `ULL` to the integer.

You can use these types in arithmetic like any other integer types. Addition, subtraction, and bitwise boolean operations on these types are open-coded on all types of machines. Multiplication is open-coded if the machine supports fullword-to-doubleword a widening multiply instruction. Division and shifts are open-coded only on machines that provide special support. The operations that are not open-coded use

special library routines that come with GNU CC.

There may be pitfalls when you use `long long` types for function arguments, unless you declare function prototypes. If a function expects type `int` for its argument, and you pass a value of type `long long int`, confusion will result because the caller and the subroutine will disagree about the number of bytes for the argument. Likewise, if the function expects `long long int` and you pass `int`. The best way to avoid such problems is to use prototypes.

Complex Numbers

GNU C supports complex data types. You can declare both complex integer types and complex floating types, using the keyword `__complex__`.

For example, `__complex__ double x;' declares `x` as a variable whose real part and imaginary part are both of type `double`. `__complex__ short int y;' declares `y` to have real and imaginary parts of type `short int`; this is not likely to be useful, but it shows that the set of complex types is complete.

To write a constant with a complex data type, use the suffix `i' or `j' (either one; they are equivalent). For example, `2.5fi` has type `__complex__ float` and `3i` has type `__complex__ int`. Such a constant always has a pure imaginary value, but you can form any complex value you like by adding one to a real constant.

To extract the real part of a complex-valued expression exp, write `__real__ exp`. Likewise, use `__imag__` to extract the imaginary part.

The operator `~' performs complex conjugation when used on a value with a complex type.

GNU CC can allocate complex automatic variables in a noncontiguous fashion; it's even possible for the real part to be in a register while the imaginary part is on the stack (or vice-versa). None of the supported debugging info formats has a way to represent noncontiguous allocation like this, so GNU CC describes a noncontiguous complex variable as if it were two separate variables of noncomplex type. If the variable's actual name is `foo`, the two fictitious variables are named `foo$real` and `foo$imag`. You can examine and set these two fictitious variables with your debugger.

A future version of GDB will know how to recognize such pairs and treat them as a single variable with a complex type.

Arrays of Length Zero

Zero-length arrays are allowed in GNU C. They are very useful as the last element of a structure which is really a header for a variable-length object:

```
struct line {
  int length;
  char contents[0];
};
```

```
{
  struct line *thisline = (struct line *)
    malloc (sizeof (struct line) + this_length);
  thisline->length = this_length;
}
```

In standard C, you would have to give `contents` a length of 1, which means either you waste space or complicate the argument to `malloc`.

Arrays of Variable Length

Variable-length automatic arrays are allowed in GNU C. These arrays are declared like any other automatic arrays, but with a length that is not a constant expression. The storage is allocated at the point of declaration and deallocated when the brace-level is exited. For example:

```
FILE *
concat_fopen (char *s1, char *s2, char *mode)
{
  char str[strlen (s1) + strlen (s2) + 1];
  strcpy (str, s1);
  strcat (str, s2);
  return fopen (str, mode);
}
```

Jumping or breaking out of the scope of the array name deallocates the storage. Jumping into the scope is not allowed; you get an error message for it.

You can use the function `alloca` to get an effect much like variable-length arrays. The function `alloca` is available in many other C implementations (but not in all). On the other hand, variable-length arrays are more elegant.

There are other differences between these two methods. Space allocated with `alloca` exists until the containing *function* returns. The space for a variable-length array is deallocated as soon as the array name's scope ends. (If you use both variable-length arrays and `alloca` in the same function, deallocation of a variable-length array will also deallocate anything more recently allocated with `alloca`.)

You can also use variable-length arrays as arguments to functions:

```
struct entry
tester (int len, char data[len][len])
{
  ...
}
```

The length of an array is computed once when the storage is allocated and is remembered for the sco of the array in case you access it with `sizeof`.

If you want to pass the array first and the length afterward, you can use a forward declaration in the parameter list--another GNU extension.

```
struct entry
tester (int len; char data[len][len], int len)
{
  ...
}
```

The `int len' before the semicolon is a parameter forward declaration, and it serves the purpose of making the name `len` known when the declaration of `data` is parsed.

You can write any number of such parameter forward declarations in the parameter list. They can be separated by commas or semicolons, but the last one must end with a semicolon, which is followed by the "real" parameter declarations. Each forward declaration must match a "real" declaration in parameter name and data type.

Macros with Variable Numbers of Arguments

In GNU C, a macro can accept a variable number of arguments, much as a function can. The syntax for defining the macro looks much like that used for a function. Here is an example:

```
#define eprintf(format, args...)  \
 fprintf (stderr, format , ## args)
```

Here `args` is a rest argument: it takes in zero or more arguments, as many as the call contains. All of them plus the commas between them form the value of `args`, which is substituted into the macro body where `args` is used. Thus, we have this expansion:

```
eprintf ("%s:%d: ", input_file_name, line_number)
==>
fprintf (stderr, "%s:%d: " , input_file_name, line_number)
```

Note that the comma after the string constant comes from the definition of `eprintf`, whereas the last comma comes from the value of `args`.

The reason for using `##' is to handle the case when `args` matches no arguments at all. In this case, `args` has an empty value. In this case, the second comma in the definition becomes an embarrassment: if it got through to the expansion of the macro, we would get something like this:

```
fprintf (stderr, "success!\n" , )
```

which is invalid C syntax. `##' gets rid of the comma, so we get the following instead:

```
fprintf (stderr, "success!\n")
```

This is a special feature of the GNU C preprocessor: `##' before a rest argument that is empty discards the preceding sequence of non-whitespace characters from the macro definition. (If another macro argument precedes, none of it is discarded.)

It might be better to discard the last preprocessor token instead of the last preceding sequence of non-whitespace characters; in fact, we may someday change this feature to do so. We advise you to write the macro definition so that the preceding sequence of non-whitespace characters is just a single token, so that the meaning will not change if we change the definition of this feature.

Non-Lvalue Arrays May Have Subscripts

Subscripting is allowed on arrays that are not lvalues, even though the unary `&' operator is not. For example, this is valid in GNU C though not valid in other C dialects:

```
struct foo {int a[4];};

struct foo f();

bar (int index)
{
  return f().a[index];
}
```

Arithmetic on `void`- and Function-Pointers

In GNU C, addition and subtraction operations are supported on pointers to `void` and on pointers to functions. This is done by treating the size of a `void` or of a function as 1.

A consequence of this is that `sizeof` is also allowed on `void` and on function types, and returns 1.

The option `-Wpointer-arith' requests a warning if these extensions are used.

Non-Constant Initializers

As in standard C++, the elements of an aggregate initializer for an automatic variable are not required to be constant expressions in GNU C. Here is an example of an initializer with run-time varying elements:

```
foo (float f, float g)
{
  float beat_freqs[2] = { f-g, f+g };
  ...
```

```
}
```

Constructor Expressions

GNU C supports constructor expressions. A constructor looks like a cast containing an initializer. Its value is an object of the type specified in the cast, containing the elements specified in the initializer.

Usually, the specified type is a structure. Assume that `struct foo` and `structure` are declared as shown:

```
struct foo {int a; char b[2];} structure;
```

Here is an example of constructing a `struct foo` with a constructor:

```
structure = ((struct foo) {x + y, 'a', 0});
```

This is equivalent to writing the following:

```
{
  struct foo temp = {x + y, 'a', 0};
  structure = temp;
}
```

You can also construct an array. If all the elements of the constructor are (made up of) simple constant expressions, suitable for use in initializers, then the constructor is an lvalue and can be coerced to a pointer to its first element, as shown here:

```
char **foo = (char *[]) { "x", "y", "z" };
```

Array constructors whose elements are not simple constants are not very useful, because the constructor is not an lvalue. There are only two valid ways to use it: to subscript it, or initialize an array variable with it. The former is probably slower than a `switch` statement, while the latter does the same thing an ordinary C initializer would do. Here is an example of subscripting an array constructor:

```
output = ((int[]) { 2, x, 28 }) [input];
```

Constructor expressions for scalar types and union types are is also allowed, but then the constructor expression is equivalent to a cast.

Labeled Elements in Initializers

Standard C requires the elements of an initializer to appear in a fixed order, the same as the order of the elements in the array or structure being initialized.

In GNU C you can give the elements in any order, specifying the array indices or structure field names

they apply to. This extension is not implemented in GNU C++.

To specify an array index, write `[index]' or `[index] =' before the element value. For example,

```
int a[6] = { [4] 29, [2] = 15 };
```

is equivalent to

```
int a[6] = { 0, 0, 15, 0, 29, 0 };
```

The index values must be constant expressions, even if the array being initialized is automatic.

To initialize a range of elements to the same value, write `[first ... last] = value'. For example,

```
int widths[] = { [0 ... 9] = 1, [10 ... 99] = 2, [100] = 3 };
```

Note that the length of the array is the highest value specified plus one.

In a structure initializer, specify the name of a field to initialize with `fieldname:' before the element value. For example, given the following structure,

```
struct point { int x, y; };
```

the following initialization

```
struct point p = { y: yvalue, x: xvalue };
```

is equivalent to

```
struct point p = { xvalue, yvalue };
```

Another syntax which has the same meaning is `.fieldname =', as shown here:

```
struct point p = { .y = yvalue, .x = xvalue };
```

You can also use an element label (with either the colon syntax or the period-equal syntax) when initializing a union, to specify which element of the union should be used. For example,

```
union foo { int i; double d; };

union foo f = { d: 4 };
```

will convert 4 to a `double` to store it in the union using the second element. By contrast, casting 4 to type `union foo` would store it into the union as the integer `i`, since it is an integer. (See section Cast to a Union Type.)

You can combine this technique of naming elements with ordinary C initialization of successive elements. Each initializer element that does not have a label applies to the next consecutive element of

the array or structure. For example,

```
int a[6] = { [1] = v1, v2, [4] = v4 };
```

is equivalent to

```
int a[6] = { 0, v1, v2, 0, v4, 0 };
```

Labeling the elements of an array initializer is especially useful when the indices are characters or belong to an `enum` type. For example:

```
int whitespace[256]
  = { [' '] = 1, ['\t'] = 1, ['\h'] = 1,
      ['\f'] = 1, ['\n'] = 1, ['\r'] = 1 };
```

Case Ranges

You can specify a range of consecutive values in a single `case` label, like this:

```
case low ... high:
```

This has the same effect as the proper number of individual `case` labels, one for each integer value from low to high, inclusive.

This feature is especially useful for ranges of ASCII character codes:

```
case 'A' ... 'Z':
```

Be careful: Write spaces around the `...`, for otherwise it may be parsed wrong when you use it with integer values. For example, write this:

```
case 1 ... 5:
```

rather than this:

```
case 1...5:
```

Cast to a Union Type

A cast to union type is similar to other casts, except that the type specified is a union type. You can specify the type either with `union tag` or with a typedef name. A cast to union is actually a constructor though, not a cast, and hence does not yield an lvalue like normal casts. (See section Constructor Expressions.)

The types that may be cast to the union type are those of the members of the union. Thus, given the

following union and variables:

```
union foo { int i; double d; };
int x;
double y;
```

both `x` and `y` can be cast to type `union` foo.

Using the cast as the right-hand side of an assignment to a variable of union type is equivalent to storing in a member of the union:

```
union foo u;
...
u = (union foo) x  ==  u.i = x
u = (union foo) y  ==  u.d = y
```

You can also use the union cast as a function argument:

```
void hack (union foo);
...
hack ((union foo) x);
```

Declaring Attributes of Functions

In GNU C, you declare certain things about functions called in your program which help the compiler optimize function calls and check your code more carefully.

The keyword `__attribute__` allows you to specify special attributes when making a declaration. This keyword is followed by an attribute specification inside double parentheses. Eight attributes, `noreturn`, `const`, `format`, `section`, `constructor`, `destructor`, `unused` and `weak` are currently defined for functions. Other attributes, including `section` are supported for variables declarations (see section Specifying Attributes of Variables) and for types (see section Specifying Attributes of Types).

You may also specify attributes with `__' preceding and following each keyword. This allows you to use them in header files without being concerned about a possible macro of the same name. For example, you may use `__noreturn__` instead of `noreturn`.

`noreturn`

A few standard library functions, such as `abort` and `exit`, cannot return. GNU CC knows this automatically. Some programs define their own functions that never return. You can declare them `noreturn` to tell the compiler this fact. For example,

```
void fatal () __attribute__ ((noreturn));

void
```

```
fatal (...)
{
  ... /* Print error message. */ ...
  exit (1);
}
```

The `noreturn` keyword tells the compiler to assume that `fatal` cannot return. It can then optimize without regard to what would happen if `fatal` ever did return. This makes slightly better code. More importantly, it helps avoid spurious warnings of uninitialized variables.

Do not assume that registers saved by the calling function are restored before calling the `noreturn` function.

It does not make sense for a `noreturn` function to have a return type other than `void`.

The attribute `noreturn` is not implemented in GNU C versions earlier than 2.5. An alternative way to declare that a function does not return, which works in the current version and in some older versions, is as follows:

```
typedef void voidfn ();

volatile voidfn fatal;
```

`const`

Many functions do not examine any values except their arguments, and have no effects except the return value. Such a function can be subject to common subexpression elimination and loop optimization just as an arithmetic operator would be. These functions should be declared with the attribute `const`. For example,

```
int square (int) __attribute__ ((const));
```

says that the hypothetical function `square` is safe to call fewer times than the program says.

The attribute `const` is not implemented in GNU C versions earlier than 2.5. An alternative way to declare that a function has no side effects, which works in the current version and in some older versions, is as follows:

```
typedef int intfn ();

extern const intfn square;
```

This approach does not work in GNU C++ from 2.6.0 on, since the language specifies that the `const' must be attached to the return value.

Note that a function that has pointer arguments and examines the data pointed to must *not* be declared `const`. Likewise, a function that calls a non-`const` function usually must not be `const`. It does not make sense for a `const` function to return `void`.

`format (archetype, string-index, first-to-check)`

The `format` attribute specifies that a function takes `printf` or `scanf` style arguments whi should be type-checked against a format string. For example, the declaration:

```
extern int
my_printf (void *my_object, const char *my_format, ...)
      __attribute__ ((format (printf, 2, 3)));
```

causes the compiler to check the arguments in calls to `my_printf` for consistency with the `printf` style format string argument `my_format`.

The parameter archetype determines how the format string is interpreted, and should be either `printf` or `scanf`. The parameter string-index specifies which argument is the format string argument (starting from 1), while first-to-check is the number of the first argument to check against the format string. For functions where the arguments are not available to be checked (such as `vprintf`), specify the third parameter as zero. In this case the compiler only checks the format string for consistency.

In the example above, the format string (`my_format`) is the second argument of the function `my_print`, and the arguments to check start with the third argument, so the correct parameters for the format attribute are 2 and 3.

The `format` attribute allows you to identify your own functions which take format strings as arguments, so that GNU CC can check the calls to these functions for errors. The compiler always checks formats for the ANSI library functions `printf`, `fprintf`, `sprintf`, `scanf`, `fscanf`, `sscanf`, `vprintf`, `vfprintf` and `vsprintf` whenever such warnings are requested (using `-Wformat'), so there is no need to modify the header file `stdio.h'.

`section ("section-name")`

Normally, the compiler places the code it generates in the `text` section. Sometimes, however, you need additional sections, or you need certain particular functions to appear in special sections. The `section` attribute specifies that a function lives in a particular section. For example, the declaration:

```
extern void foobar (void) __attribute__ ((section ("bar")));
```

puts the function `foobar` in the `bar` section.

Some file formats do not support arbitrary sections so the `section` attribute is not available on all platforms. If you need to map the entire contents of a module to a particular section, consider using the facilities of the linker instead.

`constructor`

`destructor`

The `constructor` attribute causes the function to be called automatically before execution enters `main ()`. Similarly, the `destructor` attribute causes the function to be called automatically after `main ()` has completed or `exit ()` has been called. Functions with these attributes are useful for initializing data that will be used implicitly during the execution of the program.

These attributes are not currently implemented for Objective C.

`unused`

This attribute, attached to a function, means that the function is meant to be possibly unused. GNU CC will not produce a warning for this function.

`weak`

The `weak` attribute causes the declaration to be emitted as a weak symbol rather than a global. This is primarily useful in defining library functions which can be overridden in user code, though it can also be used with non-function declarations. Weak symbols are supported for ELF targets, and also for a.out targets when using the GNU assembler and linker.

`alias ("target")`

The `alias` attribute causes the declaration to be emitted as an alias for another symbol, which must be specified. For instance,

```
void __f () { /* do something */; }
void f () __attribute__ ((weak, alias ("__f")));
```

declares `f' to be a weak alias for `__f'. In C++, the mangled name for the target must be used.

`regparm (number)`

On the Intel 386, the `regparm` attribute causes the compiler to pass up to number integer arguments in registers EAX, EDX, and ECX instead of on the stack. Functions that take a variable number of arguments will continue to be passed all of their arguments on the stack.

`stdcall`

On the Intel 386, the `stdcall` attribute causes the compiler to assume that the called function will pop off the stack space used to pass arguments, unless it takes a variable number of arguments.

`cdecl`

On the Intel 386, the `cdecl` attribute causes the compiler to assume that the called function will pop off the stack space used to pass arguments, unless it takes a variable number of arguments. This is useful to override the effects of the `-mrtd' switch.

You can specify multiple attributes in a declaration by separating them by commas within the double parentheses or by immediately following an attribute declaration with another attribute declaration.

Some people object to the `__attribute__` feature, suggesting that ANSI C's `#pragma` should be used instead. There are two reasons for not doing this.

1. It is impossible to generate `#pragma` commands from a macro.
2. There is no telling what the same `#pragma` might mean in another compiler.

These two reasons apply to almost any application that might be proposed for `#pragma`. It is basically a mistake to use `#pragma` for *anything*.

Prototypes and Old-Style Function Definitions

GNU C extends ANSI C to allow a function prototype to override a later old-style non-prototype definition. Consider the following example:

```
/* Use prototypes unless the compiler is old-fashioned.  */
#if __STDC__
#define P(x) x
#else
#define P(x) ()
#endif

/* Prototype function declaration.  */
int isroot P((uid_t));

/* Old-style function definition.  */
int
isroot (x)   /* ??? lossage here ??? */
     uid_t x;
{
  return x == 0;
}
```

Suppose the type `uid_t` happens to be `short`. ANSI C does not allow this example, because subword arguments in old-style non-prototype definitions are promoted. Therefore in this example the function definition's argument is really an `int`, which does not match the prototype argument type of `short`.

This restriction of ANSI C makes it hard to write code that is portable to traditional C compilers, because the programmer does not know whether the `uid_t` type is `short`, `int`, or `long`. Therefore, in cases like these GNU C allows a prototype to override a later old-style definition. More precisely, in GNU C, a function prototype argument type overrides the argument type specified by a later old-style definition if the former type is the same as the latter type before promotion. Thus in GNU C the above example is equivalent to the following:

```
int isroot (uid_t);

int
isroot (uid_t x)
{
  return x == 0;
}
```

GNU C++ does not support old-style function definitions, so this extension is irrelevant.

Dollar Signs in Identifier Names

In GNU C, you may use dollar signs in identifier names. This is because many traditional C implementations allow such identifiers.

On some machines, dollar signs are allowed in identifiers if you specify `-traditional'. On a few systems they are allowed by default, even if you do not use `-traditional'. But they are never allowed if you specify `-ansi'.

There are certain ANSI C programs (obscure, to be sure) that would compile incorrectly if dollar signs were permitted in identifiers. For example:

```
#define foo(a) #a
#define lose(b) foo (b)
#define test$
lose (test)
```

The Character ESC in Constants

You can use the sequence `\e' in a string or character constant to stand for the ASCII character ESC.

Inquiring on Alignment of Types or Variables

The keyword `__alignof__` allows you to inquire about how an object is aligned, or the minimum alignment usually required by a type. Its syntax is just like `sizeof`.

For example, if the target machine requires a `double` value to be aligned on an 8-byte boundary, then `__alignof__ (double)` is 8. This is true on many RISC machines. On more traditional machine designs, `__alignof__ (double)` is 4 or even 2.

Some machines never actually require alignment; they allow reference to any data type even at an odd addresses. For these machines, `__alignof__` reports the *recommended* alignment of a type.

When the operand of `__alignof__` is an lvalue rather than a type, the value is the largest alignment that the lvalue is known to have. It may have this alignment as a result of its data type, or because it is part of a structure and inherits alignment from that structure. For example, after this declaration:

```
struct foo { int x; char y; } foo1;
```

the value of `__alignof__ (foo1.y)` is probably 2 or 4, the same as `__alignof__ (int)`, even though the data type of `foo1.y` does not itself demand any alignment.

A related feature which lets you specify the alignment of an object is `__attribute__ ((aligned (alignment)))`; see the following section.

Specifying Attributes of Variables

The keyword `__attribute__` allows you to specify special attributes of variables or structure fields. This keyword is followed by an attribute specification inside double parentheses. Eight attributes are currently defined for variables: `aligned`, `mode`, `nocommon`, `packed`, `section`, `transparent_union`, `unused`, and `weak`. Other attributes are available for functions (see section Declaring Attributes of Functions) and for types (see section Specifying Attributes of Types).

You may also specify attributes with `__' preceding and following each keyword. This allows you to use them in header files without being concerned about a possible macro of the same name. For example, you may use `__aligned__` instead of `aligned`.

`aligned (alignment)`

This attribute specifies a minimum alignment for the variable or structure field, measured in bytes. For example, the declaration:

```
int x __attribute__ ((aligned (16))) = 0;
```

causes the compiler to allocate the global variable `x` on a 16-byte boundary. On a 68040, this could be used in conjunction with an `asm` expression to access the `move16` instruction which requires 16-byte aligned operands.

You can also specify the alignment of structure fields. For example, to create a double-word aligned `int` pair, you could write:

```
struct foo { int x[2] __attribute__ ((aligned (8))); };
```

This is an alternative to creating a union with a `double` member that forces the union to be double-word aligned.

It is not possible to specify the alignment of functions; the alignment of functions is determined by the machine's requirements and cannot be changed. You cannot specify alignment for a typedef name because such a name is just an alias, not a distinct type.

As in the preceding examples, you can explicitly specify the alignment (in bytes) that you wish the compiler to use for a given variable or structure field. Alternatively, you can leave out the alignment factor and just ask the compiler to align a variable or field to the maximum useful alignment for the target machine you are compiling for. For example, you could write:

```
short array[3] __attribute__ ((aligned));
```

Whenever you leave out the alignment factor in an `aligned` attribute specification, the compiler automatically sets the alignment for the declared variable or field to the largest alignment which is ever used for any data type on the target machine you are compiling for. Doing this can often make copy operations more efficient, because the compiler can use whatever instructions copy the biggest chunks of memory when performing copies to or from the variables or fields that you have aligned this way.

The `aligned` attribute can only increase the alignment; but you can decrease it by specifying `packed` as well. See below.

Note that the effectiveness of `aligned` attributes may be limited by inherent limitations in your linker. On many systems, the linker is only able to arrange for variables to be aligned up to a certain maximum alignment. (For some linkers, the maximum supported alignment may be very very small.) If your linker is only able to align variables up to a maximum of 8 byte alignment, then specifying `aligned(16)` in an `__attribute__` will still only provide you with 8 byte alignment. See your linker documentation for further information.

`mode (mode)`

This attribute specifies the data type for the declaration--whichever type corresponds to the mode mode. This in effect lets you request an integer or floating point type according to its width.

You may also specify a mode of `byte' or `__byte__' to indicate the mode corresponding to a one-byte integer, `word' or `__word__' for the mode of a one-word integer, and `pointer' or `__pointer__' for the mode used to represent pointers.

`nocommon`

This attribute specifies requests GNU CC not to place a variable "common" but instead to allocate space for it directly. If you specify the `-fno-common' flag, GNU CC will do this for all variables.

Specifying the `nocommon` attribute for a variable provides an initialization of zeros. A variable may only be initialized in one source file.

`packed`

The `packed` attribute specifies that a variable or structure field should have the smallest possible alignment--one byte for a variable, and one bit for a field, unless you specify a larger value with the `aligned` attribute.

Here is a structure in which the field `x` is packed, so that it immediately follows `a`:

```
struct foo
{
  char a;
  int x[2] __attribute__ ((packed));
};
```

`section ("section-name")`

Normally, the compiler places the objects it generates in sections like `data` and `bss`. Sometimes, however, you need additional sections, or you need certain particular variables to appear in special sections, for example to map to special hardware. The `section` attribute specifies that a variable (or function) lives in a particular section. For example, this small program uses several specific section names:

```
struct duart a __attribute__ ((section ("DUART_A"))) = { 0 };
struct duart b __attribute__ ((section ("DUART_B"))) = { 0 };
char stack[10000] __attribute__ ((section ("STACK"))) = { 0 };
```

```
int init_data_copy __attribute__ ((section ("INITDATACOPY"))) =

main()
{
  /* Initialize stack pointer */
  init_sp (stack + sizeof (stack));

  /* Initialize initialized data */
  memcpy (&init_data_copy, &data, &edata - &data);

  /* Turn on the serial ports */
  init_duart (&a);
  init_duart (&b);
}
```

Use the `section` attribute with an *initialized* definition of a *global* variable, as shown in the example. GNU CC issues a warning and otherwise ignores the `section` attribute in uninitialized variable declarations.

You may only use the `section` attribute with a fully initialized global definition because of the way linkers work. The linker requires each object be defined once, with the exception that uninitialized variables tentatively go in the `common` (or `bss`) section and can be multiply "defined". You can force a variable to be initialized with the `-fno-common' flag or the `nocommon` attribute.

Some file formats do not support arbitrary sections so the `section` attribute is not available on all platforms. If you need to map the entire contents of a module to a particular section, consider using the facilities of the linker instead.

`transparent_union`

This attribute, attached to a function argument variable which is a union, means to pass the argument in the same way that the first union member would be passed. You can also use this attribute on a `typedef` for a union data type; then it applies to all function arguments with that type.

`unused`

This attribute, attached to a variable, means that the variable is meant to be possibly unused. GNU CC will not produce a warning for this variable.

`weak`

The `weak` attribute is described in See section Declaring Attributes of Functions.

To specify multiple attributes, separate them by commas within the double parentheses: for example, `__attribute__ ((aligned (16), packed))'.

Specifying Attributes of Types

The keyword `__attribute__` allows you to specify special attributes of `struct` and `union` types when you define such types. This keyword is followed by an attribute specification inside double parentheses. Three attributes are currently defined for types: `aligned`, `packed`, and `transparent_union`. Other attributes are defined for functions (see section Declaring Attributes of Functions) and for variables (see section Specifying Attributes of Variables).

You may also specify any one of these attributes with `__' preceding and following its keyword. This allows you to use these attributes in header files without being concerned about a possible macro of the same name. For example, you may use `__aligned__` instead of `aligned`.

You may specify the `aligned` and `transparent_union` attributes either in a `typedef` declaration or just past the closing curly brace of a complete enum, struct or union type *definition* and the `packed` attribute only past the closing brace of a definition.

`aligned (alignment)`

This attribute specifies a minimum alignment (in bytes) for variables of the specified type. For example, the declarations:

```
struct S { short f[3]; } __attribute__ ((aligned (8));
typedef int more_aligned_int __attribute__ ((aligned (8));
```

force the compiler to insure (as fas as it can) that each variable whose type is `struct S` or `more_aligned_int` will be allocated and aligned *at least* on a 8-byte boundary. On a Sparc, having all variables of type `struct S` aligned to 8-byte boundaries allows the compiler to use the `ldd` and `std` (doubleword load and store) instructions when copying one variable of type `struct S` to another, thus improving run-time efficiency.

Note that the alignment of any given `struct` or `union` type is required by the ANSI C standard to be at least a perfect multiple of the lowest common multiple of the alignments of all of the members of the `struct` or `union` in question. This means that you *can* effectively adjust the alignment of a `struct` or `union` type by attaching an `aligned` attribute to any one of the members of such a type, but the notation illustrated in the example above is a more obvious, intuitive, and readable way to request the compiler to adjust the alignment of an entire `struct` or `union` type.

As in the preceding example, you can explicitly specify the alignment (in bytes) that you wish the compiler to use for a given `struct` or `union` type. Alternatively, you can leave out the alignment factor and just ask the compiler to align a type to the maximum useful alignment for the target machine you are compiling for. For example, you could write:

```
struct S { short f[3]; } __attribute__ ((aligned));
```

Whenever you leave out the alignment factor in an `aligned` attribute specification, the compiler automatically sets the alignment for the type to the largest alignment which is ever used for any data type on the target machine you are compiling for. Doing this can often make copy operations

more efficient, because the compiler can use whatever instructions copy the biggest chunks of memory when performing copies to or from the variables which have types that you have aligned this way.

In the example above, if the size of each `short` is 2 bytes, then the size of the entire `struct S` type is 6 bytes. The smallest power of two which is greater than or equal to that is 8, so the compiler sets the alignment for the entire `struct S` type to 8 bytes.

Note that although you can ask the compiler to select a time-efficient alignment for a given type and then declare only individual stand-alone objects of that type, the compiler's ability to select a time-efficient alignment is primarily useful only when you plan to create arrays of variables having the relevant (efficiently aligned) type. If you declare or use arrays of variables of an efficiently-aligned type, then it is likely that your program will also be doing pointer arithmetic (or subscripting, which amounts to the same thing) on pointers to the relevant type, and the code that the compiler generates for these pointer arithmetic operations will often be more efficient for efficiently-aligned types than for other types.

The `aligned` attribute can only increase the alignment; but you can decrease it by specifying `packed` as well. See below.

Note that the effectiveness of `aligned` attributes may be limited by inherent limitations in your linker. On many systems, the linker is only able to arrange for variables to be aligned up to a certain maximum alignment. (For some linkers, the maximum supported alignment may be very very small.) If your linker is only able to align variables up to a maximum of 8 byte alignment, then specifying `aligned(16)` in an `__attribute__` will still only provide you with 8 byte alignment. See your linker documentation for further information.

`packed`

This attribute, attached to an `enum`, `struct`, or `union` type definition, specified that the minimum required memory be used to represent the type.

Specifying this attribute for `struct` and `union` types is equivalent to specifying the `packed` attribute on each of the structure or union members. Specifying the `-fshort-enums' flag on the line is equivalent to specifying the `packed` attribute on all `enum` definitions.

You may only specify this attribute after a closing curly brace on an `enum` definition, not in a `typedef` declaration.

`transparent_union`

This attribute, attached to a `union` type definition, indicates that any variable having that union type should, if passed to a function, be passed in the same way that the first union member would be passed. For example:

```
union foo
{
  char a;
  int x[2];
} __attribute__ ((transparent_union));
```

To specify multiple attributes, separate them by commas within the double parentheses: for example, `__attribute__ ((aligned (16), packed))'.

An Inline Function is As Fast As a Macro

By declaring a function `inline`, you can direct GNU CC to integrate that function's code into the code for its callers. This makes execution faster by eliminating the function-call overhead; in addition, if any of the actual argument values are constant, their known values may permit simplifications at compile time so that not all of the inline function's code needs to be included. The effect on code size is less predictable; object code may be larger or smaller with function inlining, depending on the particular case. Inlining of functions is an optimization and it really "works" only in optimizing compilation. If you don't use `-O', no function is really inline.

To declare a function inline, use the `inline` keyword in its declaration, like this:

```
inline int
inc (int *a)
{
  (*a)++;
}
```

(If you are writing a header file to be included in ANSI C programs, write `__inline__` instead of `inline`. See section Alternate Keywords.)

You can also make all "simple enough" functions inline with the option `-finline-functions'. Note that certain usages in a function definition can make it unsuitable for inline substitution.

Note that in C and Objective C, unlike C++, the `inline` keyword does not affect the linkage of the function.

GNU CC automatically inlines member functions defined within the class body of C++ programs even if they are not explicitly declared `inline`. (You can override this with `-fno-default-inline'; see section Options Controlling C++ Dialect.)

When a function is both inline and `static`, if all calls to the function are integrated into the caller, and the function's address is never used, then the function's own assembler code is never referenced. In this case, GNU CC does not actually output assembler code for the function, unless you specify the option `-fkeep-inline-functions'. Some calls cannot be integrated for various reasons (in particular, calls that precede the function's definition cannot be integrated, and neither can recursive calls within the definition). If there is a nonintegrated call, then the function is compiled to assembler code as usual. The function must also be compiled as usual if the program refers to its address, because that can't be inlined.

When an inline function is not `static`, then the compiler must assume that there may be calls from other source files; since a global symbol can be defined only once in any program, the function must not be defined in the other source files, so the calls therein cannot be integrated. Therefore, a non-`static` inline function is always compiled on its own in the usual fashion.

If you specify both `inline` and `extern` in the function definition, then the definition is used only for inlining. In no case is the function compiled on its own, not even if you refer to its address explicitly. Such an address becomes an external reference, as if you had only declared the function, and had not defined it.

This combination of `inline` and `extern` has almost the effect of a macro. The way to use it is to put a function definition in a header file with these keywords, and put another copy of the definition (lacking `inline` and `extern`) in a library file. The definition in the header file will cause most calls to the function to be inlined. If any uses of the function remain, they will refer to the single copy in the library.

GNU C does not inline any functions when not optimizing. It is not clear whether it is better to inline or not, in this case, but we found that a correct implementation when not optimizing was difficult. So we did the easy thing, and turned it off.

Assembler Instructions with C Expression Operands

In an assembler instruction using `asm`, you can now specify the operands of the instruction using C expressions. This means no more guessing which registers or memory locations will contain the data you want to use.

You must specify an assembler instruction template much like what appears in a machine description, plus an operand constraint string for each operand.

For example, here is how to use the 68881's `fsinx` instruction:

```
asm ("fsinx %1,%0" : "=f" (result) : "f" (angle));
```

Here `angle` is the C expression for the input operand while `result` is that of the output operand. Each has `"f"' as its operand constraint, saying that a floating point register is required. The `=' in `=f' indicates that the operand is an output; all output operands' constraints must use `='. The constraints use the same language used in the machine description (see section Operand Constraints).

Each operand is described by an operand-constraint string followed by the C expression in parentheses. A colon separates the assembler template from the first output operand, and another separates the last output operand from the first input, if any. Commas separate output operands and separate inputs. The total number of operands is limited to ten or to the maximum number of operands in any instruction pattern in the machine description, whichever is greater.

If there are no output operands, and there are input operands, then there must be two consecutive colons surrounding the place where the output operands would go.
