Output operand expressions must be lvalues; the compiler can check this. The input operands need not be lvalues. The compiler cannot check whether the operands have data types that are reasonable for the instruction being executed. It does not parse the assembler instruction template and does not know what it means, or whether it is valid assembler input. The extended `asm` feature is most often used for machine instructions that the compiler itself does not know exist. If the output expression cannot be directly

addressed (for example, it is a bit field), your constraint must allow a register. In that case, GNU CC may use the register as the output of the `asm`, and then store that register into the output.

The output operands must be write-only; GNU CC will assume that the values in these operands before the instruction are dead and need not be generated. Extended asm does not support input-output or read-write operands. For this reason, the constraint character `+', which indicates such an operand, may not be used.

When the assembler instruction has a read-write operand, or an operand in which only some of the bits are to be changed, you must logically split its function into two separate operands, one input operand and one write-only output operand. The connection between them is expressed by constraints which say they need to be in the same location when the instruction executes. You can use the same C expression for both operands, or different expressions. For example, here we write the (fictitious) `combine' instruction with `bar` as its read-only source operand and `foo` as its read-write destination:

```
asm ("combine %2,%0" : "=r" (foo) : "0" (foo), "g" (bar));
```

The constraint `"0"' for operand 1 says that it must occupy the same location as operand 0. A digit in constraint is allowed only in an input operand, and it must refer to an output operand.

Only a digit in the constraint can guarantee that one operand will be in the same place as another. The mere fact that `foo` is the value of both operands is not enough to guarantee that they will be in the same place in the generated assembler code. The following would not work:

```
asm ("combine %2,%0" : "=r" (foo) : "r" (foo), "g" (bar));
```

Various optimizations or reloading could cause operands 0 and 1 to be in different registers; GNU CC knows no reason not to do so. For example, the compiler might find a copy of the value of `foo` in one register and use it for operand 1, but generate the output operand 0 in a different register (copying it afterward to `foo`'s own address). Of course, since the register for operand 1 is not even mentioned in the assembler code, the result will not work, but GNU CC can't tell that.

Some instructions clobber specific hard registers. To describe this, write a third colon after the input operands, followed by the names of the clobbered hard registers (given as strings). Here is a realistic example for the Vax:

```
asm volatile ("movc3 %0,%1,%2"
              : /* no outputs */
              : "g" (from), "g" (to), "g" (count)
              : "r0", "r1", "r2", "r3", "r4", "r5");
```

If you refer to a particular hardware register from the assembler code, then you will probably have to list the register after the third colon to tell the compiler that the register's value is modified. In many assemblers, the register names begin with `%'; to produce one `%' in the assembler code, you must write `%%' in the input.

If your assembler instruction can alter the condition code register, add `cc' to the list of clobbered registers. GNU CC on some machines represents the condition codes as a specific hardware register; `cc'

serves to name this register. On other machines, the condition code is handled differently, and specifying `cc' has no effect. But it is valid no matter what the machine.

If your assembler instruction modifies memory in an unpredictable fashion, add `memory' to the list of clobbered registers. This will cause GNU CC to not keep memory values cached in registers across the assembler instruction.

You can put multiple assembler instructions together in a single `asm` template, separated either with newlines (written as `\n') or with semicolons if the assembler allows such semicolons. The GNU assembler allows semicolons and all Unix assemblers seem to do so. The input operands are guaranteed not to use any of the clobbered registers, and neither will the output operands' addresses, so you can read and write the clobbered registers as many times as you like. Here is an example of multiple instructions in a template; it assumes that the subroutine `_foo` accepts arguments in registers 9 and 10:

```
asm ("movl %0,r9;movl %1,r10;call _foo"
     : /* no outputs */
     : "g" (from), "g" (to)
     : "r9", "r10");
```

Unless an output operand has the `&' constraint modifier, GNU CC may allocate it in the same register as an unrelated input operand, on the assumption that the inputs are consumed before the outputs are produced. This assumption may be false if the assembler code actually consists of more than one instruction. In such a case, use `&' for each output operand that may not overlap an input. See section Constraint Modifier Characters.

If you want to test the condition code produced by an assembler instruction, you must include a branch and a label in the `asm` construct, as follows:

```
asm ("clr %0;frob %1;beq 0f;mov #1,%0;0:"
     : "g" (result)
     : "g" (input));
```

This assumes your assembler supports local labels, as the GNU assembler and most Unix assemblers do.

Speaking of labels, jumps from one `asm` to another are not supported. The compiler's optimizers do not know about these jumps, and therefore they cannot take account of them when deciding how to optimize.

Usually the most convenient way to use these `asm` instructions is to encapsulate them in macros that look like functions. For example,

```
#define sin(x)       \
({ double __value, __arg = (x);   \
   asm ("fsinx %1,%0": "=f" (__value): "f" (__arg));  \
   __value; })
```

Here the variable `__arg` is used to make sure that the instruction operates on a proper `double` value, and to accept only those arguments `x` which can convert automatically to a `double`.

Another way to make sure the instruction operates on the correct data type is to use a cast in the `asm`. This is different from using a variable `__arg` in that it converts more different types. For example, if the desired type were `int`, casting the argument to `int` would accept a pointer with no complaint, while assigning the argument to an `int` variable named `__arg` would warn about using a pointer unless the caller explicitly casts it.

If an `asm` has output operands, GNU CC assumes for optimization purposes that the instruction has no side effects except to change the output operands. This does not mean that instructions with a side effect cannot be used, but you must be careful, because the compiler may eliminate them if the output operands aren't used, or move them out of loops, or replace two with one if they constitute a common subexpression. Also, if your instruction does have a side effect on a variable that otherwise appears not to change, the old value of the variable may be reused later if it happens to be found in a register.

You can prevent an `asm` instruction from being deleted, moved significantly, or combined, by writing the keyword `volatile` after the `asm`. For example:

```
#define set_priority(x)  \
asm volatile ("set_priority %0": /* no outputs */ : "g" (x))
```

An instruction without output operands will not be deleted or moved significantly, regardless, unless it is unreachable.

Note that even a volatile `asm` instruction can be moved in ways that appear insignificant to the compiler, such as across jump instructions. You can't expect a sequence of volatile `asm` instructions to remain perfectly consecutive. If you want consecutive output, use a single `asm`.

It is a natural idea to look for a way to give access to the condition code left by the assembler instruction. However, when we attempted to implement this, we found no way to make it work reliably. The problem is that output operands might need reloading, which would result in additional following "store" instructions. On most machines, these instructions would alter the condition code before there was time to test it. This problem doesn't arise for ordinary "test" and "compare" instructions because they don't have any output operands.

If you are writing a header file that should be includable in ANSI C programs, write `__asm__` instead of `asm`. See section Alternate Keywords.

Controlling Names Used in Assembler Code

You can specify the name to be used in the assembler code for a C function or variable by writing the `asm` (or `__asm__`) keyword after the declarator as follows:

```
int foo asm ("myfoo") = 2;
```

This specifies that the name to be used for the variable `foo` in the assembler code should be `myfoo' rather than the usual `_foo'.

On systems where an underscore is normally prepended to the name of a C function or variable, this

feature allows you to define names for the linker that do not start with an underscore.

You cannot use `asm` in this way in a function *definition*; but you can get the same effect by writing a declaration for the function before its definition and putting `asm` there, like this:

```
extern func () asm ("FUNC");

func (x, y)
     int x, y;
...
```

It is up to you to make sure that the assembler names you choose do not conflict with any other assembler symbols. Also, you must not use a register name; that would produce completely invalid assembler code. GNU CC does not as yet have the ability to store static variables in registers. Perhaps that will be added.

Variables in Specified Registers

GNU C allows you to put a few global variables into specified hardware registers. You can also specify the register in which an ordinary register variable should be allocated.

- Global register variables reserve registers throughout the program. This may be useful in programs such as programming language interpreters which have a couple of global variables that are accessed very often.
- Local register variables in specific registers do not reserve the registers. The compiler's data flow analysis is capable of determining where the specified registers contain live values, and where they are available for other uses.

  These local variables are sometimes convenient for use with the extended `asm` feature (see section Assembler Instructions with C Expression Operands), if you want to write one output of the assembler instruction directly into a particular register. (This will work provided the register you specify fits the constraints specified for that operand in the `asm`.)

Defining Global Register Variables

You can define a global register variable in GNU C like this:

```
register int *foo asm ("a5");
```

Here `a5` is the name of the register which should be used. Choose a register which is normally saved and restored by function calls on your machine, so that library routines will not clobber it.

Naturally the register name is cpu-dependent, so you would need to conditionalize your program according to cpu type. The register `a5` would be a good choice on a 68000 for a variable of pointer type. On machines with register windows, be sure to choose a "global" register that is not affected magically by the function call mechanism.

In addition, operating systems on one type of cpu may differ in how they name the registers; then you would need additional conditionals. For example, some 68000 operating systems call this register %a

Eventually there may be a way of asking the compiler to choose a register automatically, but first we need to figure out how it should choose and how to enable you to guide the choice. No solution is evident.

Defining a global register variable in a certain register reserves that register entirely for this use, at least within the current compilation. The register will not be allocated for any other purpose in the functions in the current compilation. The register will not be saved and restored by these functions. Stores into this register are never deleted even if they would appear to be dead, but references may be deleted or moved or simplified.

It is not safe to access the global register variables from signal handlers, or from more than one thread of control, because the system library routines may temporarily use the register for other things (unless you recompile them specially for the task at hand).

It is not safe for one function that uses a global register variable to call another such function `foo` by way of a third function `lose` that was compiled without knowledge of this variable (i.e. in a different source file in which the variable wasn't declared). This is because `lose` might save the register and put some other value there. For example, you can't expect a global register variable to be available in the comparison-function that you pass to `qsort`, since `qsort` might have put something else in that register. (If you are prepared to recompile `qsort` with the same global register variable, you can solve this problem.)

If you want to recompile `qsort` or other source files which do not actually use your global register variable, so that they will not use that register for any other purpose, then it suffices to specify the compiler option `-ffixed-reg'. You need not actually add a global register declaration to their source code.

A function which can alter the value of a global register variable cannot safely be called from a function compiled without this variable, because it could clobber the value the caller expects to find there on return. Therefore, the function which is the entry point into the part of the program that uses the global register variable must explicitly save and restore the value which belongs to its caller.

On most machines, `longjmp` will restore to each global register variable the value it had at the time of the `setjmp`. On some machines, however, `longjmp` will not change the value of global register variables. To be portable, the function that called `setjmp` should make other arrangements to save the values of the global register variables, and to restore them in a `longjmp`. This way, the same thing will happen regardless of what `longjmp` does.

All global register variable declarations must precede all function definitions. If such a declaration could appear after function definitions, the declaration would be too late to prevent the register from being used for other purposes in the preceding functions.

Global register variables may not have initial values, because an executable file has no means to supply initial contents for a register.

On the Sparc, there are reports that g3 ... g7 are suitable registers, but certain library functions, such as `getwd`, as well as the subroutines for division and remainder, modify g3 and g4. g1 and g2 are local

temporaries.

On the 68000, a2 ... a5 should be suitable, as should d2 ... d7. Of course, it will not do to use more than a few of those.

Specifying Registers for Local Variables

You can define a local register variable with a specified register like this:

```
register int *foo asm ("a5");
```

Here `a5` is the name of the register which should be used. Note that this is the same syntax used for defining global register variables, but for a local variable it would appear within a function.

Naturally the register name is cpu-dependent, but this is not a problem, since specific registers are most often useful with explicit assembler instructions (see section Assembler Instructions with C Expression Operands). Both of these things generally require that you conditionalize your program according to cpu type.

In addition, operating systems on one type of cpu may differ in how they name the registers; then you would need additional conditionals. For example, some 68000 operating systems call this register `%a5`.

Eventually there may be a way of asking the compiler to choose a register automatically, but first we need to figure out how it should choose and how to enable you to guide the choice. No solution is evident.

Defining such a register variable does not reserve the register; it remains available for other uses in places where flow control determines the variable's value is not live. However, these registers are made unavailable for use in the reload pass. I would not be surprised if excessive use of this feature leaves the compiler too few available registers to compile certain functions.

Alternate Keywords

The option `-traditional' disables certain keywords; `-ansi' disables certain others. This causes trouble when you want to use GNU C extensions, or ANSI C features, in a general-purpose header file that should be usable by all programs, including ANSI C programs and traditional ones. The keywords `asm`, `typeof` and `inline` cannot be used since they won't work in a program compiled with `-ansi', while the keywords `const`, `volatile`, `signed`, `typeof` and `inline` won't work in a program compiled with `-traditional'.

The way to solve these problems is to put `__' at the beginning and end of each problematical keyword. For example, use `__asm__` instead of `asm`, `__const__` instead of `const`, and `__inline__` instead of `inline`.

Other C compilers won't accept these alternative keywords; if you want to compile with another compiler, you can define the alternate keywords as macros to replace them with the customary keywords. It looks like this:

```
#ifndef __GNUC__
#define __asm__ asm
#endif
```

`-pedantic' causes warnings for many GNU C extensions. You can prevent such warnings within one expression by writing `__extension__` before the expression. `__extension__` has no effect aside from this.

Incomplete `enum` Types

You can define an `enum` tag without specifying its possible values. This results in an incomplete type, much like what you get if you write `struct foo` without describing the elements. A later declaration which does specify the possible values completes the type.

You can't allocate variables or storage using the type while it is incomplete. However, you can work with pointers to that type.

This extension may not be very useful, but it makes the handling of `enum` more consistent with the way `struct` and `union` are handled.

This extension is not supported by GNU C++.

Function Names as Strings

GNU CC predefines two string variables to be the name of the current function. The variable `__FUNCTION__` is the name of the function as it appears in the source. The variable `__PRETTY_FUNCTION__` is the name of the function pretty printed in a language specific fashion.

These names are always the same in a C function, but in a C++ function they may be different. For example, this program:

```
extern "C" {
extern int printf (char *, ...);
}

class a {
 public:
  sub (int i)
    {
      printf ("__FUNCTION__ = %s\n", __FUNCTION__);
      printf ("__PRETTY_FUNCTION__ = %s\n", __PRETTY_FUNCTION__);
    }
};

int
```

```
main (void)
{
  a ax;
  ax.sub (0);
  return 0;
}
```

gives this output:

```
__FUNCTION__ = sub
__PRETTY_FUNCTION__ = int  a::sub (int)
```

Go to the previous, next section.

Go to the previous, next section.

Extensions to the C++ Language

The GNU compiler provides these extensions to the C++ language (and you can also use most of the C language extensions in your C++ programs). If you want to write code that checks whether these features are available, you can test for the GNU compiler the same way as for C programs: check for a predefined macro __GNUC__. You can also use __GNUG__ to test specifically for GNU C++ (see section 'Standard Predefined Macros' in The C Preprocessor).

Named Return Values in C++

GNU C++ extends the function-definition syntax to allow you to specify a name for the result of a function outside the body of the definition, in C++ programs:

```
type
functionname (args) return resultname;
{
  ...
  body
  ...
}
```

You can use this feature to avoid an extra constructor call when a function result has a class type. For example, consider a function `m`, declared as `X v = m ();', whose result is of class `X`:

```
X
m ()
{
  X b;
  b.a = 23;
  return b;
}
```

Although `m` appears to have no arguments, in fact it has one implicit argument: the address of the return value. At invocation, the address of enough space to hold `v` is sent in as the implicit argument. Then `b` is constructed and its `a` field is set to the value 23. Finally, a copy constructor (a constructor of the form `X(X&)') is applied to `b`, with the (implicit) return value location as the target, so that `v` is now bound to the return value.

But this is wasteful. The local `b` is declared just to hold something that will be copied right out. While a compiler that combined an "elision" algorithm with interprocedural data flow analysis could conceivably eliminate all of this, it is much more practical to allow you to assist the compiler in generating efficient code by manipulating the return value explicitly, thus avoiding the local variable and copy constructor

altogether.

Using the extended GNU C++ function-definition syntax, you can avoid the temporary allocation and copying by naming `r` as your return value at the outset, and assigning to its `a` field directly:

```
X
m () return r;
{
  r.a = 23;
}
```

The declaration of `r` is a standard, proper declaration, whose effects are executed **before** any of the body of `m`.

Functions of this type impose no additional restrictions; in particular, you can execute `return` statements, or return implicitly by reaching the end of the function body ("falling off the edge"). Cases like

```
X
m () return r (23);
{
  return;
}
```

(or even `X m () return r (23); { }') are unambiguous, since the return value `r` has been initialized in either case. The following code may be hard to read, but also works predictably:

```
X
m () return r;
{
  X b;
  return b;
}
```

The return value slot denoted by `r` is initialized at the outset, but the statement `return b;' overrides this value. The compiler deals with this by destroying `r` (calling the destructor if there is one, or doing nothing if there is not), and then reinitializing `r` with `b`.

This extension is provided primarily to help people who use overloaded operators, where there is a great need to control not just the arguments, but the return values of functions. For classes where the copy constructor incurs a heavy performance penalty (especially in the common case where there is a quick default constructor), this is a major savings. The disadvantage of this extension is that you do not control when the default constructor for the return value is called: it is always called at the beginning.

Minimum and Maximum Operators in C++

It is very convenient to have operators which return the "minimum" or the "maximum" of two arguments. In GNU C++ (but not in GNU C),

`a <? b`

is the minimum, returning the smaller of the numeric values a and b;

`a >? b`

is the maximum, returning the larger of the numeric values a and b.

These operations are not primitive in ordinary C++, since you can use a macro to return the minimum of two things in C++, as in the following example.

```
#define MIN(X,Y) ((X) < (Y) ? : (X) : (Y))
```

You might then use `int min = MIN (i, j);' to set min to the minimum value of variables i and j.

However, side effects in `X` or `Y` may cause unintended behavior. For example, `MIN (i++, j++)` will fail, incrementing the smaller counter twice. A GNU C extension allows you to write safe macros that avoid this kind of problem (see section Naming an Expression's Type). However, writing `MIN` and `MAX` as macros also forces you to use function-call notation notation for a fundamental arithmetic operation. Using GNU C++ extensions, you can write `int min = i <? j;' instead.

Since `<?` and `>?` are built into the compiler, they properly handle expressions with side-effects; `int min = i++ <? j++;' works correctly.

`goto` and Destructors in GNU C++

In C++ programs, you can safely use the `goto` statement. When you use it to exit a block which contains aggregates requiring destructors, the destructors will run before the `goto` transfers control. (In ANSI C++, `goto` is restricted to targets within the current block.)

The compiler still forbids using `goto` to *enter* a scope that requires constructors.

Declarations and Definitions in One Header

C++ object definitions can be quite complex. In principle, your source code will need two kinds of things for each object that you use across more than one source file. First, you need an interface specification, describing its structure with type declarations and function prototypes. Second, you need the implementation itself. It can be tedious to maintain a separate interface description in a header file, in parallel to the actual implementation. It is also dangerous, since separate interface and implementation definitions may not remain parallel.

With GNU C++, you can use a single header file for both purposes.

Warning: The mechanism to specify this is in transition. For the nonce, you must use one of

two `#pragma` commands; in a future release of GNU C++, an alternative mechanism will make these `#pragma` commands unnecessary.

The header file contains the full definitions, but is marked with `#pragma interface' in the source code. This allows the compiler to use the header file only as an interface specification when ordinary source files incorporate it with `#include`. In the single source file where the full implementation belongs, you can use either a naming convention or `#pragma implementation' to indicate this alternate use of the header file.

`#pragma interface`

`#pragma interface "subdir/objects.h"`

Use this directive in *header files* that define object classes, to save space in most of the object files that use those classes. Normally, local copies of certain information (backup copies of inline member functions, debugging information, and the internal tables that implement virtual functions) must be kept in each object file that includes class definitions. You can use this pragma to avoid such duplication. When a header file containing `#pragma interface' is included in a compilation, this auxiliary information will not be generated (unless the main input source file itself uses `#pragma implementation'). Instead, the object files will contain references to be resolved at link time.

The second form of this directive is useful for the case where you have multiple headers with the same name in different directories. If you use this form, you must specify the same string to `#pragma implementation'.

`#pragma implementation`

`#pragma implementation "objects.h"`

Use this pragma in a *main input file*, when you want full output from included header files to be generated (and made globally visible). The included header file, in turn, should use `#pragma interface'. Backup copies of inline member functions, debugging information, and the internal tables used to implement virtual functions are all generated in implementation files.

If you use `#pragma implementation' with no argument, it applies to an include file with the same basename(3) as your source file. For example, in `allclass.cc', `#pragma implementation' by itself is equivalent to `#pragma implementation "allclass.h"'.

In versions of GNU C++ prior to 2.6.0 `allclass.h' was treated as an implementation file whenever you would include it from `allclass.cc' even if you never specified `#pragma implementation'. This was deemed to be more trouble than it was worth, however, and disabled.

If you use an explicit `#pragma implementation', it must appear in your source file *before* you include the affected header files.

Use the string argument if you want a single implementation file to include code from multiple header files. (You must also use `#include' to include the header file; `#pragma implementation' only specifies how to use the file--it doesn't actually include it.)

There is no way to split up the contents of a single header file into multiple implementation files.

`#pragma implementation' and `#pragma interface' also have an effect on function inlining.

If you define a class in a header file marked with `#pragma interface', the effect on a function defined in that class is similar to an explicit `extern` declaration--the compiler emits no code at all to define an independent version of the function. Its definition is used only for inlining with its callers.

Conversely, when you include the same header file in a main source file that declares it as `#pragma implementation', the compiler emits code for the function itself; this defines a version of the function that can be found via pointers (or by callers compiled without inlining). If all calls to the function can be inlined, you can avoid emitting the function by compiling with `-fno-implement-inlines'. If any calls were not inlined, you will get linker errors.

Where's the Template?

C++ templates are the first language feature to require more intelligence from the environment than one usually finds on a UNIX system. Somehow the compiler and linker have to make sure that each template instance occurs exactly once in the executable if it is needed, and not at all otherwise. There are two basic approaches to this problem, which I will refer to as the Borland model and the Cfront model.

Borland model

> Borland C++ solved the template instantiation problem by adding the code equivalent of common blocks to their linker; template instances are emitted in each translation unit that uses them, and they are collapsed together at run time. The advantage of this model is that the linker only has to consider the object files themselves; there is no external complexity to worry about. This disadvantage is that compilation time is increased because the template code is being compiled repeatedly. Code written for this model tends to include definitions of all member templates in the header file, since they must be seen to be compiled.

Cfront model

> The AT&T C++ translator, Cfront, solved the template instantiation problem by creating the notion of a template repository, an automatically maintained place where template instances are stored. As individual object files are built, notes are placed in the repository to record where templates and potential type arguments were seen so that the subsequent instantiation step knows where to find them. At link time, any needed instances are generated and linked in. The advantages of this model are more optimal compilation speed and the ability to use the system linker; to implement the Borland model a compiler vendor also needs to replace the linker. The disadvantages are vastly increased complexity, and thus potential for error; theoretically, this should be just as transparent, but in practice it has been very difficult to build multiple programs in one directory and one program in multiple directories using Cfront. Code written for this model tends to separate definitions of non-inline member templates into a separate file, which is magically found by the link preprocessor when a template needs to be instantiated.

Currently, g++ implements neither automatic model. The g++ team hopes to have a repository working for 2.7.0. In the mean time, you have three options for dealing with template instantiations:

1. Do nothing. Pretend g++ does implement automatic instantiation management. Code written for the Borland model will work fine, but each translation unit will contain instances of each of the templates it uses. In a large program, this can lead to an unacceptable amount of code duplication.
2. Add `#pragma interface' to all files containing template definitions. For each of these files, add

`#pragma implementation "filename"' to the top of some `.C' file which `#include's it. Then compile everything with -fexternal-templates. The templates will then only be expanded in the translation unit which implements them (i.e. has a `#pragma implementation' line for the file where they live); all other files will use external references. If you're lucky, everything should work properly. If you get undefined symbol errors, you need to make sure that each template instance which is used in the program is used in the file which implements that template. If you don't have any use for a particular instance in that file, you can just instantiate it explicitly, using the syntax from the latest C++ working paper:

```
template class A<int>;
template ostream& operator << (ostream&, const A<int>&);
```

This strategy will work with code written for either model. If you are using code written for the Cfront model, the file containing a class template and the file containing its member templates should be implemented in the same translation unit.

A slight variation on this approach is to use the flag -falt-external-templates instead; this flag causes template instances to be emitted in the translation unit that implements the header where they are first instantiated, rather than the one which implements the file where the templates are defined. This header must be the same in all translation units, or things are likely to break.

See section Declarations and Definitions in One Header, for more discussion of these pragmas.

3. Explicitly instantiate all the template instances you use, and compile with -fno-implicit-templates. This is probably your best bet; it may require more knowledge of exactly which templates you are using, but it's less mysterious than the previous approach, and it doesn't require any `#pragma's or other g++-specific code. You can scatter the instantiations throughout your program, you can create one big file to do all the instantiations, or you can create tiny files like

```
#include "Foo.h"
#include "Foo.cc"

template class Foo<int>;
```

for each instance you need, and create a template instantiation library from those. I'm partial to the last, but your mileage may vary. If you are using Cfront-model code, you can probably get away with not using -fno-implicit-templates when compiling files that don't `#include' the member template definitions.

Type Abstraction using Signatures

In GNU C++, you can use the keyword `signature` to define a completely abstract class interface as a datatype. You can connect this abstraction with actual classes using signature pointers. If you want to use signatures, run the GNU compiler with the `-fhandle-signatures' command-line option. (With this option, the compiler reserves a second keyword `sigof` as well, for a future extension.)

Roughly, signatures are type abstractions or interfaces of classes. Some other languages have similar

facilities. C++ signatures are related to ML's signatures, Haskell's type classes, definition modules in Modula-2, interface modules in Modula-3, abstract types in Emerald, type modules in Trellis/Owl, categories in Scratchpad II, and types in POOL-I. For a more detailed discussion of signatures, see Signatures: A C++ Extension for Type Abstraction and Subtype Polymorphism by Gerald Baumgartner and Vincent F. Russo (Tech report CSD--TR--93--059, Dept. of Computer Sciences, Purdue University, December 1994, to appear in *Software Practice & Experience*). You can get the tech report by anonymous FTP from `ftp.cs.purdue.edu` in `` `pub/reports/TR93-059.PS.Z' ``.

Syntactically, a signature declaration is a collection of member function declarations and nested type declarations. For example, this signature declaration defines a new abstract type `S` with member functions `int foo ()' and `int bar (int)':

```
signature S
{
  int foo ();
  int bar (int);
};
```

Since signature types do not include implementation definitions, you cannot write an instance of a signature directly. Instead, you can define a pointer to any class that contains the required interfaces as a signature pointer. Such a class implements the signature type.

To use a class as an implementation of `S`, you must ensure that the class has public member functions `int foo ()' and `int bar (int)'. The class can have other member functions as well, public or not; as long as it offers what's declared in the signature, it is suitable as an implementation of that signature type.

For example, suppose that `C` is a class that meets the requirements of signature `S` (`C` conforms to `S`). Then

```
C obj;
S * p = &obj;
```

defines a signature pointer `p` and initializes it to point to an object of type `C`. The member function call `int i = p->foo ();' executes `obj.foo ()'.

Abstract virtual classes provide somewhat similar facilities in standard C++. There are two main advantages to using signatures instead:

1. Subtyping becomes independent from inheritance. A class or signature type `T` is a subtype of a signature type `S` independent of any inheritance hierarchy as long as all the member functions declared in `S` are also found in `T`. So you can define a subtype hierarchy that is completely independent from any inheritance (implementation) hierarchy, instead of being forced to use types that mirror the class inheritance hierarchy.
2. Signatures allow you to work with existing class hierarchies as implementations of a signature type. If those class hierarchies are only available in compiled form, you're out of luck with abstract virtual classes, since an abstract virtual class cannot be retrofitted on top of existing class hierarchies. So you would be required to write interface classes as subtypes of the abstract virtual class.

There is one more detail about signatures. A signature declaration can contain member function *definitions* as well as member function declarations. A signature member function with a full definition is called a *default implementation*; classes need not contain that particular interface in order to conform. For example, a class `C` can conform to the signature

```
signature T
{
  int f (int);
  int f0 () { return f (0); };
};
```

whether or not `C` implements the member function `int f0 ()'. If you define `C::f0`, that definition takes precedence; otherwise, the default implementation `S::f0` applies.

Go to the previous, next section.

Known Causes of Trouble with GNU CC

This section describes known problems that affect users of GNU CC. Most of these are not GNU CC bugs per se--if they were, we would fix them. But the result for a user may be like the result of a bug.

Some of these problems are due to bugs in other software, some are missing features that are too much work to add, and some are places where people's opinions differ as to what is best.

Actual Bugs We Haven't Fixed Yet

- The `fixincludes` script interacts badly with automounters; if the directory of system header files is automounted, it tends to be unmounted while `fixincludes` is running. This would seem to be a bug in the automounter. We don't know any good way to work around it.
- The `fixproto` script will sometimes add prototypes for the `sigsetjmp` and `siglongjmp` functions that reference the `jmp_buf` type before that type is defined. To work around this, edit the offending file and place the typedef in front of the prototypes.
- There are several obscure case of mis-using struct, union, and enum tags that are not detected as errors by the compiler.
- When `-pedantic-errors' is specified, GNU C will incorrectly give an error message when a function name is specified in an expression involving the comma operator.
- Loop unrolling doesn't work properly for certain C++ programs. This is a bug in the C++ front end. It sometimes emits incorrect debug info, and the loop unrolling code is unable to recover from this error.

Installation Problems

This is a list of problems (and some apparent problems which don't really mean anything is wrong) that show up during installation of GNU CC.

- On certain systems, defining certain environment variables such as `CC` can interfere with the functioning of `make`.
- If you encounter seemingly strange errors when trying to build the compiler in a directory other than the source directory, it could be because you have previously configured the compiler in the source directory. Make sure you have done all the necessary preparations. See section Compilation in a Separate Directory.
- If you build GNU CC on a BSD system using a directory stored in a System V file system, problems may occur in running `fixincludes` if the System V file system doesn't support symbolic links. These problems result in a failure to fix the declaration of `size_t` in `` `sys/types.h' ``. If you find that `size_t` is a signed type and that type mismatches occur, this could be the cause.

The solution is not to use such a directory for building GNU CC.

- In previous versions of GNU CC, the `gcc` driver program looked for `as` and `ld` in various places; for example, in files beginning with `/usr/local/lib/gcc-'. GNU CC version 2 looks for them in the directory `/usr/local/lib/gcc-lib/target/version'.

  Thus, to use a version of `as` or `ld` that is not the system default, for example `gas` or GNU `ld`, you must put them in that directory (or make links to them from that directory).
- Some commands executed when making the compiler may fail (return a non-zero status) and be ignored by `make`. These failures, which are often due to files that were not found, are expected, and can safely be ignored.
- It is normal to have warnings in compiling certain files about unreachable code and about enumeration type clashes. These files' names begin with `insn-'. Also, `real.c' may get some warnings that you can ignore.
- Sometimes `make` recompiles parts of the compiler when installing the compiler. In one case, this was traced down to a bug in `make`. Either ignore the problem or switch to GNU Make.
- If you have installed a program known as purify, you may find that it causes errors while linking `enquire`, which is part of building GNU CC. The fix is to get rid of the file `real-ld` which purify installs--so that GNU CC won't try to use it.
- On Linux SLS 1.01, there is a problem with `libc.a': it does not contain the obstack functions. However, GNU CC assumes that the obstack functions are in `libc.a' when it is the GNU C library. To work around this problem, change the __GNU_LIBRARY__ conditional around line 31 to `#if 1'.
- On some 386 systems, building the compiler never finishes because `enquire` hangs due to a hardware problem in the motherboard--it reports floating point exceptions to the kernel incorrectly. You can install GNU CC except for `float.h' by patching out the command to run `enquire`. You may also be able to fix the problem for real by getting a replacement motherboard. This problem was observed in Revision E of the Micronics motherboard, and is fixed in Revision F. It has also been observed in the MYLEX MXA-33 motherboard.

  If you encounter this problem, you may also want to consider removing the FPU from the socket during the compilation. Alternatively, if you are running SCO Unix, you can reboot and force the FPU to be ignored. To do this, type `hd(40)unix auto ignorefpu'.
- On some 386 systems, GNU CC crashes trying to compile `enquire.c'. This happens on machines that don't have a 387 FPU chip. On 386 machines, the system kernel is supposed to emulate the 387 when you don't have one. The crash is due to a bug in the emulator.

  One of these systems is the Unix from Interactive Systems: 386/ix. On this system, an alternate emulator is provided, and it does work. To use it, execute this command as super-user:

  ```
  ln /etc/emulator.rel1 /etc/emulator
  ```

  and then reboot the system. (The default emulator file remains present under the name `emulator.dflt'.)

  Try using `/etc/emulator.att', if you have such a problem on the SCO system.

Another system which has this problem is Esix. We don't know whether it has an alternate emulator that works.

On NetBSD 0.8, a similar problem manifests itself as these error messages:

```
enquire.c: In function `fprop':
enquire.c:2328: floating overflow
```

- On SCO systems, when compiling GNU CC with the system's compiler, do not use `-O'. Some versions of the system's compiler miscompile GNU CC with `-O'.
- Sometimes on a Sun 4 you may observe a crash in the program `genflags` or `genoutput` while building GNU CC. This is said to be due to a bug in `sh`. You can probably get around it by running `genflags` or `genoutput` manually and then retrying the `make`.
- On Solaris 2, executables of GNU CC version 2.0.2 are commonly available, but they have a bug that shows up when compiling current versions of GNU CC: undefined symbol errors occur during assembly if you use `-g'.

  The solution is to compile the current version of GNU CC without `-g'. That makes a working compiler which you can use to recompile with `-g'.
- Solaris 2 comes with a number of optional OS packages. Some of these packages are needed to use GNU CC fully. If you did not install all optional packages when installing Solaris, you will need to verify that the packages that GNU CC needs are installed.

  To check whether an optional package is installed, use the `pkginfo` command. To add an optional package, use the `pkgadd` command. For further details, see the Solaris documentation.

  For Solaris 2.0 and 2.1, GNU CC needs six packages: `SUNWarc', `SUNWbtool', `SUNWesu', `SUNWhea', `SUNWlibm', and `SUNWtoo'.

  For Solaris 2.2, GNU CC needs an additional seventh package: `SUNWsprot'.
- On Solaris 2, trying to use the linker and other tools in `` `/usr/ucb' `` to install GNU CC has been observed to cause trouble. For example, the linker may hang indefinitely. The fix is to remove `` `/usr/ucb' `` from your `PATH`.
- If you use the 1.31 version of the MIPS assembler (such as was shipped with Ultrix 3.1), you will need to use the -fno-delayed-branch switch when optimizing floating point code. Otherwise, the assembler will complain when the GCC compiler fills a branch delay slot with a floating point instruction, such as `add.d`.
- If on a MIPS system you get an error message saying "does not have gp sections for all it's [sic] sectons [sic]", don't worry about it. This happens whenever you use GAS with the MIPS linker, but there is not really anything wrong, and it is okay to use the output file. You can stop such warnings by installing the GNU linker.

  It would be nice to extend GAS to produce the gp tables, but they are optional, and there should not be a warning about their absence.
- In Ultrix 4.0 on the MIPS machine, `` `stdio.h' `` does not work with GNU CC at all unless it has been fixed with `fixincludes`. This causes problems in building GNU CC. Once GNU CC is

installed, the problems go away.

To work around this problem, when making the stage 1 compiler, specify this option to Make:

```
GCC_FOR_TARGET="./xgcc -B./ -I./include"
```

When making stage 2 and stage 3, specify this option:

```
CFLAGS="-g -I./include"
```

- Users have reported some problems with version 2.0 of the MIPS compiler tools that were shipped with Ultrix 4.1. Version 2.10 which came with Ultrix 4.2 seems to work fine.

  Users have also reported some problems with version 2.20 of the MIPS compiler tools that were shipped with RISC/os 4.x. The earlier version 2.11 seems to work fine.
- Some versions of the MIPS linker will issue an assertion failure when linking code that uses `alloca` against shared libraries on RISC-OS 5.0, and DEC's OSF/1 systems. This is a bug in the linker, that is supposed to be fixed in future revisions. To protect against this, GNU CC passes `-non_shared' to the linker unless you pass an explicit `-shared' or `-call_shared' switch.
- On System V release 3, you may get this error message while linking:

  ```
  ld fatal: failed to write symbol name something
   in strings table for file whatever
  ```

  This probably indicates that the disk is full or your ULIMIT won't allow the file to be as large as it needs to be.

  This problem can also result because the kernel parameter `MAXUMEM` is too small. If so, you must regenerate the kernel and make the value much larger. The default value is reported to be 1024; a value of 32768 is said to work. Smaller values may also work.
- On System V, if you get an error like this,

  ```
  /usr/local/lib/bison.simple: In function `yyparse':
  /usr/local/lib/bison.simple:625: virtual memory exhausted
  ```

  that too indicates a problem with disk space, ULIMIT, or `MAXUMEM`.
- Current GNU CC versions probably do not work on version 2 of the NeXT operating system.
- On NeXTStep 3.0, the Objective C compiler does not work, due, apparently, to a kernel bug that it happens to trigger. This problem does not happen on 3.1.
- On the Tower models 4n0 and 6n0, by default a process is not allowed to have more than one megabyte of memory. GNU CC cannot compile itself (or many other programs) with `-O' in that much memory.

  To solve this problem, reconfigure the kernel adding the following line to the configuration file:

  ```
  MAXUMEM = 4096
  ```

- On HP 9000 series 300 or 400 running HP-UX release 8.0, there is a bug in the assembler that must be fixed before GNU CC can be built. This bug manifests itself during the first stage of compilation, while building `libgcc2.a':

```
_floatdisf
cc1: warning: `-g' option not supported on this version of GCC
cc1: warning: `-g1' option not supported on this version of GCC
./xgcc: Internal compiler error: program as got fatal signal 11
```

  A patched version of the assembler is available by anonymous ftp from `altdorf.ai.mit.edu` as the file `archive/cph/hpux-8.0-assembler'. If you have HP software support, the patch can also be obtained directly from HP, as described in the following note:

  > This is the patched assembler, to patch SR#1653-010439, where the assembler aborts on floating point constants.
  >
  > The bug is not really in the assembler, but in the shared library version of the function "cvtnum(3c)". The bug on "cvtnum(3c)" is SR#4701-078451. Anyway, the attached assembler uses the archive library version of "cvtnum(3c)" and thus does not exhibit the bug.

  This patch is also known as PHCO_4484.
- On HP-UX version 8.05, but not on 8.07 or more recent versions, the `fixproto` shell script triggers a bug in the system shell. If you encounter this problem, upgrade your operating system or use BASH (the GNU shell) to run `fixproto`.
- Some versions of the Pyramid C compiler are reported to be unable to compile GNU CC. You must use an older version of GNU CC for bootstrapping. One indication of this problem is if you get a crash when GNU CC compiles the function `muldi3` in file `libgcc2.c'.

  You may be able to succeed by getting GNU CC version 1, installing it, and using it to compile GNU CC version 2. The bug in the Pyramid C compiler does not seem to affect GNU CC version 1.
- There may be similar problems on System V Release 3.1 on 386 systems.
- On the Intel Paragon (an i860 machine), if you are using operating system version 1.0, you will get warnings or errors about redefinition of `va_arg` when you build GNU CC.

  If this happens, then you need to link most programs with the library `iclib.a'. You must also modify `stdio.h' as follows: before the lines

```
#if     defined(__i860__) && !defined(_VA_LIST)
#include <va_list.h>
```

  insert the line

```
#if __PGC__
```

  and after the lines

```
extern int  vprintf(const char *, va_list );
extern int  vsprintf(char *, const char *, va_list );
#endif
```

insert the line

```
#endif /* __PGC__ */
```

These problems don't exist in operating system version 1.1.

- On the Altos 3068, programs compiled with GNU CC won't work unless you fix a kernel bug. This happens using system versions V.2.2 1.0gT1 and V.2.2 1.0e and perhaps later versions as well. See the file `README.ALTOS'.
- You will get several sorts of compilation and linking errors on the we32k if you don't follow the special instructions. See section Configurations Supported by GNU CC.
- A bug in the HP-UX 8.05 (and earlier) shell will cause the fixproto program to report an error of the form:

  ```
  ./fixproto: sh internal 1K buffer overflow
  ```

  To fix this, change the first line of the fixproto script to look like:

  ```
  #!/bin/ksh
  ```

Cross-Compiler Problems

You may run into problems with cross compilation on certain machines, for several reasons.

- Cross compilation can run into trouble for certain machines because some target machines' assemblers require floating point numbers to be written as *integer* constants in certain contexts.

  The compiler writes these integer constants by examining the floating point value as an integer and printing that integer, because this is simple to write and independent of the details of the floating point representation. But this does not work if the compiler is running on a different machine with an incompatible floating point format, or even a different byte-ordering.

  In addition, correct constant folding of floating point values requires representing them in the target machine's format. (The C standard does not quite require this, but in practice it is the only way to win.)

  It is now possible to overcome these problems by defining macros such as REAL_VALUE_TYPE. But doing so is a substantial amount of work for each target machine. See section Cross Compilation and Floating Point.

- At present, the program `mips-tfile' which adds debug support to object files on MIPS systems does not work in a cross compile environment.

Interoperation

This section lists various difficulties encountered in using GNU C or GNU C++ together with other compilers or with the assemblers, linkers, libraries and debuggers on certain systems.

- Objective C does not work on the RS/6000.
- GNU C++ does not do name mangling in the same way as other C++ compilers. This means that object files compiled with one compiler cannot be used with another.

  This effect is intentional, to protect you from more subtle problems. Compilers differ as to many internal details of C++ implementation, including: how class instances are laid out, how multiple inheritance is implemented, and how virtual function calls are handled. If the name encoding were made the same, your programs would link against libraries provided from other compilers--but the programs would then crash when run. Incompatible libraries are then detected at link time, rather than at run time.
- Older GDB versions sometimes fail to read the output of GNU CC version 2. If you have trouble, get GDB version 4.4 or later.
- DBX rejects some files produced by GNU CC, though it accepts similar constructs in output from PCC. Until someone can supply a coherent description of what is valid DBX input and what is not, there is nothing I can do about these problems. You are on your own.
- The GNU assembler (GAS) does not support PIC. To generate PIC code, you must use some other assembler, such as `` `/bin/as' ``.
- On some BSD systems, including some versions of Ultrix, use of profiling causes static variable destructors (currently used only in C++) not to be run.
- Use of `-I/usr/include' may cause trouble.

  Many systems come with header files that won't work with GNU CC unless corrected by `fixincludes`. The corrected header files go in a new directory; GNU CC searches this directory before `` `/usr/include' ``. If you use `-I/usr/include', this tells GNU CC to search `` `/usr/include' `` earlier on, before the corrected headers. The result is that you get the uncorrected header files.

  Instead, you should use these options (when compiling C programs):

  ```
  -I/usr/local/lib/gcc-lib/target/version/include -I/usr/include
  ```

  For C++ programs, GNU CC also uses a special directory that defines C++ interfaces to standard C subroutines. This directory is meant to be searched *before* other standard include directories, so that it takes precedence. If you are compiling C++ programs and specifying include directories explicitly, use this option first, then the two options above:

  ```
  -I/usr/local/lib/g++-include
  ```
- On some SGI systems, when you use `-lgl_s' as an option, it gets translated magically to `-lgl_s -lX11_s -lc_s'. Naturally, this does not happen when you use GNU CC. You must specify all three options explicitly.

- On a Sparc, GNU CC aligns all values of type `double` on an 8-byte boundary, and it expects every `double` to be so aligned. The Sun compiler usually gives `double` values 8-byte alignment, with one exception: function arguments of type `double` may not be aligned.

  As a result, if a function compiled with Sun CC takes the address of an argument of type `double` and passes this pointer of type `double *` to a function compiled with GNU CC, dereferencing the pointer may cause a fatal signal.

  One way to solve this problem is to compile your entire program with GNU CC. Another solution is to modify the function that is compiled with Sun CC to copy the argument into a local variable; local variables are always properly aligned. A third solution is to modify the function that uses the pointer to dereference it via the following function `access_double` instead of directly with `*':

```
inline double
access_double (double *unaligned_ptr)
{
  union d2i { double d; int i[2]; };

  union d2i *p = (union d2i *) unaligned_ptr;
  union d2i u;

  u.i[0] = p->i[0];
  u.i[1] = p->i[1];

  return u.d;
}
```

  Storing into the pointer can be done likewise with the same union.

- On Solaris, the `malloc` function in the `libmalloc.a' library may allocate memory that is only 4 byte aligned. Since GNU CC on the Sparc assumes that doubles are 8 byte aligned, this may result in a fatal signal if doubles are stored in memory allocated by the `libmalloc.a' library.

  The solution is to not use the `libmalloc.a' library. Use instead `malloc` and related functions from `libc.a'; they do not have this problem.

- Sun forgot to include a static version of `libdl.a' with some versions of SunOS (mainly 4.1). This results in undefined symbols when linking static binaries (that is, if you use `-static'). If you see undefined symbols `_dlclose`, `_dlsym` or `_dlopen` when linking, compile and link against the file `mit/util/misc/dlsym.c' from the MIT version of X windows.

- The 128-bit long double format that the Sparc port supports currently works by using the architecturally defined quad-word floating point instructions. Since there is no hardware that supports these instructions they must be emulated by the operating system. Long doubles do not work in Sun OS versions 4.0.3 and earlier, because the kernel eumulator uses an obsolete and incompatible format. Long doubles do not work in Sun OS version 4.1.1 due to a problem in a Sun library. Long doubles do work on Sun OS versions 4.1.2 and higher, but GNU CC does not enable them by default. Long doubles appear to work in Sun OS 5.x (Solaris 2.x).

- On HP-UX version 9.01 on the HP PA, the HP compiler `cc` does not compile GNU CC correctly.

We do not yet know why. However, GNU CC compiled on earlier HP-UX versions works properly on HP-UX 9.01 and can compile itself properly on 9.01.

- On the HP PA machine, ADB sometimes fails to work on functions compiled with GNU CC. Specifically, it fails to work on functions that use `alloca` or variable-size arrays. This is because GNU CC doesn't generate HP-UX unwind descriptors for such functions. It may even be impossible to generate them.
- Debugging (`-g') is not supported on the HP PA machine, unless you use the preliminary GNU tools (see section Installing GNU CC).
- Taking the address of a label may generate errors from the HP-UX PA assembler. GAS for the PA does not have this problem.
- Using floating point parameters for indirect calls to static functions will not work when using the HP assembler. There simply is no way for GCC to specify what registers hold arguments for static functions when using the HP assembler. GAS for the PA does not have this problem.
- In extremely rare cases involvving some very large functions you may receive errors from the HP linker complaining about an out of bounds unconditional branch offset. This used to occur more often in previous versions of GNU CC, but is now exceptionally rare. If you should run into it, you can work around by making your function smaller.
- GNU CC compiled code sometimes emits warnings from the HP-UX assembler of the form:

```
(warning) Use of GR3 when
  frame >= 8192 may cause conflict.
```

  These warnings are harmless and can be safely ignored.
- The current version of the assembler (`/bin/as') for the RS/6000 has certain problems that prevent the `-g' option in GCC from working. Note that `Makefile.in' uses `-g' by default when compiling `libgcc2.c'.

  IBM has produced a fixed version of the assembler. The upgraded assembler unfortunately was not included in any of the AIX 3.2 update PTF releases (3.2.2, 3.2.3, or 3.2.3e). Users of AIX 3.1 should request PTF U403044 from IBM and users of AIX 3.2 should request PTF U416277. See the file `README.RS6000' for more details on these updates.

  You can test for the presense of a fixed assembler by using the command

```
as -u < /dev/null
```

  If the command exits normally, the assembler fix already is installed. If the assembler complains that "-u" is an unknown flag, you need to order the fix.
- On the IBM RS/6000, compiling code of the form

```
extern int foo;

... foo ...
```

```
static int foo;
```

will cause the linker to report an undefined symbol `foo`. Although this behavior differs from most other systems, it is not a bug because redefining an `extern` variable as `static` is undefined in ANSI C.

- AIX on the RS/6000 provides support (NLS) for environments outside of the United States. Compilers and assemblers use NLS to support locale-specific representations of various objects including floating-point numbers ("." vs "," for separating decimal fractions). There have been problems reported where the library linked with GCC does not produce the same floating-point formats that the assembler accepts. If you have this problem, set the LANG environment variable to "C" or "En_US".
- Even if you specify `-fdollars-in-identifiers', you cannot successfully use `$' in identifiers on the RS/6000 due to a restriction in the IBM assembler. GAS supports these identifiers.
- On the RS/6000, XLC version 1.3.0.0 will miscompile `` `jump.c' ``. XLC version 1.3.0.1 or later fixes this problem. You can obtain XLC-1.3.0.2 by requesting PTF 421749 from IBM.
- There is an assembler bug in versions of DG/UX prior to 5.4.2.01 that occurs when the `fldcr' instruction is used. GNU CC uses `fldcr' on the 88100 to serialize volatile memory references. Use the option `-mno-serialize-volatile' if your version of the assembler has this bug.
- On VMS, GAS versions 1.38.1 and earlier may cause spurious warning messages from the linker. These warning messages complain of mismatched psect attributes. You can ignore them. See section Installing GNU CC on VMS.
- On NewsOS version 3, if you include both of the files `` `stddef.h' `` and `` `sys/types.h' ``, you get an error because there are two typedefs of `size_t`. You should change `` `sys/types.h' `` by adding these lines around the definition of `size_t`:

  ```
  #ifndef _SIZE_T
  #define _SIZE_T
  actual typedef here
  #endif
  ```

- On the Alliant, the system's own convention for returning structures and unions is unusual, and is not compatible with GNU CC no matter what options are used.
- On the IBM RT PC, the MetaWare HighC compiler (hc) uses a different convention for structure and union returning. Use the option `-mhc-struct-return' to tell GNU CC to use a convention compatible with it.
- On Ultrix, the Fortran compiler expects registers 2 through 5 to be saved by function calls. However, the C compiler uses conventions compatible with BSD Unix: registers 2 through 5 may be clobbered by function calls.

  GNU CC uses the same convention as the Ultrix C compiler. You can use these options to produce code compatible with the Fortran compiler:

  ```
  -fcall-saved-r2 -fcall-saved-r3 -fcall-saved-r4 -fcall-saved-r5
  ```

- On the WE32k, you may find that programs compiled with GNU CC do not work with the

standard shared C library. You may need to link with the ordinary C compiler. If you do so, yc must specify the following options:

```
-L/usr/local/lib/gcc-lib/we32k-att-sysv/2.7.0 -lgcc -lc_s
```

The first specifies where to find the library `libgcc.a' specified with the `-lgcc' option.

GNU CC does linking by invoking `ld`, just as `cc` does, and there is no reason why it *should* matter which compilation program you use to invoke `ld`. If someone tracks this problem down, it can probably be fixed easily.

- On the Alpha, you may get assembler errors about invalid syntax as a result of floating point constants. This is due to a bug in the C library functions `ecvt`, `fcvt` and `gcvt`. Given valid floating point numbers, they sometimes print `NaN'.
- On Irix 4.0.5F (and perhaps in some other versions), an assembler bug sometimes reorders instructions incorrectly when optimization is turned on. If you think this may be happening to you, try using the GNU assembler; GAS version 2.1 supports ECOFF on Irix.

  Or use the `-noasmopt' option when you compile GNU CC with itself, and then again when you compile your program. (This is a temporary kludge to turn off assembler optimization on Irix.) If this proves to be what you need, edit the assembler spec in the file `specs` so that it unconditionally passes `-O0' to the assembler, and never passes `-O2' or `-O3'.

Problems Compiling Certain Programs

Certain programs have problems compiling.

- Parse errors may occur compiling X11 on a Decstation running Ultrix 4.2 because of problems in DEC's versions of the X11 header files `X11/Xlib.h` and `X11/Xutil.h`. People recommend adding `-I/usr/include/mit' to use the MIT versions of the header files, using the `-traditional' switch to turn off ANSI C, or fixing the header files by adding this:

  ```
  #ifdef __STDC__
  #define NeedFunctionPrototypes 0
  #endif
  ```

- If you have trouble compiling Perl on a SunOS 4 system, it may be because Perl specifies `-I/usr/ucbinclude'. This accesses the unfixed header files. Perl specifies the options

  ```
  -traditional -Dvolatile=__volatile__
  -I/usr/include/sun -I/usr/ucbinclude
  -fpcc-struct-return
  ```

  most of which are unnecessary with GCC 2.4.5 and newer versions. You can make a properly working Perl by setting `ccflags` to `-fwritable-strings' (implied by the `-traditional' in the original options) and `cppflags` to empty in `config.sh`, then typing `./doSH; make depend; make'.

- On various 386 Unix systems derived from System V, including SCO, ISC, and ESIX, you ma get error messages about running out of virtual memory while compiling certain programs.

  You can prevent this problem by linking GNU CC with the GNU malloc (which thus replaces the malloc that comes with the system). GNU malloc is available as a separate package, and also in the file `src/gmalloc.c' in the GNU Emacs 19 distribution.

  If you have installed GNU malloc as a separate library package, use this option when you relink GNU CC:

  ```
  MALLOC=/usr/local/lib/libgmalloc.a
  ```

  Alternatively, if you have compiled `gmalloc.c' from Emacs 19, copy the object file to `gmalloc.o' and use this option when you relink GNU CC:

  ```
  MALLOC=gmalloc.o
  ```

Incompatibilities of GNU CC

There are several noteworthy incompatibilities between GNU C and most existing (non-ANSI) versions of C. The `-traditional' option eliminates many of these incompatibilities, *but not all*, by telling GNU C to behave like the other C compilers.

- GNU CC normally makes string constants read-only. If several identical-looking string constants are used, GNU CC stores only one copy of the string.

  One consequence is that you cannot call `mktemp` with a string constant argument. The function `mktemp` always alters the string its argument points to.

  Another consequence is that `sscanf` does not work on some systems when passed a string constant as its format control string or input. This is because `sscanf` incorrectly tries to write into the string constant. Likewise `fscanf` and `scanf`.

  The best solution to these problems is to change the program to use `char`-array variables with initialization strings for these purposes instead of string constants. But if this is not possible, you can use the `-fwritable-strings' flag, which directs GNU CC to handle string constants the same way most C compilers do. `-traditional' also has this effect, among others.
- `-2147483648` is positive.

  This is because 2147483648 cannot fit in the type `int`, so (following the ANSI C rules) its data type is `unsigned long int`. Negating this value yields 2147483648 again.
- GNU CC does not substitute macro arguments when they appear inside of string constants. For example, the following macro in GNU CC

  ```
  #define foo(a) "a"
  ```

  will produce output `"a"` regardless of what the argument a is.

The `-traditional' option directs GNU CC to handle such cases (among others) in the old-fashioned (non-ANSI) fashion.

- When you use `setjmp` and `longjmp`, the only automatic variables guaranteed to remain valid are those declared `volatile`. This is a consequence of automatic register allocation. Consider this function:

```
jmp_buf j;

foo ()
{
  int a, b;

  a = fun1 ();
  if (setjmp (j))
    return a;

  a = fun2 ();
  /* longjmp (j) may occur in fun3. */
  return a + fun3 ();
}
```

  Here `a` may or may not be restored to its first value when the `longjmp` occurs. If `a` is allocated in a register, then its first value is restored; otherwise, it keeps the last value stored in it.

  If you use the `-W' option with the `-O' option, you will get a warning when GNU CC thinks such a problem might be possible.

  The `-traditional' option directs GNU C to put variables in the stack by default, rather than in registers, in functions that call `setjmp`. This results in the behavior found in traditional C compilers.

- Programs that use preprocessing directives in the middle of macro arguments do not work with GNU CC. For example, a program like this will not work:

```
foobar (
#define luser
        hack)
```

  ANSI C does not permit such a construct. It would make sense to support it when `-traditional' is used, but it is too much work to implement.

- Declarations of external variables and functions within a block apply only to the block containing the declaration. In other words, they have the same scope as any other declaration in the same place.

  In some other C compilers, a `extern` declaration affects all the rest of the file even if it happens within a block.

The `-traditional' option directs GNU C to treat all `extern` declarations as global, like traditional compilers.

- In traditional C, you can combine `long`, etc., with a typedef name, as shown here:

```
typedef int foo;
typedef long foo bar;
```

  In ANSI C, this is not allowed: `long` and other type modifiers require an explicit `int`. Because this criterion is expressed by Bison grammar rules rather than C code, the `-traditional' flag cannot alter it.

- PCC allows typedef names to be used as function parameters. The difficulty described immediately above applies here too.
- PCC allows whitespace in the middle of compound assignment operators such as `+='. GNU CC, following the ANSI standard, does not allow this. The difficulty described immediately above applies here too.
- GNU CC complains about unterminated character constants inside of preprocessing conditionals that fail. Some programs have English comments enclosed in conditionals that are guaranteed to fail; if these comments contain apostrophes, GNU CC will probably report an error. For example, this code would produce an error:

```
#if 0
You can't expect this to work.
#endif
```

  The best solution to such a problem is to put the text into an actual C comment delimited by `/*...*/'. However, `-traditional' suppresses these error messages.

- Many user programs contain the declaration `long time ();'. In the past, the system header files on many systems did not actually declare `time`, so it did not matter what type your program declared it to return. But in systems with ANSI C headers, `time` is declared to return `time_t`, and if that is not the same as `long`, then `long time ();' is erroneous.

  The solution is to change your program to use `time_t` as the return type of `time`.

- When compiling functions that return `float`, PCC converts it to a double. GNU CC actually returns a `float`. If you are concerned with PCC compatibility, you should declare your functions to return `double`; you might as well say what you mean.
- When compiling functions that return structures or unions, GNU CC output code normally uses a method different from that used on most versions of Unix. As a result, code compiled with GNU CC cannot call a structure-returning function compiled with PCC, and vice versa.

  The method used by GNU CC is as follows: a structure or union which is 1, 2, 4 or 8 bytes long is returned like a scalar. A structure or union with any other size is stored into an address supplied by the caller (usually in a special, fixed register, but on some machines it is passed on the stack). The machine-description macros `STRUCT_VALUE` and `STRUCT_INCOMING_VALUE` tell GNU CC where to pass this address.

By contrast, PCC on most target machines returns structures and unions of any size by copying data into an area of static storage, and then returning the address of that storage as if it were a pointer value. The caller must copy the data from that memory area to the place where the value is wanted. GNU CC does not use this method because it is slower and nonreentrant.

On some newer machines, PCC uses a reentrant convention for all structure and union returning. GNU CC on most of these machines uses a compatible convention when returning structures and unions in memory, but still returns small structures and unions in registers.

You can tell GNU CC to use a compatible convention for all structure and union returning with the option `-fpcc-struct-return'.

- GNU C complains about program fragments such as `0x74ae-0x4000' which appear to be two hexadecimal constants separated by the minus operator. Actually, this string is a single preprocessing token. Each such token must correspond to one token in C. Since this does not, GNU C prints an error message. Although it may appear obvious that what is meant is an operator and two values, the ANSI C standard specifically requires that this be treated as erroneous.

  A preprocessing token is a preprocessing number if it begins with a digit and is followed by letters, underscores, digits, periods and `e+', `e-', `E+', or `E-' character sequences.

  To make the above program fragment valid, place whitespace in front of the minus sign. This whitespace will end the preprocessing number.

Fixed Header Files

GNU CC needs to install corrected versions of some system header files. This is because most target systems have some header files that won't work with GNU CC unless they are changed. Some have bugs, some are incompatible with ANSI C, and some depend on special features of other compilers.

Installing GNU CC automatically creates and installs the fixed header files, by running a program called `fixincludes` (or for certain targets an alternative such as `fixinc.svr4`). Normally, you don't need to pay attention to this. But there are cases where it doesn't do the right thing automatically.

- If you update the system's header files, such as by installing a new system version, the fixed header files of GNU CC are not automatically updated. The easiest way to update them is to reinstall GNU CC. (If you want to be clever, look in the makefile and you can find a shortcut.)
- On some systems, in particular SunOS 4, header file directories contain machine-specific symbolic links in certain places. This makes it possible to share most of the header files among hosts running the same version of SunOS 4 on different machine models.

  The programs that fix the header files do not understand this special way of using symbolic links; therefore, the directory of fixed header files is good only for the machine model used to build it.

  In SunOS 4, only programs that look inside the kernel will notice the difference between machine models. Therefore, for most purposes, you need not be concerned about this.

  It is possible to make separate sets of fixed header files for the different machine models, and arrange a structure of symbolic links so as to use the proper set, but you'll have to do this by hand.

- On Lynxos, GNU CC by default does not fix the header files. This is because bugs in the shell cause the `fixincludes` script to fail.

  This means you will encounter problems due to bugs in the system header files. It may be no comfort that they aren't GNU CC's fault, but it does mean that there's nothing for us to do about them.

Standard Libraries

GNU CC by itself attempts to be what the ISO/ANSI C standard calls a conforming freestanding implementation. This means all ANSI C language features are available, as well as the contents of `` `float.h' ``, `` `limits.h' ``, `` `stdarg.h' ``, and `` `stddef.h' ``. The rest of the C library is supplied by the vendor of the operating system. If that C library doesn't conform to the C standards, then your programs might get warnings (especially when using `-Wall') that you don't expect.

For example, the `sprintf` function on SunOS 4.1.3 returns `char *` while the C standard says that `sprintf` returns an `int`. The `fixincludes` program could make the prototype for this function match the Standard, but that would be wrong, since the function will still return `char *`.

If you need a Standard compliant library, then you need to find one, as GNU CC does not provide one. The GNU C library (called `glibc`) has been ported to a number of operating systems, and provides ANSI/ISO, POSIX, BSD and SystemV compatibility. You could also ask your operating system vendor if newer libraries are available.

Disappointments and Misunderstandings

These problems are perhaps regrettable, but we don't know any practical way around them.

- Certain local variables aren't recognized by debuggers when you compile with optimization.

  This occurs because sometimes GNU CC optimizes the variable out of existence. There is no way to tell the debugger how to compute the value such a variable "would have had", and it is not clear that would be desirable anyway. So GNU CC simply does not mention the eliminated variable when it writes debugging information.

  You have to expect a certain amount of disagreement between the executable and your source code, when you use optimization.

- Users often think it is a bug when GNU CC reports an error for code like this:

```
int foo (struct mumble *);

struct mumble { ... };

int foo (struct mumble *x)
{ ... }
```

This code really is erroneous, because the scope of `struct mumble` in the prototype is limi to the argument list containing it. It does not refer to the `struct mumble` defined with file scope immediately below--they are two unrelated types with similar names in different scopes.

But in the definition of `foo`, the file-scope type is used because that is available to be inherited. Thus, the definition and the prototype do not match, and you get an error.

This behavior may seem silly, but it's what the ANSI standard specifies. It is easy enough for you to make your code work by moving the definition of `struct mumble` above the prototype. It's not worth being incompatible with ANSI C just to avoid an error for the example shown above.

- Accesses to bitfields even in volatile objects works by accessing larger objects, such as a byte or a word. You cannot rely on what size of object is accessed in order to read or write the bitfield; it may even vary for a given bitfield according to the precise usage.

  If you care about controlling the amount of memory that is accessed, use volatile but do not use bitfields.

- GNU CC comes with shell scripts to fix certain known problems in system header files. They install corrected copies of various header files in a special directory where only GNU CC will normally look for them. The scripts adapt to various systems by searching all the system header files for the problem cases that we know about.

  If new system header files are installed, nothing automatically arranges to update the corrected header files. You will have to reinstall GNU CC to fix the new header files. More specifically, go to the build directory and delete the files `` `stmp-fixinc' `` and `` `stmp-headers' ``, and the subdirectory `include`; then do `make install' again.

- On 68000 systems, you can get paradoxical results if you test the precise values of floating point numbers. For example, you can find that a floating point value which is not a NaN is not equal to itself. This results from the fact that the the floating point registers hold a few more bits of precision than fit in a `double` in memory. Compiled code moves values between memory and floating point registers at its convenience, and moving them into memory truncates them.

  You can partially avoid this problem by using the `-ffloat-store' option (see section Options That Control Optimization).

- On the MIPS, variable argument functions using `` `varargs.h' `` cannot have a floating point value for the first argument. The reason for this is that in the absence of a prototype in scope, if the first argument is a floating point, it is passed in a floating point register, rather than an integer register.

  If the code is rewritten to use the ANSI standard `` `stdarg.h' `` method of variable arguments, and the prototype is in scope at the time of the call, everything will work fine.

Common Misunderstandings with GNU C++

C++ is a complex language and an evolving one, and its standard definition (the ANSI C++ draft standard) is also evolving. As a result, your C++ compiler may occasionally surprise you, even when its behavior is correct. This section discusses some areas that frequently give rise to questions of this sort.

Declare *and* Define Static Members

When a class has static data members, it is not enough to *declare* the static member; you must also *define* it. For example:

```
class Foo
{
  ...
  void method();
  static int bar;
};
```

This declaration only establishes that the class `Foo` has an `int` named `Foo::bar`, and a member function named `Foo::method`. But you still need to define *both* `method` and `bar` elsewhere. According to the draft ANSI standard, you must supply an initializer in one (and only one) source file, such as:

```
int Foo::bar = 0;
```

Other C++ compilers may not correctly implement the standard behavior. As a result, when you switch to `g++` from one of these compilers, you may discover that a program that appeared to work correctly in fact does not conform to the standard: `g++` reports as undefined symbols any static data members that lack definitions.

Temporaries May Vanish Before You Expect

It is dangerous to use pointers or references to *portions* of a temporary object. The compiler may very well delete the object before you expect it to, leaving a pointer to garbage. The most common place where this problem crops up is in classes like the libg++ `String` class, that define a conversion function to type `char *` or `const char *`. However, any class that returns a pointer to some internal structure is potentially subject to this problem.

For example, a program may use a function `strfunc` that returns `String` objects, and another function `charfunc` that operates on pointers to `char`:

```
String strfunc ();
void charfunc (const char *);
```

In this situation, it may seem natural to write `charfunc (strfunc ());' based on the knowledge that class `String` has an explicit conversion to `char` pointers. However, what really happens is akin to `charfunc (strfunc ().convert ());', where the `convert` method is a function to do the same data conversion normally performed by a cast. Since the last use of the temporary `String` object is the call to the conversion function, the compiler may delete that object before actually calling `charfunc`. The compiler has no way of knowing that deleting the `String` object will invalidate the pointer. The pointer then points to garbage, so that by the time `charfunc` is called, it gets an invalid argument.

Code like this may run successfully under some other compilers, especially those that delete tempora relatively late. However, the GNU C++ behavior is also standard-conformant, so if your program depends on late destruction of temporaries it is not portable.

If you think this is surprising, you should be aware that the ANSI C++ committee continues to debate the lifetime-of-temporaries problem.

For now, at least, the safe way to write such code is to give the temporary a name, which forces it to remain until the end of the scope of the name. For example:

```
String& tmp = strfunc ();
charfunc (tmp);
```

Caveats of using `protoize`

The conversion programs `protoize` and `unprotoize` can sometimes change a source file in a way that won't work unless you rearrange it.

- `protoize` can insert references to a type name or type tag before the definition, or in a file where they are not defined.

  If this happens, compiler error messages should show you where the new references are, so fixing the file by hand is straightforward.
- There are some C constructs which `protoize` cannot figure out. For example, it can't determine argument types for declaring a pointer-to-function variable; this you must do by hand. `protoize` inserts a comment containing `???' each time it finds such a variable; so you can find all such variables by searching for this string. ANSI C does not require declaring the argument types of pointer-to-function types.
- Using `unprotoize` can easily introduce bugs. If the program relied on prototypes to bring about conversion of arguments, these conversions will not take place in the program without prototypes. One case in which you can be sure `unprotoize` is safe is when you are removing prototypes that were made with `protoize`; if the program worked before without any prototypes, it will work again without them.

  You can find all the places where this problem might occur by compiling the program with the `-Wconversion' option. It prints a warning whenever an argument is converted.
- Both conversion programs can be confused if there are macro calls in and around the text to be converted. In other words, the standard syntax for a declaration or definition must not result from expanding a macro. This problem is inherent in the design of C and cannot be fixed. If only a few functions have confusing macro calls, you can easily convert them manually.
- `protoize` cannot get the argument types for a function whose definition was not actually compiled due to preprocessing conditionals. When this happens, `protoize` changes nothing in regard to such a function. `protoize` tries to detect such instances and warn about them.

  You can generally work around this problem by using `protoize` step by step, each time specifying a different set of `-D' options for compilation, until all of the functions have been

converted. There is no automatic way to verify that you have got them all, however.

- Confusion may result if there is an occasion to convert a function declaration or definition in a region of source code where there is more than one formal parameter list present. Thus, attempts to convert code containing multiple (conditionally compiled) versions of a single function header (in the same vicinity) may not produce the desired (or expected) results.

  If you plan on converting source files which contain such code, it is recommended that you first make sure that each conditionally compiled region of source code which contains an alternative function header also contains at least one additional follower token (past the final right parenthesis of the function header). This should circumvent the problem.
- `unprotoize` can become confused when trying to convert a function definition or declaration which contains a declaration for a pointer-to-function formal argument which has the same name as the function being defined or declared. We recommand you avoid such choices of formal parameter names.
- You might also want to correct some of the indentation by hand and break long lines. (The conversion programs don't write lines longer than eighty characters in any case.)

Certain Changes We Don't Want to Make

This section lists changes that people frequently request, but which we do not make because we think GNU CC is better without them.

- Checking the number and type of arguments to a function which has an old-fashioned definition and no prototype.

  Such a feature would work only occasionally--only for calls that appear in the same file as the called function, following the definition. The only way to check all calls reliably is to add a prototype for the function. But adding a prototype eliminates the motivation for this feature. So the feature is not worthwhile.
- Warning about using an expression whose type is signed as a shift count.

  Shift count operands are probably signed more often than unsigned. Warning about this would cause far more annoyance than good.
- Warning about assigning a signed value to an unsigned variable.

  Such assignments must be very common; warning about them would cause more annoyance than good.
- Warning about unreachable code.

  It's very common to have unreachable code in machine-generated programs. For example, this happens normally in some files of GNU C itself.
- Warning when a non-void function value is ignored.

  Coming as I do from a Lisp background, I balk at the idea that there is something dangerous about discarding a value. There are functions that return values which some callers may find useful; it makes no sense to clutter the program with a cast to `void` whenever the value isn't useful.

- Assuming (for optimization) that the address of an external symbol is never zero.

  This assumption is false on certain systems when `#pragma weak' is used.

- Making `-fshort-enums' the default.

  This would cause storage layout to be incompatible with most other C compilers. And it doesn't seem very important, given that you can get the same result in other ways. The case where it matters most is when the enumeration-valued object is inside a structure, and in that case you can specify a field width explicitly.

- Making bitfields unsigned by default on particular machines where "the ABI standard" says to do so.

  The ANSI C standard leaves it up to the implementation whether a bitfield declared plain `int` is signed or not. This in effect creates two alternative dialects of C.

  The GNU C compiler supports both dialects; you can specify the signed dialect with `-fsigned-bitfields' and the unsigned dialect with `-funsigned-bitfields'. However, this leaves open the question of which dialect to use by default.

  Currently, the preferred dialect makes plain bitfields signed, because this is simplest. Since `int` is the same as `signed int` in every other context, it is cleanest for them to be the same in bitfields as well.

  Some computer manufacturers have published Application Binary Interface standards which specify that plain bitfields should be unsigned. It is a mistake, however, to say anything about this issue in an ABI. This is because the handling of plain bitfields distinguishes two dialects of C. Both dialects are meaningful on every type of machine. Whether a particular object file was compiled using signed bitfields or unsigned is of no concern to other object files, even if they access the same bitfields in the same data structures.

  A given program is written in one or the other of these two dialects. The program stands a chance to work on most any machine if it is compiled with the proper dialect. It is unlikely to work at all if compiled with the wrong dialect.

  Many users appreciate the GNU C compiler because it provides an environment that is uniform across machines. These users would be inconvenienced if the compiler treated plain bitfields differently on certain machines.

  Occasionally users write programs intended only for a particular machine type. On these occasions, the users would benefit if the GNU C compiler were to support by default the same dialect as the other compilers on that machine. But such applications are rare. And users writing a program to run on more than one type of machine cannot possibly benefit from this kind of compatibility.

  This is why GNU CC does and will treat plain bitfields in the same fashion on all types of machines (by default).

  There are some arguments for making bitfields unsigned by default on all machines. If, for example, this becomes a universal de facto standard, it would make sense for GNU CC to go along

with it. This is something to be considered in the future.

(Of course, users strongly concerned about portability should indicate explicitly in each bitfield whether it is signed or not. In this way, they write programs which have the same meaning in both C dialects.)

- Undefining `__STDC__` when `-ansi' is not used.

  Currently, GNU CC defines `__STDC__` as long as you don't use `-traditional'. This provides good results in practice.

  Programmers normally use conditionals on `__STDC__` to ask whether it is safe to use certain features of ANSI C, such as function prototypes or ANSI token concatenation. Since plain `gcc' supports all the features of ANSI C, the correct answer to these questions is "yes".

  Some users try to use `__STDC__` to check for the availability of certain library facilities. This is actually incorrect usage in an ANSI C program, because the ANSI C standard says that a conforming freestanding implementation should define `__STDC__` even though it does not have the library facilities. `gcc -ansi -pedantic' is a conforming freestanding implementation, and it is therefore required to define `__STDC__`, even though it does not come with an ANSI C library.

  Sometimes people say that defining `__STDC__` in a compiler that does not completely conform to the ANSI C standard somehow violates the standard. This is illogical. The standard is a standard for compilers that claim to support ANSI C, such as `gcc -ansi'---not for other compilers such as plain `gcc'. Whatever the ANSI C standard says is relevant to the design of plain `gcc' without `-ansi' only for pragmatic reasons, not as a requirement.

- Undefining `__STDC__` in C++.

  Programs written to compile with C++-to-C translators get the value of `__STDC__` that goes with the C compiler that is subsequently used. These programs must test `__STDC__` to determine what kind of C preprocessor that compiler uses: whether they should concatenate tokens in the ANSI C fashion or in the traditional fashion.

  These programs work properly with GNU C++ if `__STDC__` is defined. They would not work otherwise.

  In addition, many header files are written to provide prototypes in ANSI C but not in traditional C. Many of these header files can work without change in C++ provided `__STDC__` is defined. If `__STDC__` is not defined, they will all fail, and will all need to be changed to test explicitly for C++ as well.

- Deleting "empty" loops.

  GNU CC does not delete "empty" loops because the most likely reason you would put one in a program is to have a delay. Deleting them will not make real programs run any faster, so it would be pointless.

  It would be different if optimization of a nonempty loop could produce an empty one. But this generally can't happen.

- Making side effects happen in the same order as in some other compiler.

It is never safe to depend on the order of evaluation of side effects. For example, a function ca like this may very well behave differently from one compiler to another:

```
void func (int, int);

int i = 2;
func (i++, i++);
```

There is no guarantee (in either the C or the C++ standard language definitions) that the increments will be evaluated in any particular order. Either increment might happen first. `func` might get the arguments `2, 3', or it might get `3, 2', or even `2, 2'.

- Not allowing structures with volatile fields in registers.

  Strictly speaking, there is no prohibition in the ANSI C standard against allowing structures with volatile fields in registers, but it does not seem to make any sense and is probably not what you wanted to do. So the compiler will give an error message in this case.

Warning Messages and Error Messages

The GNU compiler can produce two kinds of diagnostics: errors and warnings. Each kind has a different purpose:

- *Errors* report problems that make it impossible to compile your program. GNU CC reports errors with the source file name and line number where the problem is apparent.
- *Warnings* report other unusual conditions in your code that *may* indicate a problem, although compilation can (and does) proceed. Warning messages also report the source file name and line number, but include the text `warning:' to distinguish them from error messages.

Warnings may indicate danger points where you should check to make sure that your program really does what you intend; or the use of obsolete features; or the use of nonstandard features of GNU C or C++. Many warnings are issued only if you ask for them, with one of the `-W' options (for instance, `-Wall' requests a variety of useful warnings).

GNU CC always tries to compile your program if possible; it never gratuitously rejects a program whose meaning is clear merely because (for instance) it fails to conform to a standard. In some cases, however, the C and C++ standards specify that certain extensions are forbidden, and a diagnostic *must* be issued by a conforming compiler. The `-pedantic' option tells GNU CC to issue warnings in such cases; `-pedantic-errors' says to make them errors instead. This does not mean that *all* non-ANSI constructs get warnings or errors.

See section Options to Request or Suppress Warnings, for more detail on these and related command-line options.

Go to the previous, next section.

Go to the previous, next section.

Reporting Bugs

Your bug reports play an essential role in making GNU CC reliable.

When you encounter a problem, the first thing to do is to see if it is already known. See section Known Causes of Trouble with GNU CC. If it isn't known, then you should report the problem.

Reporting a bug may help you by bringing a solution to your problem, or it may not. (If it does not, look in the service directory; see section How To Get Help with GNU CC.) In any case, the principal function of a bug report is to help the entire community by making the next version of GNU CC work better. Bug reports are your contribution to the maintenance of GNU CC.

Since the maintainers are very overloaded, we cannot respond to every bug report. However, if the bug has not been fixed, we are likely to send you a patch and ask you to tell us whether it works.

In order for a bug report to serve its purpose, you must include the information that makes for fixing the bug.

Have You Found a Bug?

If you are not sure whether you have found a bug, here are some guidelines:

- If the compiler gets a fatal signal, for any input whatever, that is a compiler bug. Reliable compilers never crash.
- If the compiler produces invalid assembly code, for any input whatever (except an `asm` statement), that is a compiler bug, unless the compiler reports errors (not just warnings) which would ordinarily prevent the assembler from being run.
- If the compiler produces valid assembly code that does not correctly execute the input source code, that is a compiler bug.

  However, you must double-check to make sure, because you may have run into an incompatibility between GNU C and traditional C (see section Incompatibilities of GNU CC). These incompatibilities might be considered bugs, but they are inescapable consequences of valuable features.

  Or you may have a program whose behavior is undefined, which happened by chance to give the desired results with another C or C++ compiler.

  For example, in many nonoptimizing compilers, you can write `x;' at the end of a function instead of `return x;', with the same results. But the value of the function is undefined if `return` is omitted; it is not a bug when GNU CC produces different results.

  Problems often result from expressions with two increment operators, as in `f (*p++, *p++)`. Your previous compiler might have interpreted that expression the way you intended; GNU CC

might interpret it another way. Neither compiler is wrong. The bug is in your code.

After you have localized the error to a single source line, it should be easy to check for these things. If your program is correct and well defined, you have found a compiler bug.

- If the compiler produces an error message for valid input, that is a compiler bug.
- If the compiler does not produce an error message for invalid input, that is a compiler bug. However, you should note that your idea of "invalid input" might be my idea of "an extension" or "support for traditional practice".
- If you are an experienced user of C or C++ compilers, your suggestions for improvement of GNU CC or GNU C++ are welcome in any case.

Where to Report Bugs

Send bug reports for GNU C to `bug-gcc@prep.ai.mit.edu'.

Send bug reports for GNU C++ to `bug-g++@prep.ai.mit.edu'. If your bug involves the C++ class library libg++, send mail to `bug-lib-g++@prep.ai.mit.edu'. If you're not sure, you can send the bug report to both lists.

Do not send bug reports to `help-gcc@prep.ai.mit.edu' or to the newsgroup `gnu.gcc.help'. Most users of GNU CC do not want to receive bug reports. Those that do, have asked to be on `bug-gcc' and/or `bug-g++'.

The mailing lists `bug-gcc' and `bug-g++' both have newsgroups which serve as repeaters: `gnu.gcc.bug' and `gnu.g++.bug'. Each mailing list and its newsgroup carry exactly the same messages.

Often people think of posting bug reports to the newsgroup instead of mailing them. This appears to work, but it has one problem which can be crucial: a newsgroup posting does not contain a mail path back to the sender. Thus, if maintainers need more information, they may be unable to reach you. For this reason, you should always send bug reports by mail to the proper mailing list.

As a last resort, send bug reports on paper to:

```
GNU Compiler Bugs
Free Software Foundation
675 Mass Ave
Cambridge, MA 02139
```

How to Report Bugs

The fundamental principle of reporting bugs usefully is this: **report all the facts**. If you are not sure whether to state a fact or leave it out, state it!

Often people omit facts because they think they know what causes the problem and they conclude that some details don't matter. Thus, you might assume that the name of the variable you use in an example does not matter. Well, probably it doesn't, but one cannot be sure. Perhaps the bug is a stray memory

reference which happens to fetch from the location where that name is stored in memory; perhaps, if the name were different, the contents of that location would fool the compiler into doing the right thing despite the bug. Play it safe and give a specific, complete example. That is the easiest thing for you to do, and the most helpful.

Keep in mind that the purpose of a bug report is to enable someone to fix the bug if it is not known. It isn't very important what happens if the bug is already known. Therefore, always write your bug reports on the assumption that the bug is not known.

Sometimes people give a few sketchy facts and ask, "Does this ring a bell?" This cannot help us fix a bug, so it is basically useless. We respond by asking for enough details to enable us to investigate. You might as well expedite matters by sending them to begin with.

Try to make your bug report self-contained. If we have to ask you for more information, it is best if you include all the previous information in your response, as well as the information that was missing.

Please report each bug in a separate message. This makes it easier for us to track which bugs have been fixed and to forward your bugs reports to the appropriate maintainer.

Do not compress and encode any part of your bug report using programs such as `uuencode'. If you do so it will slow down the processing of your bug. If you must submit multiple large files, use `shar', which allows us to read your message without having to run any decompression programs.

To enable someone to investigate the bug, you should include all these things:

- The version of GNU CC. You can get this by running it with the `-v' option.

  Without this, we won't know whether there is any point in looking for the bug in the current version of GNU CC.
- A complete input file that will reproduce the bug. If the bug is in the C preprocessor, send a source file and any header files that it requires. If the bug is in the compiler proper (`cc1'), run your source file through the C preprocessor by doing `gcc -E sourcefile > outfile', then include the contents of outfile in the bug report. (When you do this, use the same `-I', `-D' or `-U' options that you used in actual compilation.)

  A single statement is not enough of an example. In order to compile it, it must be embedded in a complete file of compiler input; and the bug might depend on the details of how this is done.

  Without a real example one can compile, all anyone can do about your bug report is wish you luck. It would be futile to try to guess how to provoke the bug. For example, bugs in register allocation and reloading frequently depend on every little detail of the function they happen in.

  Even if the input file that fails comes from a GNU program, you should still send the complete test case. Don't ask the GNU CC maintainers to do the extra work of obtaining the program in question--they are all overworked as it is. Also, the problem may depend on what is in the header files on your system; it is unreliable for the GNU CC maintainers to try the problem with the header files available to them. By sending CPP output, you can eliminate this source of uncertainty and save us a certain percentage of wild goose chases.
- The command arguments you gave GNU CC or GNU C++ to compile that example and observe

the bug. For example, did you use `-O'? To guarantee you won't omit something important, list the options.

If we were to try to guess the arguments, we would probably guess wrong and then we would not encounter the bug.

- The type of machine you are using, and the operating system name and version number.
- The operands you gave to the `configure` command when you installed the compiler.
- A complete list of any modifications you have made to the compiler source. (We don't promise to investigate the bug unless it happens in an unmodified compiler. But if you've made modifications and don't tell us, then you are sending us on a wild goose chase.)

  Be precise about these changes. A description in English is not enough--send a context diff for them.

  Adding files of your own (such as a machine description for a machine we don't support) is a modification of the compiler source.
- Details of any other deviations from the standard procedure for installing GNU CC.
- A description of what behavior you observe that you believe is incorrect. For example, "The compiler gets a fatal signal," or, "The assembler instruction at line 208 in the output is incorrect."

  Of course, if the bug is that the compiler gets a fatal signal, then one can't miss it. But if the bug is incorrect output, the maintainer might not notice unless it is glaringly wrong. None of us has time to study all the assembler code from a 50-line C program just on the chance that one instruction might be wrong. We need *you* to do this part!

  Even if the problem you experience is a fatal signal, you should still say so explicitly. Suppose something strange is going on, such as, your copy of the compiler is out of synch, or you have encountered a bug in the C library on your system. (This has happened!) Your copy might crash and the copy here would not. If you *said* to expect a crash, then when the compiler here fails to crash, we would know that the bug was not happening. If you don't say to expect a crash, then we would not know whether the bug was happening. We would not be able to draw any conclusion from our observations.

  If the problem is a diagnostic when compiling GNU CC with some other compiler, say whether it is a warning or an error.

  Often the observed symptom is incorrect output when your program is run. Sad to say, this is not enough information unless the program is short and simple. None of us has time to study a large program to figure out how it would work if compiled correctly, much less which line of it was compiled wrong. So you will have to do that. Tell us which source line it is, and what incorrect result happens when that line is executed. A person who understands the program can find this as easily as finding a bug in the program itself.
- If you send examples of assembler code output from GNU CC or GNU C++, please use `-g' when you make them. The debugging information includes source line numbers which are essential for correlating the output with the input.
- If you wish to mention something in the GNU CC source, refer to it by context, not by line

number.

The line numbers in the development sources don't match those in your sources. Your line numbers would convey no useful information to the maintainers.

- Additional information from a debugger might enable someone to find a problem on a machine which he does not have available. However, you need to think when you collect this information if you want it to have any chance of being useful.

  For example, many people send just a backtrace, but that is never useful by itself. A simple backtrace with arguments conveys little about GNU CC because the compiler is largely data-driven; the same functions are called over and over for different RTL insns, doing different things depending on the details of the insn.

  Most of the arguments listed in the backtrace are useless because they are pointers to RTL list structure. The numeric values of the pointers, which the debugger prints in the backtrace, have no significance whatever; all that matters is the contents of the objects they point to (and most of the contents are other such pointers).

  In addition, most compiler passes consist of one or more loops that scan the RTL insn sequence. The most vital piece of information about such a loop--which insn it has reached--is usually in a local variable, not in an argument.

  What you need to provide in addition to a backtrace are the values of the local variables for several stack frames up. When a local variable or an argument is an RTX, first print its value and then use the GDB command `pr` to print the RTL expression that it points to. (If GDB doesn't run on your machine, use your debugger to call the function `debug_rtx` with the RTX as an argument.) In general, whenever a variable is a pointer, its value is no use without the data it points to.

Here are some things that are not necessary:

- A description of the envelope of the bug.

  Often people who encounter a bug spend a lot of time investigating which changes to the input file will make the bug go away and which changes will not affect it.

  This is often time consuming and not very useful, because the way we will find the bug is by running a single example under the debugger with breakpoints, not by pure deduction from a series of examples. You might as well save your time for something else.

  Of course, if you can find a simpler example to report *instead* of the original one, that is a convenience. Errors in the output will be easier to spot, running under the debugger will take less time, etc. Most GNU CC bugs involve just one function, so the most straightforward way to simplify an example is to delete all the function definitions except the one where the bug occurs. Those earlier in the file may be replaced by external declarations if the crucial function depends on them. (Exception: inline functions may affect compilation of functions defined later in the file.)

  However, simplification is not vital; if you don't want to do this, report the bug anyway and send the entire test case you used.

- In particular, some people insert conditionals `#ifdef BUG' around a statement which, if removed,

makes the bug not happen. These are just clutter; we won't pay any attention to them anyway. Besides, you should send us cpp output, and that can't have conditionals.

- A patch for the bug.

  A patch for the bug is useful if it is a good one. But don't omit the necessary information, such as the test case, on the assumption that a patch is all we need. We might see problems with your patch and decide to fix the problem another way, or we might not understand it at all.

  Sometimes with a program as complicated as GNU CC it is very hard to construct an example that will make the program follow a certain path through the code. If you don't send the example, we won't be able to construct one, so we won't be able to verify that the bug is fixed.

  And if we can't understand what bug you are trying to fix, or why your patch should be an improvement, we won't install it. A test case will help us to understand.

  See section Sending Patches for GNU CC, for guidelines on how to make it easy for us to understand and install your patches.

- A guess about what the bug is or what it depends on.

  Such guesses are usually wrong. Even I can't guess right about such things without first using the debugger to find the facts.

- A core dump file.

  We have no way of examining a core dump for your type of machine unless we have an identical system--and if we do have one, we should be able to reproduce the crash ourselves.

Sending Patches for GNU CC

If you would like to write bug fixes or improvements for the GNU C compiler, that is very helpful. Send suggested fixes to the bug report mailing list, `bug-gcc@prep.ai.mit.edu`.

Please follow these guidelines so we can study your patches efficiently. If you don't follow these guidelines, your information might still be useful, but using it will take extra work. Maintaining GNU C is a lot of work in the best of circumstances, and we can't keep up unless you do your best to help.

- Send an explanation with your changes of what problem they fix or what improvement they bring about. For a bug fix, just include a copy of the bug report, and explain why the change fixes the bug.

  (Referring to a bug report is not as good as including it, because then we will have to look it up, and we have probably already deleted it if we've already fixed the bug.)

- Always include a proper bug report for the problem you think you have fixed. We need to convince ourselves that the change is right before installing it. Even if it is right, we might have trouble judging it if we don't have a way to reproduce the problem.
- Include all the comments that are appropriate to help people reading the source in the future understand why this change was needed.
- Don't mix together changes made for different reasons. Send them *individually*.

If you make two changes for separate reasons, then we might not want to install them both. We might want to install just one. If you send them all jumbled together in a single set of diffs, we have to do extra work to disentangle them--to figure out which parts of the change serve which purpose. If we don't have time for this, we might have to ignore your changes entirely.

If you send each change as soon as you have written it, with its own explanation, then the two changes never get tangled up, and we can consider each one properly without any extra work to disentangle them.

Ideally, each change you send should be impossible to subdivide into parts that we might want to consider separately, because each of its parts gets its motivation from the other parts.

- Send each change as soon as that change is finished. Sometimes people think they are helping us by accumulating many changes to send them all together. As explained above, this is absolutely the worst thing you could do.

  Since you should send each change separately, you might as well send it right away. That gives us the option of installing it immediately if it is important.

- Use `diff -c' to make your diffs. Diffs without context are hard for us to install reliably. More than that, they make it hard for us to study the diffs to decide whether we want to install them. Unidiff format is better than contextless diffs, but not as easy to read as `-c' format.

  If you have GNU diff, use `diff -cp', which shows the name of the function that each change occurs in.

- Write the change log entries for your changes. We get lots of changes, and we don't have time to do all the change log writing ourselves.

  Read the `ChangeLog' file to see what sorts of information to put in, and to learn the style that we use. The purpose of the change log is to show people where to find what was changed. So you need to be specific about what functions you changed; in large functions, it's often helpful to indicate where within the function the change was.

  On the other hand, once you have shown people where to find the change, you need not explain its purpose. Thus, if you add a new function, all you need to say about it is that it is new. If you feel that the purpose needs explaining, it probably does--but the explanation will be much more useful if you put it in comments in the code.

  If you would like your name to appear in the header line for who made the change, send us the header line.

- When you write the fix, keep in mind that we can't install a change that would break other systems.

  People often suggest fixing a problem by changing machine-independent files such as `toplev.c' to do something special that a particular system needs. Sometimes it is totally obvious that such changes would break GNU CC for almost all users. We can't possibly make a change like that. At best it might tell us how to write another patch that would solve the problem acceptably.

  Sometimes people send fixes that *might* be an improvement in general--but it is hard to be sure of

this. It's hard to install such changes because we have to study them very carefully. Of course, a good explanation of the reasoning by which you concluded the change was correct can help convince us.

The safest changes are changes to the configuration files for a particular machine. These are safe because they can't create new bugs on other machines.

Please help us keep up with the workload by designing the patch in a form that is good to install.

How To Get Help with GNU CC

If you need help installing, using or changing GNU CC, there are two ways to find it:

- Send a message to a suitable network mailing list. First try `bug-gcc@prep.ai.mit.edu`, and if that brings no response, try `help-gcc@prep.ai.mit.edu`.
- Look in the service directory for someone who might help you for a fee. The service directory is found in the file named `` `SERVICE' `` in the GNU CC distribution.

Go to the previous, next section.

Go to the previous, next section.

Using GNU CC on VMS

Here is how to use GNU CC on VMS.

Include Files and VMS

Due to the differences between the filesystems of Unix and VMS, GNU CC attempts to translate file names in `#include' into names that VMS will understand. The basic strategy is to prepend a prefix to the specification of the include file, convert the whole filename to a VMS filename, and then try to open the file. GNU CC tries various prefixes one by one until one of them succeeds:

1. The first prefix is the `GNU_CC_INCLUDE:' logical name: this is where GNU C header files are traditionally stored. If you wish to store header files in non-standard locations, then you can assign the logical `GNU_CC_INCLUDE' to be a search list, where each element of the list is suitable for use with a rooted logical.
2. The next prefix tried is `SYS$SYSROOT:[SYSLIB.]'. This is where VAX-C header files are traditionally stored.
3. If the include file specification by itself is a valid VMS filename, the preprocessor then uses this name with no prefix in an attempt to open the include file.
4. If the file specification is not a valid VMS filename (i.e. does not contain a device or a directory specifier, and contains a `/' character), the preprocessor tries to convert it from Unix syntax to VMS syntax.

   Conversion works like this: the first directory name becomes a device, and the rest of the directories are converted into VMS-format directory names. For example, the name `X11/foobar.h' is translated to `X11:[000000]foobar.h' or `X11:foobar.h', whichever one can be opened. This strategy allows you to assign a logical name to point to the actual location of the header files.
5. If none of these strategies succeeds, the `#include' fails.

Include directives of the form:

```
#include foobar
```

are a common source of incompatibility between VAX-C and GNU CC. VAX-C treats this much like a standard `#include <foobar.h>` directive. That is incompatible with the ANSI C behavior implemented by GNU CC: to expand the name `foobar` as a macro. Macro expansion should eventually yield one of the two standard formats for `#include`:

```
#include "file"
#include <file>
```

If you have this problem, the best solution is to modify the source to convert the `#include` directiv one of the two standard forms. That will work with either compiler. If you want a quick and dirty fix, define the file names as macros with the proper expansion, like this:

```
#define stdio <stdio.h>
```

This will work, as long as the name doesn't conflict with anything else in the program.

Another source of incompatibility is that VAX-C assumes that:

```
#include "foobar"
```

is actually asking for the file `` `foobar.h' ``. GNU CC does not make this assumption, and instead takes what you ask for literally; it tries to read the file `` `foobar' ``. The best way to avoid this problem is to always specify the desired file extension in your include directives.

GNU CC for VMS is distributed with a set of include files that is sufficient to compile most general purpose programs. Even though the GNU CC distribution does not contain header files to define constants and structures for some VMS system-specific functions, there is no reason why you cannot use GNU CC with any of these functions. You first may have to generate or create header files, either by using the public domain utility `UNSDL` (which can be found on a DECUS tape), or by extracting the relevant modules from one of the system macro libraries, and using an editor to construct a C header file.

A `#include` file name cannot contain a DECNET node name. The preprocessor reports an I/O error if you attempt to use a node name, whether explicitly, or implicitly via a logical name.

Global Declarations and VMS

GNU CC does not provide the `globalref`, `globaldef` and `globalvalue` keywords of VAX-C. You can get the same effect with an obscure feature of GAS, the GNU assembler. (This requires GAS version 1.39 or later.) The following macros allow you to use this feature in a fairly natural way:

```
#ifdef __GNUC__
#define GLOBALREF(TYPE,NAME)                            \
  TYPE NAME                                             \
  asm ("_$$PsectAttributes_GLOBALSYMBOL$$" #NAME)
#define GLOBALDEF(TYPE,NAME,VALUE)                      \
  TYPE NAME                                             \
  asm ("_$$PsectAttributes_GLOBALSYMBOL$$" #NAME)       \
    = VALUE
#define GLOBALVALUEREF(TYPE,NAME)                       \
  const TYPE NAME[1]                                    \
  asm ("_$$PsectAttributes_GLOBALVALUE$$" #NAME)
#define GLOBALVALUEDEF(TYPE,NAME,VALUE)                 \
  const TYPE NAME[1]                                    \
  asm ("_$$PsectAttributes_GLOBALVALUE$$" #NAME)        \
```

```
    = {VALUE}
#else
#define GLOBALREF(TYPE,NAME) \
  globalref TYPE NAME
#define GLOBALDEF(TYPE,NAME,VALUE) \
  globaldef TYPE NAME = VALUE
#define GLOBALVALUEDEF(TYPE,NAME,VALUE) \
  globalvalue TYPE NAME = VALUE
#define GLOBALVALUEREF(TYPE,NAME) \
  globalvalue TYPE NAME
#endif
```

(The `_$$PsectAttributes_GLOBALSYMBOL` prefix at the start of the name is removed by the assembler, after it has modified the attributes of the symbol). These macros are provided in the VMS binaries distribution in a header file `` `GNU_HACKS.H' ``. An example of the usage is:

```
GLOBALREF (int, ijk);
GLOBALDEF (int, jkl, 0);
```

The macros `GLOBALREF` and `GLOBALDEF` cannot be used straightforwardly for arrays, since there is no way to insert the array dimension into the declaration at the right place. However, you can declare an array with these macros if you first define a typedef for the array type, like this:

```
typedef int intvector[10];
GLOBALREF (intvector, foo);
```

Array and structure initializers will also break the macros; you can define the initializer to be a macro of its own, or you can expand the `GLOBALDEF` macro by hand. You may find a case where you wish to use the `GLOBALDEF` macro with a large array, but you are not interested in explicitly initializing each element of the array. In such cases you can use an initializer like: `{0,}`, which will initialize the entire array to `0`.

A shortcoming of this implementation is that a variable declared with `GLOBALVALUEREF` or `GLOBALVALUEDEF` is always an array. For example, the declaration:

```
GLOBALVALUEREF(int, ijk);
```

declares the variable `ijk` as an array of type `int [1]`. This is done because a globalvalue is actually a constant; its "value" is what the linker would normally consider an address. That is not how an integer value works in C, but it is how an array works. So treating the symbol as an array name gives consistent results--with the exception that the value seems to have the wrong type. **Don't try to access an element of the array.** It doesn't have any elements. The array "address" may not be the address of actual storage.

The fact that the symbol is an array may lead to warnings where the variable is used. Insert type casts to avoid the warnings. Here is an example; it takes advantage of the ANSI C feature allowing macros that expand to use the same name as the macro itself.

```
GLOBALVALUEREF (int, ss$_normal);
GLOBALVALUEDEF (int, xyzzy,123);
#ifdef __GNUC__
#define ss$_normal ((int) ss$_normal)
#define xyzzy ((int) xyzzy)
#endif
```

Don't use `globaldef` or `globalref` with a variable whose type is an enumeration type; this is not implemented. Instead, make the variable an integer, and use a `globalvaluedef` for each of the enumeration values. An example of this would be:

```
#ifdef __GNUC__
GLOBALDEF (int, color, 0);
GLOBALVALUEDEF (int, RED, 0);
GLOBALVALUEDEF (int, BLUE, 1);
GLOBALVALUEDEF (int, GREEN, 3);
#else
enum globaldef color {RED, BLUE, GREEN = 3};
#endif
```

Other VMS Issues

GNU CC automatically arranges for `main` to return 1 by default if you fail to specify an explicit return value. This will be interpreted by VMS as a status code indicating a normal successful completion. Version 1 of GNU CC did not provide this default.

GNU CC on VMS works only with the GNU assembler, GAS. You need version 1.37 or later of GAS in order to produce value debugging information for the VMS debugger. Use the ordinary VMS linker with the object files produced by GAS.

Under previous versions of GNU CC, the generated code would occasionally give strange results when linked to the sharable `` `VAXCRTL' `` library. Now this should work.

A caveat for use of `const` global variables: the `const` modifier must be specified in every external declaration of the variable in all of the source files that use that variable. Otherwise the linker will issue warnings about conflicting attributes for the variable. Your program will still work despite the warnings, but the variable will be placed in writable storage.

Although the VMS linker does distinguish between upper and lower case letters in global symbols, most VMS compilers convert all such symbols into upper case and most run-time library routines also have upper case names. To be able to reliably call such routines, GNU CC (by means of the assembler GAS) converts global symbols into upper case like other VMS compilers. However, since the usual practice in C is to distinguish case, GNU CC (via GAS) tries to preserve usual C behavior by augmenting each name that is not all lower case. This means truncating the name to at most 23 characters and then adding more characters at the end which encode the case pattern of those 23. Names which contain at least one dollar sign are an exception; they are converted directly into upper case without augmentation.

Name augmentation yields bad results for programs that use precompiled libraries (such as Xlib) which were generated by another compiler. You can use the compiler option `/NOCASE_HACK' to inhibit augmentation; it makes external C functions and variables case-independent as is usual on VMS. Alternatively, you could write all references to the functions and variables in such libraries using lower case; this will work on VMS, but is not portable to other systems. The compiler option `/NAMES' also provides control over global name handling.

Function and variable names are handled somewhat differently with GNU C++. The GNU C++ compiler performs name mangling on function names, which means that it adds information to the function name to describe the data types of the arguments that the function takes. One result of this is that the name of a function can become very long. Since the VMS linker only recognizes the first 31 characters in a name, special action is taken to ensure that each function and variable has a unique name that can be represented in 31 characters.

If the name (plus a name augmentation, if required) is less than 32 characters in length, then no special action is performed. If the name is longer than 31 characters, the assembler (GAS) will generate a hash string based upon the function name, truncate the function name to 23 characters, and append the hash string to the truncated name. If the `/VERBOSE' compiler option is used, the assembler will print both the full and truncated names of each symbol that is truncated.

The `/NOCASE_HACK' compiler option should not be used when you are compiling programs that use libg++. libg++ has several instances of objects (i.e. `Filebuf` and `filebuf`) which become indistinguishable in a case-insensitive environment. This leads to cases where you need to inhibit augmentation selectively (if you were using libg++ and Xlib in the same program, for example). There is no special feature for doing this, but you can get the result by defining a macro for each mixed case symbol for which you wish to inhibit augmentation. The macro should expand into the lower case equivalent of itself. For example:

```
#define StuDlyCapS studlycaps
```

These macro definitions can be placed in a header file to minimize the number of changes to your source code.

Go to the previous, next section.

GNU CC and Portability

The main goal of GNU CC was to make a good, fast compiler for machines in the class that the GNU system aims to run on: 32-bit machines that address 8-bit bytes and have several general registers. Elegance, theoretical power and simplicity are only secondary.

GNU CC gets most of the information about the target machine from a machine description which gives an algebraic formula for each of the machine's instructions. This is a very clean way to describe the target. But when the compiler needs information that is difficult to express in this fashion, I have not hesitated to define an ad-hoc parameter to the machine description. The purpose of portability is to reduce the total work needed on the compiler; it was not of interest for its own sake.

GNU CC does not contain machine dependent code, but it does contain code that depends on machine parameters such as endianness (whether the most significant byte has the highest or lowest address of the bytes in a word) and the availability of autoincrement addressing. In the RTL-generation pass, it is often necessary to have multiple strategies for generating code for a particular kind of syntax tree, strategies that are usable for different combinations of parameters. Often I have not tried to address all possible cases, but only the common ones or only the ones that I have encountered. As a result, a new target may require additional strategies. You will know if this happens because the compiler will call `abort`. Fortunately, the new strategies can be added in a machine-independent fashion, and will affect only the target machines that need them.

Go to the previous, next section.

Go to the previous, next section.

Interfacing to GNU CC Output

GNU CC is normally configured to use the same function calling convention normally in use on the target system. This is done with the machine-description macros described (see section Target Description Macros).

However, returning of structure and union values is done differently on some target machines. As a result, functions compiled with PCC returning such types cannot be called from code compiled with GNU CC, and vice versa. This does not cause trouble often because few Unix library routines return structures or unions.

GNU CC code returns structures and unions that are 1, 2, 4 or 8 bytes long in the same registers used for `int` or `double` return values. (GNU CC typically allocates variables of such types in registers also.) Structures and unions of other sizes are returned by storing them into an address passed by the caller (usually in a register). The machine-description macros `STRUCT_VALUE` and `STRUCT_INCOMING_VALUE` tell GNU CC where to pass this address.

By contrast, PCC on most target machines returns structures and unions of any size by copying the data into an area of static storage, and then returning the address of that storage as if it were a pointer value. The caller must copy the data from that memory area to the place where the value is wanted. This is slower than the method used by GNU CC, and fails to be reentrant.

On some target machines, such as RISC machines and the 80386, the standard system convention is to pass to the subroutine the address of where to return the value. On these machines, GNU CC has been configured to be compatible with the standard compiler, when this method is used. It may not be compatible for structures of 1, 2, 4 or 8 bytes.

GNU CC uses the system's standard convention for passing arguments. On some machines, the first few arguments are passed in registers; in others, all are passed on the stack. It would be possible to use registers for argument passing on any machine, and this would probably result in a significant speedup. But the result would be complete incompatibility with code that follows the standard convention. So this change is practical only if you are switching to GNU CC as the sole C compiler for the system. We may implement register argument passing on certain machines once we have a complete GNU system so that we can compile the libraries with GNU CC.

On some machines (particularly the Sparc), certain types of arguments are passed "by invisible reference". This means that the value is stored in memory, and the address of the memory location is passed to the subroutine.

If you use `longjmp`, beware of automatic variables. ANSI C says that automatic variables that are not declared `volatile` have undefined values after a `longjmp`. And this is all GNU CC promises to do, because it is very difficult to restore register variables correctly, and one of GNU CC's features is that it can put variables in registers without your asking it to.

If you want a variable to be unaltered by `longjmp`, and you don't want to write `volatile` because old

C compilers don't accept it, just take the address of the variable. If a variable's address is ever taken, even if just to compute it and ignore it, then the variable cannot go in a register:

```
{
  int careful;
  &careful;
  ...
}
```

Code compiled with GNU CC may call certain library routines. Most of them handle arithmetic for which there are no instructions. This includes multiply and divide on some machines, and floating point operations on any machine for which floating point support is disabled with `-msoft-float'. Some standard parts of the C library, such as `bcopy` or `memcpy`, are also called automatically. The usual function call interface is used for calling the library routines.

These library routines should be defined in the library `` `libgcc.a' ``, which GNU CC automatically searches whenever it links a program. On machines that have multiply and divide instructions, if hardware floating point is in use, normally `` `libgcc.a' `` is not needed, but it is searched just in case.

Each arithmetic function is defined in `` `libgcc1.c' `` to use the corresponding C arithmetic operator. As long as the file is compiled with another C compiler, which supports all the C arithmetic operators, this file will work portably. However, `` `libgcc1.c' `` does not work if compiled with GNU CC, because each arithmetic function would compile into a call to itself!

Go to the previous, next section.

Passes and Files of the Compiler

The overall control structure of the compiler is in `toplev.c'. This file is responsible for initialization, decoding arguments, opening and closing files, and sequencing the passes.

The parsing pass is invoked only once, to parse the entire input. The RTL intermediate code for a function is generated as the function is parsed, a statement at a time. Each statement is read in as a syntax tree and then converted to RTL; then the storage for the tree for the statement is reclaimed. Storage for types (and the expressions for their sizes), declarations, and a representation of the binding contours and how they nest, remain until the function is finished being compiled; these are all needed to output the debugging information.

Each time the parsing pass reads a complete function definition or top-level declaration, it calls either the function `rest_of_compilation`, or the function `rest_of_decl_compilation` in `toplev.c', which are responsible for all further processing necessary, ending with output of the assembler language. All other compiler passes run, in sequence, within `rest_of_compilation`. When that function returns from compiling a function definition, the storage used for that function definition's compilation is entirely freed, unless it is an inline function (see section An Inline Function is As Fast As a Macro).

Here is a list of all the passes of the compiler and their source files. Also included is a description of where debugging dumps can be requested with `-d' options.

- Parsing. This pass reads the entire text of a function definition, constructing partial syntax trees. This and RTL generation are no longer truly separate passes (formerly they were), but it is easier to think of them as separate.

  The tree representation does not entirely follow C syntax, because it is intended to support other languages as well.

  Language-specific data type analysis is also done in this pass, and every tree node that represents an expression has a data type attached. Variables are represented as declaration nodes.

  Constant folding and some arithmetic simplifications are also done during this pass.

  The language-independent source files for parsing are `stor-layout.c', `fold-const.c', and `tree.c'. There are also header files `tree.h' and `tree.def' which define the format of the tree representation.

  The source files to parse C are `c-parse.in', `c-decl.c', `c-typeck.c', `c-aux-info.c', `c-convert.c', and `c-lang.c' along with header files `c-lex.h', and `c-tree.h'.

  The source files for parsing C++ are `cp-parse.y', `cp-class.c', `cp-cvt.c', `cp-decl.c', `cp-decl2.c', `cp-dem.c', `cp-except.c', `cp-expr.c', `cp-init.c', `cp-lex.c', `cp-method.c', `cp-ptree.c',

`cp-search.c', `cp-tree.c', `cp-type2.c', and `cp-typeck.c', along with header files `cp-tree.def', `cp-tree.h', and `cp-decl.h'.

The special source files for parsing Objective C are `objc-parse.y', `objc-actions.c', `objc-tree.def', and `objc-actions.h'. Certain C-specific files are used for this as well.

The file `c-common.c' is also used for all of the above languages.

- RTL generation. This is the conversion of syntax tree into RTL code. It is actually done statement-by-statement during parsing, but for most purposes it can be thought of as a separate pass.

  This is where the bulk of target-parameter-dependent code is found, since often it is necessary for strategies to apply only when certain standard kinds of instructions are available. The purpose of named instruction patterns is to provide this information to the RTL generation pass.

  Optimization is done in this pass for `if`-conditions that are comparisons, boolean operations or conditional expressions. Tail recursion is detected at this time also. Decisions are made about how best to arrange loops and how to output `switch` statements.

  The source files for RTL generation include `stmt.c', `calls.c', `expr.c', `explow.c', `expmed.c', `function.c', `optabs.c' and `emit-rtl.c'. Also, the file `insn-emit.c', generated from the machine description by the program `genemit`, is used in this pass. The header file `expr.h' is used for communication within this pass.

  The header files `insn-flags.h' and `insn-codes.h', generated from the machine description by the programs `genflags` and `gencodes`, tell this pass which standard names are available for use and which patterns correspond to them.

  Aside from debugging information output, none of the following passes refers to the tree structure representation of the function (only part of which is saved).

  The decision of whether the function can and should be expanded inline in its subsequent callers is made at the end of rtl generation. The function must meet certain criteria, currently related to the size of the function and the types and number of parameters it has. Note that this function may contain loops, recursive calls to itself (tail-recursive functions can be inlined!), gotos, in short, all constructs supported by GNU CC. The file `integrate.c' contains the code to save a function's rtl for later inlining and to inline that rtl when the function is called. The header file `integrate.h' is also used for this purpose.

  The option `-dr' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.rtl' to the input file name.

- Jump optimization. This pass simplifies jumps to the following instruction, jumps across jumps, and jumps to jumps. It deletes unreferenced labels and unreachable code, except that unreachable code that contains a loop is not recognized as unreachable in this pass. (Such loops are deleted later in the basic block analysis.) It also converts some code originally written with jumps into sequences of instructions that directly set values from the results of comparisons, if the machine has such instructions.

Jump optimization is performed two or three times. The first time is immediately following RTL generation. The second time is after CSE, but only if CSE says repeated jump optimization is needed. The last time is right before the final pass. That time, cross-jumping and deletion of no-op move instructions are done together with the optimizations described above.

The source file of this pass is `jump.c'.

The option `-dj' causes a debugging dump of the RTL code after this pass is run for the first time. This dump file's name is made by appending `.jump' to the input file name.

- Register scan. This pass finds the first and last use of each register, as a guide for common subexpression elimination. Its source is in `regclass.c'.
- Jump threading. This pass detects a condition jump that branches to an identical or inverse test. Such jumps can be `threaded' through the second conditional test. The source code for this pass is in `jump.c'. This optimization is only performed if `-fthread-jumps' is enabled.
- Common subexpression elimination. This pass also does constant propagation. Its source file is `cse.c'. If constant propagation causes conditional jumps to become unconditional or to become no-ops, jump optimization is run again when CSE is finished.

  The option `-ds' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.cse' to the input file name.
- Loop optimization. This pass moves constant expressions out of loops, and optionally does strength-reduction and loop unrolling as well. Its source files are `loop.c' and `unroll.c', plus the header `loop.h' used for communication between them. Loop unrolling uses some functions in `integrate.c' and the header `integrate.h'.

  The option `-dL' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.loop' to the input file name.
- If `-frerun-cse-after-loop' was enabled, a second common subexpression elimination pass is performed after the loop optimization pass. Jump threading is also done again at this time if it was specified.

  The option `-dt' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.cse2' to the input file name.
- Stupid register allocation is performed at this point in a nonoptimizing compilation. It does a little data flow analysis as well. When stupid register allocation is in use, the next pass executed is the reloading pass; the others in between are skipped. The source file is `stupid.c'.
- Data flow analysis (`flow.c'). This pass divides the program into basic blocks (and in the process deletes unreachable loops); then it computes which pseudo-registers are live at each point in the program, and makes the first instruction that uses a value point at the instruction that computed the value.

  This pass also deletes computations whose results are never used, and combines memory references with add or subtract instructions to make autoincrement or autodecrement addressing.

  The option `-df' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.flow' to the input file name. If stupid register allocation is in use, this dump

file reflects the full results of such allocation.

- Instruction combination (`combine.c'). This pass attempts to combine groups of two or three instructions that are related by data flow into single instructions. It combines the RTL expressions for the instructions by substitution, simplifies the result using algebra, and then attempts to match the result against the machine description.

  The option `-dc' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.combine' to the input file name.

- Instruction scheduling (`sched.c'). This pass looks for instructions whose output will not be available by the time that it is used in subsequent instructions. (Memory loads and floating point instructions often have this behavior on RISC machines). It re-orders instructions within a basic block to try to separate the definition and use of items that otherwise would cause pipeline stalls.

  Instruction scheduling is performed twice. The first time is immediately after instruction combination and the second is immediately after reload.

  The option `-dS' causes a debugging dump of the RTL code after this pass is run for the first time. The dump file's name is made by appending `.sched' to the input file name.

- Register class preferencing. The RTL code is scanned to find out which register class is best for each pseudo register. The source file is `regclass.c'.

- Local register allocation (`local-alloc.c'). This pass allocates hard registers to pseudo registers that are used only within one basic block. Because the basic block is linear, it can use fast and powerful techniques to do a very good job.

  The option `-dl' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.lreg' to the input file name.

- Global register allocation (`global.c'). This pass allocates hard registers for the remaining pseudo registers (those whose life spans are not contained in one basic block).

- Reloading. This pass renumbers pseudo registers with the hardware registers numbers they were allocated. Pseudo registers that did not get hard registers are replaced with stack slots. Then it finds instructions that are invalid because a value has failed to end up in a register, or has ended up in a register of the wrong kind. It fixes up these instructions by reloading the problematical values temporarily into registers. Additional instructions are generated to do the copying.

  The reload pass also optionally eliminates the frame pointer and inserts instructions to save and restore call-clobbered registers around calls.

  Source files are `reload.c' and `reload1.c', plus the header `reload.h' used for communication between them.

  The option `-dg' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.greg' to the input file name.

- Instruction scheduling is repeated here to try to avoid pipeline stalls due to memory loads generated for spilled pseudo registers.

  The option `-dR' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.sched2' to the input file name.

- Jump optimization is repeated, this time including cross-jumping and deletion of no-op move instructions.

  The option `-dJ' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.jump2' to the input file name.
- Delayed branch scheduling. This optional pass attempts to find instructions that can go into the delay slots of other instructions, usually jumps and calls. The source file name is `reorg.c'.

  The option `-dd' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.dbr' to the input file name.
- Conversion from usage of some hard registers to usage of a register stack may be done at this point. Currently, this is supported only for the floating-point registers of the Intel 80387 coprocessor. The source file name is `reg-stack.c'.

  The options `-dk' causes a debugging dump of the RTL code after this pass. This dump file's name is made by appending `.stack' to the input file name.
- Final. This pass outputs the assembler code for the function. It is also responsible for identifying spurious test and compare instructions. Machine-specific peephole optimizations are performed at the same time. The function entry and exit sequences are generated directly as assembler code in this pass; they never exist as RTL.

  The source files are `final.c' plus `insn-output.c'; the latter is generated automatically from the machine description by the tool `genoutput'. The header file `conditions.h' is used for communication between these files.
- Debugging information output. This is run after final because it must output the stack slot offsets for pseudo registers that did not get hard registers. Source files are `dbxout.c' for DBX symbol table format, `sdbout.c' for SDB symbol table format, and `dwarfout.c' for DWARF symbol table format.

Some additional files are used by all or many passes:

- Every pass uses `machmode.def' and `machmode.h' which define the machine modes.
- Several passes use `real.h', which defines the default representation of floating point constants and how to operate on them.
- All the passes that work with RTL use the header files `rtl.h' and `rtl.def', and subroutines in file `rtl.c'. The tools `gen*` also use these files to read and work with the machine description RTL.
- Several passes refer to the header file `insn-config.h' which contains a few parameters (C macro definitions) generated automatically from the machine description RTL by the tool `genconfig`.
- Several passes use the instruction recognizer, which consists of `recog.c' and `recog.h', plus the files `insn-recog.c' and `insn-extract.c' that are generated automatically from the machine description by the tools `genrecog' and `genextract'.
- Several passes use the header files `regs.h' which defines the information recorded about pseudo register usage, and `basic-block.h' which defines the information recorded about basic blocks.

- `hard-reg-set.h' defines the type HARD_REG_SET, a bit-vector with a bit for each hard register, and some macros to manipulate it. This type is just int if the machine has few enough hard registers; otherwise it is an array of int and some of the macros expand into loops.
- Several passes use instruction attributes. A definition of the attributes defined for a particular machine is in file `insn-attr.h', which is generated from the machine description by the program `genattr'. The file `insn-attrtab.c' contains subroutines to obtain the attribute values for insns. It is generated from the machine description by the program `genattrtab'.

Go to the previous, next section.

RTL Representation

Most of the work of the compiler is done on an intermediate representation called register transfer language. In this language, the instructions to be output are described, pretty much one by one, in an algebraic form that describes what the instruction does.

RTL is inspired by Lisp lists. It has both an internal form, made up of structures that point at other structures, and a textual form that is used in the machine description and in printed debugging dumps. The textual form uses nested parentheses to indicate the pointers in the internal form.

RTL Object Types

RTL uses five kinds of objects: expressions, integers, wide integers, strings and vectors. Expressions are the most important ones. An RTL expression ("RTX", for short) is a C structure, but it is usually referred to with a pointer; a type that is given the typedef name `rtx`.

An integer is simply an `int`; their written form uses decimal digits. A wide integer is an integral object whose type is `HOST_WIDE_INT` (see section The Configuration File); their written form uses decimal digits.

A string is a sequence of characters. In core it is represented as a `char *` in usual C fashion, and it is written in C syntax as well. However, strings in RTL may never be null. If you write an empty string in a machine description, it is represented in core as a null pointer rather than as a pointer to a null character. In certain contexts, these null pointers instead of strings are valid. Within RTL code, strings are most commonly found inside `symbol_ref` expressions, but they appear in other contexts in the RTL expressions that make up machine descriptions.

A vector contains an arbitrary number of pointers to expressions. The number of elements in the vector is explicitly present in the vector. The written form of a vector consists of square brackets (`[...]') surrounding the elements, in sequence and with whitespace separating them. Vectors of length zero are not created; null pointers are used instead.

Expressions are classified by expression codes (also called RTX codes). The expression code is a name defined in `rtl.def'`, which is also (in upper case) a C enumeration constant. The possible expression codes and their meanings are machine-independent. The code of an RTX can be extracted with the macro `GET_CODE (x)` and altered with `PUT_CODE (x, newcode)`.

The expression code determines how many operands the expression contains, and what kinds of objects they are. In RTL, unlike Lisp, you cannot tell by looking at an operand what kind of object it is. Instead, you must know from its context--from the expression code of the containing expression. For example, in an expression of code `subreg`, the first operand is to be regarded as an expression and the second operand as an integer. In an expression of code `plus`, there are two operands, both of which are to be regarded as expressions. In a `symbol_ref` expression, there is one operand, which is to be regarded as

a string.

Expressions are written as parentheses containing the name of the expression type, its flags and machine mode if any, and then the operands of the expression (separated by spaces).

Expression code names in the `md' file are written in lower case, but when they appear in C code they are written in upper case. In this manual, they are shown as follows: `const_int`.

In a few contexts a null pointer is valid where an expression is normally wanted. The written form of this is `(nil)`.

Access to Operands

For each expression type `rtl.def' specifies the number of contained objects and their kinds, with four possibilities: `e' for expression (actually a pointer to an expression), `i' for integer, `w' for wide integer, `s' for string, and `E' for vector of expressions. The sequence of letters for an expression code is called its format. Thus, the format of `subreg` is `ei'.

A few other format characters are used occasionally:

`u`

`u' is equivalent to `e' except that it is printed differently in debugging dumps. It is used for pointers to insns.

`n`

`n' is equivalent to `i' except that it is printed differently in debugging dumps. It is used for the line number or code number of a `note` insn.

`S`

`S' indicates a string which is optional. In the RTL objects in core, `S' is equivalent to `s', but when the object is read, from an `md' file, the string value of this operand may be omitted. An omitted string is taken to be the null string.

`V`

`V' indicates a vector which is optional. In the RTL objects in core, `V' is equivalent to `E', but when the object is read from an `md' file, the vector value of this operand may be omitted. An omitted vector is effectively the same as a vector of no elements.

`0`

`0' means a slot whose contents do not fit any normal category. `0' slots are not printed at all in dumps, and are often used in special ways by small parts of the compiler.

There are macros to get the number of operands, the format, and the class of an expression code:

`GET_RTX_LENGTH (code)`

Number of operands of an RTX of code code.

`GET_RTX_FORMAT (code)`

The format of an RTX of code code, as a C string.

`GET_RTX_CLASS (code)`

A single character representing the type of RTX operation that code code performs.

The following classes are defined:

`o`

An RTX code that represents an actual object, such as `reg` or `mem`. `subreg` is not in this class.

`<`

An RTX code for a comparison. The codes in this class are `NE`, `EQ`, `LE`, `LT`, `GE`, `GT`, `LEU`, `LTU`, `GEU`, `GTU`.

`1`

An RTX code for a unary arithmetic operation, such as `neg`.

`c`

An RTX code for a commutative binary operation, other than `NE` and `EQ` (which have class `<').

`2`

An RTX code for a noncommutative binary operation, such as `MINUS`.

`b`

An RTX code for a bitfield operation, either `ZERO_EXTRACT` or `SIGN_EXTRACT`.

`3`

An RTX code for other three input operations, such as `IF_THEN_ELSE`.

`i`

An RTX code for a machine insn (`INSN`, `JUMP_INSN`, and `CALL_INSN`).

`m`

An RTX code for something that matches in insns, such as `MATCH_DUP`.

`x`

All other RTX codes.

Operands of expressions are accessed using the macros `XEXP`, `XINT`, `XWINT` and `XSTR`. Each of these macros takes two arguments: an expression-pointer (RTX) and an operand number (counting from zero). Thus,

```
XEXP (x, 2)
```

accesses operand 2 of expression x, as an expression.

```
XINT (x, 2)
```

accesses the same operand as an integer. `XSTR`, used in the same fashion, would access it as a string.

Any operand can be accessed as an integer, as an expression or as a string. You must choose the correct method of access for the kind of value actually stored in the operand. You would do this based on the expression code of the containing expression. That is also how you would know how many operands

there are.

For example, if x is a `subreg` expression, you know that it has two operands which can be correctly accessed as `XEXP (x, 0)` and `XINT (x, 1)`. If you did `XINT (x, 0)`, you would get the address of the expression operand but cast as an integer; that might occasionally be useful, but it would be cleaner to write `(int) XEXP (x, 0)`. `XEXP (x, 1)` would also compile without error, and would return the second, integer operand cast as an expression pointer, which would probably result in a crash when accessed. Nothing stops you from writing `XEXP (x, 28)` either, but this will access memory past the end of the expression with unpredictable results.

Access to operands which are vectors is more complicated. You can use the macro `XVEC` to get the vector-pointer itself, or the macros `XVECEXP` and `XVECLEN` to access the elements and length of a vector.

`XVEC (exp, idx)`

Access the vector-pointer which is operand number idx in exp.

`XVECLEN (exp, idx)`

Access the length (number of elements) in the vector which is in operand number idx in exp. This value is an `int`.

`XVECEXP (exp, idx, eltnum)`

Access element number eltnum in the vector which is in operand number idx in exp. This value is an RTX.

It is up to you to make sure that eltnum is not negative and is less than `XVECLEN (exp, idx)`.

All the macros defined in this section expand into lvalues and therefore can be used to assign the operands, lengths and vector elements as well as to access them.

Flags in an RTL Expression

RTL expressions contain several flags (one-bit bitfields) that are used in certain types of expression. Most often they are accessed with the following macros:

`MEM_VOLATILE_P (x)`

In `mem` expressions, nonzero for volatile memory references. Stored in the `volatil` field and printed as `/v'.

`MEM_IN_STRUCT_P (x)`

In `mem` expressions, nonzero for reference to an entire structure, union or array, or to a component of one. Zero for references to a scalar variable or through a pointer to a scalar. Stored in the `in_struct` field and printed as `/s'.

`REG_LOOP_TEST_P`

In `reg` expressions, nonzero if this register's entire life is contained in the exit test code for some loop. Stored in the `in_struct` field and printed as `/s'.

`REG_USERVAR_P (x)`

In a `reg`, nonzero if it corresponds to a variable present in the user's source code. Zero for

temporaries generated internally by the compiler. Stored in the `volatil` field and printed as

`REG_FUNCTION_VALUE_P (x)`

Nonzero in a `reg` if it is the place in which this function's value is going to be returned. (This happens only in a hard register.) Stored in the `integrated` field and printed as `/i'.

The same hard register may be used also for collecting the values of functions called by this one, but `REG_FUNCTION_VALUE_P` is zero in this kind of use.

`SUBREG_PROMOTED_VAR_P`

Nonzero in a `subreg` if it was made when accessing an object that was promoted to a wider mode in accord with the `PROMOTED_MODE` machine description macro (see section Storage Layout). In this case, the mode of the `subreg` is the declared mode of the object and the mode of `SUBREG_REG` is the mode of the register that holds the object. Promoted variables are always either sign- or zero-extended to the wider mode on every assignment. Stored in the `in_struct` field and printed as `/s'.

`SUBREG_PROMOTED_UNSIGNED_P`

Nonzero in a `subreg` that has `SUBREG_PROMOTED_VAR_P` nonzero if the object being referenced is kept zero-extended and zero if it is kept sign-extended. Stored in the `unchanging` field and printed as `/u'.

`RTX_UNCHANGING_P (x)`

Nonzero in a `reg` or `mem` if the value is not changed. (This flag is not set for memory references via pointers to constants. Such pointers only guarantee that the object will not be changed explicitly by the current function. The object might be changed by other functions or by aliasing.) Stored in the `unchanging` field and printed as `/u'.

`RTX_INTEGRATED_P (insn)`

Nonzero in an insn if it resulted from an in-line function call. Stored in the `integrated` field and printed as `/i'. This may be deleted; nothing currently depends on it.

`SYMBOL_REF_USED (x)`

In a `symbol_ref`, indicates that x has been used. This is normally only used to ensure that x is only declared external once. Stored in the `used` field.

`SYMBOL_REF_FLAG (x)`

In a `symbol_ref`, this is used as a flag for machine-specific purposes. Stored in the `volatil` field and printed as `/v'.

`LABEL_OUTSIDE_LOOP_P`

In `label_ref` expressions, nonzero if this is a reference to a label that is outside the innermost loop containing the reference to the label. Stored in the `in_struct` field and printed as `/s'.

`INSN_DELETED_P (insn)`

In an insn, nonzero if the insn has been deleted. Stored in the `volatil` field and printed as `/v'.

`INSN_ANNULLED_BRANCH_P (insn)`

In an `insn` in the delay slot of a branch insn, indicates that an annulling branch should be used. See the discussion under `sequence` below. Stored in the `unchanging` field and printed as `/u'.

`INSN_FROM_TARGET_P (insn)`

In an `insn` in a delay slot of a branch, indicates that the insn is from the target of the branch. If the branch insn has `INSN_ANNULLED_BRANCH_P` set, this insn should only be executed if the branch is taken. For annulled branches with this bit clear, the insn should be executed only if the branch is not taken. Stored in the `in_struct` field and printed as `/s'.

`CONSTANT_POOL_ADDRESS_P (x)`

Nonzero in a `symbol_ref` if it refers to part of the current function's "constants pool". These are addresses close to the beginning of the function, and GNU CC assumes they can be addressed directly (perhaps with the help of base registers). Stored in the `unchanging` field and printed as `/u'.

`CONST_CALL_P (x)`

In a `call_insn`, indicates that the insn represents a call to a const function. Stored in the `unchanging` field and printed as `/u'.

`LABEL_PRESERVE_P (x)`

In a `code_label`, indicates that the label can never be deleted. Labels referenced by a non-local goto will have this bit set. Stored in the `in_struct` field and printed as `/s'.

`SCHED_GROUP_P (insn)`

During instruction scheduling, in an insn, indicates that the previous insn must be scheduled together with this insn. This is used to ensure that certain groups of instructions will not be split up by the instruction scheduling pass, for example, `use` insns before a `call_insn` may not be separated from the `call_insn`. Stored in the `in_struct` field and printed as `/s'.

These are the fields which the above macros refer to:

`used`

Normally, this flag is used only momentarily, at the end of RTL generation for a function, to count the number of times an expression appears in insns. Expressions that appear more than once are copied, according to the rules for shared structure (see section Structure Sharing Assumptions).

In a `symbol_ref`, it indicates that an external declaration for the symbol has already been written.

In a `reg`, it is used by the leaf register renumbering code to ensure that each register is only renumbered once.

`volatil`

This flag is used in `mem`, `symbol_ref` and `reg` expressions and in insns. In RTL dump files, it is printed as `/v'.

In a `mem` expression, it is 1 if the memory reference is volatile. Volatile memory references may not be deleted, reordered or combined.

In a `symbol_ref` expression, it is used for machine-specific purposes.

In a `reg` expression, it is 1 if the value is a user-level variable. 0 indicates an internal compiler temporary.

In an insn, 1 means the insn has been deleted.

`in_struct`

In `mem` expressions, it is 1 if the memory datum referred to is all or part of a structure or array; 0 if it is (or might be) a scalar variable. A reference through a C pointer has 0 because the pointer might point to a scalar variable. This information allows the compiler to determine something about possible cases of aliasing.

In an insn in the delay slot of a branch, 1 means that this insn is from the target of the branch.

During instruction scheduling, in an insn, 1 means that this insn must be scheduled as part of a group together with the previous insn.

In `reg` expressions, it is 1 if the register has its entire life contained within the test expression of some loop.

In `subreg` expressions, 1 means that the `subreg` is accessing an object that has had its mode promoted from a wider mode.

In `label_ref` expressions, 1 means that the referenced label is outside the innermost loop containing the insn in which the `label_ref` was found.

In `code_label` expressions, it is 1 if the label may never be deleted. This is used for labels which are the target of non-local gotos.

In an RTL dump, this flag is represented as `/s'.

`unchanging`

In `reg` and `mem` expressions, 1 means that the value of the expression never changes.

In `subreg` expressions, it is 1 if the `subreg` references an unsigned object whose mode has been promoted to a wider mode.

In an insn, 1 means that this is an annulling branch.

In a `symbol_ref` expression, 1 means that this symbol addresses something in the per-function constants pool.

In a `call_insn`, 1 means that this instruction is a call to a const function.

In an RTL dump, this flag is represented as `/u'.

`integrated`

In some kinds of expressions, including insns, this flag means the rtl was produced by procedure integration.

In a `reg` expression, this flag indicates the register containing the value to be returned by the current function. On machines that pass parameters in registers, the same register number may be used for parameters as well, but this flag is not set on such uses.

Machine Modes

A machine mode describes a size of data object and the representation used for it. In the C code, machine modes are represented by an enumeration type, `enum machine_mode`, defined in `machmode.def'`. Each RTL expression has room for a machine mode and so do certain kinds of tree expressions (declarations and types, to be precise).

In debugging dumps and machine descriptions, the machine mode of an RTL expression is written after the expression code with a colon to separate them. The letters `mode' which appear at the end of each machine mode name are omitted. For example, `(reg:SI 38)` is a `reg` expression with machine mode `SImode`. If the mode is `VOIDmode`, it is not written at all.

Here is a table of machine modes. The term "byte" below refers to an object of `BITS_PER_UNIT` bits (see section Storage Layout).

`QImode`
: "Quarter-Integer" mode represents a single byte treated as an integer.

`HImode`
: "Half-Integer" mode represents a two-byte integer.

`PSImode`
: "Partial Single Integer" mode represents an integer which occupies four bytes but which doesn't really use all four. On some machines, this is the right mode to use for pointers.

`SImode`
: "Single Integer" mode represents a four-byte integer.

`PDImode`
: "Partial Double Integer" mode represents an integer which occupies eight bytes but which doesn't really use all eight. On some machines, this is the right mode to use for certain pointers.

`DImode`
: "Double Integer" mode represents an eight-byte integer.

`TImode`
: "Tetra Integer" (?) mode represents a sixteen-byte integer.

`SFmode`
: "Single Floating" mode represents a single-precision (four byte) floating point number.

`DFmode`
: "Double Floating" mode represents a double-precision (eight byte) floating point number.

`XFmode`
: "Extended Floating" mode represents a triple-precision (twelve byte) floating point number. This mode is used for IEEE extended floating point. On some systems not all bits within these bytes will actually be used.

`TFmode`
: "Tetra Floating" mode represents a quadruple-precision (sixteen byte) floating point number.

`CCmode`

"Condition Code" mode represents the value of a condition code, which is a machine-specific set of bits used to represent the result of a comparison operation. Other machine-specific modes may also be used for the condition code. These modes are not used on machines that use `cc0` (see see section Condition Code Status).

`BLKmode`

"Block" mode represents values that are aggregates to which none of the other modes apply. In RTL, only memory references can have this mode, and only if they appear in string-move or vector instructions. On machines which have no such instructions, `BLKmode` will not appear in RTL.

`VOIDmode`

Void mode means the absence of a mode or an unspecified mode. For example, RTL expressions of code `const_int` have mode `VOIDmode` because they can be taken to have whatever mode the context requires. In debugging dumps of RTL, `VOIDmode` is expressed by the absence of any mode.

`SCmode, DCmode, XCmode, TCmode`

These modes stand for a complex number represented as a pair of floating point values. The floating point values are in `SFmode`, `DFmode`, `XFmode`, and `TFmode`, respectively.

`CQImode, CHImode, CSImode, CDImode, CTImode, COImode`

These modes stand for a complex number represented as a pair of integer values. The integer values are in `QImode`, `HImode`, `SImode`, `DImode`, `TImode`, and `OImode`, respectively.

The machine description defines `Pmode` as a C macro which expands into the machine mode used for addresses. Normally this is the mode whose size is `BITS_PER_WORD`, `SImode` on 32-bit machines.

The only modes which a machine description *must* support are `QImode`, and the modes corresponding to `BITS_PER_WORD`, `FLOAT_TYPE_SIZE` and `DOUBLE_TYPE_SIZE`. The compiler will attempt to use `DImode` for 8-byte structures and unions, but this can be prevented by overriding the definition of `MAX_FIXED_MODE_SIZE`. Alternatively, you can have the compiler use `TImode` for 16-byte structures and unions. Likewise, you can arrange for the C type `short int` to avoid using `HImode`.

Very few explicit references to machine modes remain in the compiler and these few references will soon be removed. Instead, the machine modes are divided into mode classes. These are represented by the enumeration type `enum mode_class` defined in `` `machmode.h' ``. The possible mode classes are:

`MODE_INT`

Integer modes. By default these are `QImode`, `HImode`, `SImode`, `DImode`, and `TImode`.

`MODE_PARTIAL_INT`

The "partial integer" modes, `PSImode` and `PDImode`.

`MODE_FLOAT`

floating point modes. By default these are `SFmode`, `DFmode`, `XFmode` and `TFmode`.

`MODE_COMPLEX_INT`

Complex integer modes. (These are not currently implemented).

`MODE_COMPLEX_FLOAT`

Complex floating point modes. By default these are `SCmode`, `DCmode`, `XCmode`, and `TCmode`.

`MODE_FUNCTION`

Algol or Pascal function variables including a static chain. (These are not currently implemented).

`MODE_CC`

Modes representing condition code values. These are `CCmode` plus any modes listed in the `EXTRA_CC_MODES` macro. See section Defining Jump Instruction Patterns, also see section Condition Code Status.

`MODE_RANDOM`

This is a catchall mode class for modes which don't fit into the above classes. Currently `VOIDmode` and `BLKmode` are in `MODE_RANDOM`.

Here are some C macros that relate to machine modes:

`GET_MODE (x)`

Returns the machine mode of the RTX x.

`PUT_MODE (x, newmode)`

Alters the machine mode of the RTX x to be newmode.

`NUM_MACHINE_MODES`

Stands for the number of machine modes available on the target machine. This is one greater than the largest numeric value of any machine mode.

`GET_MODE_NAME (m)`

Returns the name of mode m as a string.

`GET_MODE_CLASS (m)`

Returns the mode class of mode m.

`GET_MODE_WIDER_MODE (m)`

Returns the next wider natural mode. For example, the expression `GET_MODE_WIDER_MODE (QImode)` returns `HImode`.

`GET_MODE_SIZE (m)`

Returns the size in bytes of a datum of mode m.

`GET_MODE_BITSIZE (m)`

Returns the size in bits of a datum of mode m.

`GET_MODE_MASK (m)`

Returns a bitmask containing 1 for all bits in a word that fit within mode m. This macro can only be used for modes whose bitsize is less than or equal to `HOST_BITS_PER_INT`.

`GET_MODE_ALIGNMENT (m))`

Return the required alignment, in bits, for an object of mode m.

`GET_MODE_UNIT_SIZE (m)`

Returns the size in bytes of the subunits of a datum of mode m. This is the same as `GET_MODE_SIZE` except in the case of complex modes. For them, the unit size is the size of the real or imaginary part.

`GET_MODE_NUNITS (m)`

Returns the number of units contained in a mode, i.e., `GET_MODE_SIZE` divided by `GET_MODE_UNIT_SIZE`.

`GET_CLASS_NARROWEST_MODE (c)`

Returns the narrowest mode in mode class c.

The global variables `byte_mode` and `word_mode` contain modes whose classes are `MODE_INT` and whose bitsizes are either `BITS_PER_UNIT` or `BITS_PER_WORD`, respectively. On 32-bit machines, these are `QImode` and `SImode`, respectively.

Constant Expression Types

The simplest RTL expressions are those that represent constant values.

`(const_int i)`

This type of expression represents the integer value i. i is customarily accessed with the macro `INTVAL` as in `INTVAL (exp)`, which is equivalent to `XWINT (exp, 0)`.

There is only one expression object for the integer value zero; it is the value of the variable `const0_rtx`. Likewise, the only expression for integer value one is found in `const1_rtx`, the only expression for integer value two is found in `const2_rtx`, and the only expression for integer value negative one is found in `constm1_rtx`. Any attempt to create an expression of code `const_int` and value zero, one, two or negative one will return `const0_rtx`, `const1_rtx`, `const2_rtx` or `constm1_rtx` as appropriate.

Similarly, there is only one object for the integer whose value is `STORE_FLAG_VALUE`. It is found in `const_true_rtx`. If `STORE_FLAG_VALUE` is one, `const_true_rtx` and `const1_rtx` will point to the same object. If `STORE_FLAG_VALUE` is -1, `const_true_rtx` and `constm1_rtx` will point to the same object.

`(const_double:m addr i0 i1 ...)`

Represents either a floating-point constant of mode m or an integer constant too large to fit into `HOST_BITS_PER_WIDE_INT` bits but small enough to fit within twice that number of bits (GNU CC does not provide a mechanism to represent even larger constants). In the latter case, m will be `VOIDmode`.

addr is used to contain the `mem` expression that corresponds to the location in memory that at which the constant can be found. If it has not been allocated a memory location, but is on the chain of all `const_double` expressions in this compilation (maintained using an undisplayed field), addr contains `const0_rtx`. If it is not on the chain, addr contains `cc0_rtx`. addr is customarily accessed with the macro `CONST_DOUBLE_MEM` and the chain field via `CONST_DOUBLE_CHAIN`.

If m is `VOIDmode`, the bits of the value are stored in i0 and i1. i0 is customarily accessed with the macro `CONST_DOUBLE_LOW` and i1 with `CONST_DOUBLE_HIGH`.

If the constant is floating point (regardless of its precision), then the number of integers used to

store the value depends on the size of `REAL_VALUE_TYPE` (see section Cross Compilation a Floating Point). The integers represent a floating point number, but not precisely in the target machine's or host machine's floating point format. To convert them to the precise bit pattern used by the target machine, use the macro `REAL_VALUE_TO_TARGET_DOUBLE` and friends (see section Output of Data).

The macro `CONST0_RTX (mode)` refers to an expression with value 0 in mode mode. If mode mode is of mode class `MODE_INT`, it returns `const0_rtx`. Otherwise, it returns a `CONST_DOUBLE` expression in mode mode. Similarly, the macro `CONST1_RTX (mode)` refers to an expression with value 1 in mode mode and similarly for `CONST2_RTX`.

`(const_string str)`

Represents a constant string with value str. Currently this is used only for insn attributes (see section Instruction Attributes) since constant strings in C are placed in memory.

`(symbol_ref:mode symbol)`

Represents the value of an assembler label for data. symbol is a string that describes the name of the assembler label. If it starts with a `*', the label is the rest of symbol not including the `*'. Otherwise, the label is symbol, usually prefixed with `_'.

The `symbol_ref` contains a mode, which is usually `Pmode`. Usually that is the only mode for which a symbol is directly valid.

`(label_ref label)`

Represents the value of an assembler label for code. It contains one operand, an expression, which must be a `code_label` that appears in the instruction sequence to identify the place where the label should go.

The reason for using a distinct expression type for code label references is so that jump optimization can distinguish them.

`(const:m exp)`

Represents a constant that is the result of an assembly-time arithmetic computation. The operand, exp, is an expression that contains only constants (`const_int`, `symbol_ref` and `label_ref` expressions) combined with `plus` and `minus`. However, not all combinations are valid, since the assembler cannot do arbitrary arithmetic on relocatable symbols.

m should be `Pmode`.

`(high:m exp)`

Represents the high-order bits of exp, usually a `symbol_ref`. The number of bits is machine-dependent and is normally the number of bits specified in an instruction that initializes the high order bits of a register. It is used with `lo_sum` to represent the typical two-instruction sequence used in RISC machines to reference a global memory location.

m should be `Pmode`.

Registers and Memory

Here are the RTL expression types for describing access to machine registers and to main memory.

`(reg:m n)`

For small values of the integer n (those that are less than `FIRST_PSEUDO_REGISTER`), this stands for a reference to machine register number n: a hard register. For larger values of n, it stands for a temporary value or pseudo register. The compiler's strategy is to generate code assuming an unlimited number of such pseudo registers, and later convert them into hard registers or into memory references.

m is the machine mode of the reference. It is necessary because machines can generally refer to each register in more than one mode. For example, a register may contain a full word but there may be instructions to refer to it as a half word or as a single byte, as well as instructions to refer to it as a floating point number of various precisions.

Even for a register that the machine can access in only one mode, the mode must always be specified.

The symbol `FIRST_PSEUDO_REGISTER` is defined by the machine description, since the number of hard registers on the machine is an invariant characteristic of the machine. Note, however, that not all of the machine registers must be general registers. All the machine registers that can be used for storage of data are given hard register numbers, even those that can be used only in certain instructions or can hold only certain types of data.

A hard register may be accessed in various modes throughout one function, but each pseudo register is given a natural mode and is accessed only in that mode. When it is necessary to describe an access to a pseudo register using a nonnatural mode, a `subreg` expression is used.

A `reg` expression with a machine mode that specifies more than one word of data may actually stand for several consecutive registers. If in addition the register number specifies a hardware register, then it actually represents several consecutive hardware registers starting with the specified one.

Each pseudo register number used in a function's RTL code is represented by a unique `reg` expression.

Some pseudo register numbers, those within the range of `FIRST_VIRTUAL_REGISTER` to `LAST_VIRTUAL_REGISTER` only appear during the RTL generation phase and are eliminated before the optimization phases. These represent locations in the stack frame that cannot be determined until RTL generation for the function has been completed. The following virtual register numbers are defined:

`VIRTUAL_INCOMING_ARGS_REGNUM`

This points to the first word of the incoming arguments passed on the stack. Normally these arguments are placed there by the caller, but the callee may have pushed some arguments that were previously passed in registers.

When RTL generation is complete, this virtual register is replaced by the sum of the register

given by `ARG_POINTER_REGNUM` and the value of `FIRST_PARM_OFFSET`.

`VIRTUAL_STACK_VARS_REGNUM`

If `FRAME_GROWS_DOWNWARD` is defined, this points to immediately above the first variable on the stack. Otherwise, it points to the first variable on the stack.

`VIRTUAL_STACK_VARS_REGNUM` is replaced with the sum of the register given by `FRAME_POINTER_REGNUM` and the value `STARTING_FRAME_OFFSET`.

`VIRTUAL_STACK_DYNAMIC_REGNUM`

This points to the location of dynamically allocated memory on the stack immediately after the stack pointer has been adjusted by the amount of memory desired.

This virtual register is replaced by the sum of the register given by `STACK_POINTER_REGNUM` and the value `STACK_DYNAMIC_OFFSET`.

`VIRTUAL_OUTGOING_ARGS_REGNUM`

This points to the location in the stack at which outgoing arguments should be written when the stack is pre-pushed (arguments pushed using push insns should always use `STACK_POINTER_REGNUM`).

This virtual register is replaced by the sum of the register given by `STACK_POINTER_REGNUM` and the value `STACK_POINTER_OFFSET`.

- (subreg:m reg wordnum) `subreg` expressions are used to refer to a register in a machine mode other than its natural one, or to refer to one register of a multi-word `reg` that actually refers to several registers.

Each pseudo-register has a natural mode. If it is necessary to operate on it in a different mode--for example, to perform a fullword move instruction on a pseudo-register that contains a single byte--the pseudo-register must be enclosed in a `subreg`. In such a case, wordnum is zero.

Usually m is at least as narrow as the mode of reg, in which case it is restricting consideration to only the bits of reg that are in m.

Sometimes m is wider than the mode of reg. These `subreg` expressions are often called paradoxical. They are used in cases where we want to refer to an object in a wider mode but do not care what value the additional bits have. The reload pass ensures that paradoxical references are only made to hard registers.

The other use of `subreg` is to extract the individual registers of a multi-register value. Machine modes such as `DImode` and `TImode` can indicate values longer than a word, values which usually require two or more consecutive registers. To access one of the registers, use a `subreg` with mode `SImode` and a wordnum that says which register.

Storing in a non-paradoxical `subreg` has undefined results for bits belonging to the same word as the `subreg`. This laxity makes it easier to generate efficient code for such instructions. To represent an instruction that preserves all the bits outside of those in the `subreg`, use `strict_low_part` around the `subreg`.

The compilation parameter `WORDS_BIG_ENDIAN`, if set to 1, says that word number zero is the most

significant part; otherwise, it is the least significant part.

Between the combiner pass and the reload pass, it is possible to have a paradoxical `subreg` which contains a `mem` instead of a `reg` as its first operand. After the reload pass, it is also possible to have a non-paradoxical `subreg` which contains a `mem`; this usually occurs when the `mem` is a stack slot which replaced a pseudo register.

Note that it is not valid to access a `DFmode` value in `SFmode` using a `subreg`. On some machines the most significant part of a `DFmode` value does not have the same format as a single-precision floating value.

It is also not valid to access a single word of a multi-word value in a hard register when less registers can hold the value than would be expected from its size. For example, some 32-bit machines have floating-point registers that can hold an entire `DFmode` value. If register 10 were such a register `(subreg:SI (reg:DF 10) 1)` would be invalid because there is no way to convert that reference to a single machine register. The reload pass prevents `subreg` expressions such as these from being formed.

The first operand of a `subreg` expression is customarily accessed with the `SUBREG_REG` macro and the second operand is customarily accessed with the `SUBREG_WORD` macro.

- (scratch:m) This represents a scratch register that will be required for the execution of a single instruction and not used subsequently. It is converted into a `reg` by either the local register allocator or the reload pass.

`scratch` is usually present inside a `clobber` operation (see section Side Effect Expressions).

- (cc0) This refers to the machine's condition code register. It has no operands and may not have a machine mode. There are two ways to use it:
  - To stand for a complete set of condition code flags. This is best on most machines, where each comparison sets the entire series of flags.

    With this technique, `(cc0)` may be validly used in only two contexts: as the destination of an assignment (in test and compare instructions) and in comparison operators comparing against zero (`const_int` with value zero; that is to say, `const0_rtx`).
  - To stand for a single flag that is the result of a single condition. This is useful on machines that have only a single flag bit, and in which comparison instructions must specify the condition to test.

    With this technique, `(cc0)` may be validly used in only two contexts: as the destination of an assignment (in test and compare instructions) where the source is a comparison operator, and as the first operand of `if_then_else` (in a conditional branch).

There is only one expression object of code `cc0`; it is the value of the variable `cc0_rtx`. Any attempt to create an expression of code `cc0` will return `cc0_rtx`.

Instructions can set the condition code implicitly. On many machines, nearly all instructions set the condition code based on the value that they compute or store. It is not necessary to record these actions explicitly in the RTL because the machine description includes a prescription for recognizing the instructions that do so (by means of the macro `NOTICE_UPDATE_CC`). See section Condition Code

Status. Only instructions whose sole purpose is to set the condition code, and instructions that use the condition code, need mention `(cc0)`.

On some machines, the condition code register is given a register number and a `reg` is used instead of `(cc0)`. This is usually the preferable approach if only a small subset of instructions modify the condition code. Other machines store condition codes in general registers; in such cases a pseudo register should be used.

Some machines, such as the Sparc and RS/6000, have two sets of arithmetic instructions, one that sets and one that does not set the condition code. This is best handled by normally generating the instruction that does not set the condition code, and making a pattern that both performs the arithmetic and sets the condition code register (which would not be `(cc0)` in this case). For examples, search for `addcc' and `andcc' in `sparc.md'.

- (pc) This represents the machine's program counter. It has no operands and may not have a machine mode. `(pc)` may be validly used only in certain specific contexts in jump instructions.

There is only one expression object of code `pc`; it is the value of the variable `pc_rtx`. Any attempt to create an expression of code `pc` will return `pc_rtx`.

All instructions that do not jump alter the program counter implicitly by incrementing it, but there is no need to mention this in the RTL.

- (mem:m addr) This RTX represents a reference to main memory at an address represented by the expression addr. m specifies how large a unit of memory is accessed.

RTL Expressions for Arithmetic

Unless otherwise specified, all the operands of arithmetic expressions must be valid for mode m. An operand is valid for mode m if it has mode m, or if it is a `const_int` or `const_double` and m is a mode of class `MODE_INT`.

For commutative binary operations, constants should be placed in the second operand.

`(plus:m x y)`

Represents the sum of the values represented by x and y carried out in machine mode m.

`(lo_sum:m x y)`

Like `plus`, except that it represents that sum of x and the low-order bits of y. The number of low order bits is machine-dependent but is normally the number of bits in a `Pmode` item minus the number of bits set by the `high` code (see section Constant Expression Types).

m should be `Pmode`.

`(minus:m x y)`

Like `plus` but represents subtraction.

`(compare:m x y)`

Represents the result of subtracting y from x for purposes of comparison. The result is computed without overflow, as if with infinite precision.

Of course, machines can't really subtract with infinite precision. However, they can pretend to do so when only the sign of the result will be used, which is the case when the result is stored in the condition code. And that is the only way this kind of expression may validly be used: as a value to be stored in the condition codes.

The mode m is not related to the modes of x and y, but instead is the mode of the condition code value. If `(cc0)` is used, it is `VOIDmode`. Otherwise it is some mode in class `MODE_CC`, often `CCmode`. See section Condition Code Status.

Normally, x and y must have the same mode. Otherwise, `compare` is valid only if the mode of x is in class `MODE_INT` and y is a `const_int` or `const_double` with mode `VOIDmode`. The mode of x determines what mode the comparison is to be done in; thus it must not be `VOIDmode`.

If one of the operands is a constant, it should be placed in the second operand and the comparison code adjusted as appropriate.

A `compare` specifying two `VOIDmode` constants is not valid since there is no way to know in what mode the comparison is to be performed; the comparison must either be folded during the compilation or the first operand must be loaded into a register while its mode is still known.

`(neg:m x)`

Represents the negation (subtraction from zero) of the value represented by x, carried out in mode m.

`(mult:m x y)`

Represents the signed product of the values represented by x and y carried out in machine mode m.

Some machines support a multiplication that generates a product wider than the operands. Write the pattern for this as

```
(mult:m (sign_extend:m x) (sign_extend:m y))
```

where m is wider than the modes of x and y, which need not be the same.

Write patterns for unsigned widening multiplication similarly using `zero_extend`.

`(div:m x y)`

Represents the quotient in signed division of x by y, carried out in machine mode m. If m is a floating point mode, it represents the exact quotient; otherwise, the integerized quotient.

Some machines have division instructions in which the operands and quotient widths are not all the same; you should represent such instructions using `truncate` and `sign_extend` as in,

```
(truncate:m1 (div:m2 x (sign_extend:m2 y)))
```

`(udiv:m x y)`

Like `div` but represents unsigned division.

`(mod:m x y)`

`(umod:m x y)`

Like `div` and `udiv` but represent the remainder instead of the quotient.

`(smin:m x y)`

`(smax:m x y)`

Represents the smaller (for `smin`) or larger (for `smax`) of x and y, interpreted as signed integers in mode m.

`(umin:m x y)`

`(umax:m x y)`

Like `smin` and `smax`, but the values are interpreted as unsigned integers.

`(not:m x)`

Represents the bitwise complement of the value represented by x, carried out in mode m, which must be a fixed-point machine mode.

`(and:m x y)`

Represents the bitwise logical-and of the values represented by x and y, carried out in machine mode m, which must be a fixed-point machine mode.

`(ior:m x y)`

Represents the bitwise inclusive-or of the values represented by x and y, carried out in machine mode m, which must be a fixed-point mode.

`(xor:m x y)`

Represents the bitwise exclusive-or of the values represented by x and y, carried out in machine mode m, which must be a fixed-point mode.

`(ashift:m x c)`

Represents the result of arithmetically shifting x left by c places. x have mode m, a fixed-point machine mode. c be a fixed-point mode or be a constant with mode `VOIDmode`; which mode is determined by the mode called for in the machine description entry for the left-shift instruction. For example, on the Vax, the mode of c is `QImode` regardless of m.

`(lshiftrt:m x c)`

`(ashiftrt:m x c)`

Like `ashift` but for right shift. Unlike the case for left shift, these two operations are distinct.

`(rotate:m x c)`

`(rotatert:m x c)`

Similar but represent left and right rotate. If c is a constant, use `rotate`.

`(abs:m x)`

Represents the absolute value of x, computed in mode m.

`(sqrt:m x)`

Represents the square root of x, computed in mode m. Most often m will be a floating point mode.

`(ffs:m x)`

Represents one plus the index of the least significant 1-bit in x, represented as an integer of mode m. (The value is zero if x is zero.) The mode of x need not be m; depending on the target machine,

various mode combinations may be valid.

Comparison Operations

Comparison operators test a relation on two operands and are considered to represent a machine-dependent nonzero value described by, but not necessarily equal to, `STORE_FLAG_VALUE` (see section Miscellaneous Parameters) if the relation holds, or zero if it does not. The mode of the comparison operation is independent of the mode of the data being compared. If the comparison operation is being tested (e.g., the first operand of an `if_then_else`), the mode must be `VOIDmode`. If the comparison operation is producing data to be stored in some variable, the mode must be in class `MODE_INT`. All comparison operations producing data must use the same mode, which is machine-specific.

There are two ways that comparison operations may be used. The comparison operators may be used to compare the condition codes `(cc0)` against zero, as in `(eq (cc0) (const_int 0))`. Such a construct actually refers to the result of the preceding instruction in which the condition codes were set. The instructing setting the condition code must be adjacent to the instruction using the condition code; only `note` insns may separate them.

Alternatively, a comparison operation may directly compare two data objects. The mode of the comparison is determined by the operands; they must both be valid for a common machine mode. A comparison with both operands constant would be invalid as the machine mode could not be deduced from it, but such a comparison should never exist in RTL due to constant folding.

In the example above, if `(cc0)` were last set to `(compare x y)`, the comparison operation is identical to `(eq x y)`. Usually only one style of comparisons is supported on a particular machine, but the combine pass will try to merge the operations to produce the `eq` shown in case it exists in the context of the particular insn involved.

Inequality comparisons come in two flavors, signed and unsigned. Thus, there are distinct expression codes `gt` and `gtu` for signed and unsigned greater-than. These can produce different results for the same pair of integer values: for example, 1 is signed greater-than -1 but not unsigned greater-than, because -1 when regarded as unsigned is actually `0xffffffff` which is greater than 1.

The signed comparisons are also used for floating point values. Floating point comparisons are distinguished by the machine modes of the operands.

`(eq:m x y)`

1 if the values represented by x and y are equal, otherwise 0.

`(ne:m x y)`

1 if the values represented by x and y are not equal, otherwise 0.

`(gt:m x y)`

1 if the x is greater than y. If they are fixed-point, the comparison is done in a signed sense.

`(gtu:m x y)`

Like `gt` but does unsigned comparison, on fixed-point numbers only.

`(lt:m x y)`
`(ltu:m x y)`

Like `gt` and `gtu` but test for "less than".

`(ge:m x y)`
`(geu:m x y)`

Like `gt` and `gtu` but test for "greater than or equal".

`(le:m x y)`
`(leu:m x y)`

Like `gt` and `gtu` but test for "less than or equal".

`(if_then_else cond then else)`

This is not a comparison operation but is listed here because it is always used in conjunction with a comparison operation. To be precise, cond is a comparison expression. This expression represents a choice, according to cond, between the value represented by then and the one represented by else.

On most machines, `if_then_else` expressions are valid only to express conditional jumps.

`(cond [test1 value1 test2 value2 ...] default)`

Similar to `if_then_else`, but more general. Each of test1, test2, ... is performed in turn. The result of this expression is the value corresponding to the first non-zero test, or default if none of the tests are non-zero expressions.

This is currently not valid for instruction patterns and is supported only for insn attributes. See section Instruction Attributes.

Bit Fields

Special expression codes exist to represent bitfield instructions. These types of expressions are lvalues in RTL; they may appear on the left side of an assignment, indicating insertion of a value into the specified bit field.

`(sign_extract:m loc size pos)`

This represents a reference to a sign-extended bit field contained or starting in loc (a memory or register reference). The bit field is size bits wide and starts at bit pos. The compilation option `BITS_BIG_ENDIAN` says which end of the memory unit pos counts from.

If loc is in memory, its mode must be a single-byte integer mode. If loc is in a register, the mode to use is specified by the operand of the `insv` or `extv` pattern (see section Standard Pattern Names For Generation) and is usually a full-word integer mode.

The mode of pos is machine-specific and is also specified in the `insv` or `extv` pattern.

The mode m is the same as the mode that would be used for loc if it were a register.

`(zero_extract:m loc size pos)`

Like `sign_extract` but refers to an unsigned or zero-extended bit field. The same sequenc bits are extracted, but they are filled to an entire word with zeros instead of by sign-extension.

Conversions

All conversions between machine modes must be represented by explicit conversion operations. For example, an expression which is the sum of a byte and a full word cannot be written as `(plus:SI (reg:QI 34) (reg:SI 80))` because the `plus` operation requires two operands of the same machine mode. Therefore, the byte-sized operand is enclosed in a conversion operation, as in

```
(plus:SI (sign_extend:SI (reg:QI 34)) (reg:SI 80))
```

The conversion operation is not a mere placeholder, because there may be more than one way of converting from a given starting mode to the desired final mode. The conversion operation code says how to do it.

For all conversion operations, x must not be `VOIDmode` because the mode in which to do the conversion would not be known. The conversion must either be done at compile-time or x must be placed into a register.

`(sign_extend:m x)`

Represents the result of sign-extending the value x to machine mode m. m must be a fixed-point mode and x a fixed-point value of a mode narrower than m.

`(zero_extend:m x)`

Represents the result of zero-extending the value x to machine mode m. m must be a fixed-point mode and x a fixed-point value of a mode narrower than m.

`(float_extend:m x)`

Represents the result of extending the value x to machine mode m. m must be a floating point mode and x a floating point value of a mode narrower than m.

`(truncate:m x)`

Represents the result of truncating the value x to machine mode m. m must be a fixed-point mode and x a fixed-point value of a mode wider than m.

`(float_truncate:m x)`

Represents the result of truncating the value x to machine mode m. m must be a floating point mode and x a floating point value of a mode wider than m.

`(float:m x)`

Represents the result of converting fixed point value x, regarded as signed, to floating point mode m.

`(unsigned_float:m x)`

Represents the result of converting fixed point value x, regarded as unsigned, to floating point mode m.

`(fix:m x)`

When m is a fixed point mode, represents the result of converting floating point value x to mo m, regarded as signed. How rounding is done is not specified, so this operation may be used validly in compiling C code only for integer-valued operands.

`(unsigned_fix:m x)`

Represents the result of converting floating point value x to fixed point mode m, regarded as unsigned. How rounding is done is not specified.

`(fix:m x)`

When m is a floating point mode, represents the result of converting floating point value x (valid for mode m) to an integer, still represented in floating point mode m, by rounding towards zero.

Declarations

Declaration expression codes do not represent arithmetic operations but rather state assertions about their operands.

`(strict_low_part (subreg:m (reg:n r) 0))`

This expression code is used in only one context: as the destination operand of a `set` expression. In addition, the operand of this expression must be a non-paradoxical `subreg` expression.

The presence of `strict_low_part` says that the part of the register which is meaningful in mode n, but is not part of mode m, is not to be altered. Normally, an assignment to such a subreg is allowed to have undefined effects on the rest of the register when m is less than a word.

Side Effect Expressions

The expression codes described so far represent values, not actions. But machine instructions never produce values; they are meaningful only for their side effects on the state of the machine. Special expression codes are used to represent side effects.

The body of an instruction is always one of these side effect codes; the codes described above, which represent values, appear only as the operands of these.

`(set lval x)`

Represents the action of storing the value of x into the place represented by lval. lval must be an expression representing a place that can be stored in: `reg` (or `subreg` or `strict_low_part`), `mem`, `pc` or `cc0`.

If lval is a `reg`, `subreg` or `mem`, it has a machine mode; then x must be valid for that mode.

If lval is a `reg` whose machine mode is less than the full width of the register, then it means that the part of the register specified by the machine mode is given the specified value and the rest of the register receives an undefined value. Likewise, if lval is a `subreg` whose machine mode is narrower than the mode of the register, the rest of the register can be changed in an undefined way.

If lval is a `strict_low_part` of a `subreg`, then the part of the register specified by the machine mode of the `subreg` is given the value x and the rest of the register is not changed.

If lval is `(cc0)`, it has no machine mode, and x may be either a `compare` expression or a value that may have any mode. The latter case represents a "test" instruction. The expression `(set (cc0) (reg:m n))` is equivalent to `(set (cc0) (compare (reg:m n) (const_int 0)))`. Use the former expression to save space during the compilation.

If lval is `(pc)`, we have a jump instruction, and the possibilities for x are very limited. It may be a `label_ref` expression (unconditional jump). It may be an `if_then_else` (conditional jump), in which case either the second or the third operand must be `(pc)` (for the case which does not jump) and the other of the two must be a `label_ref` (for the case which does jump). x may also be a `mem` or `(plus:SI (pc) y)`, where y may be a `reg` or a `mem`; these unusual patterns are used to represent jumps through branch tables.

If lval is neither `(cc0)` nor `(pc)`, the mode of lval must not be `VOIDmode` and the mode of x must be valid for the mode of lval.

lval is customarily accessed with the `SET_DEST` macro and x with the `SET_SRC` macro.

`(return)`

As the sole expression in a pattern, represents a return from the current function, on machines where this can be done with one instruction, such as Vaxes. On machines where a multi-instruction "epilogue" must be executed in order to return from the function, returning is done by jumping to a label which precedes the epilogue, and the `return` expression code is never used.

Inside an `if_then_else` expression, represents the value to be placed in `pc` to return to the caller.

Note that an insn pattern of `(return)` is logically equivalent to `(set (pc) (return))`, but the latter form is never used.

`(call function nargs)`

Represents a function call. function is a `mem` expression whose address is the address of the function to be called. nargs is an expression which can be used for two purposes: on some machines it represents the number of bytes of stack argument; on others, it represents the number of argument registers.

Each machine has a standard machine mode which function must have. The machine description defines macro `FUNCTION_MODE` to expand into the requisite mode name. The purpose of this mode is to specify what kind of addressing is allowed, on machines where the allowed kinds of addressing depend on the machine mode being addressed.

`(clobber x)`

Represents the storing or possible storing of an unpredictable, undescribed value into x, which must be a `reg`, `scratch` or `mem` expression.

One place this is used is in string instructions that store standard values into particular hard registers. It may not be worth the trouble to describe the values that are stored, but it is essential to inform the compiler that the registers will be altered, lest it attempt to keep data in them across the string instruction.

If x is `(mem:BLK (const_int 0))`, it means that all memory locations must be presumed

clobbered.

Note that the machine description classifies certain hard registers as "call-clobbered". All function call instructions are assumed by default to clobber these registers, so there is no need to use `clobber` expressions to indicate this fact. Also, each function call is assumed to have the potential to alter any memory location, unless the function is declared `const`.

If the last group of expressions in a `parallel` are each a `clobber` expression whose arguments are `reg` or `match_scratch` (see section RTL Template) expressions, the combiner phase can add the appropriate `clobber` expressions to an insn it has constructed when doing so will cause a pattern to be matched.

This feature can be used, for example, on a machine that whose multiply and add instructions don't use an MQ register but which has an add-accumulate instruction that does clobber the MQ register. Similarly, a combined instruction might require a temporary register while the constituent instructions might not.

When a `clobber` expression for a register appears inside a `parallel` with other side effects, the register allocator guarantees that the register is unoccupied both before and after that insn. However, the reload phase may allocate a register used for one of the inputs unless the `&' constraint is specified for the selected alternative (see section Constraint Modifier Characters). You can clobber either a specific hard register, a pseudo register, or a `scratch` expression; in the latter two cases, GNU CC will allocate a hard register that is available there for use as a temporary.

For instructions that require a temporary register, you should use `scratch` instead of a pseudo-register because this will allow the combiner phase to add the `clobber` when required. You do this by coding (`clobber` (`match_scratch` ...)). If you do clobber a pseudo register, use one which appears nowhere else--generate a new one each time. Otherwise, you may confuse CSE.

There is one other known use for clobbering a pseudo register in a `parallel`: when one of the input operands of the insn is also clobbered by the insn. In this case, using the same pseudo register in the clobber and elsewhere in the insn produces the expected results.

`(use x)`

Represents the use of the value of x. It indicates that the value in x at this point in the program is needed, even though it may not be apparent why this is so. Therefore, the compiler will not attempt to delete previous instructions whose only effect is to store a value in x. x must be a `reg` expression.

During the delayed branch scheduling phase, x may be an insn. This indicates that x previously was located at this place in the code and its data dependencies need to be taken into account. These `use` insns will be deleted before the delayed branch scheduling phase exits.

`(parallel [x0 x1 ...])`

Represents several side effects performed in parallel. The square brackets stand for a vector; the operand of `parallel` is a vector of expressions. x0, x1 and so on are individual side effect expressions--expressions of code `set`, `call`, `return`, `clobber` or `use`.

"In parallel" means that first all the values used in the individual side-effects are computed, and second all the actual side-effects are performed. For example,

```
(parallel [(set (reg:SI 1) (mem:SI (reg:SI 1)))
           (set (mem:SI (reg:SI 1)) (reg:SI 1))])
```

says unambiguously that the values of hard register 1 and the memory location addressed by it are interchanged. In both places where `(reg:SI 1)` appears as a memory address it refers to the value in register 1 *before* the execution of the insn.

It follows that it is *incorrect* to use `parallel` and expect the result of one `set` to be available for the next one. For example, people sometimes attempt to represent a jump-if-zero instruction this way:

```
(parallel [(set (cc0) (reg:SI 34))
           (set (pc) (if_then_else
                       (eq (cc0) (const_int 0))
                       (label_ref ...)
                       (pc)))])
```

But this is incorrect, because it says that the jump condition depends on the condition code value *before* this instruction, not on the new value that is set by this instruction.

Peephole optimization, which takes place together with final assembly code output, can produce insns whose patterns consist of a `parallel` whose elements are the operands needed to output the resulting assembler code--often `reg`, `mem` or constant expressions. This would not be well-formed RTL at any other stage in compilation, but it is ok then because no further optimization remains to be done. However, the definition of the macro `NOTICE_UPDATE_CC`, if any, must deal with such insns if you define any peephole optimizations.

`(sequence [insns ...])`

Represents a sequence of insns. Each of the insns that appears in the vector is suitable for appearing in the chain of insns, so it must be an `insn`, `jump_insn`, `call_insn`, `code_label`, `barrier` or `note`.

A `sequence` RTX is never placed in an actual insn during RTL generation. It represents the sequence of insns that result from a `define_expand` *before* those insns are passed to `emit_insn` to insert them in the chain of insns. When actually inserted, the individual sub-insns are separated out and the `sequence` is forgotten.

After delay-slot scheduling is completed, an insn and all the insns that reside in its delay slots are grouped together into a `sequence`. The insn requiring the delay slot is the first insn in the vector; subsequent insns are to be placed in the delay slot.

`INSN_ANNULLED_BRANCH_P` is set on an insn in a delay slot to indicate that a branch insn should be used that will conditionally annul the effect of the insns in the delay slots. In such a case, `INSN_FROM_TARGET_P` indicates that the insn is from the target of the branch and should be executed only if the branch is taken; otherwise the insn should be executed only if the branch is

not taken. See section Delay Slot Scheduling.

These expression codes appear in place of a side effect, as the body of an insn, though strictly speaking they do not always describe side effects as such:

`(asm_input s)`

Represents literal assembler code as described by the string s.

`(unspec [operands ...] index)`

`(unspec_volatile [operands ...] index)`

Represents a machine-specific operation on operands. index selects between multiple machine-specific operations. `unspec_volatile` is used for volatile operations and operations that may trap; `unspec` is used for other operations.

These codes may appear inside a `pattern` of an insn, inside a `parallel`, or inside an expression.

`(addr_vec:m [lr0 lr1 ...])`

Represents a table of jump addresses. The vector elements lr0, etc., are `label_ref` expressions. The mode m specifies how much space is given to each address; normally m would be `Pmode`.

`(addr_diff_vec:m base [lr0 lr1 ...])`

Represents a table of jump addresses expressed as offsets from base. The vector elements lr0, etc., are `label_ref` expressions and so is base. The mode m specifies how much space is given to each address-difference.

Embedded Side-Effects on Addresses

Four special side-effect expression codes appear as memory addresses.

`(pre_dec:m x)`

Represents the side effect of decrementing x by a standard amount and represents also the value that x has after being decremented. x must be a `reg` or `mem`, but most machines allow only a `reg`. m must be the machine mode for pointers on the machine in use. The amount x is decremented by is the length in bytes of the machine mode of the containing memory reference of which this expression serves as the address. Here is an example of its use:

```
(mem:DF (pre_dec:SI (reg:SI 39)))
```

This says to decrement pseudo register 39 by the length of a `DFmode` value and use the result to address a `DFmode` value.

`(pre_inc:m x)`

Similar, but specifies incrementing x instead of decrementing it.

`(post_dec:m x)`

Represents the same side effect as `pre_dec` but a different value. The value represented here is the value x has *before* being decremented.

`(post_inc:m x)`

Similar, but specifies incrementing x instead of decrementing it.

These embedded side effect expressions must be used with care. Instruction patterns may not use them. Until the `flow' pass of the compiler, they may occur only to represent pushes onto the stack. The `flow' pass finds cases where registers are incremented or decremented in one instruction and used as an address shortly before or after; these cases are then transformed to use pre- or post-increment or -decrement.

If a register used as the operand of these expressions is used in another address in an insn, the original value of the register is used. Uses of the register outside of an address are not permitted within the same insn as a use in an embedded side effect expression because such insns behave differently on different machines and hence must be treated as ambiguous and disallowed.

An instruction that can be represented with an embedded side effect could also be represented using `parallel` containing an additional `set` to describe how the address register is altered. This is not done because machines that allow these operations at all typically allow them wherever a memory address is called for. Describing them as additional parallel stores would require doubling the number of entries in the machine description.

Assembler Instructions as Expressions

The RTX code `asm_operands` represents a value produced by a user-specified assembler instruction. It is used to represent an `asm` statement with arguments. An `asm` statement with a single output operand, like this:

```
asm ("foo %1,%2,%0" : "=a" (outputvar) : "g" (x + y), "di" (*z));
```

is represented using a single `asm_operands` RTX which represents the value that is stored in `outputvar`:

```
(set rtx-for-outputvar
     (asm_operands "foo %1,%2,%0" "a" 0
                   [rtx-for-addition-result rtx-for-*z]
                   [(asm_input:m1 "g")
                    (asm_input:m2 "di")]))
```

Here the operands of the `asm_operands` RTX are the assembler template string, the output-operand's constraint, the index-number of the output operand among the output operands specified, a vector of input operand RTX's, and a vector of input-operand modes and constraints. The mode m1 is the mode of the sum `x+y`; m2 is that of `*z`.

When an `asm` statement has multiple output values, its insn has several such `set` RTX's inside of a `parallel`. Each `set` contains a `asm_operands`; all of these share the same assembler template and vectors, but each contains the constraint for the respective output operand. They are also distinguished by the output-operand index number, which is 0, 1, ... for successive output operands.

Insns

The RTL representation of the code for a function is a doubly-linked chain of objects called insns. Insns are expressions with special codes that are used for no other purpose. Some insns are actual instructions; others represent dispatch tables for `switch` statements; others represent labels to jump to or various sorts of declarative information.

In addition to its own specific data, each insn must have a unique id-number that distinguishes it from all other insns in the current function (after delayed branch scheduling, copies of an insn with the same id-number may be present in multiple places in a function, but these copies will always be identical and will only appear inside a `sequence`), and chain pointers to the preceding and following insns. These three fields occupy the same position in every insn, independent of the expression code of the insn. They could be accessed with `XEXP` and `XINT`, but instead three special macros are always used:

`INSN_UID (i)`

Accesses the unique id of insn i.

`PREV_INSN (i)`

Accesses the chain pointer to the insn preceding i. If i is the first insn, this is a null pointer.

`NEXT_INSN (i)`

Accesses the chain pointer to the insn following i. If i is the last insn, this is a null pointer.

The first insn in the chain is obtained by calling `get_insns`; the last insn is the result of calling `get_last_insn`. Within the chain delimited by these insns, the `NEXT_INSN` and `PREV_INSN` pointers must always correspond: if insn is not the first insn,

```
NEXT_INSN (PREV_INSN (insn)) == insn
```

is always true and if insn is not the last insn,

```
PREV_INSN (NEXT_INSN (insn)) == insn
```

is always true.

After delay slot scheduling, some of the insns in the chain might be `sequence` expressions, which contain a vector of insns. The value of `NEXT_INSN` in all but the last of these insns is the next insn in the vector; the value of `NEXT_INSN` of the last insn in the vector is the same as the value of `NEXT_INSN` for the `sequence` in which it is contained. Similar rules apply for `PREV_INSN`.

This means that the above invariants are not necessarily true for insns inside `sequence` expressions. Specifically, if insn is the first insn in a `sequence`, `NEXT_INSN (PREV_INSN (insn))` is the insn containing the `sequence` expression, as is the value of `PREV_INSN (NEXT_INSN (insn))` is insn is the last insn in the `sequence` expression. You can use these expressions to find the containing `sequence` expression.

Every insn has one of the following six expression codes:

`insn`

The expression code `insn` is used for instructions that do not jump and do not do function calls. `sequence` expressions are always contained in insns with code `insn` even if one of those insns should jump or do function calls.

Insns with code `insn` have four additional fields beyond the three mandatory ones listed above. These four are described in a table below.

`jump_insn`

The expression code `jump_insn` is used for instructions that may jump (or, more generally, may contain `label_ref` expressions). If there is an instruction to return from the current function, it is recorded as a `jump_insn`.

`jump_insn` insns have the same extra fields as `insn` insns, accessed in the same way and in addition contain a field `JUMP_LABEL` which is defined once jump optimization has completed.

For simple conditional and unconditional jumps, this field contains the `code_label` to which this insn will (possibly conditionally) branch. In a more complex jump, `JUMP_LABEL` records one of the labels that the insn refers to; the only way to find the others is to scan the entire body of the insn.

Return insns count as jumps, but since they do not refer to any labels, they have zero in the `JUMP_LABEL` field.

`call_insn`

The expression code `call_insn` is used for instructions that may do function calls. It is important to distinguish these instructions because they imply that certain registers and memory locations may be altered unpredictably.

`call_insn` insns have the same extra fields as `insn` insns, accessed in the same way and in addition contain a field `CALL_INSN_FUNCTION_USAGE`, which contains a list (chain of `expr_list` expressions) containing `use` and `clobber` expressions that denote hard registers used or clobbered by the called function. A register specified in a `clobber` in this list is modified *after* the execution of the `call_insn`, while a register in a `clobber` in the body of the `call_insn` is clobbered before the insn completes execution. `clobber` expressions in this list augment registers specified in `CALL_USED_REGISTERS` (see section Basic Characteristics of Registers).

`code_label`

A `code_label` insn represents a label that a jump insn can jump to. It contains two special fields of data in addition to the three standard ones. `CODE_LABEL_NUMBER` is used to hold the label number, a number that identifies this label uniquely among all the labels in the compilation (not just in the current function). Ultimately, the label is represented in the assembler output as an assembler label, usually of the form `Ln' where n is the label number.

When a `code_label` appears in an RTL expression, it normally appears within a `label_ref` which represents the address of the label, as a number.

The field `LABEL_NUSES` is only defined once the jump optimization phase is completed and contains the number of times this label is referenced in the current function.

`barrier`

Barriers are placed in the instruction stream when control cannot flow past them. They are placed after unconditional jump instructions to indicate that the jumps are unconditional and after calls to `volatile` functions, which do not return (e.g., `exit`). They contain no information beyond the three standard fields.

`note`

`note` insns are used to represent additional debugging and declarative information. They contain two nonstandard fields, an integer which is accessed with the macro `NOTE_LINE_NUMBER` and a string accessed with `NOTE_SOURCE_FILE`.

If `NOTE_LINE_NUMBER` is positive, the note represents the position of a source line and `NOTE_SOURCE_FILE` is the source file name that the line came from. These notes control generation of line number data in the assembler output.

Otherwise, `NOTE_LINE_NUMBER` is not really a line number but a code with one of the following values (and `NOTE_SOURCE_FILE` must contain a null pointer):

`NOTE_INSN_DELETED`

Such a note is completely ignorable. Some passes of the compiler delete insns by altering them into notes of this kind.

`NOTE_INSN_BLOCK_BEG`

`NOTE_INSN_BLOCK_END`

These types of notes indicate the position of the beginning and end of a level of scoping of variable names. They control the output of debugging information.

`NOTE_INSN_LOOP_BEG`

`NOTE_INSN_LOOP_END`

These types of notes indicate the position of the beginning and end of a `while` or `for` loop. They enable the loop optimizer to find loops quickly.

`NOTE_INSN_LOOP_CONT`

Appears at the place in a loop that `continue` statements jump to.

`NOTE_INSN_LOOP_VTOP`

This note indicates the place in a loop where the exit test begins for those loops in which the exit test has been duplicated. This position becomes another virtual start of the loop when considering loop invariants.

`NOTE_INSN_FUNCTION_END`

Appears near the end of the function body, just before the label that `return` statements jump to (on machine where a single instruction does not suffice for returning). This note may be deleted by jump optimization.

`NOTE_INSN_SETJMP`

Appears following each call to `setjmp` or a related function.

These codes are printed symbolically when they appear in debugging dumps.

The machine mode of an insn is normally `VOIDmode`, but some phases use the mode for various purposes; for example, the reload pass sets it to `HImode` if the insn needs reloading but not register elimination and `QImode` if both are required. The common subexpression elimination pass sets the mode of an insn to `QImode` when it is the first insn in a block that has already been processed.

Here is a table of the extra fields of `insn`, `jump_insn` and `call_insn` insns:

`PATTERN (i)`

An expression for the side effect performed by this insn. This must be one of the following codes: `set`, `call`, `use`, `clobber`, `return`, `asm_input`, `asm_output`, `addr_vec`, `addr_diff_vec`, `trap_if`, `unspec`, `unspec_volatile`, `parallel`, or `sequence`. If it is a `parallel`, each element of the `parallel` must be one these codes, except that `parallel` expressions cannot be nested and `addr_vec` and `addr_diff_vec` are not permitted inside a `parallel` expression.

`INSN_CODE (i)`

An integer that says which pattern in the machine description matches this insn, or -1 if the matching has not yet been attempted.

Such matching is never attempted and this field remains -1 on an insn whose pattern consists of a single `use`, `clobber`, `asm_input`, `addr_vec` or `addr_diff_vec` expression.

Matching is also never attempted on insns that result from an `asm` statement. These contain at least one `asm_operands` expression. The function `asm_noperands` returns a non-negative value for such insns.

In the debugging output, this field is printed as a number followed by a symbolic representation that locates the pattern in the `` `md' `` file as some small positive or negative offset from a named pattern.

`LOG_LINKS (i)`

A list (chain of `insn_list` expressions) giving information about dependencies between instructions within a basic block. Neither a jump nor a label may come between the related insns.

`REG_NOTES (i)`

A list (chain of `expr_list` and `insn_list` expressions) giving miscellaneous information about the insn. It is often information pertaining to the registers used in this insn.

The `LOG_LINKS` field of an insn is a chain of `insn_list` expressions. Each of these has two operands: the first is an insn, and the second is another `insn_list` expression (the next one in the chain). The last `insn_list` in the chain has a null pointer as second operand. The significant thing about the chain is which insns appear in it (as first operands of `insn_list` expressions). Their order is not significant.

This list is originally set up by the flow analysis pass; it is a null pointer until then. Flow only adds links for those data dependencies which can be used for instruction combination. For each insn, the flow analysis pass adds a link to insns which store into registers values that are used for the first time in this insn. The instruction scheduling pass adds extra links so that every dependence will be represented. Links represent data dependencies, antidependencies and output dependencies; the machine mode of the link distinguishes these three types: antidependencies have mode `REG_DEP_ANTI`, output dependencies

have mode `REG_DEP_OUTPUT`, and data dependencies have mode `VOIDmode`.

The `REG_NOTES` field of an insn is a chain similar to the `LOG_LINKS` field but it includes `expr_list` expressions in addition to `insn_list` expressions. There are several kinds of register notes, which are distinguished by the machine mode, which in a register note is really understood as being an `enum reg_note`. The first operand op of the note is data whose meaning depends on the kind of note.

The macro `REG_NOTE_KIND (x)` returns the kind of register note. Its counterpart, the macro `PUT_REG_NOTE_KIND (x, newkind)` sets the register note type of x to be newkind.

Register notes are of three classes: They may say something about an input to an insn, they may say something about an output of an insn, or they may create a linkage between two insns. There are also a set of values that are only used in `LOG_LINKS`.

These register notes annotate inputs to an insn:

`REG_DEAD`

The value in op dies in this insn; that is to say, altering the value immediately after this insn would not affect the future behavior of the program.

This does not necessarily mean that the register op has no useful value after this insn since it may also be an output of the insn. In such a case, however, a `REG_DEAD` note would be redundant and is usually not present until after the reload pass, but no code relies on this fact.

`REG_INC`

The register op is incremented (or decremented; at this level there is no distinction) by an embedded side effect inside this insn. This means it appears in a `post_inc`, `pre_inc`, `post_dec` or `pre_dec` expression.

`REG_NONNEG`

The register op is known to have a nonnegative value when this insn is reached. This is used so that decrement and branch until zero instructions, such as the m68k dbra, can be matched.

The `REG_NONNEG` note is added to insns only if the machine description has a `decrement_and_branch_until_zero' pattern.

`REG_NO_CONFLICT`

This insn does not cause a conflict between op and the item being set by this insn even though it might appear that it does. In other words, if the destination register and op could otherwise be assigned the same register, this insn does not prevent that assignment.

Insns with this note are usually part of a block that begins with a `clobber` insn specifying a multi-word pseudo register (which will be the output of the block), a group of insns that each set one word of the value and have the `REG_NO_CONFLICT` note attached, and a final insn that copies the output to itself with an attached `REG_EQUAL` note giving the expression being computed. This block is encapsulated with `REG_LIBCALL` and `REG_RETVAL` notes on the first and last insns, respectively.

`REG_LABEL`

This insn uses op, a `code_label`, but is not a `jump_insn`. The presence of this note allows

jump optimization to be aware that op is, in fact, being used.

The following notes describe attributes of outputs of an insn:

`REG_EQUIV`

`REG_EQUAL`

This note is only valid on an insn that sets only one register and indicates that that register will be equal to op at run time; the scope of this equivalence differs between the two types of notes. The value which the insn explicitly copies into the register may look different from op, but they will be equal at run time. If the output of the single `set` is a `strict_low_part` expression, the note refers to the register that is contained in `SUBREG_REG` of the `subreg` expression. For `REG_EQUIV`, the register is equivalent to op throughout the entire function, and could validly be replaced in all its occurrences by op. ("Validly" here refers to the data flow of the program; simple replacement may make some insns invalid.) For example, when a constant is loaded into a register that is never assigned any other value, this kind of note is used.

When a parameter is copied into a pseudo-register at entry to a function, a note of this kind records that the register is equivalent to the stack slot where the parameter was passed. Although in this case the register may be set by other insns, it is still valid to replace the register by the stack slot throughout the function.

In the case of `REG_EQUAL`, the register that is set by this insn will be equal to op at run time at the end of this insn but not necessarily elsewhere in the function. In this case, op is typically an arithmetic expression. For example, when a sequence of insns such as a library call is used to perform an arithmetic operation, this kind of note is attached to the insn that produces or copies the final value.

These two notes are used in different ways by the compiler passes. `REG_EQUAL` is used by passes prior to register allocation (such as common subexpression elimination and loop optimization) to tell them how to think of that value. `REG_EQUIV` notes are used by register allocation to indicate that there is an available substitute expression (either a constant or a `mem` expression for the location of a parameter on the stack) that may be used in place of a register if insufficient registers are available.

Except for stack homes for parameters, which are indicated by a `REG_EQUIV` note and are not useful to the early optimization passes and pseudo registers that are equivalent to a memory location throughout there entire life, which is not detected until later in the compilation, all equivalences are initially indicated by an attached `REG_EQUAL` note. In the early stages of register allocation, a `REG_EQUAL` note is changed into a `REG_EQUIV` note if op is a constant and the insn represents the only set of its destination register.

Thus, compiler passes prior to register allocation need only check for `REG_EQUAL` notes and passes subsequent to register allocation need only check for `REG_EQUIV` notes.

`REG_UNUSED`

The register op being set by this insn will not be used in a subsequent insn. This differs from a `REG_DEAD` note, which indicates that the value in an input will not be used subsequently. These two notes are independent; both may be present for the same register.

`REG_WAS_0`

The single output of this insn contained zero before this insn. op is the insn that set it to zero. You can rely on this note if it is present and op has not been deleted or turned into a `note`; its absence implies nothing.

These notes describe linkages between insns. They occur in pairs: one insn has one of a pair of notes that points to a second insn, which has the inverse note pointing back to the first insn.

`REG_RETVAL`

This insn copies the value of a multi-insn sequence (for example, a library call), and op is the first insn of the sequence (for a library call, the first insn that was generated to set up the arguments for the library call).

Loop optimization uses this note to treat such a sequence as a single operation for code motion purposes and flow analysis uses this note to delete such sequences whose results are dead.

A `REG_EQUAL` note will also usually be attached to this insn to provide the expression being computed by the sequence.

`REG_LIBCALL`

This is the inverse of `REG_RETVAL`: it is placed on the first insn of a multi-insn sequence, and it points to the last one.

`REG_CC_SETTER`

`REG_CC_USER`

On machines that use `cc0`, the insns which set and use `cc0` set and use `cc0` are adjacent. However, when branch delay slot filling is done, this may no longer be true. In this case a `REG_CC_USER` note will be placed on the insn setting `cc0` to point to the insn using `cc0` and a `REG_CC_SETTER` note will be placed on the insn using `cc0` to point to the insn setting `cc0`.

These values are only used in the `LOG_LINKS` field, and indicate the type of dependency that each link represents. Links which indicate a data dependence (a read after write dependence) do not use any code, they simply have mode `VOIDmode`, and are printed without any descriptive text.

`REG_DEP_ANTI`

This indicates an anti dependence (a write after read dependence).

`REG_DEP_OUTPUT`

This indicates an output dependence (a write after write dependence).

For convenience, the machine mode in an `insn_list` or `expr_list` is printed using these symbolic codes in debugging dumps.

The only difference between the expression codes `insn_list` and `expr_list` is that the first operand of an `insn_list` is assumed to be an insn and is printed in debugging dumps as the insn's unique id; the first operand of an `expr_list` is printed in the ordinary way as an expression.

RTL Representation of Function-Call Insns

Insns that call subroutines have the RTL expression code `call_insn`. These insns must satisfy special rules, and their bodies must use a special RTL expression code, `call`.

A `call` expression has two operands, as follows:

```
(call (mem:fm addr) nbytes)
```

Here nbytes is an operand that represents the number of bytes of argument data being passed to the subroutine, fm is a machine mode (which must equal as the definition of the `FUNCTION_MODE` macro in the machine description) and addr represents the address of the subroutine.

For a subroutine that returns no value, the `call` expression as shown above is the entire body of the insn, except that the insn might also contain `use` or `clobber` expressions.

For a subroutine that returns a value whose mode is not `BLKmode`, the value is returned in a hard register. If this register's number is r, then the body of the call insn looks like this:

```
(set (reg:m r)
     (call (mem:fm addr) nbytes))
```

This RTL expression makes it clear (to the optimizer passes) that the appropriate register receives a useful value in this insn.

When a subroutine returns a `BLKmode` value, it is handled by passing to the subroutine the address of a place to store the value. So the call insn itself does not "return" any value, and it has the same RTL form as a call that returns nothing.

On some machines, the call instruction itself clobbers some register, for example to contain the return address. `call_insn` insns on these machines should have a body which is a `parallel` that contains both the `call` expression and `clobber` expressions that indicate which registers are destroyed. Similarly, if the call instruction requires some register other than the stack pointer that is not explicitly mentioned it its RTL, a `use` subexpression should mention that register.

Functions that are called are assumed to modify all registers listed in the configuration macro `CALL_USED_REGISTERS` (see section Basic Characteristics of Registers) and, with the exception of `const` functions and library calls, to modify all of memory.

Insns containing just `use` expressions directly precede the `call_insn` insn to indicate which registers contain inputs to the function. Similarly, if registers other than those in `CALL_USED_REGISTERS` are clobbered by the called function, insns containing a single `clobber` follow immediately after the call to indicate which registers.

Structure Sharing Assumptions

The compiler assumes that certain kinds of RTL expressions are unique; there do not exist two distinct objects representing the same value. In other cases, it makes an opposite assumption: that no RTL expression object of a certain kind appears in more than one place in the containing structure.

These assumptions refer to a single function; except for the RTL objects that describe global variables and external functions, and a few standard objects such as small integer constants, no RTL objects are common to two functions.

- Each pseudo-register has only a single `reg` object to represent it, and therefore only a single machine mode.
- For any symbolic label, there is only one `symbol_ref` object referring to it.
- There is only one `const_int` expression with value 0, only one with value 1, and only one with value -1. Some other integer values are also stored uniquely.
- There is only one `pc` expression.
- There is only one `cc0` expression.
- There is only one `const_double` expression with value 0 for each floating point mode. Likewise for values 1 and 2.
- No `label_ref` or `scratch` appears in more than one place in the RTL structure; in other words, it is safe to do a tree-walk of all the insns in the function and assume that each time a `label_ref` or `scratch` is seen it is distinct from all others that are seen.
- Only one `mem` object is normally created for each static variable or stack slot, so these objects are frequently shared in all the places they appear. However, separate but equal objects for these variables are occasionally made.
- When a single `asm` statement has multiple output operands, a distinct `asm_operands` expression is made for each output operand. However, these all share the vector which contains the sequence of input operands. This sharing is used later on to test whether two `asm_operands` expressions come from the same statement, so all optimizations must carefully preserve the sharing if they copy the vector at all.
- No RTL object appears in more than one place in the RTL structure except as described above. Many passes of the compiler rely on this by assuming that they can modify RTL objects in place without unwanted side-effects on other insns.
- During initial RTL generation, shared structure is freely introduced. After all the RTL for a function has been generated, all shared structure is copied by `unshare_all_rtl` in `` `emit-rtl.c' ``, after which the above rules are guaranteed to be followed.
- During the combiner pass, shared structure within an insn can exist temporarily. However, the shared structure is copied before the combiner is finished with the insn. This is done by calling `copy_rtx_if_shared`, which is a subroutine of `unshare_all_rtl`.

Reading RTL

To read an RTL object from a file, call `read_rtx`. It takes one argument, a stdio stream, and returns a single RTL object.

Reading RTL from a file is very slow. This is not currently a problem since reading RTL occurs only as part of building the compiler.

People frequently have the idea of using RTL stored as text in a file as an interface between a language front end and the bulk of GNU CC. This idea is not feasible.

GNU CC was designed to use RTL internally only. Correct RTL for a given program is very dependent on the particular target machine. And the RTL does not contain all the information about the program.

The proper way to interface GNU CC to a new language front end is with the "tree" data structure. There is no manual for this data structure, but it is described in the files `` `tree.h' `` and `` `tree.def' ``.

Go to the previous, next section.

Go to the previous, next section.

Machine Descriptions

A machine description has two parts: a file of instruction patterns (`.md' file) and a C header file of macro definitions.

The `.md' file for a target machine contains a pattern for each instruction that the target machine supports (or at least each instruction that is worth telling the compiler about). It may also contain comments. A semicolon causes the rest of the line to be a comment, unless the semicolon is inside a quoted string.

See the next chapter for information on the C header file.

Everything about Instruction Patterns

Each instruction pattern contains an incomplete RTL expression, with pieces to be filled in later, operand constraints that restrict how the pieces can be filled in, and an output pattern or C code to generate the assembler output, all wrapped up in a `define_insn` expression.

A `define_insn` is an RTL expression containing four or five operands:

1. An optional name. The presence of a name indicate that this instruction pattern can perform a certain standard job for the RTL-generation pass of the compiler. This pass knows certain names and will use the instruction patterns with those names, if the names are defined in the machine description.

   The absence of a name is indicated by writing an empty string where the name should go. Nameless instruction patterns are never used for generating RTL code, but they may permit several simpler insns to be combined later on.

   Names that are not thus known and used in RTL-generation have no effect; they are equivalent to no name at all.
2. The RTL template (see section RTL Template) is a vector of incomplete RTL expressions which show what the instruction should look like. It is incomplete because it may contain `match_operand`, `match_operator`, and `match_dup` expressions that stand for operands of the instruction.

   If the vector has only one element, that element is the template for the instruction pattern. If the vector has multiple elements, then the instruction pattern is a `parallel` expression containing the elements described.
3. A condition. This is a string which contains a C expression that is the final test to decide whether an insn body matches this pattern.

   For a named pattern, the condition (if present) may not depend on the data in the insn being matched, but only the target-machine-type flags. The compiler needs to test these conditions during initialization in order to learn exactly which named instructions are available in a particular run.

   For nameless patterns, the condition is applied only when matching an individual insn, and only after the insn has matched the pattern's recognition template. The insn's operands may be found in the vector `operands`.

4. The output template: a string that says how to output matching insns as assembler code. `%' in this string specifies where to substitute the value of an operand. See section Output Templates and Operand Substitution.

   When simple substitution isn't general enough, you can specify a piece of C code to compute the output. See section C Statements for Assembler Output.

5. Optionally, a vector containing the values of attributes for insns matching this pattern. See section Instruction Attributes.

Example of `define_insn`

Here is an actual example of an instruction pattern, for the 68000/68020.

```
(define_insn "tstsi"
  [(set (cc0)
        (match_operand:SI 0 "general_operand" "rm"))]
  ""
  "*
{ if (TARGET_68020 || ! ADDRESS_REG_P (operands[0]))
    return \"tstl %0\";
  return \"cmpl #0,%0\"; }")
```

This is an instruction that sets the condition codes based on the value of a general operand. It has no condition, so any insn whose RTL description has the form shown may be handled according to this pattern. The name `tstsi' means "test a `SImode` value" and tells the RTL generation pass that, when it is necessary to test such a value, an insn to do so can be constructed using this pattern.

The output control string is a piece of C code which chooses which output template to return based on the kind of operand and the specific type of CPU for which code is being generated.

`"rm"' is an operand constraint. Its meaning is explained below.

RTL Template

The RTL template is used to define which insns match the particular pattern and how to find their operands. For named patterns, the RTL template also says how to construct an insn from specified operands.

Construction involves substituting specified operands into a copy of the template. Matching involves determining the values that serve as the operands in the insn being matched. Both of these activities are controlled by special expression types that direct matching and substitution of the operands.

`(match_operand:m n predicate constraint)`

This expression is a placeholder for operand number n of the insn. When constructing an insn, operand number n will be substituted at this point. When matching an insn, whatever appears at this position in the insn will be taken as operand number n; but it must satisfy predicate or this instruction pattern will not match at all.

Operand numbers must be chosen consecutively counting from zero in each instruction pattern. Th may be only one `match_operand` expression in the pattern for each operand number. Usually operands are numbered in the order of appearance in `match_operand` expressions.

predicate is a string that is the name of a C function that accepts two arguments, an expression and a machine mode. During matching, the function will be called with the putative operand as the expression and m as the mode argument (if m is not specified, `VOIDmode` will be used, which normally causes predicate to accept any mode). If it returns zero, this instruction pattern fails to match. predicate may be an empty string; then it means no test is to be done on the operand, so anything which occurs in this position is valid.

Most of the time, predicate will reject modes other than m---but not always. For example, the predicate `address_operand` uses m as the mode of memory ref that the address should be valid for. Many predicates accept `const_int` nodes even though their mode is `VOIDmode`.

constraint controls reloading and the choice of the best register class to use for a value, as explained later (see section Operand Constraints).

People are often unclear on the difference between the constraint and the predicate. The predicate helps decide whether a given insn matches the pattern. The constraint plays no role in this decision; instead, it controls various decisions in the case of an insn which does match.

On CISC machines, the most common predicate is `"general_operand"`. This function checks that the putative operand is either a constant, a register or a memory reference, and that it is valid for mode m.

For an operand that must be a register, predicate should be `"register_operand"`. Using `"general_operand"` would be valid, since the reload pass would copy any non-register operands through registers, but this would make GNU CC do extra work, it would prevent invariant operands (such as constant) from being removed from loops, and it would prevent the register allocator from doing the best possible job. On RISC machines, it is usually most efficient to allow predicate to accept only objects that the constraints allow.

For an operand that must be a constant, you must be sure to either use `"immediate_operand"` for predicate, or make the instruction pattern's extra condition require a constant, or both. You cannot expect the constraints to do this work! If the constraints allow only constants, but the predicate allows something else, the compiler will crash when that case arises.

`(match_scratch:m n constraint)`

This expression is also a placeholder for operand number n and indicates that operand must be a `scratch` or `reg` expression.

When matching patterns, this is equivalent to

```
(match_operand:m n "scratch_operand" pred)
```

but, when generating RTL, it produces a (`scratch`:m) expression.

If the last few expressions in a `parallel` are `clobber` expressions whose operands are either a hard register or `match_scratch`, the combiner can add or delete them when necessary. See section Side Effect Expressions.

`(match_dup n)`

This expression is also a placeholder for operand number n. It is used when the operand needs to appear more than once in the insn.

In construction, `match_dup` acts just like `match_operand`: the operand is substituted into the insn being constructed. But in matching, `match_dup` behaves differently. It assumes that operand number n has already been determined by a `match_operand` appearing earlier in the recognition template, and it matches only an identical-looking expression.

`(match_operator:m n predicate [operands...])`

This pattern is a kind of placeholder for a variable RTL expression code.

When constructing an insn, it stands for an RTL expression whose expression code is taken from that of operand n, and whose operands are constructed from the patterns operands.

When matching an expression, it matches an expression if the function predicate returns nonzero on that expression *and* the patterns operands match the operands of the expression.

Suppose that the function `commutative_operator` is defined as follows, to match any expression whose operator is one of the commutative arithmetic operators of RTL and whose mode is mode:

```
int
commutative_operator (x, mode)
     rtx x;
     enum machine_mode mode;
{
  enum rtx_code code = GET_CODE (x);
  if (GET_MODE (x) != mode)
    return 0;
  return (GET_RTX_CLASS (code) == 'c'
          || code == EQ || code == NE);
}
```

Then the following pattern will match any RTL expression consisting of a commutative operator applied to two general operands:

```
(match_operator:SI 3 "commutative_operator"
  [(match_operand:SI 1 "general_operand" "g")
   (match_operand:SI 2 "general_operand" "g")])
```

Here the vector `[operands...]` contains two patterns because the expressions to be matched all contain two operands.

When this pattern does match, the two operands of the commutative operator are recorded as operands 1 and 2 of the insn. (This is done by the two instances of `match_operand`.) Operand 3 of the insn will be the entire commutative expression: use `GET_CODE (operands[3])` to see which commutative operator was used.

The machine mode m of `match_operator` works like that of `match_operand`: it is passed as the second argument to the predicate function, and that function is solely responsible for deciding whether

the expression to be matched "has" that mode.

When constructing an insn, argument 3 of the gen-function will specify the operation (i.e. the expression code) for the expression to be made. It should be an RTL expression, whose expression code is copied into a new expression whose operands are arguments 1 and 2 of the gen-function. The subexpressions of argument 3 are not used; only its expression code matters.

When `match_operator` is used in a pattern for matching an insn, it usually best if the operand number of the `match_operator` is higher than that of the actual operands of the insn. This improves register allocation because the register allocator often looks at operands 1 and 2 of insns to see if it can do register tying.

There is no way to specify constraints in `match_operator`. The operand of the insn which corresponds to the `match_operator` never has any constraints because it is never reloaded as a whole. However, if parts of its operands are matched by `match_operand` patterns, those parts may have constraints of their own.

`(match_op_dup:m n[operands...])`

Like `match_dup`, except that it applies to operators instead of operands. When constructing an insn, operand number n will be substituted at this point. But in matching, `match_op_dup` behaves differently. It assumes that operand number n has already been determined by a `match_operator` appearing earlier in the recognition template, and it matches only an identical-looking expression.

`(match_parallel n predicate [subpat...])`

This pattern is a placeholder for an insn that consists of a `parallel` expression with a variable number of elements. This expression should only appear at the top level of an insn pattern.

When constructing an insn, operand number n will be substituted at this point. When matching an insn, it matches if the body of the insn is a `parallel` expression with at least as many elements as the vector of subpat expressions in the `match_parallel`, if each subpat matches the corresponding element of the `parallel`, *and* the function predicate returns nonzero on the `parallel` that is the body of the insn. It is the responsibility of the predicate to validate elements of the `parallel` beyond those listed in the `match_parallel`.

A typical use of `match_parallel` is to match load and store multiple expressions, which can contain a variable number of elements in a `parallel`. For example,

```
(define_insn ""
  [(match_parallel 0 "load_multiple_operation"
     [(set (match_operand:SI 1 "gpc_reg_operand" "=r")
           (match_operand:SI 2 "memory_operand" "m"))
      (use (reg:SI 179))
      (clobber (reg:SI 179))])]
  ""
  "loadm 0,0,%1,%2")
```

This example comes from `a29k.md'. The function `load_multiple_operations` is defined in `a29k.c' and checks that subsequent elements in the `parallel` are the same as the `set` in the pattern, except that they are referencing subsequent registers and memory locations.

An insn that matches this pattern might look like:

```
(parallel
 [(set (reg:SI 20) (mem:SI (reg:SI 100)))
  (use (reg:SI 179))
  (clobber (reg:SI 179))
  (set (reg:SI 21)
       (mem:SI (plus:SI (reg:SI 100)
                        (const_int 4))))
  (set (reg:SI 22)
       (mem:SI (plus:SI (reg:SI 100)
                        (const_int 8))))])
```

`(match_par_dup n [subpat...])`

Like `match_op_dup`, but for `match_parallel` instead of `match_operator`.

`(address (match_operand:m n "address_operand" ""))`

This complex of expressions is a placeholder for an operand number n in a "load address" instruction: an operand which specifies a memory location in the usual way, but for which the actual operand value used is the address of the location, not the contents of the location.

`address` expressions never appear in RTL code, only in machine descriptions. And they are used only in machine descriptions that do not use the operand constraint feature. When operand constraints are in use, the letter `p' in the constraint serves this purpose.

m is the machine mode of the *memory location being addressed*, not the machine mode of the address itself. That mode is always the same on a given target machine (it is `Pmode`, which normally is `SImode`), so there is no point in mentioning it; thus, no machine mode is written in the `address` expression. If some day support is added for machines in which addresses of different kinds of objects appear differently or are used differently (such as the PDP-10), different formats would perhaps need different machine modes and these modes might be written in the `address` expression.

Output Templates and Operand Substitution

The output template is a string which specifies how to output the assembler code for an instruction pattern. Most of the template is a fixed string which is output literally. The character `%' is used to specify where to substitute an operand; it can also be used to identify places where different variants of the assembler require different syntax.

In the simplest case, a `%' followed by a digit n says to output operand n at that point in the string.

`%' followed by a letter and a digit says to output an operand in an alternate fashion. Four letters have standard, built-in meanings described below. The machine description macro `PRINT_OPERAND` can define additional letters with nonstandard meanings.

`%cdigit' can be used to substitute an operand that is a constant value without the syntax that normally indicates an immediate operand.

`%ndigit' is like `%cdigit' except that the value of the constant is negated before printing.

`%adigit' can be used to substitute an operand as if it were a memory reference, with the actual operand treated as the address. This may be useful when outputting a "load address" instruction, because often the assembler syntax for such an instruction requires you to write the operand as if it were a memory reference.

`%ldigit' is used to substitute a `label_ref` into a jump instruction.

`%=' outputs a number which is unique to each instruction in the entire compilation. This is useful for making local labels to be referred to more than once in a single template that generates multiple assembler instructions.

`%' followed by a punctuation character specifies a substitution that does not use an operand. Only one case is standard: `%%' outputs a `%' into the assembler code. Other nonstandard cases can be defined in the `PRINT_OPERAND` macro. You must also define which punctuation characters are valid with the `PRINT_OPERAND_PUNCT_VALID_P` macro.

The template may generate multiple assembler instructions. Write the text for the instructions, with `\;' between them.

When the RTL contains two operands which are required by constraint to match each other, the output template must refer only to the lower-numbered operand. Matching operands are not always identical, and the rest of the compiler arranges to put the proper RTL expression for printing into the lower-numbered operand.

One use of nonstandard letters or punctuation following `%' is to distinguish between different assembler languages for the same machine; for example, Motorola syntax versus MIT syntax for the 68000. Motorola syntax requires periods in most opcode names, while MIT syntax does not. For example, the opcode `movel' in MIT syntax is `move.l' in Motorola syntax. The same file of patterns is used for both kinds of output syntax, but the character sequence `%.' is used in each place where Motorola syntax wants a period. The `PRINT_OPERAND` macro for Motorola syntax defines the sequence to output a period; the macro for MIT syntax defines it to do nothing.

As a special case, a template consisting of the single character # instructs the compiler to first split the insn, and then output the resulting instructions separately. This helps eliminate redundancy in the output templates. If you have a `define_insn` that needs to emit multiple assembler instructions, and there is an matching `define_split` already defined, then you can simply use # as the output template instead of writing an output template that emits the multiple assembler instructions.

If `ASSEMBLER_DIALECT` is defined, you can use `{option0|option1|option2}' constructs in the templates. These describe multiple variants of assembler language syntax. See section Output of Assembler Instructions.

C Statements for Assembler Output

Often a single fixed template string cannot produce correct and efficient assembler code for all the cases that are recognized by a single instruction pattern. For example, the opcodes may depend on the kinds of operands; or some unfortunate combinations of operands may require extra machine instructions.

If the output control string starts with a `@', then it is actually a series of templates, each on a separate line. (Blank lines and leading spaces and tabs are ignored.) The templates correspond to the pattern's constraint

alternatives (see section Multiple Alternative Constraints). For example, if a target machine has a two-address add instruction `addr' to add into a register and another `addm' to add a register to memory, you might write this pattern:

```
(define_insn "addsi3"
  [(set (match_operand:SI 0 "general_operand" "=r,m")
        (plus:SI (match_operand:SI 1 "general_operand" "0,0")
                 (match_operand:SI 2 "general_operand" "g,r")))]
  ""
  "@
   addr %2,%0
   addm %2,%0")
```

If the output control string starts with a `*', then it is not an output template but rather a piece of C program that should compute a template. It should execute a `return` statement to return the template-string you want. Most such templates use C string literals, which require doublequote characters to delimit them. To include these doublequote characters in the string, prefix each one with `\'.

The operands may be found in the array `operands`, whose C data type is `rtx []`.

It is very common to select different ways of generating assembler code based on whether an immediate operand is within a certain range. Be careful when doing this, because the result of `INTVAL` is an integer on the host machine. If the host machine has more bits in an `int` than the target machine has in the mode in which the constant will be used, then some of the bits you get from `INTVAL` will be superfluous. For proper results, you must carefully disregard the values of those bits.

It is possible to output an assembler instruction and then go on to output or compute more of them, using the subroutine `output_asm_insn`. This receives two arguments: a template-string and a vector of operands. The vector may be `operands`, or it may be another array of `rtx` that you declare locally and initialize yourself.

When an insn pattern has multiple alternatives in its constraints, often the appearance of the assembler code is determined mostly by which alternative was matched. When this is so, the C code can test the variable `which_alternative`, which is the ordinal number of the alternative that was actually satisfied (0 for the first, 1 for the second alternative, etc.).

For example, suppose there are two opcodes for storing zero, `clrreg' for registers and `clrmem' for memory locations. Here is how a pattern could use `which_alternative` to choose between them:

```
(define_insn ""
  [(set (match_operand:SI 0 "general_operand" "=r,m")
        (const_int 0))]
  ""
  "*
  return (which_alternative == 0
          ? \"clrreg %0\" : \"clrmem %0\");
  ")
```

The example above, where the assembler code to generate was *solely* determined by the alternative, could

also have been specified as follows, having the output control string start with a `@':

```
(define_insn ""
  [(set (match_operand:SI 0 "general_operand" "=r,m")
        (const_int 0))]
  ""
  "@
   clrreg %0
   clrmem %0")
```

Operand Constraints

Each `match_operand` in an instruction pattern can specify a constraint for the type of operands allowed. Constraints can say whether an operand may be in a register, and which kinds of register; whether the operand can be a memory reference, and which kinds of address; whether the operand may be an immediate constant, and which possible values it may have. Constraints can also require two operands to match.

Simple Constraints

The simplest kind of constraint is a string full of letters, each of which describes one kind of operand that is permitted. Here are the letters that are allowed:

`m'

A memory operand is allowed, with any kind of address that the machine supports in general.

`o'

A memory operand is allowed, but only if the address is offsettable. This means that adding a small integer (actually, the width in bytes of the operand, as determined by its machine mode) may be added to the address and the result is also a valid memory address.

For example, an address which is constant is offsettable; so is an address that is the sum of a register and a constant (as long as a slightly larger constant is also within the range of address-offsets supported by the machine); but an autoincrement or autodecrement address is not offsettable. More complicated indirect/indexed addresses may or may not be offsettable depending on the other addressing modes that the machine supports.

Note that in an output operand which can be matched by another operand, the constraint letter `o' is valid only when accompanied by both `<' (if the target machine has predecrement addressing) and `>' (if the target machine has preincrement addressing).

`V'

A memory operand that is not offsettable. In other words, anything that would fit the `m' constraint but not the `o' constraint.

`<'

A memory operand with autodecrement addressing (either predecrement or postdecrement) is allowed.

`>'

A memory operand with autoincrement addressing (either preincrement or postincrement) is allowed.

`r'

A register operand is allowed provided that it is in a general register.

`d', `a', `f', ...

Other letters can be defined in machine-dependent fashion to stand for particular classes of registers. `d', `a' and `f' are defined on the 68000/68020 to stand for data, address and floating point registers.

`i'

An immediate integer operand (one with constant value) is allowed. This includes symbolic constants whose values will be known only at assembly time.

`n'

An immediate integer operand with a known numeric value is allowed. Many systems cannot support assembly-time constants for operands less than a word wide. Constraints for these operands should use `n' rather than `i'.

`I', `J', `K', ... `P'

Other letters in the range `I' through `P' may be defined in a machine-dependent fashion to permit immediate integer operands with explicit integer values in specified ranges. For example, on the 68000, `I' is defined to stand for the range of values 1 to 8. This is the range permitted as a shift count in the shift instructions.

`E'

An immediate floating operand (expression code `const_double`) is allowed, but only if the target floating point format is the same as that of the host machine (on which the compiler is running).

`F'

An immediate floating operand (expression code `const_double`) is allowed.

`G', `H'

`G' and `H' may be defined in a machine-dependent fashion to permit immediate floating operands in particular ranges of values.

`s'

An immediate integer operand whose value is not an explicit integer is allowed.

This might appear strange; if an insn allows a constant operand with a value not known at compile time, it certainly must allow any known value. So why use `s' instead of `i'? Sometimes it allows better code to be generated.

For example, on the 68000 in a fullword instruction it is possible to use an immediate operand; but if the immediate value is between -128 and 127, better code results from loading the value into a register and using the register. This is because the load into the register can be done with a `moveq' instruction. We arrange for this to happen by defining the letter `K' to mean "any integer outside the range -128 to 127", and then specifying `Ks' in the operand constraints.

`g'

Any register, memory or immediate integer operand is allowed, except for registers that are not general registers.

`X'

Any operand whatsoever is allowed, even if it does not satisfy `general_operand`. This is normally used in the constraint of a `match_scratch` when certain alternatives will not actually require a

scratch register.

`0', `1', `2', ... `9'

An operand that matches the specified operand number is allowed. If a digit is used together with letters within the same alternative, the digit should come last.

This is called a matching constraint and what it really means is that the assembler has only a single operand that fills two roles considered separate in the RTL insn. For example, an add insn has two input operands and one output operand in the RTL, but on most CISC machines an add instruction really has only two operands, one of them an input-output operand:

```
addl #35,r12
```

Matching constraints are used in these circumstances. More precisely, the two operands that match must include one input-only operand and one output-only operand. Moreover, the digit must be a smaller number than the number of the operand that uses it in the constraint.

For operands to match in a particular case usually means that they are identical-looking RTL expressions. But in a few special cases specific kinds of dissimilarity are allowed. For example, `*x` as an input operand will match `*x++` as an output operand. For proper results in such cases, the output template should always use the output-operand's number when printing the operand.

`p'

An operand that is a valid memory address is allowed. This is for "load address" and "push address" instructions.

`p' in the constraint must be accompanied by `address_operand` as the predicate in the `match_operand`. This predicate interprets the mode specified in the `match_operand` as the mode of the memory reference for which the address would be valid.

`Q', `R', `S', ... `U'

Letters in the range `Q' through `U' may be defined in a machine-dependent fashion to stand for arbitrary operand types. The machine description macro `EXTRA_CONSTRAINT` is passed the operand as its first argument and the constraint letter as its second operand.

A typical use for this would be to distinguish certain types of memory references that affect other insn operands.

Do not define these constraint letters to accept register references (`reg`); the reload pass does not expect this and would not handle it properly.

In order to have valid assembler code, each operand must satisfy its constraint. But a failure to do so does not prevent the pattern from applying to an insn. Instead, it directs the compiler to modify the code so that the constraint will be satisfied. Usually this is done by copying an operand into a register.

Contrast, therefore, the two instruction patterns that follow:

```
(define_insn ""
  [(set (match_operand:SI 0 "general_operand" "=r")
        (plus:SI (match_dup 0)
                 (match_operand:SI 1 "general_operand" "r")))]
```

```
  ""
  "...")
```

which has two operands, one of which must appear in two places, and

```
(define_insn ""
  [(set (match_operand:SI 0 "general_operand" "=r")
        (plus:SI (match_operand:SI 1 "general_operand" "0")
                 (match_operand:SI 2 "general_operand" "r")))]
  ""
  "...")
```

which has three operands, two of which are required by a constraint to be identical. If we are considering an insn of the form

```
(insn n prev next
  (set (reg:SI 3)
       (plus:SI (reg:SI 6) (reg:SI 109)))
  ...)
```

the first pattern would not apply at all, because this insn does not contain two identical subexpressions in the right place. The pattern would say, "That does not look like an add instruction; try other patterns." The second pattern would say, "Yes, that's an add instruction, but there is something wrong with it." It would direct the reload pass of the compiler to generate additional insns to make the constraint true. The results might look like this:

```
(insn n2 prev n
  (set (reg:SI 3) (reg:SI 6))
  ...)

(insn n n2 next
  (set (reg:SI 3)
       (plus:SI (reg:SI 3) (reg:SI 109)))
  ...)
```

It is up to you to make sure that each operand, in each pattern, has constraints that can handle any RTL expression that could be present for that operand. (When multiple alternatives are in use, each pattern must, for each possible combination of operand expressions, have at least one alternative which can handle that combination of operands.) The constraints don't need to *allow* any possible operand--when this is the case, they do not constrain--but they must at least point the way to reloading any possible operand so that it will fit.

- If the constraint accepts whatever operands the predicate permits, there is no problem: reloading is never necessary for this operand.

  For example, an operand whose constraints permit everything except registers is safe provided its predicate rejects registers.

  An operand whose predicate accepts only constant values is safe provided its constraints include the

letter `i'. If any possible constant value is accepted, then nothing less than `i' will do; if the predica more selective, then the constraints may also be more selective.

- Any operand expression can be reloaded by copying it into a register. So if an operand's constraints allow some kind of register, it is certain to be safe. It need not permit all classes of registers; the compiler knows how to copy a register into another register of the proper class in order to make an instruction valid.
- A nonoffsettable memory reference can be reloaded by copying the address into a register. So if the constraint uses the letter `o', all memory references are taken care of.
- A constant operand can be reloaded by allocating space in memory to hold it as preinitialized data. Then the memory reference can be used in place of the constant. So if the constraint uses the letters `o' or `m', constant operands are not a problem.
- If the constraint permits a constant and a pseudo register used in an insn was not allocated to a hard register and is equivalent to a constant, the register will be replaced with the constant. If the predicate does not permit a constant and the insn is re-recognized for some reason, the compiler will crash. Thus the predicate must always recognize any objects allowed by the constraint.

If the operand's predicate can recognize registers, but the constraint does not permit them, it can make the compiler crash. When this operand happens to be a register, the reload pass will be stymied, because it does not know how to copy a register temporarily into memory.

Multiple Alternative Constraints

Sometimes a single instruction has multiple alternative sets of possible operands. For example, on the 68000, a logical-or instruction can combine register or an immediate value into memory, or it can combine any kind of operand into a register; but it cannot combine one memory location into another.

These constraints are represented as multiple alternatives. An alternative can be described by a series of letters for each operand. The overall constraint for an operand is made from the letters for this operand from the first alternative, a comma, the letters for this operand from the second alternative, a comma, and so on until the last alternative. Here is how it is done for fullword logical-or on the 68000:

```
(define_insn "iorsi3"
  [(set (match_operand:SI 0 "general_operand" "=m,d")
        (ior:SI (match_operand:SI 1 "general_operand" "%0,0")
                (match_operand:SI 2 "general_operand" "dKs,dmKs")))]
  ...)
```

The first alternative has `m' (memory) for operand 0, `0' for operand 1 (meaning it must match operand 0), and `dKs' for operand 2. The second alternative has `d' (data register) for operand 0, `0' for operand 1, and `dmKs' for operand 2. The `=' and `%' in the constraints apply to all the alternatives; their meaning is explained in the next section (see section Register Class Preferences).

If all the operands fit any one alternative, the instruction is valid. Otherwise, for each alternative, the compiler counts how many instructions must be added to copy the operands so that that alternative applies. The alternative requiring the least copying is chosen. If two alternatives need the same amount of copying, the one that comes first is chosen. These choices can be altered with the `?' and `!' characters:

?

Disparage slightly the alternative that the `?' appears in, as a choice when no alternative applies exactly. The compiler regards this alternative as one unit more costly for each `?' that appears in it

!

Disparage severely the alternative that the `!' appears in. This alternative can still be used if it fits without reloading, but if reloading is needed, some other alternative will be used.

When an insn pattern has multiple alternatives in its constraints, often the appearance of the assembler code is determined mostly by which alternative was matched. When this is so, the C code for writing the assembler code can use the variable `which_alternative`, which is the ordinal number of the alternative that was actually satisfied (0 for the first, 1 for the second alternative, etc.). See section C Statements for Assembler Output.

Register Class Preferences

The operand constraints have another function: they enable the compiler to decide which kind of hardware register a pseudo register is best allocated to. The compiler examines the constraints that apply to the insns that use the pseudo register, looking for the machine-dependent letters such as `d' and `a' that specify classes of registers. The pseudo register is put in whichever class gets the most "votes". The constraint letters `g' and `r' also vote: they vote in favor of a general register. The machine description says which registers are considered general.

Of course, on some machines all registers are equivalent, and no register classes are defined. Then none of this complexity is relevant.

Constraint Modifier Characters

Here are constraint modifier characters.

`='

Means that this operand is write-only for this instruction: the previous value is discarded and replaced by output data.

`+'

Means that this operand is both read and written by the instruction.

When the compiler fixes up the operands to satisfy the constraints, it needs to know which operands are inputs to the instruction and which are outputs from it. `=' identifies an output; `+' identifies an operand that is both input and output; all other operands are assumed to be input only.

`&'

Means (in a particular alternative) that this operand is written before the instruction is finished using the input operands. Therefore, this operand may not lie in a register that is used as an input operand or as part of any memory address.

`&' applies only to the alternative in which it is written. In constraints with multiple alternatives, sometimes one alternative requires `&' while others do not. See, for example, the `movdf' insn of the 68000.

`&' does not obviate the need to write `='.

`%'

Declares the instruction to be commutative for this operand and the following operand. This means that the compiler may interchange the two operands if that is the cheapest way to make all operands fit the constraints. This is often used in patterns for addition instructions that really have only two operands: the result must go in one of the arguments. Here for example, is how the 68000 halfword-add instruction is defined:

```
(define_insn "addhi3"
  [(set (match_operand:HI 0 "general_operand" "=m,r")
     (plus:HI (match_operand:HI 1 "general_operand" "%0,0")
              (match_operand:HI 2 "general_operand" "di,g")))]
  ...)
```

`#'

Says that all following characters, up to the next comma, are to be ignored as a constraint. They are significant only for choosing register preferences.

`*'

Says that the following character should be ignored when choosing register preferences. `*' has no effect on the meaning of the constraint as a constraint, and no effect on reloading.

Here is an example: the 68000 has an instruction to sign-extend a halfword in a data register, and can also sign-extend a value by copying it into an address register. While either kind of register is acceptable, the constraints on an address-register destination are less strict, so it is best if register allocation makes an address register its goal. Therefore, `*' is used so that the `d' constraint letter (for data register) is ignored when computing register preferences.

```
(define_insn "extendhisi2"
  [(set (match_operand:SI 0 "general_operand" "=*d,a")
        (sign_extend:SI
         (match_operand:HI 1 "general_operand" "0,g")))]
  ...)
```

Constraints for Particular Machines

Whenever possible, you should use the general-purpose constraint letters in `asm` arguments, since they will convey meaning more readily to people reading your code. Failing that, use the constraint letters that usually have very similar meanings across architectures. The most commonly used constraints are `m' and `r' (for memory and general-purpose registers respectively; see section Simple Constraints), and `I', usually the letter indicating the most common immediate-constant format.

For each machine architecture, the `config/machine.h' file defines additional constraints. These constraints are used by the compiler itself for instruction generation, as well as for `asm` statements; therefore, some of the constraints are not particularly interesting for `asm`. The constraints are defined through these macros:

`REG_CLASS_FROM_LETTER`

Register class constraints (usually lower case).

`CONST_OK_FOR_LETTER_P`

Immediate constant constraints, for non-floating point constants of word size or smaller precision (usually upper case).

`CONST_DOUBLE_OK_FOR_LETTER_P`

Immediate constant constraints, for all floating point constants and for constants of greater than word size precision (usually upper case).

`EXTRA_CONSTRAINT`

Special cases of registers or memory. This macro is not required, and is only defined for some machines.

Inspecting these macro definitions in the compiler source for your machine is the best way to be certain you have the right constraints. However, here is a summary of the machine-dependent constraints available on some particular machines.

ARM family---`arm.h'

`f`

Floating-point register

`F`

One of the floating-point constants 0.0, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0 or 10.0

`G`

Floating-point constant that would satisfy the constraint `F' if it were negated

`I`

Integer that is valid as an immediate operand in a data processing instruction. That is, an integer in the range 0 to 255 rotated by a multiple of 2

`J`

Integer in the range -4095 to 4095

`K`

Integer that satisfies constraint `I' when inverted (ones complement)

`L`

Integer that satisfies constraint `I' when negated (twos complement)

`M`

Integer in the range 0 to 32

`Q`

A memory reference where the exact address is in a single register (``m'' is preferable for `asm` statements)

`R`

An item in the constant pool

`S`

A symbol in the text segment of the current file

- AMD 29000 family---`a29k.h'

`l`

Local register 0

`b`

Byte Pointer (`BP') register

`q`

`Q' register

`h`

Special purpose register

`A`

First accumulator register

`a`

Other accumulator register

`f`

Floating point register

`I`

Constant greater than 0, less than 0x100

`J`

Constant greater than 0, less than 0x10000

`K`

Constant whose high 24 bits are on (1)

`L`

16 bit constant whose high 8 bits are on (1)

`M`

32 bit constant whose high 16 bits are on (1)

`N`

32 bit negative constant that fits in 8 bits

`O`

The constant 0x80000000 or, on the 29050, any 32 bit constant whose low 16 bits are 0.

`P`

16 bit negative constant that fits in 8 bits

`G`

`H`

A floating point constant (in `asm` statements, use the machine independent `E' or `F' instead)

- IBM RS6000---`rs6000.h'`

`b`

Address base register

`f`

Floating point register

`h`

`MQ', `CTR', or `LINK' register

`q`
: `MQ' register

`c`
: `CTR' register

`l`
: `LINK' register

`x`
: `CR' register (condition register) number 0

`y`
: `CR' register (condition register)

`I`
: Signed 16 bit constant

`J`
: Constant whose low 16 bits are 0

`K`
: Constant whose high 16 bits are 0

`L`
: Constant suitable as a mask operand

`M`
: Constant larger than 31

`N`
: Exact power of 2

`O`
: Zero

`P`
: Constant whose negation is a signed 16 bit constant

`G`
: Floating point constant that can be loaded into a register with one instruction per word

`Q`
: Memory operand that is an offset from a register (`m' is preferable for `asm` statements)

- Intel 386---`` `i386.h' ``

`q`
: `a', `b`, `c`, or `d` register

`A`
: `a', or `d` register (for 64-bit ints)

`f`
: Floating point register

`t`
: First (top of stack) floating point register

`u`
: Second floating point register

`a`
: `a' register

`b`
: `b' register

`c`
: `c' register

`d`
: `d' register

`D`
: `di' register

`S`
: `si' register

`I`
: Constant in range 0 to 31 (for 32 bit shifts)

`J`
: Constant in range 0 to 63 (for 64 bit shifts)

`K`
: `0xff'

`L`
: `0xffff'

`M`
: 0, 1, 2, or 3 (shifts for `lea` instruction)

`G`
: Standard 80387 floating point constant

- Intel 960---`` `i960.h' ``

`f`
: Floating point register (`fp0` to `fp3`)

`l`
: Local register (`r0` to `r15`)

`b`
: Global register (`g0` to `g15`)

`d`
: Any local or global register

`I`

Integers from 0 to 31

`J`

0

`K`

Integers from -31 to 0

`G`

Floating point 0

`H`

Floating point 1

- MIPS---`mips.h'`

`d`

General-purpose integer register

`f`

Floating-point register (if available)

`h`

`Hi' register

`l`

`Lo' register

`x`

`Hi' or `Lo' register

`y`

General-purpose integer register

`z`

Floating-point status register

`I`

Signed 16 bit constant (for arithmetic instructions)

`J`

Zero

`K`

Zero-extended 16-bit constant (for logic instructions)

`L`

Constant with low 16 bits zero (can be loaded with `lui`)

`M`

32 bit constant which requires two instructions to load (a constant which is not `I', `K', or `L')

`N`

Negative 16 bit constant

`O`

Exact power of two

`P`

Positive 16 bit constant

`G`

Floating point zero

`Q`

Memory reference that can be loaded with more than one instruction (`m' is preferable for `asm` statements)

`R`

Memory reference that can be loaded with one instruction (`m' is preferable for `asm` statements)

`S`

Memory reference in external OSF/rose PIC format (`m' is preferable for `asm` statements)

- Motorola 680x0---`m68k.h'

`a`

Address register

`d`

Data register

`f`

68881 floating-point register, if available

`x`

Sun FPA (floating-point) register, if available

`y`

First 16 Sun FPA registers, if available

`I`

Integer in the range 1 to 8

`J`

16 bit signed number

`K`

Signed number whose magnitude is greater than 0x80

`L`

Integer in the range -8 to -1

`G`

Floating point constant that is not a 68881 constant

`H`

Floating point constant that can be used by Sun FPA

- SPARC---`sparc.h'

`f`

Floating-point register

`I`

Signed 13 bit constant

`J`

Zero

`K`

32 bit constant with the low 12 bits clear (a constant that can be loaded with the `sethi` instruction)

`G`

Floating-point zero

`H`

Signed 13 bit constant, sign-extended to 32 or 64 bits

`Q`

Memory reference that can be loaded with one instruction (`m' is more appropriate for `asm` statements)

`S`

Constant, or memory address

`T`

Memory address aligned to an 8-byte boundary

`U`

Even register

Not Using Constraints

Some machines are so clean that operand constraints are not required. For example, on the Vax, an operand valid in one context is valid in any other context. On such a machine, every operand constraint would be `g', excepting only operands of "load address" instructions which are written as if they referred to a memory location's contents but actual refer to its address. They would have constraint `p'.

For such machines, instead of writing `g' and `p' for all the constraints, you can choose to write a description with empty constraints. Then you write `""' for the constraint in every `match_operand`. Address operands are identified by writing an `address` expression around the `match_operand`, not by their constraints.

When the machine description has just empty constraints, certain parts of compilation are skipped, making the compiler faster. However, few machines actually do not need constraints; all machine descriptions now in existence use constraints.

Standard Pattern Names For Generation

Here is a table of the instruction names that are meaningful in the RTL generation pass of the compiler. Giving one of these names to an instruction pattern tells the RTL generation pass that it can use the pattern in to accomplish a certain task.

`movm'

Here m stands for a two-letter machine mode name, in lower case. This instruction pattern moves data with that machine mode from operand 1 to operand 0. For example, `movsi' moves full-word data.

If operand 0 is a `subreg` with mode m of a register whose own mode is wider than m, the effect of this instruction is to store the specified value in the part of the register that corresponds to mode m. The effect on the rest of the register is undefined.

This class of patterns is special in several ways. First of all, each of these names *must* be defined, because there is no other way to copy a datum from one place to another.

Second, these patterns are not used solely in the RTL generation pass. Even the reload pass can generate move insns to copy values from stack slots into temporary registers. When it does so, one of the operands is a hard register and the other is an operand that can need to be reloaded into a register.

Therefore, when given such a pair of operands, the pattern must generate RTL which needs no reloading and needs no temporary registers--no registers other than the operands. For example, if you support the pattern with a `define_expand`, then in such a case the `define_expand` mustn't call `force_reg` or any other such function which might generate new pseudo registers.

This requirement exists even for subword modes on a RISC machine where fetching those modes from memory normally requires several insns and some temporary registers. Look in `` `spur.md' `` to see how the requirement can be satisfied.

During reload a memory reference with an invalid address may be passed as an operand. Such an address will be replaced with a valid address later in the reload pass. In this case, nothing may be done with the address except to use it as it stands. If it is copied, it will not be replaced with a valid address. No attempt should be made to make such an address into a valid address and no routine (such as `change_address`) that will do so may be called. Note that `general_operand` will fail when applied to such an address.

The global variable `reload_in_progress` (which must be explicitly declared if required) can be used to determine whether such special handling is required.

The variety of operands that have reloads depends on the rest of the machine description, but typically on a RISC machine these can only be pseudo registers that did not get hard registers, while on other machines explicit memory references will get optional reloads.

If a scratch register is required to move an object to or from memory, it can be allocated using `gen_reg_rtx` prior to reload. But this is impossible during and after reload. If there are cases needing scratch registers after reload, you must define `SECONDARY_INPUT_RELOAD_CLASS` and perhaps also `SECONDARY_OUTPUT_RELOAD_CLASS` to detect them, and provide patterns `reload_inm' or `reload_outm' to handle them. See section Register Classes.

The constraints on a `movem' must permit moving any hard register to any other hard register provided that `HARD_REGNO_MODE_OK` permits mode m in both registers and `REGISTER_MOVE_COST` applied to their classes returns a value of 2.

It is obligatory to support floating point `movem' instructions into and out of any registers that can hold fixed point values, because unions and structures (which have modes `SImode` or `DImode`) can be in those registers and they may have floating point members.

There may also be a need to support fixed point `movem' instructions in and out of floating point registers. Unfortunately, I have forgotten why this was so, and I don't know whether it is still true. If `HARD_REGNO_MODE_OK` rejects fixed point values in floating point registers, then the constraints of

the fixed point `movem' instructions must be designed to avoid ever trying to reload into a floating point register.

`reload_inm'

`reload_outm'

Like `movm', but used when a scratch register is required to move between operand 0 and operand 1. Operand 2 describes the scratch register. See the discussion of the `SECONDARY_RELOAD_CLASS` macro in see section Register Classes.

`movstrictm'

Like `movm' except that if operand 0 is a `subreg` with mode m of a register whose natural mode is wider, the `movstrictm' instruction is guaranteed not to alter any of the register except the part which belongs to mode m.

`load_multiple'

Load several consecutive memory locations into consecutive registers. Operand 0 is the first of the consecutive registers, operand 1 is the first memory location, and operand 2 is a constant: the number of consecutive registers.

Define this only if the target machine really has such an instruction; do not define this if the most efficient way of loading consecutive registers from memory is to do them one at a time.

On some machines, there are restrictions as to which consecutive registers can be stored into memory, such as particular starting or ending register numbers or only a range of valid counts. For those machines, use a `define_expand` (see section Defining RTL Sequences for Code Generation) and make the pattern fail if the restrictions are not met.

Write the generated insn as a `parallel` with elements being a `set` of one register from the appropriate memory location (you may also need `use` or `clobber` elements). Use a `match_parallel` (see section RTL Template) to recognize the insn. See `a29k.md' and `rs6000.md' for examples of the use of this insn pattern.

`store_multiple'

Similar to `load_multiple', but store several consecutive registers into consecutive memory locations. Operand 0 is the first of the consecutive memory locations, operand 1 is the first register, and operand 2 is a constant: the number of consecutive registers.

`addm3'

Add operand 2 and operand 1, storing the result in operand 0. All operands must have mode m. This can be used even on two-address machines, by means of constraints requiring operands 1 and 0 to be the same location.

`subm3', `mulm3'

`divm3', `udivm3', `modm3', `umodm3'

`sminm3', `smaxm3', `uminm3', `umaxm3'

`andm3', `iorm3', `xorm3'

Similar, for other arithmetic operations.

`mulhisi3'

Multiply operands 1 and 2, which have mode `HImode`, and store a `SImode` product in operand 0.

`mulqihi3', `mulsidi3'

Similar widening-multiplication instructions of other widths.

`umulqihi3', `umulhisi3', `umulsidi3'

Similar widening-multiplication instructions that do unsigned multiplication.

`mulm3_highpart'

Perform a signed multiplication of operands 1 and 2, which have mode m, and store the most significant half of the product in operand 0. The least significant half of the product is discarded.

`umulm3_highpart'

Similar, but the multiplication is unsigned.

`divmodm4'

Signed division that produces both a quotient and a remainder. Operand 1 is divided by operand 2 to produce a quotient stored in operand 0 and a remainder stored in operand 3.

For machines with an instruction that produces both a quotient and a remainder, provide a pattern for `divmodm4' but do not provide patterns for `divm3' and `modm3'. This allows optimization in the relatively common case when both the quotient and remainder are computed.

If an instruction that just produces a quotient or just a remainder exists and is more efficient than the instruction that produces both, write the output routine of `divmodm4' to call `find_reg_note` and look for a `REG_UNUSED` note on the quotient or remainder and generate the appropriate instruction.

`udivmodm4'

Similar, but does unsigned division.

`ashlm3'

Arithmetic-shift operand 1 left by a number of bits specified by operand 2, and store the result in operand 0. Here m is the mode of operand 0 and operand 1; operand 2's mode is specified by the instruction pattern, and the compiler will convert the operand to that mode before generating the instruction.

`ashrm3', `lshrm3', `rotlm3', `rotrm3'

Other shift and rotate instructions, analogous to the `ashlm3` instructions.

`negm2'

Negate operand 1 and store the result in operand 0.

`absm2'

Store the absolute value of operand 1 into operand 0.

`sqrtm2'

Store the square root of operand 1 into operand 0.

The `sqrt` built-in function of C always uses the mode which corresponds to the C data type `double`.

`ffsm2'

Store into operand 0 one plus the index of the least significant 1-bit of operand 1. If operand 1 is zero, store zero. m is the mode of operand 0; operand 1's mode is specified by the instruction pattern, and the compiler will convert the operand to that mode before generating the instruction.

The `ffs` built-in function of C always uses the mode which corresponds to the C data type `int`.

`one_cmplm2'

Store the bitwise-complement of operand 1 into operand 0.

`cmpm'

Compare operand 0 and operand 1, and set the condition codes. The RTL pattern should look like this:

```
(set (cc0) (compare (match_operand:m 0 ...)
                    (match_operand:m 1 ...)))
```

`tstm'

Compare operand 0 against zero, and set the condition codes. The RTL pattern should look like this:

```
(set (cc0) (match_operand:m 0 ...))
```

`tstm' patterns should not be defined for machines that do not use `(cc0)`. Doing so would confuse the optimizer since it would no longer be clear which `set` operations were comparisons. The `cmpm' patterns should be used instead.

`movstrm'

Block move instruction. The addresses of the destination and source strings are the first two operands, and both are in mode `Pmode`. The number of bytes to move is the third operand, in mode m.

The fourth operand is the known shared alignment of the source and destination, in the form of a `const_int` rtx. Thus, if the compiler knows that both source and destination are word-aligned, it may provide the value 4 for this operand.

These patterns need not give special consideration to the possibility that the source and destination strings might overlap.

`cmpstrm'

Block compare instruction, with five operands. Operand 0 is the output; it has mode m. The remaining four operands are like the operands of `movstrm'. The two memory blocks specified are compared byte by byte in lexicographic order. The effect of the instruction is to store a value in operand 0 whose sign indicates the result of the comparison.

Compute the length of a string, with three operands. Operand 0 is the result (of mode m), operand 1 is a `mem` referring to the first character of the string, operand 2 is the character to search for (normally zero), and operand 3 is a constant describing the known alignment of the beginning of the string.

`floatmn2'

Convert signed integer operand 1 (valid for fixed point mode m) to floating point mode n and store in operand 0 (which has mode n).

`floatunsmn2'

Convert unsigned integer operand 1 (valid for fixed point mode m) to floating point mode n and store in operand 0 (which has mode n).

`fixmn2'

Convert operand 1 (valid for floating point mode m) to fixed point mode n as a signed number and store in operand 0 (which has mode n). This instruction's result is defined only when the value of operand 1 is an integer.

`fixunsmn2'

Convert operand 1 (valid for floating point mode m) to fixed point mode n as an unsigned number and store in operand 0 (which has mode n). This instruction's result is defined only when the value of operand 1 is an integer.

`ftruncm2'

Convert operand 1 (valid for floating point mode m) to an integer value, still represented in floating point mode m, and store it in operand 0 (valid for floating point mode m).

`fix_truncmn2'

Like `fixmn2' but works for any floating point value of mode m by converting the value to an integer.

`fixuns_truncmn2'

Like `fixunsmn2' but works for any floating point value of mode m by converting the value to an integer.

`truncmn'

Truncate operand 1 (valid for mode m) to mode n and store in operand 0 (which has mode n). Both modes must be fixed point or both floating point.

`extendmn'

Sign-extend operand 1 (valid for mode m) to mode n and store in operand 0 (which has mode n). Both modes must be fixed point or both floating point.

`zero_extendmn'

Zero-extend operand 1 (valid for mode m) to mode n and store in operand 0 (which has mode n). Both modes must be fixed point.

`extv'

Extract a bit field from operand 1 (a register or memory operand), where operand 2 specifies the width in bits and operand 3 the starting bit, and store it in operand 0. Operand 0 must have mode `word_mode`. Operand 1 may have mode `byte_mode` or `word_mode`; often `word_mode` is allowed only for registers. Operands 2 and 3 must be valid for `word_mode`.

The RTL generation pass generates this instruction only with constants for operands 2 and 3.

The bit-field value is sign-extended to a full word integer before it is stored in operand 0.

`extzv'

Like `extv' except that the bit-field value is zero-extended.

`insv'

Store operand 3 (which must be valid for `word_mode`) into a bit field in operand 0, where operand 1 specifies the width in bits and operand 2 the starting bit. Operand 0 may have mode `byte_mode` or `word_mode`; often `word_mode` is allowed only for registers. Operands 1 and 2 must be valid for `word_mode`.

The RTL generation pass generates this instruction only with constants for operands 1 and 2.

`movmodecc'

Conditionally move operand 2 or operand 3 into operand 0 according to the comparison in operand 1. If the comparison is true, operand 2 is moved into operand 0, otherwise operand 3 is moved.

The mode of the operands being compared need not be the same as the operands being moved. So machines, sparc64 for example, have instructions that conditionally move an integer value based the floating point condition codes and vice versa.

If the machine does not have conditional move instructions, do not define these patterns.

`scond'

Store zero or nonzero in the operand according to the condition codes. Value stored is nonzero iff the condition cond is true. cond is the name of a comparison operation expression code, such as `eq`, `lt` or `leu`.

You specify the mode that the operand must have when you write the `match_operand` expression. The compiler automatically sees which mode you have used and supplies an operand of that mode.

The value stored for a true condition must have 1 as its low bit, or else must be negative. Otherwise the instruction is not suitable and you should omit it from the machine description. You describe to the compiler exactly which value is stored by defining the macro `STORE_FLAG_VALUE` (see section Miscellaneous Parameters). If a description cannot be found that can be used for all the `scond' patterns, you should omit those operations from the machine description.

These operations may fail, but should do so only in relatively uncommon cases; if they would fail for common cases involving integer comparisons, it is best to omit these patterns.

If these operations are omitted, the compiler will usually generate code that copies the constant one to the target and branches around an assignment of zero to the target. If this code is more efficient than the potential instructions used for the `scond' pattern followed by those required to convert the result into a 1 or a zero in `SImode`, you should omit the `scond' operations from the machine description.

`bcond'

Conditional branch instruction. Operand 0 is a `label_ref` that refers to the label to jump to. Jump if the condition codes meet condition cond.

Some machines do not follow the model assumed here where a comparison instruction is followed by a conditional branch instruction. In that case, the `cmpm' (and `tstm') patterns should simply store the operands away and generate all the required insns in a `define_expand` (see section Defining RTL Sequences for Code Generation) for the conditional branch operations. All calls to expand `bcond' patterns are immediately preceded by calls to expand either a `cmpm' pattern or a `tstm' pattern.

Machines that use a pseudo register for the condition code value, or where the mode used for the comparison depends on the condition being tested, should also use the above mechanism. See section Defining Jump Instruction Patterns

The above discussion also applies to the `movmodecc' and `scond' patterns.

`call'

Subroutine call instruction returning no value. Operand 0 is the function to call; operand 1 is the number of bytes of arguments pushed (in mode `SImode`, except it is normally a `const_int`); operand 2 is the number of registers used as operands.

On most machines, operand 2 is not actually stored into the RTL pattern. It is supplied for the sake of some RISC machines which need to put this information into the assembler code; they can put it in the

RTL instead of operand 1.

Operand 0 should be a `mem` RTX whose address is the address of the function. Note, however, that this address can be a `symbol_ref` expression even if it would not be a legitimate memory address on the target machine. If it is also not a valid argument for a call instruction, the pattern for this operation should be a `define_expand` (see section Defining RTL Sequences for Code Generation) that places the address into a register and uses that register in the call instruction.

`call_value'

Subroutine call instruction returning a value. Operand 0 is the hard register in which the value is returned. There are three more operands, the same as the three operands of the `call' instruction (but with numbers increased by one).

Subroutines that return `BLKmode` objects use the `call' insn.

`call_pop', `call_value_pop'

Similar to `call' and `call_value', except used if defined and if `RETURN_POPS_ARGS` is non-zero. They should emit a `parallel` that contains both the function call and a `set` to indicate the adjustment made to the frame pointer.

For machines where `RETURN_POPS_ARGS` can be non-zero, the use of these patterns increases the number of functions for which the frame pointer can be eliminated, if desired.

`untyped_call'

Subroutine call instruction returning a value of any type. Operand 0 is the function to call; operand 1 is a memory location where the result of calling the function is to be stored; operand 2 is a `parallel` expression where each element is a `set` expression that indicates the saving of a function return value into the result block.

This instruction pattern should be defined to support `__builtin_apply` on machines where special instructions are needed to call a subroutine with arbitrary arguments or to save the value returned. This instruction pattern is required on machines that have multiple registers that can hold a return value (i.e. `FUNCTION_VALUE_REGNO_P` is true for more than one register).

`return'

Subroutine return instruction. This instruction pattern name should be defined only if a single instruction can do all the work of returning from a function.

Like the `movm' patterns, this pattern is also used after the RTL generation phase. In this case it is to support machines where multiple instructions are usually needed to return from a function, but some class of functions only requires one instruction to implement a return. Normally, the applicable functions are those which do not need to save any registers or allocate stack space.

For such machines, the condition specified in this pattern should only be true when `reload_completed` is non-zero and the function's epilogue would only be a single instruction. For machines with register windows, the routine `leaf_function_p` may be used to determine if a register window push is required.

Machines that have conditional return instructions should define patterns such as

```
(define_insn ""
```

```
[(set (pc)
      (if_then_else (match_operator
                        0 "comparison_operator"
                        [(cc0) (const_int 0)])
                    (return)
                    (pc)))]
"condition"
"...")
```

where condition would normally be the same condition specified on the named `return' pattern.

`untyped_return'

Untyped subroutine return instruction. This instruction pattern should be defined to support `__builtin_return` on machines where special instructions are needed to return a value of any type.

Operand 0 is a memory location where the result of calling a function with `__builtin_apply` is stored; operand 1 is a `parallel` expression where each element is a `set` expression that indicates the restoring of a function return value from the result block.

`nop'

No-op instruction. This instruction pattern name should always be defined to output a no-op in assembler code. `(const_int 0)` will do as an RTL pattern.

`indirect_jump'

An instruction to jump to an address which is operand zero. This pattern name is mandatory on all machines.

`casesi'

Instruction to jump through a dispatch table, including bounds checking. This instruction takes five operands:

The index to dispatch on, which has mode `SImode`.

The lower bound for indices in the table, an integer constant.

The total range of indices in the table--the largest index minus the smallest one (both inclusive).

A label that precedes the table itself.

A label to jump to if the index has a value outside the bounds. (If the machine-description macro `CASE_DROPS_THROUGH` is defined, then an out-of-bounds index drops through to the code following the jump table instead of jumping to this label. In that case, this label is not actually used by the `casesi' instruction, but it is always provided as an operand.)

The table is a `addr_vec` or `addr_diff_vec` inside of a `jump_insn`. The number of elements in the table is one plus the difference between the upper bound and the lower bound.

`tablejump'

Instruction to jump to a variable address. This is a low-level capability which can be used to implement a dispatch table when there is no `casesi' pattern.

This pattern requires two operands: the address or offset, and a label which should immediately precede the jump table. If the macro `CASE_VECTOR_PC_RELATIVE` is defined then the first

operand is an offset which counts from the address of the table; otherwise, it is an absolute address to jump to. In either case, the first operand has mode `Pmode`.

The `tablejump' insn is always the last insn before the jump table it uses. Its assembler code normally has no need to use the second operand, but you should incorporate it in the RTL pattern so that the jump optimizer will not delete the table as unreachable code.

`save_stack_block'

`save_stack_function'

`save_stack_nonlocal'

`restore_stack_block'

`restore_stack_function'

`restore_stack_nonlocal'

Most machines save and restore the stack pointer by copying it to or from an object of mode `Pmode`. Do not define these patterns on such machines.

Some machines require special handling for stack pointer saves and restores. On those machines, define the patterns corresponding to the non-standard cases by using a `define_expand` (see section Defining RTL Sequences for Code Generation) that produces the required insns. The three types of saves and restores are:

`save_stack_block' saves the stack pointer at the start of a block that allocates a variable-sized object, and `restore_stack_block' restores the stack pointer when the block is exited.

`save_stack_function' and `restore_stack_function' do a similar job for the outermost block of a function and are used when the function allocates variable-sized objects or calls `alloca`. Only the epilogue uses the restored stack pointer, allowing a simpler save or restore sequence on some machines.

`save_stack_nonlocal' is used in functions that contain labels branched to by nested functions. It saves the stack pointer in such a way that the inner function can use `restore_stack_nonlocal' to restore the stack pointer. The compiler generates code to restore the frame and argument pointer registers, but some machines require saving and restoring additional data such as register window information or stack backchains. Place insns in these patterns to save and restore any such required data.

When saving the stack pointer, operand 0 is the save area and operand 1 is the stack pointer. The mode used to allocate the save area is the mode of operand 0. You must specify an integral mode, or `VOIDmode` if no save area is needed for a particular type of save (either because no save is needed or because a machine-specific save area can be used). Operand 0 is the stack pointer and operand 1 is the save area for restore operations. If `save_stack_block' is defined, operand 0 must not be `VOIDmode` since these saves can be arbitrarily nested.

A save area is a `mem` that is at a constant offset from `virtual_stack_vars_rtx` when the stack pointer is saved for use by nonlocal gotos and a `reg` in the other two cases.

`allocate_stack'

Subtract (or add if `STACK_GROWS_DOWNWARD` is undefined) operand 0 from the stack pointer to create space for dynamically allocated data.

Do not define this pattern if all that must be done is the subtraction. Some machines require other operations such as stack probes or maintaining the back chain. Define this pattern to emit those operations in addition to updating the stack pointer.

When the Order of Patterns Matters

Sometimes an insn can match more than one instruction pattern. Then the pattern that appears first in the machine description is the one used. Therefore, more specific patterns (patterns that will match fewer things) and faster instructions (those that will produce better code when they do match) should usually go first in the description.

In some cases the effect of ordering the patterns can be used to hide a pattern when it is not valid. For example, the 68000 has an instruction for converting a fullword to floating point and another for converting a byte to floating point. An instruction converting an integer to floating point could match either one. We put the pattern to convert the fullword first to make sure that one will be used rather than the other. (Otherwise a large integer might be generated as a single-byte immediate quantity, which would not work.) Instead of using this pattern ordering it would be possible to make the pattern for convert-a-byte smart enough to deal properly with any constant value.

Interdependence of Patterns

Every machine description must have a named pattern for each of the conditional branch names `bcond'. The recognition template must always have the form

```
(set (pc)
     (if_then_else (cond (cc0) (const_int 0))
                   (label_ref (match_operand 0 "" ""))
                   (pc)))
```

In addition, every machine description must have an anonymous pattern for each of the possible reverse-conditional branches. Their templates look like

```
(set (pc)
     (if_then_else (cond (cc0) (const_int 0))
                   (pc)
                   (label_ref (match_operand 0 "" ""))))
```

They are necessary because jump optimization can turn direct-conditional branches into reverse-conditional branches.

It is often convenient to use the `match_operator` construct to reduce the number of patterns that must be specified for branches. For example,

```
(define_insn ""
  [(set (pc)
        (if_then_else (match_operator 0 "comparison_operator"
```

```
                                    [(cc0) (const_int 0)])
                      (pc)
                      (label_ref (match_operand 1 "" ""))))]
  "condition"
  "...")
```

In some cases machines support instructions identical except for the machine mode of one or more operands. For example, there may be "sign-extend halfword" and "sign-extend byte" instructions whose patterns are

```
(set (match_operand:SI 0 ...)
     (extend:SI (match_operand:HI 1 ...)))

(set (match_operand:SI 0 ...)
     (extend:SI (match_operand:QI 1 ...)))
```

Constant integers do not specify a machine mode, so an instruction to extend a constant value could match either pattern. The pattern it actually will match is the one that appears first in the file. For correct results, this must be the one for the widest possible mode (`HImode`, here). If the pattern matches the `QImode` instruction, the results will be incorrect if the constant value does not actually fit that mode.

Such instructions to extend constants are rarely generated because they are optimized away, but they do occasionally happen in nonoptimized compilations.

If a constraint in a pattern allows a constant, the reload pass may replace a register with a constant permitted by the constraint in some cases. Similarly for memory references. Because of this substitution, you should not provide separate patterns for increment and decrement instructions. Instead, they should be generated from the same pattern that supports register-register add insns by examining the operands and generating the appropriate machine instruction.

Defining Jump Instruction Patterns

For most machines, GNU CC assumes that the machine has a condition code. A comparison insn sets the condition code, recording the results of both signed and unsigned comparison of the given operands. A separate branch insn tests the condition code and branches or not according its value. The branch insns come in distinct signed and unsigned flavors. Many common machines, such as the Vax, the 68000 and the 32000, work this way.

Some machines have distinct signed and unsigned compare instructions, and only one set of conditional branch instructions. The easiest way to handle these machines is to treat them just like the others until the final stage where assembly code is written. At this time, when outputting code for the compare instruction, peek ahead at the following branch using `next_cc0_user (insn)`. (The variable `insn` refers to the insn being output, in the output-writing code in an instruction pattern.) If the RTL says that is an unsigned branch, output an unsigned compare; otherwise output a signed compare. When the branch itself is output, you can treat signed and unsigned branches identically.

The reason you can do this is that GNU CC always generates a pair of consecutive RTL insns, possibly separated by `note` insns, one to set the condition code and one to test it, and keeps the pair inviolate until the end.

To go with this technique, you must define the machine-description macro `NOTICE_UPDATE_CC` to do `CC_STATUS_INIT`; in other words, no compare instruction is superfluous.

Some machines have compare-and-branch instructions and no condition code. A similar technique works for them. When it is time to "output" a compare instruction, record its operands in two static variables. When outputting the branch-on-condition-code instruction that follows, actually output a compare-and-branch instruction that uses the remembered operands.

It also works to define patterns for compare-and-branch instructions. In optimizing compilation, the pair of compare and branch instructions will be combined according to these patterns. But this does not happen if optimization is not requested. So you must use one of the solutions above in addition to any special patterns you define.

In many RISC machines, most instructions do not affect the condition code and there may not even be a separate condition code register. On these machines, the restriction that the definition and use of the condition code be adjacent insns is not necessary and can prevent important optimizations. For example, on the IBM RS/6000, there is a delay for taken branches unless the condition code register is set three instructions earlier than the conditional branch. The instruction scheduler cannot perform this optimization if it is not permitted to separate the definition and use of the condition code register.

On these machines, do not use `(cc0)`, but instead use a register to represent the condition code. If there is a specific condition code register in the machine, use a hard register. If the condition code or comparison result can be placed in any general register, or if there are multiple condition registers, use a pseudo register.

On some machines, the type of branch instruction generated may depend on the way the condition code was produced; for example, on the 68k and Sparc, setting the condition code directly from an add or subtract instruction does not clear the overflow bit the way that a test instruction does, so a different branch instruction must be used for some conditional branches. For machines that use `(cc0)`, the set and use of the condition code must be adjacent (separated only by `note` insns) allowing flags in `cc_status` to be used. (See section Condition Code Status.) Also, the comparison and branch insns can be located from each other by using the functions `prev_cc0_setter` and `next_cc0_user`.

However, this is not true on machines that do not use `(cc0)`. On those machines, no assumptions can be made about the adjacency of the compare and branch insns and the above methods cannot be used. Instead, we use the machine mode of the condition code register to record different formats of the condition code register.

Registers used to store the condition code value should have a mode that is in class `MODE_CC`. Normally, it will be `CCmode`. If additional modes are required (as for the add example mentioned above in the Sparc), define the macro `EXTRA_CC_MODES` to list the additional modes required (see section Condition Code Status). Also define `EXTRA_CC_NAMES` to list the names of those modes and `SELECT_CC_MODE` to choose a mode given an operand of a compare.

If it is known during RTL generation that a different mode will be required (for example, if the machine has separate compare instructions for signed and unsigned quantities, like most IBM processors), they can be specified at that time.

If the cases that require different modes would be made by instruction combination, the macro `SELECT_CC_MODE` determines which machine mode should be used for the comparison result. The patterns should be written using that mode. To support the case of the add on the Sparc discussed above, we have the

pattern

```
(define_insn ""
  [(set (reg:CC_NOOV 0)
        (compare:CC_NOOV
          (plus:SI (match_operand:SI 0 "register_operand" "%r")
                   (match_operand:SI 1 "arith_operand" "rI"))
          (const_int 0)))]
  ""
  "...")
```

The `SELECT_CC_MODE` macro on the Sparc returns `CC_NOOVmode` for comparisons whose argument is a `plus`.

Canonicalization of Instructions

There are often cases where multiple RTL expressions could represent an operation performed by a single machine instruction. This situation is most commonly encountered with logical, branch, and multiply-accumulate instructions. In such cases, the compiler attempts to convert these multiple RTL expressions into a single canonical form to reduce the number of insn patterns required.

In addition to algebraic simplifications, following canonicalizations are performed:

- For commutative and comparison operators, a constant is always made the second operand. If a machine only supports a constant as the second operand, only patterns that match a constant in the second operand need be supplied.

  For these operators, if only one operand is a `neg`, `not`, `mult`, `plus`, or `minus` expression, it will be the first operand.
- For the `compare` operator, a constant is always the second operand on machines where `cc0` is used (see section Defining Jump Instruction Patterns). On other machines, there are rare cases where the compiler might want to construct a `compare` with a constant as the first operand. However, these cases are not common enough for it to be worthwhile to provide a pattern matching a constant as the first operand unless the machine actually has such an instruction.

  An operand of `neg`, `not`, `mult`, `plus`, or `minus` is made the first operand under the same conditions as above.
- `(minus x (const_int n))` is converted to `(plus x (const_int -n))`.
- Within address computations (i.e., inside `mem`), a left shift is converted into the appropriate multiplication by a power of two.

  De`Morgan's Law is used to move bitwise negation inside a bitwise logical-and or logical-or operation. If this results in only one operand being a `not` expression, it will be the first one.

  A machine that has an instruction that performs a bitwise logical-and of one operand with the bitwise negation of the other should specify the pattern for that instruction as

  ```
  (define_insn ""
  ```

```
  [(set (match_operand:m 0 ...)
        (and:m (not:m (match_operand:m 1 ...))
               (match_operand:m 2 ...)))]
  "..."
  "...")
```

Similarly, a pattern for a "NAND" instruction should be written

```
(define_insn ""
  [(set (match_operand:m 0 ...)
        (ior:m (not:m (match_operand:m 1 ...))
               (not:m (match_operand:m 2 ...))))]
  "..."
  "...")
```

In both cases, it is not necessary to include patterns for the many logically equivalent RTL expressions.

- The only possible RTL expressions involving both bitwise exclusive-or and bitwise negation are `(xor:m x y)` and `(not:m (xor:m x y))`.
- The sum of three items, one of which is a constant, will only appear in the form

```
(plus:m (plus:m x y) constant)
```

- On machines that do not use `cc0`, `(compare x (const_int 0))` will be converted to x.
- Equality comparisons of a group of bits (usually a single bit) with zero will be written using `zero_extract` rather than the equivalent `and` or `sign_extract` operations.

Machine-Specific Peephole Optimizers

In addition to instruction patterns the `md' file may contain definitions of machine-specific peephole optimizations.

The combiner does not notice certain peephole optimizations when the data flow in the program does not suggest that it should try them. For example, sometimes two consecutive insns related in purpose can be combined even though the second one does not appear to use a register computed in the first one. A machine-specific peephole optimizer can detect such opportunities.

A definition looks like this:

```
(define_peephole
  [insn-pattern-1
   insn-pattern-2
   ...]
  "condition"
  "template"
  "optional insn-attributes")
```

The last string operand may be omitted if you are not using any machine-specific information in this ma description. If present, it must obey the same rules as in a `define_insn`.

In this skeleton, insn-pattern-1 and so on are patterns to match consecutive insns. The optimization applies to a sequence of insns when insn-pattern-1 matches the first one, insn-pattern-2 matches the next, and so on.

Each of the insns matched by a peephole must also match a `define_insn`. Peepholes are checked only at the last stage just before code generation, and only optionally. Therefore, any insn which would match a peephole but no `define_insn` will cause a crash in code generation in an unoptimized compilation, or at various optimization stages.

The operands of the insns are matched with `match_operands`, `match_operator`, and `match_dup`, as usual. What is not usual is that the operand numbers apply to all the insn patterns in the definition. So, you can check for identical operands in two insns by using `match_operand` in one insn and `match_dup` in the other.

The operand constraints used in `match_operand` patterns do not have any direct effect on the applicability of the peephole, but they will be validated afterward, so make sure your constraints are general enough to apply whenever the peephole matches. If the peephole matches but the constraints are not satisfied, the compiler will crash.

It is safe to omit constraints in all the operands of the peephole; or you can write constraints which serve as a double-check on the criteria previously tested.

Once a sequence of insns matches the patterns, the condition is checked. This is a C expression which makes the final decision whether to perform the optimization (we do so if the expression is nonzero). If condition is omitted (in other words, the string is empty) then the optimization is applied to every sequence of insns that matches the patterns.

The defined peephole optimizations are applied after register allocation is complete. Therefore, the peephole definition can check which operands have ended up in which kinds of registers, just by looking at the operands.

The way to refer to the operands in condition is to write `operands[i]` for operand number i (as matched by `(match_operand i ...)`). Use the variable `insn` to refer to the last of the insns being matched; use `prev_nonnote_insn` to find the preceding insns.

When optimizing computations with intermediate results, you can use condition to match only when the intermediate results are not used elsewhere. Use the C expression `dead_or_set_p (insn, op)`, where insn is the insn in which you expect the value to be used for the last time (from the value of `insn`, together with use of `prev_nonnote_insn`), and op is the intermediate value (from `operands[i]`).

Applying the optimization means replacing the sequence of insns with one new insn. The template controls ultimate output of assembler code for this combined insn. It works exactly like the template of a `define_insn`. Operand numbers in this template are the same ones used in matching the original sequence of insns.

The result of a defined peephole optimizer does not need to match any of the insn patterns in the machine description; it does not even have an opportunity to match them. The peephole optimizer definition itself serves as the insn pattern to control how the insn is output.

Defined peephole optimizers are run as assembler code is being output, so the insns they produce are never

combined or rearranged in any way.

Here is an example, taken from the 68000 machine description:

```
(define_peephole
  [(set (reg:SI 15) (plus:SI (reg:SI 15) (const_int 4)))
   (set (match_operand:DF 0 "register_operand" "=f")
        (match_operand:DF 1 "register_operand" "ad"))]
  "FP_REG_P (operands[0]) && ! FP_REG_P (operands[1])"
  "*
{
  rtx xoperands[2];
  xoperands[1] = gen_rtx (REG, SImode, REGNO (operands[1]) + 1);
#ifdef MOTOROLA
  output_asm_insn (\"move.l %1,(sp)\", xoperands);
  output_asm_insn (\"move.l %1,-(sp)\", operands);
  return \"fmove.d (sp)+,%0\";
#else
  output_asm_insn (\"movel %1,sp@\", xoperands);
  output_asm_insn (\"movel %1,sp@-\", operands);
  return \"fmoved sp@+,%0\";
#endif
}
")
```

The effect of this optimization is to change

```
jbsr _foobar
addql #4,sp
movel d1,sp@-
movel d0,sp@-
fmoved sp@+,fp0
```

into

```
jbsr _foobar
movel d1,sp@
movel d0,sp@-
fmoved sp@+,fp0
```

insn-pattern-1 and so on look *almost* like the second operand of `define_insn`. There is one important difference: the second operand of `define_insn` consists of one or more RTX's enclosed in square brackets. Usually, there is only one: then the same action can be written as an element of a `define_peephole`. But when there are multiple actions in a `define_insn`, they are implicitly enclosed in a `parallel`. Then you must explicitly write the `parallel`, and the square brackets within it, in the `define_peephole`. Thus, if an insn pattern looks like this,

```
(define_insn "divmodsi4"
```

```
  [(set (match_operand:SI 0 "general_operand" "=d")
        (div:SI (match_operand:SI 1 "general_operand" "0")
                (match_operand:SI 2 "general_operand" "dmsK")))
   (set (match_operand:SI 3 "general_operand" "=d")
        (mod:SI (match_dup 1) (match_dup 2)))]
  "TARGET_68020"
  "divsl%.l %2,%3:%0")
```

then the way to mention this insn in a peephole is as follows:

```
(define_peephole
  [...
   (parallel
    [(set (match_operand:SI 0 "general_operand" "=d")
          (div:SI (match_operand:SI 1 "general_operand" "0")
                  (match_operand:SI 2 "general_operand" "dmsK")))
     (set (match_operand:SI 3 "general_operand" "=d")
          (mod:SI (match_dup 1) (match_dup 2)))])
   ...]
  ...)
```

Defining RTL Sequences for Code Generation

On some target machines, some standard pattern names for RTL generation cannot be handled with single insn, but a sequence of RTL insns can represent them. For these target machines, you can write a `define_expand` to specify how to generate the sequence of RTL.

A `define_expand` is an RTL expression that looks almost like a `define_insn`; but, unlike the latter, a `define_expand` is used only for RTL generation and it can produce more than one RTL insn.

A `define_expand` RTX has four operands:

- The name. Each `define_expand` must have a name, since the only use for it is to refer to it by name.
- The RTL template. This is just like the RTL template for a `define_peephole` in that it is a vector of RTL expressions each being one insn.
- The condition, a string containing a C expression. This expression is used to express how the availability of this pattern depends on subclasses of target machine, selected by command-line options when GNU CC is run. This is just like the condition of a `define_insn` that has a standard name. Therefore, the condition (if present) may not depend on the data in the insn being matched, but only the target-machine-type flags. The compiler needs to test these conditions during initialization in order to learn exactly which named instructions are available in a particular run.
- The preparation statements, a string containing zero or more C statements which are to be executed before RTL code is generated from the RTL template.

  Usually these statements prepare temporary registers for use as internal operands in the RTL template, but they can also generate RTL insns directly by calling routines such as `emit_insn`, etc. Any such insns precede the ones that come from the RTL template.

Every RTL insn emitted by a `define_expand` must match some `define_insn` in the machine description. Otherwise, the compiler will crash when trying to generate code for the insn or trying to optimize it.

The RTL template, in addition to controlling generation of RTL insns, also describes the operands that need to be specified when this pattern is used. In particular, it gives a predicate for each operand.

A true operand, which needs to be specified in order to generate RTL from the pattern, should be described with a `match_operand` in its first occurrence in the RTL template. This enters information on the operand's predicate into the tables that record such things. GNU CC uses the information to preload the operand into a register if that is required for valid RTL code. If the operand is referred to more than once, subsequent references should use `match_dup`.

The RTL template may also refer to internal "operands" which are temporary registers or labels used only within the sequence made by the `define_expand`. Internal operands are substituted into the RTL template with `match_dup`, never with `match_operand`. The values of the internal operands are not passed in as arguments by the compiler when it requests use of this pattern. Instead, they are computed within the pattern, in the preparation statements. These statements compute the values and store them into the appropriate elements of `operands` so that `match_dup` can find them.

There are two special macros defined for use in the preparation statements: `DONE` and `FAIL`. Use them with a following semicolon, as a statement.

`DONE`

> Use the `DONE` macro to end RTL generation for the pattern. The only RTL insns resulting from the pattern on this occasion will be those already emitted by explicit calls to `emit_insn` within the preparation statements; the RTL template will not be generated.

`FAIL`

> Make the pattern fail on this occasion. When a pattern fails, it means that the pattern was not truly available. The calling routines in the compiler will try other strategies for code generation using other patterns.
>
> Failure is currently supported only for binary (addition, multiplication, shifting, etc.) and bitfield (`extv`, `extzv`, and `insv`) operations.

Here is an example, the definition of left-shift for the SPUR chip:

```
(define_expand "ashlsi3"
  [(set (match_operand:SI 0 "register_operand" "")
        (ashift:SI
          (match_operand:SI 1 "register_operand" "")
          (match_operand:SI 2 "nonmemory_operand" "")))]
  ""
  "

{
  if (GET_CODE (operands[2]) != CONST_INT
      || (unsigned) INTVAL (operands[2]) > 3)
```

```
    FAIL;
}")
```

This example uses `define_expand` so that it can generate an RTL insn for shifting when the shift-count is in the supported range of 0 to 3 but fail in other cases where machine insns aren't available. When it fails, the compiler tries another strategy using different patterns (such as, a library call).

If the compiler were able to handle nontrivial condition-strings in patterns with names, then it would be possible to use a `define_insn` in that case. Here is another case (zero-extension on the 68000) which makes more use of the power of `define_expand`:

```
(define_expand "zero_extendhisi2"
  [(set (match_operand:SI 0 "general_operand" "")
        (const_int 0))
   (set (strict_low_part
          (subreg:HI
            (match_dup 0)
            0))
        (match_operand:HI 1 "general_operand" ""))]
  ""
  "operands[1] = make_safe_from (operands[1], operands[0]);")
```

Here two RTL insns are generated, one to clear the entire output operand and the other to copy the input operand into its low half. This sequence is incorrect if the input operand refers to [the old value of] the output operand, so the preparation statement makes sure this isn't so. The function `make_safe_from` copies the `operands[1]` into a temporary register if it refers to `operands[0]`. It does this by emitting another RTL insn.

Finally, a third example shows the use of an internal operand. Zero-extension on the SPUR chip is done by `and`-ing the result against a halfword mask. But this mask cannot be represented by a `const_int` because the constant value is too large to be legitimate on this machine. So it must be copied into a register with `force_reg` and then the register used in the `and`.

```
(define_expand "zero_extendhisi2"
  [(set (match_operand:SI 0 "register_operand" "")
        (and:SI (subreg:SI
                  (match_operand:HI 1 "register_operand" "")
                  0)
                (match_dup 2)))]
  ""
  "operands[2]
     = force_reg (SImode, gen_rtx (CONST_INT,
                                   VOIDmode, 65535)); ")
```

Note: If the `define_expand` is used to serve a standard binary or unary arithmetic operation or a bitfield operation, then the last insn it generates must not be a `code_label`, `barrier` or `note`. It must be an `insn`, `jump_insn` or `call_insn`. If you don't need a real insn at the end, emit an insn to copy the result of the operation into itself. Such an insn will generate no code, but it can avoid problems in the compiler.

Defining How to Split Instructions

There are two cases where you should specify how to split a pattern into multiple insns. On machines that have instructions requiring delay slots (see section Delay Slot Scheduling) or that have instructions whose output is not available for multiple cycles (see section Specifying Function Units), the compiler phases that optimize these cases need to be able to move insns into one-instruction delay slots. However, some insns may generate more than one machine instruction. These insns cannot be placed into a delay slot.

Often you can rewrite the single insn as a list of individual insns, each corresponding to one machine instruction. The disadvantage of doing so is that it will cause the compilation to be slower and require more space. If the resulting insns are too complex, it may also suppress some optimizations. The compiler splits the insn if there is a reason to believe that it might improve instruction or delay slot scheduling.

The insn combiner phase also splits putative insns. If three insns are merged into one insn with a complex expression that cannot be matched by some `define_insn` pattern, the combiner phase attempts to split the complex pattern into two insns that are recognized. Usually it can break the complex pattern into two patterns by splitting out some subexpression. However, in some other cases, such as performing an addition of a large constant in two insns on a RISC machine, the way to split the addition into two insns is machine-dependent.

The `define_split` definition tells the compiler how to split a complex insn into several simpler insns. It looks like this:

```
(define_split
  [insn-pattern]
  "condition"
  [new-insn-pattern-1
   new-insn-pattern-2
   ...]
  "preparation statements")
```

insn-pattern is a pattern that needs to be split and condition is the final condition to be tested, as in a `define_insn`. When an insn matching insn-pattern and satisfying condition is found, it is replaced in the insn list with the insns given by new-insn-pattern-1, new-insn-pattern-2, etc.

The preparation statements are similar to those statements that are specified for `define_expand` (see section Defining RTL Sequences for Code Generation) and are executed before the new RTL is generated to prepare for the generated code or emit some insns whose pattern is not fixed. Unlike those in `define_expand`, however, these statements must not generate any new pseudo-registers. Once reload has completed, they also must not allocate any space in the stack frame.

Patterns are matched against insn-pattern in two different circumstances. If an insn needs to be split for delay slot scheduling or insn scheduling, the insn is already known to be valid, which means that it must have been matched by some `define_insn` and, if `reload_completed` is non-zero, is known to satisfy the constraints of that `define_insn`. In that case, the new insn patterns must also be insns that are matched by some `define_insn` and, if `reload_completed` is non-zero, must also satisfy the constraints of those definitions.

As an example of this usage of `define_split`, consider the following example from `a29k.md', which splits a `sign_extend` from `HImode` to `SImode` into a pair of shift insns:

```
(define_split
  [(set (match_operand:SI 0 "gen_reg_operand" "")
        (sign_extend:SI (match_operand:HI 1 "gen_reg_operand" "")))]
  ""
  [(set (match_dup 0)
        (ashift:SI (match_dup 1)
                   (const_int 16)))
   (set (match_dup 0)
        (ashiftrt:SI (match_dup 0)
                     (const_int 16)))]
  "
{ operands[1] = gen_lowpart (SImode, operands[1]); }")
```

When the combiner phase tries to split an insn pattern, it is always the case that the pattern is *not* matched by any `define_insn`. The combiner pass first tries to split a single `set` expression and then the same `set` expression inside a `parallel`, but followed by a `clobber` of a pseudo-reg to use as a scratch register. In these cases, the combiner expects exactly two new insn patterns to be generated. It will verify that these patterns match some `define_insn` definitions, so you need not do this test in the `define_split` (of course, there is no point in writing a `define_split` that will never produce insns that match).

Here is an example of this use of `define_split`, taken from `rs6000.md':

```
(define_split
  [(set (match_operand:SI 0 "gen_reg_operand" "")
        (plus:SI (match_operand:SI 1 "gen_reg_operand" "")
                 (match_operand:SI 2 "non_add_cint_operand" "")))]
  ""
  [(set (match_dup 0) (plus:SI (match_dup 1) (match_dup 3)))
   (set (match_dup 0) (plus:SI (match_dup 0) (match_dup 4)))]
"
{
  int low = INTVAL (operands[2]) & 0xffff;
  int high = (unsigned) INTVAL (operands[2]) >> 16;

  if (low & 0x8000)
    high++, low |= 0xffff0000;

  operands[3] = gen_rtx (CONST_INT, VOIDmode, high << 16);
  operands[4] = gen_rtx (CONST_INT, VOIDmode, low);
}")
```

Here the predicate `non_add_cint_operand` matches any `const_int` that is *not* a valid operand of a single add insn. The add with the smaller displacement is written so that it can be substituted into the address of a subsequent operation.

An example that uses a scratch register, from the same file, generates an equality comparison of a regist and a large constant:

```
(define_split
  [(set (match_operand:CC 0 "cc_reg_operand" "")
        (compare:CC (match_operand:SI 1 "gen_reg_operand" "")
                    (match_operand:SI 2 "non_short_cint_operand" "")))
   (clobber (match_operand:SI 3 "gen_reg_operand" ""))]
  "find_single_use (operands[0], insn, 0)
   && (GET_CODE (*find_single_use (operands[0], insn, 0)) == EQ
       || GET_CODE (*find_single_use (operands[0], insn, 0)) == NE)"
  [(set (match_dup 3) (xor:SI (match_dup 1) (match_dup 4)))
   (set (match_dup 0) (compare:CC (match_dup 3) (match_dup 5)))]
  "
{
  /* Get the constant we are comparing against, C, and see what it
     looks like sign-extended to 16 bits.  Then see what constant
     could be XOR'ed with C to get the sign-extended value.  */

  int c = INTVAL (operands[2]);
  int sextc = (c << 16) >> 16;
  int xorv = c ^ sextc;

  operands[4] = gen_rtx (CONST_INT, VOIDmode, xorv);
  operands[5] = gen_rtx (CONST_INT, VOIDmode, sextc);
}")
```

To avoid confusion, don't write a single `define_split` that accepts some insns that match some `define_insn` as well as some insns that don't. Instead, write two separate `define_split` definitions, one for the insns that are valid and one for the insns that are not valid.

Instruction Attributes

In addition to describing the instruction supported by the target machine, the `md' file also defines a group of attributes and a set of values for each. Every generated insn is assigned a value for each attribute. One possible attribute would be the effect that the insn has on the machine's condition code. This attribute can then be used by `NOTICE_UPDATE_CC` to track the condition codes.

Defining Attributes and their Values

The `define_attr` expression is used to define each attribute required by the target machine. It looks like:

```
(define_attr name list-of-values default)
```

name is a string specifying the name of the attribute being defined.

list-of-values is either a string that specifies a comma-separated list of values that can be assigned to the

attribute, or a null string to indicate that the attribute takes numeric values.

default is an attribute expression that gives the value of this attribute for insns that match patterns whose definition does not include an explicit value for this attribute. See section Example of Attribute Specifications, for more information on the handling of defaults. See section Constant Attributes, for information on attributes that do not depend on any particular insn.

For each defined attribute, a number of definitions are written to the `insn-attr.h' file. For cases where an explicit set of values is specified for an attribute, the following are defined:

- A `#define' is written for the symbol `HAVE_ATTR_name'.
- An enumeral class is defined for `attr_name' with elements of the form `upper-name_upper-value' where the attribute name and value are first converted to upper case.
- A function `get_attr_name' is defined that is passed an insn and returns the attribute value for that insn.

For example, if the following is present in the `md' file:

```
(define_attr "type" "branch,fp,load,store,arith" ...)
```

the following lines will be written to the file `insn-attr.h'.

```
#define HAVE_ATTR_type
enum attr_type {TYPE_BRANCH, TYPE_FP, TYPE_LOAD,
                TYPE_STORE, TYPE_ARITH};
extern enum attr_type get_attr_type ();
```

If the attribute takes numeric values, no `enum` type will be defined and the function to obtain the attribute's value will return `int`.

Attribute Expressions

RTL expressions used to define attributes use the codes described above plus a few specific to attribute definitions, to be discussed below. Attribute value expressions must have one of the following forms:

`(const_int i)`

The integer i specifies the value of a numeric attribute. i must be non-negative.

The value of a numeric attribute can be specified either with a `const_int` or as an integer represented as a string in `const_string`, `eq_attr` (see below), and `set_attr` (see section Assigning Attribute Values to Insns) expressions.

`(const_string value)`

The string value specifies a constant attribute value. If value is specified as `"*"', it means that the default value of the attribute is to be used for the insn containing this expression. `"*"' obviously cannot be used in the default expression of a `define_attr`.

If the attribute whose value is being specified is numeric, value must be a string containing a non-negative integer (normally `const_int` would be used in this case). Otherwise, it must contain one of the valid values for the attribute.

`(if_then_else test true-value false-value)`

test specifies an attribute test, whose format is defined below. The value of this expression is true-value if test is true, otherwise it is false-value.

`(cond [test1 value1 ...] default)`

The first operand of this expression is a vector containing an even number of expressions and consisting of pairs of test and value expressions. The value of the `cond` expression is that of the value corresponding to the first true test expression. If none of the test expressions are true, the value of the `cond` expression is that of the default expression.

test expressions can have one of the following forms:

`(const_int i)`

This test is true if i is non-zero and false otherwise.

`(not test)`

`(ior test1 test2)`

`(and test1 test2)`

These tests are true if the indicated logical function is true.

`(match_operand:m n pred constraints)`

This test is true if operand n of the insn whose attribute value is being determined has mode m (this part of the test is ignored if m is `VOIDmode`) and the function specified by the string pred returns a non-zero value when passed operand n and mode m (this part of the test is ignored if pred is the null string).

The constraints operand is ignored and should be the null string.

`(le arith1 arith2)`

`(leu arith1 arith2)`

`(lt arith1 arith2)`

`(ltu arith1 arith2)`

`(gt arith1 arith2)`

`(gtu arith1 arith2)`

`(ge arith1 arith2)`

`(geu arith1 arith2)`

`(ne arith1 arith2)`

`(eq arith1 arith2)`

These tests are true if the indicated comparison of the two arithmetic expressions is true. Arithmetic expressions are formed with `plus`, `minus`, `mult`, `div`, `mod`, `abs`, `neg`, `and`, `ior`, `xor`, `not`, `ashift`, `lshiftrt`, and `ashiftrt` expressions.

`const_int` and `symbol_ref` are always valid terms (see section Computing the Length of an Insn,for additional forms). `symbol_ref` is a string denoting a C expression that yields an `int` when evaluated by the `get_attr_...' routine. It should normally be a global variable.

`(eq_attr name value)`

name is a string specifying the name of an attribute.

value is a string that is either a valid value for attribute name, a comma-separated list of values, or followed by a value or list. If value does not begin with a `!', this test is true if the value of the name attribute of the current insn is in the list specified by value. If value begins with a `!', this test is true if the attribute's value is *not* in the specified list.

For example,

```
(eq_attr "type" "load,store")
```

is equivalent to

```
(ior (eq_attr "type" "load") (eq_attr "type" "store"))
```

If name specifies an attribute of `alternative', it refers to the value of the compiler variable `which_alternative` (see section C Statements for Assembler Output) and the values must be small integers. For example,

```
(eq_attr "alternative" "2,3")
```

is equivalent to

```
(ior (eq (symbol_ref "which_alternative") (const_int 2))
     (eq (symbol_ref "which_alternative") (const_int 3)))
```

Note that, for most attributes, an `eq_attr` test is simplified in cases where the value of the attribute being tested is known for all insns matching a particular pattern. This is by far the most common case.

`(attr_flag name)`

The value of an `attr_flag` expression is true if the flag specified by name is true for the `insn` currently being scheduled.

name is a string specifying one of a fixed set of flags to test. Test the flags `forward` and `backward` to determine the direction of a conditional branch. Test the flags `very_likely`, `likely`, `very_unlikely`, and `unlikely` to determine if a conditional branch is expected to be taken.

If the `very_likely` flag is true, then the `likely` flag is also true. Likewise for the `very_unlikely` and `unlikely` flags.

This example describes a conditional branch delay slot which can be nullified for forward branches that are taken (annul-true) or for backward branches which are not taken (annul-false).

```
(define_delay (eq_attr "type" "cbranch")
  [(eq_attr "in_branch_delay" "true")
   (and (eq_attr "in_branch_delay" "true")
        (attr_flag "forward"))
   (and (eq_attr "in_branch_delay" "true")
        (attr_flag "backward"))])
```

The `forward` and `backward` flags are false if the current `insn` being scheduled is not a conditional branch.

The `very_likely` and `likely` flags are true if the `insn` being scheduled is not a conditional branch. The The `very_unlikely` and `unlikely` flags are false if the `insn` being scheduled is not a conditional branch.

`attr_flag` is only used during delay slot scheduling and has no meaning to other passes of the compiler.

Assigning Attribute Values to Insns

The value assigned to an attribute of an insn is primarily determined by which pattern is matched by that insn (or which `define_peephole` generated it). Every `define_insn` and `define_peephole` can have an optional last argument to specify the values of attributes for matching insns. The value of any attribute not specified in a particular insn is set to the default value for that attribute, as specified in its `define_attr`. Extensive use of default values for attributes permits the specification of the values for only one or two attributes in the definition of most insn patterns, as seen in the example in the next section.

The optional last argument of `define_insn` and `define_peephole` is a vector of expressions, each of which defines the value for a single attribute. The most general way of assigning an attribute's value is to use a `set` expression whose first operand is an `attr` expression giving the name of the attribute being set. The second operand of the `set` is an attribute expression (see section Attribute Expressions) giving the value of the attribute.

When the attribute value depends on the `alternative' attribute (i.e., which is the applicable alternative in the constraint of the insn), the `set_attr_alternative` expression can be used. It allows the specification of a vector of attribute expressions, one for each alternative.

When the generality of arbitrary attribute expressions is not required, the simpler `set_attr` expression can be used, which allows specifying a string giving either a single attribute value or a list of attribute values, one for each alternative.

The form of each of the above specifications is shown below. In each case, name is a string specifying the attribute to be set.

`(set_attr name value-string)`

value-string is either a string giving the desired attribute value, or a string containing a comma-separated list giving the values for succeeding alternatives. The number of elements must match the number of alternatives in the constraint of the insn pattern.

Note that it may be useful to specify `*' for some alternative, in which case the attribute will assume its default value for insns matching that alternative.

`(set_attr_alternative name [value1 value2 ...])`

Depending on the alternative of the insn, the value will be one of the specified values. This is a shorthand for using a `cond` with tests on the `alternative' attribute.

`(set (attr name) value)`

The first operand of this `set` must be the special RTL expression `attr`, whose sole operand is a string giving the name of the attribute being set. value is the value of the attribute.

The following shows three different ways of representing the same attribute value specification:

```
(set_attr "type" "load,store,arith")

(set_attr_alternative "type"
                      [(const_string "load") (const_string "store")
                       (const_string "arith")])

(set (attr "type")
     (cond [(eq_attr "alternative" "1") (const_string "load")
            (eq_attr "alternative" "2") (const_string "store")]
           (const_string "arith")))
```

The `define_asm_attributes` expression provides a mechanism to specify the attributes assigned to insns produced from an `asm` statement. It has the form:

```
(define_asm_attributes [attr-sets])
```

where attr-sets is specified the same as for both the `define_insn` and the `define_peephole` expressions.

These values will typically be the "worst case" attribute values. For example, they might indicate that the condition code will be clobbered.

A specification for a `length` attribute is handled specially. The way to compute the length of an `asm` insn is to multiply the length specified in the expression `define_asm_attributes` by the number of machine instructions specified in the `asm` statement, determined by counting the number of semicolons and newlines in the string. Therefore, the value of the `length` attribute specified in a `define_asm_attributes` should be the maximum possible length of a single machine instruction.

Example of Attribute Specifications

The judicious use of defaulting is important in the efficient use of insn attributes. Typically, insns are divided into types and an attribute, customarily called `type`, is used to represent this value. This attribute is normally used only to define the default value for other attributes. An example will clarify this usage.

Assume we have a RISC machine with a condition code and in which only full-word operations are performed in registers. Let us assume that we can divide all insns into loads, stores, (integer) arithmetic operations, floating point operations, and branches.

Here we will concern ourselves with determining the effect of an insn on the condition code and will limit ourselves to the following possible effects: The condition code can be set unpredictably (clobbered), not be changed, be set to agree with the results of the operation, or only changed if the item previously set into the condition code has been modified.

Here is part of a sample `` `md' `` file for such a machine:

```
(define_attr "type" "load,store,arith,fp,branch" (const_string "arith"))

(define_attr "cc" "clobber,unchanged,set,change0"
```

```
             (cond [(eq_attr "type" "load")
                        (const_string "change0")
                    (eq_attr "type" "store,branch")
                        (const_string "unchanged")
                    (eq_attr "type" "arith")
                        (if_then_else (match_operand:SI 0 "" "")
                                      (const_string "set")
                                      (const_string "clobber"))]
                   (const_string "clobber")))

(define_insn ""
  [(set (match_operand:SI 0 "general_operand" "=r,r,m")
        (match_operand:SI 1 "general_operand" "r,m,r"))]
  ""
  "@
   move %0,%1
   load %0,%1
   store %0,%1"
  [(set_attr "type" "arith,load,store")])
```

Note that we assume in the above example that arithmetic operations performed on quantities smaller than a machine word clobber the condition code since they will set the condition code to a value corresponding to the full-word result.

Computing the Length of an Insn

For many machines, multiple types of branch instructions are provided, each for different length branch displacements. In most cases, the assembler will choose the correct instruction to use. However, when the assembler cannot do so, GCC can when a special attribute, the `length' attribute, is defined. This attribute must be defined to have numeric values by specifying a null string in its `define_attr`.

In the case of the `length' attribute, two additional forms of arithmetic terms are allowed in test expressions:

`(match_dup n)`

This refers to the address of operand n of the current insn, which must be a `label_ref`.

`(pc)`

This refers to the address of the *current* insn. It might have been more consistent with other usage to make this the address of the *next* insn but this would be confusing because the length of the current insn is to be computed.

For normal insns, the length will be determined by value of the `length' attribute. In the case of `addr_vec` and `addr_diff_vec` insn patterns, the length is computed as the number of vectors multiplied by the size of each vector.

Lengths are measured in addressable storage units (bytes).

The following macros can be used to refine the length computation:

`FIRST_INSN_ADDRESS`

When the `length` insn attribute is used, this macro specifies the value to be assigned to the addr of the first insn in a function. If not specified, 0 is used.

`ADJUST_INSN_LENGTH (insn, length)`

If defined, modifies the length assigned to instruction insn as a function of the context in which it is used. length is an lvalue that contains the initially computed length of the insn and should be updated with the correct length of the insn. If updating is required, insn must not be a varying-length insn.

This macro will normally not be required. A case in which it is required is the ROMP. On this machine, the size of an `addr_vec` insn must be increased by two to compensate for the fact that alignment may be required.

The routine that returns `get_attr_length` (the value of the `length` attribute) can be used by the output routine to determine the form of the branch instruction to be written, as the example below illustrates.

As an example of the specification of variable-length branches, consider the IBM 360. If we adopt the convention that a register will be set to the starting address of a function, we can jump to labels within 4k of the start using a four-byte instruction. Otherwise, we need a six-byte sequence to load the address from memory and then branch to it.

On such a machine, a pattern for a branch instruction might be specified as follows:

```
(define_insn "jump"
  [(set (pc)
        (label_ref (match_operand 0 "" "")))]
  ""
  "*
{
   return (get_attr_length (insn) == 4
           ? \"b %l0\" : \"l r15,=a(%l0); br r15\");
}"
  [(set (attr "length") (if_then_else (lt (match_dup 0) (const_int 4096))
                                      (const_int 4)
                                      (const_int 6)))])
```

Constant Attributes

A special form of `define_attr`, where the expression for the default value is a `const` expression, indicates an attribute that is constant for a given run of the compiler. Constant attributes may be used to specify which variety of processor is used. For example,

```
(define_attr "cpu" "m88100,m88110,m88000"
 (const
  (cond [(symbol_ref "TARGET_88100") (const_string "m88100")
         (symbol_ref "TARGET_88110") (const_string "m88110")]
        (const_string "m88000"))))

(define_attr "memory" "fast,slow"
```

```
(const
 (if_then_else (symbol_ref "TARGET_FAST_MEM")
               (const_string "fast")
               (const_string "slow"))))
```

The routine generated for constant attributes has no parameters as it does not depend on any particular insn. RTL expressions used to define the value of a constant attribute may use the `symbol_ref` form, but may not use either the `match_operand` form or `eq_attr` forms involving insn attributes.

Delay Slot Scheduling

The insn attribute mechanism can be used to specify the requirements for delay slots, if any, on a target machine. An instruction is said to require a delay slot if some instructions that are physically after the instruction are executed as if they were located before it. Classic examples are branch and call instructions, which often execute the following instruction before the branch or call is performed.

On some machines, conditional branch instructions can optionally annul instructions in the delay slot. This means that the instruction will not be executed for certain branch outcomes. Both instructions that annul if the branch is true and instructions that annul if the branch is false are supported. Delay slot scheduling differs from instruction scheduling in that determining whether an instruction needs a delay slot is dependent only on the type of instruction being generated, not on data flow between the instructions. See the next section for a discussion of data-dependent instruction scheduling.

The requirement of an insn needing one or more delay slots is indicated via the `define_delay` expression. It has the following form:

```
(define_delay test
              [delay-1 annul-true-1 annul-false-1
               delay-2 annul-true-2 annul-false-2
               ...])
```

test is an attribute test that indicates whether this `define_delay` applies to a particular insn. If so, the number of required delay slots is determined by the length of the vector specified as the second argument. An insn placed in delay slot n must satisfy attribute test delay-n. annul-true-n is an attribute test that specifies which insns may be annulled if the branch is true. Similarly, annul-false-n specifies which insns in the delay slot may be annulled if the branch is false. If annulling is not supported for that delay slot, `(nil)` should be coded.

For example, in the common case where branch and call insns require a single delay slot, which may contain any insn other than a branch or call, the following would be placed in the `` `md' `` file:

```
(define_delay (eq_attr "type" "branch,call")
              [(eq_attr "type" "!branch,call") (nil) (nil)])
```

Multiple `define_delay` expressions may be specified. In this case, each such expression specifies different delay slot requirements and there must be no insn for which tests in two `define_delay` expressions are both true.

For example, if we have a machine that requires one delay slot for branches but two for calls, no delay slot

can contain a branch or call insn, and any valid insn in the delay slot for the branch can be annulled if th branch is true, we might represent this as follows:

```
(define_delay (eq_attr "type" "branch")
   [(eq_attr "type" "!branch,call")
    (eq_attr "type" "!branch,call")
    (nil)])

(define_delay (eq_attr "type" "call")
              [(eq_attr "type" "!branch,call") (nil) (nil)
               (eq_attr "type" "!branch,call") (nil) (nil)])
```

Specifying Function Units

On most RISC machines, there are instructions whose results are not available for a specific number of cycles. Common cases are instructions that load data from memory. On many machines, a pipeline stall will result if the data is referenced too soon after the load instruction.

In addition, many newer microprocessors have multiple function units, usually one for integer and one for floating point, and often will incur pipeline stalls when a result that is needed is not yet ready.

The descriptions in this section allow the specification of how much time must elapse between the execution of an instruction and the time when its result is used. It also allows specification of when the execution of an instruction will delay execution of similar instructions due to function unit conflicts.

For the purposes of the specifications in this section, a machine is divided into function units, each of which execute a specific class of instructions in first-in-first-out order. Function units that accept one instruction each cycle and allow a result to be used in the succeeding instruction (usually via forwarding) need not be specified. Classic RISC microprocessors will normally have a single function unit, which we can call `memory'. The newer "superscalar" processors will often have function units for floating point operations, usually at least a floating point adder and multiplier.

Each usage of a function units by a class of insns is specified with a `define_function_unit` expression, which looks like this:

```
(define_function_unit name multiplicity simultaneity
                      test ready-delay issue-delay
                     [conflict-list])
```

name is a string giving the name of the function unit.

multiplicity is an integer specifying the number of identical units in the processor. If more than one unit is specified, they will be scheduled independently. Only truly independent units should be counted; a pipelined unit should be specified as a single unit. (The only common example of a machine that has multiple function units for a single instruction class that are truly independent and not pipelined are the two multiply and two increment units of the CDC 6600.)

simultaneity specifies the maximum number of insns that can be executing in each instance of the function unit simultaneously or zero if the unit is pipelined and has no limit.

All `define_function_unit` definitions referring to function unit name must have the same name a values for multiplicity and simultaneity.

test is an attribute test that selects the insns we are describing in this definition. Note that an insn may use more than one function unit and a function unit may be specified in more than one `define_function_unit`.

ready-delay is an integer that specifies the number of cycles after which the result of the instruction can be used without introducing any stalls.

issue-delay is an integer that specifies the number of cycles after the instruction matching the test expression begins using this unit until a subsequent instruction can begin. A cost of N indicates an N-1 cycle delay. A subsequent instruction may also be delayed if an earlier instruction has a longer ready-delay value. This blocking effect is computed using the simultaneity, ready-delay, issue-delay, and conflict-list terms. For a normal non-pipelined function unit, simultaneity is one, the unit is taken to block for the ready-delay cycles of the executing insn, and smaller values of issue-delay are ignored.

conflict-list is an optional list giving detailed conflict costs for this unit. If specified, it is a list of condition test expressions to be applied to insns chosen to execute in name following the particular insn matching test that is already executing in name. For each insn in the list, issue-delay specifies the conflict cost; for insns not in the list, the cost is zero. If not specified, conflict-list defaults to all instructions that use the function unit.

Typical uses of this vector are where a floating point function unit can pipeline either single- or double-precision operations, but not both, or where a memory unit can pipeline loads, but not stores, etc.

As an example, consider a classic RISC machine where the result of a load instruction is not available for two cycles (a single "delay" instruction is required) and where only one load instruction can be executed simultaneously. This would be specified as:

```
(define_function_unit "memory" 1 1 (eq_attr "type" "load") 2 0)
```

For the case of a floating point function unit that can pipeline either single or double precision, but not both, the following could be specified:

```
(define_function_unit
   "fp" 1 0 (eq_attr "type" "sp_fp") 4 4 [(eq_attr "type" "dp_fp")])
(define_function_unit
   "fp" 1 0 (eq_attr "type" "dp_fp") 4 4 [(eq_attr "type" "sp_fp")])
```

Note: The scheduler attempts to avoid function unit conflicts and uses all the specifications in the `define_function_unit` expression. It has recently come to our attention that these specifications may not allow modeling of some of the newer "superscalar" processors that have insns using multiple pipelined units. These insns will cause a potential conflict for the second unit used during their execution and there is no way of representing that conflict. We welcome any examples of how function unit conflicts work in such processors and suggestions for their representation.

Target Description Macros

In addition to the file `machine.md', a machine description includes a C header file conventionally given the name `machine.h'. This header file defines numerous macros that convey the information about the target machine that does not fit into the scheme of the `.md' file. The file `tm.h' should be a link to `machine.h'. The header file `config.h' includes `tm.h' and most compiler source files include `config.h'.

Controlling the Compilation Driver, `gcc'

You can control the compilation driver.

`SWITCH_TAKES_ARG (char)`

A C expression which determines whether the option `-char' takes arguments. The value should be the number of arguments that option takes--zero, for many options.

By default, this macro is defined to handle the standard options properly. You need not define it unless you wish to add additional options which take arguments.

`WORD_SWITCH_TAKES_ARG (name)`

A C expression which determines whether the option `-name' takes arguments. The value should be the number of arguments that option takes--zero, for many options. This macro rather than `SWITCH_TAKES_ARG` is used for multi-character option names.

By default, this macro is defined as `DEFAULT_WORD_SWITCH_TAKES_ARG`, which handles the standard options properly. You need not define `WORD_SWITCH_TAKES_ARG` unless you wish to add additional options which take arguments. Any redefinition should call `DEFAULT_WORD_SWITCH_TAKES_ARG` and then check for additional options.

`SWITCHES_NEED_SPACES`

A string-valued C expression which is nonempty if the linker needs a space between the `-L' or `-o' option and its argument.

If this macro is not defined, the default value is 0.

`CPP_SPEC`

A C string constant that tells the GNU CC driver program options to pass to CPP. It can also specify how to translate options you give to GNU CC into options for GNU CC to pass to the CPP.

Do not define this macro if it does not need to do anything.

`NO_BUILTIN_SIZE_TYPE`

If this macro is defined, the preprocessor will not define the builtin macro `__SIZE_TYPE__`. The macro `__SIZE_TYPE__` must then be defined by `CPP_SPEC` instead.

This should be defined if `SIZE_TYPE` depends on target dependent flags which are not accessible

to the preprocessor. Otherwise, it should not be defined.

`NO_BUILTIN_PTRDIFF_TYPE`

If this macro is defined, the preprocessor will not define the builtin macro `__PTRDIFF_TYPE__`. The macro `__PTRDIFF_TYPE__` must then be defined by `CPP_SPEC` instead.

This should be defined if `PTRDIFF_TYPE` depends on target dependent flags which are not accessible to the preprocessor. Otherwise, it should not be defined.

`SIGNED_CHAR_SPEC`

A C string constant that tells the GNU CC driver program options to pass to CPP. By default, this macro is defined to pass the option `-D__CHAR_UNSIGNED__' to CPP if `char` will be treated as `unsigned char` by `cc1`.

Do not define this macro unless you need to override the default definition.

`CC1_SPEC`

A C string constant that tells the GNU CC driver program options to pass to `cc1`. It can also specify how to translate options you give to GNU CC into options for GNU CC to pass to the `cc1`.

Do not define this macro if it does not need to do anything.

`CC1PLUS_SPEC`

A C string constant that tells the GNU CC driver program options to pass to `cc1plus`. It can also specify how to translate options you give to GNU CC into options for GNU CC to pass to the `cc1plus`.

Do not define this macro if it does not need to do anything.

`ASM_SPEC`

A C string constant that tells the GNU CC driver program options to pass to the assembler. It can also specify how to translate options you give to GNU CC into options for GNU CC to pass to the assembler. See the file `` `sun3.h' `` for an example of this.

Do not define this macro if it does not need to do anything.

`ASM_FINAL_SPEC`

A C string constant that tells the GNU CC driver program how to run any programs which cleanup after the normal assembler. Normally, this is not needed. See the file `` `mips.h' `` for an example of this.

Do not define this macro if it does not need to do anything.

`LINK_SPEC`

A C string constant that tells the GNU CC driver program options to pass to the linker. It can also specify how to translate options you give to GNU CC into options for GNU CC to pass to the linker.

Do not define this macro if it does not need to do anything.

`LIB_SPEC`

Another C string constant used much like `LINK_SPEC`. The difference between the two is that

`LIB_SPEC` is used at the end of the command given to the linker.

If this macro is not defined, a default is provided that loads the standard C library from the usual place. See `gcc.c'.

`LIBGCC_SPEC`

Another C string constant that tells the GNU CC driver program how and when to place a reference to `libgcc.a' into the linker command line. This constant is placed both before and after the value of `LIB_SPEC`.

If this macro is not defined, the GNU CC driver provides a default that passes the string `-lgcc' to the linker unless the `-shared' option is specified.

`STARTFILE_SPEC`

Another C string constant used much like `LINK_SPEC`. The difference between the two is that `STARTFILE_SPEC` is used at the very beginning of the command given to the linker.

If this macro is not defined, a default is provided that loads the standard C startup file from the usual place. See `gcc.c'.

`ENDFILE_SPEC`

Another C string constant used much like `LINK_SPEC`. The difference between the two is that `ENDFILE_SPEC` is used at the very end of the command given to the linker.

Do not define this macro if it does not need to do anything.

`LINK_LIBGCC_SPECIAL`

Define this macro meaning that `gcc` should find the library `libgcc.a' by hand, rather than passing the argument `-lgcc' to tell the linker to do the search; also, `gcc` should not generate `-L' options to pass to the linker (as it normally does).

`LINK_LIBGCC_SPECIAL_1`

Define this macro meaning that `gcc` should find the library `libgcc.a' by hand, rather than passing the argument `-lgcc' to tell the linker to do the search.

`RELATIVE_PREFIX_NOT_LINKDIR`

Define this macro to tell `gcc` that it should only translate a `-B' prefix into a `-L' linker option if the prefix indicates an absolute file name.

`STANDARD_EXEC_PREFIX`

Define this macro as a C string constant if you wish to override the standard choice of `/usr/local/lib/gcc-lib/' as the default prefix to try when searching for the executable files of the compiler.

`MD_EXEC_PREFIX`

If defined, this macro is an additional prefix to try after `STANDARD_EXEC_PREFIX`. `MD_EXEC_PREFIX` is not searched when the `-b' option is used, or the compiler is built as a cross compiler.

`STANDARD_STARTFILE_PREFIX`

Define this macro as a C string constant if you wish to override the standard choice of

`/usr/local/lib/' as the default prefix to try when searching for startup files such as `crt0.o'.

`MD_STARTFILE_PREFIX`

If defined, this macro supplies an additional prefix to try after the standard prefixes. `MD_EXEC_PREFIX` is not searched when the `-b' option is used, or when the compiler is built as a cross compiler.

`MD_STARTFILE_PREFIX_1`

If defined, this macro supplies yet another prefix to try after the standard prefixes. It is not searched when the `-b' option is used, or when the compiler is built as a cross compiler.

`INIT_ENVIRONMENT`

Define this macro as a C string constant if you with to set environment variables for programs called by the driver, such as the assembler and loader. The driver passes the value of this macro to `putenv` to initialize the necessary environment variables.

`LOCAL_INCLUDE_DIR`

Define this macro as a C string constant if you wish to override the standard choice of `/usr/local/include' as the default prefix to try when searching for local header files. `LOCAL_INCLUDE_DIR` comes before `SYSTEM_INCLUDE_DIR` in the search order.

Cross compilers do not use this macro and do not search either `/usr/local/include' or its replacement.

`SYSTEM_INCLUDE_DIR`

Define this macro as a C string constant if you wish to specify a system-specific directory to search for header files before the standard directory. `SYSTEM_INCLUDE_DIR` comes before `STANDARD_INCLUDE_DIR` in the search order.

Cross compilers do not use this macro and do not search the directory specified.

`STANDARD_INCLUDE_DIR`

Define this macro as a C string constant if you wish to override the standard choice of `/usr/include' as the default prefix to try when searching for header files.

Cross compilers do not use this macro and do not search either `/usr/include' or its replacement.

`INCLUDE_DEFAULTS`

Define this macro if you wish to override the entire default search path for include files. The default search path includes `GCC_INCLUDE_DIR`, `LOCAL_INCLUDE_DIR`, `SYSTEM_INCLUDE_DIR`, `GPLUSPLUS_INCLUDE_DIR`, and `STANDARD_INCLUDE_DIR`. In addition, `GPLUSPLUS_INCLUDE_DIR` and `GCC_INCLUDE_DIR` are defined automatically by `Makefile', and specify private search areas for GCC. The directory `GPLUSPLUS_INCLUDE_DIR` is used only for C++ programs.

The definition should be an initializer for an array of structures. Each array element should have two elements: the directory name (a string constant) and a flag for C++-only directories. Mark the end of the array with a null element. For example, here is the definition used for VMS:

```
#define INCLUDE_DEFAULTS \
{                                       \
  { "GNU_GXX_INCLUDE:", 1},             \
  { "GNU_CC_INCLUDE:", 0},              \
  { "SYS$SYSROOT:[SYSLIB.]", 0},        \
  { ".", 0},                            \
  { 0, 0}                               \
}
```

Here is the order of prefixes tried for exec files:

1. Any prefixes specified by the user with `-B'.
2. The environment variable `GCC_EXEC_PREFIX`, if any.
3. The directories specified by the environment variable `COMPILER_PATH`.
4. The macro `STANDARD_EXEC_PREFIX`.
5. `/usr/lib/gcc/'.
6. The macro `MD_EXEC_PREFIX`, if any.

Here is the order of prefixes tried for startfiles:

1. Any prefixes specified by the user with `-B'.
2. The environment variable `GCC_EXEC_PREFIX`, if any.
3. The directories specified by the environment variable `LIBRARY_PATH` (native only, cross compilers do not use this).
4. The macro `STANDARD_EXEC_PREFIX`.
5. `/usr/lib/gcc/'.
6. The macro `MD_EXEC_PREFIX`, if any.
7. The macro `MD_STARTFILE_PREFIX`, if any.
8. The macro `STANDARD_STARTFILE_PREFIX`.
9. `/lib/'.
10. `/usr/lib/'.

Run-time Target Specification

Here are run-time target specifications.

`CPP_PREDEFINES`

Define this to be a string constant containing `-D' options to define the predefined macros that identify this machine and system. These macros will be predefined unless the `-ansi' option is specified.

In addition, a parallel set of macros are predefined, whose names are made by appending `__' at the beginning and at the end. These `__' macros are permitted by the ANSI standard, so they are

predefined regardless of whether `-ansi' is specified.

For example, on the Sun, one can use the following value:

```
"-Dmc68000 -Dsun -Dunix"
```

The result is to define the macros `__mc68000__`, `__sun__` and `__unix__` unconditionally, and the macros `mc68000`, `sun` and `unix` provided `-ansi' is not specified.

`extern int target_flags;`

This declaration should be present.

`TARGET_...`

This series of macros is to allow compiler command arguments to enable or disable the use of optional features of the target machine. For example, one machine description serves both the 68000 and the 68020; a command argument tells the compiler whether it should use 68020-only instructions or not. This command argument works by means of a macro `TARGET_68020` that tests a bit in `target_flags`.

Define a macro `TARGET_featurename` for each such option. Its definition should test a bit in `target_flags`; for example:

```
#define TARGET_68020 (target_flags & 1)
```

One place where these macros are used is in the condition-expressions of instruction patterns. Note how `TARGET_68020` appears frequently in the 68000 machine description file, `m68k.md'. Another place they are used is in the definitions of the other macros in the `machine.h' file.

`TARGET_SWITCHES`

This macro defines names of command options to set and clear bits in `target_flags`. Its definition is an initializer with a subgrouping for each command option.

Each subgrouping contains a string constant, that defines the option name, and a number, which contains the bits to set in `target_flags`. A negative number says to clear bits instead; the negative of the number is which bits to clear. The actual option name is made by appending `-m' to the specified name.

One of the subgroupings should have a null string. The number in this grouping is the default value for `target_flags`. Any target options act starting with that value.

Here is an example which defines `-m68000' and `-m68020' with opposite meanings, and picks the latter as the default:

```
#define TARGET_SWITCHES \
  { { "68020", 1},      \
    { "68000", -1},     \
    { "", 1}}
```

`TARGET_OPTIONS`

This macro is similar to `TARGET_SWITCHES` but defines names of command options that ha values. Its definition is an initializer with a subgrouping for each command option.

Each subgrouping contains a string constant, that defines the fixed part of the option name, and the address of a variable. The variable, type `char *`, is set to the variable part of the given option if the fixed part matches. The actual option name is made by appending `-m' to the specified name.

Here is an example which defines `-mshort-data-number'. If the given option is `-mshort-data-512', the variable `m88k_short_data` will be set to the string `"512"`.

```
extern char *m88k_short_data;
#define TARGET_OPTIONS \
 { { "short-data-", &m88k_short_data } }
```

`TARGET_VERSION`

This macro is a C statement to print on `stderr` a string describing the particular machine description choice. Every machine description should define `TARGET_VERSION`. For example:

```
#ifdef MOTOROLA
#define TARGET_VERSION \
  fprintf (stderr, " (68k, Motorola syntax)");
#else
#define TARGET_VERSION \
  fprintf (stderr, " (68k, MIT syntax)");
#endif
```

`OVERRIDE_OPTIONS`

Sometimes certain combinations of command options do not make sense on a particular target machine. You can define a macro `OVERRIDE_OPTIONS` to take account of this. This macro, if defined, is executed once just after all the command options have been parsed.

Don't use this macro to turn on various extra optimizations for `-O'. That is what `OPTIMIZATION_OPTIONS` is for.

`OPTIMIZATION_OPTIONS (level)`

Some machines may desire to change what optimizations are performed for various optimization levels. This macro, if defined, is executed once just after the optimization level is determined and before the remainder of the command options have been parsed. Values set in this macro are used as the default values for the other command line options.

level is the optimization level specified; 2 if `-O2' is specified, 1 if `-O' is specified, and 0 if neither is specified.

You should not use this macro to change options that are not machine-specific. These should uniformly selected by the same optimization level on all supported machines. Use this macro to enable machbine-specific optimizations.

Do not examine `write_symbols` in this macro! The debugging options are not supposed to alter the generated code.

`CAN_DEBUG_WITHOUT_FP`

Define this macro if debugging can be performed even without a frame pointer. If this macro is defined, GNU CC will turn on the `-fomit-frame-pointer' option whenever `-O' is specified.

Storage Layout

Note that the definitions of the macros in this table which are sizes or alignments measured in bits do not need to be constant. They can be C expressions that refer to static variables, such as the `target_flags`. See section Run-time Target Specification.

`BITS_BIG_ENDIAN`

Define this macro to have the value 1 if the most significant bit in a byte has the lowest number; otherwise define it to have the value zero. This means that bit-field instructions count from the most significant bit. If the machine has no bit-field instructions, then this must still be defined, but it doesn't matter which value it is defined to. This macro need not be a constant.

This macro does not affect the way structure fields are packed into bytes or words; that is controlled by `BYTES_BIG_ENDIAN`.

`BYTES_BIG_ENDIAN`

Define this macro to have the value 1 if the most significant byte in a word has the lowest number. This macro need not be a constant.

`WORDS_BIG_ENDIAN`

Define this macro to have the value 1 if, in a multiword object, the most significant word has the lowest number. This applies to both memory locations and registers; GNU CC fundamentally assumes that the order of words in memory is the same as the order in registers. This macro need not be a constant.

`LIBGCC2_WORDS_BIG_ENDIAN`

Define this macro if WORDS_BIG_ENDIAN is not constant. This must be a constant value with the same meaning as WORDS_BIG_ENDIAN, which will be used only when compiling libgcc2.c. Typically the value will be set based on preprocessor defines.

`FLOAT_WORDS_BIG_ENDIAN`

Define this macro to have the value 1 if `DFmode`, `XFmode` or `TFmode` floating point numbers are stored in memory with the word containing the sign bit at the lowest address; otherwise define it to have the value 0. This macro need not be a constant.

You need not define this macro if the ordering is the same as for multi-word integers.

`BITS_PER_UNIT`

Define this macro to be the number of bits in an addressable storage unit (byte); normally 8.

`BITS_PER_WORD`

Number of bits in a word; normally 32.

`MAX_BITS_PER_WORD`

Maximum number of bits in a word. If this is undefined, the default is `BITS_PER_WORD`.

Otherwise, it is the constant value that is the largest value that `BITS_PER_WORD` can have at run-time.

`UNITS_PER_WORD`

Number of storage units in a word; normally 4.

`MIN_UNITS_PER_WORD`

Minimum number of units in a word. If this is undefined, the default is `UNITS_PER_WORD`. Otherwise, it is the constant value that is the smallest value that `UNITS_PER_WORD` can have at run-time.

`POINTER_SIZE`

Width of a pointer, in bits. You must specify a value no wider than the width of `Pmode`. If it is not equal to the width of `Pmode`, you must define `POINTERS_EXTEND_UNSIGNED`.

`POINTERS_EXTEND_UNSIGNED`

A C expression whose value is nonzero if pointers that need to be extended from being `POINTER_SIZE` bits wide to `Pmode` are sign-extended and zero if they are zero-extended.

You need not define this macro if the `POINTER_SIZE` is equal to the width of `Pmode`.

`PROMOTE_MODE (m, unsignedp, type)`

A macro to update m and unsignedp when an object whose type is type and which has the specified mode and signedness is to be stored in a register. This macro is only called when type is a scalar type.

On most RISC machines, which only have operations that operate on a full register, define this macro to set m to `word_mode` if m is an integer mode narrower than `BITS_PER_WORD`. In most cases, only integer modes should be widened because wider-precision floating-point operations are usually more expensive than their narrower counterparts.

For most machines, the macro definition does not change unsignedp. However, some machines, have instructions that preferentially handle either signed or unsigned quantities of certain modes. For example, on the DEC Alpha, 32-bit loads from memory and 32-bit add instructions sign-extend the result to 64 bits. On such machines, set unsignedp according to which kind of extension is more efficient.

Do not define this macro if it would never modify m.

`PROMOTE_FUNCTION_ARGS`

Define this macro if the promotion described by `PROMOTE_MODE` should also be done for outgoing function arguments.

`PROMOTE_FUNCTION_RETURN`

Define this macro if the promotion described by `PROMOTE_MODE` should also be done for the return value of functions.

If this macro is defined, `FUNCTION_VALUE` must perform the same promotions done by `PROMOTE_MODE`.

`PROMOTE_FOR_CALL_ONLY`

Define this macro if the promotion described by `PROMOTE_MODE` should *only* be performed f outgoing function arguments or function return values, as specified by `PROMOTE_FUNCTION_ARGS` and `PROMOTE_FUNCTION_RETURN`, respectively.

`PARM_BOUNDARY`

Normal alignment required for function parameters on the stack, in bits. All stack parameters receive at least this much alignment regardless of data type. On most machines, this is the same as the size of an integer.

`STACK_BOUNDARY`

Define this macro if you wish to preserve a certain alignment for the stack pointer. The definition is a C expression for the desired alignment (measured in bits).

If `PUSH_ROUNDING` is not defined, the stack will always be aligned to the specified boundary. If `PUSH_ROUNDING` is defined and specifies a less strict alignment than `STACK_BOUNDARY`, the stack may be momentarily unaligned while pushing arguments.

`FUNCTION_BOUNDARY`

Alignment required for a function entry point, in bits.

`BIGGEST_ALIGNMENT`

Biggest alignment that any data type can require on this machine, in bits.

`BIGGEST_FIELD_ALIGNMENT`

Biggest alignment that any structure field can require on this machine, in bits. If defined, this overrides `BIGGEST_ALIGNMENT` for structure fields only.

`MAX_OFILE_ALIGNMENT`

Biggest alignment supported by the object file format of this machine. Use this macro to limit the alignment which can be specified using the `__attribute__ ((aligned (n)))` construct. If not defined, the default value is `BIGGEST_ALIGNMENT`.

`DATA_ALIGNMENT (type, basic-align)`

If defined, a C expression to compute the alignment for a static variable. type is the data type, and basic-align is the alignment that the object would ordinarily have. The value of this macro is used instead of that alignment to align the object.

If this macro is not defined, then basic-align is used.

One use of this macro is to increase alignment of medium-size data to make it all fit in fewer cache lines. Another is to cause character arrays to be word-aligned so that `strcpy` calls that copy constants to character arrays can be done inline.

`CONSTANT_ALIGNMENT (constant, basic-align)`

If defined, a C expression to compute the alignment given to a constant that is being placed in memory. constant is the constant and basic-align is the alignment that the object would ordinarily have. The value of this macro is used instead of that alignment to align the object.

If this macro is not defined, then basic-align is used.

The typical use of this macro is to increase alignment for string constants to be word aligned so

that `strcpy` calls that copy constants can be done inline.

`EMPTY_FIELD_BOUNDARY`

Alignment in bits to be given to a structure bit field that follows an empty field such as `int : 0;`.

Note that `PCC_BITFIELD_TYPE_MATTERS` also affects the alignment that results from an empty field.

`STRUCTURE_SIZE_BOUNDARY`

Number of bits which any structure or union's size must be a multiple of. Each structure or union's size is rounded up to a multiple of this.

If you do not define this macro, the default is the same as `BITS_PER_UNIT`.

`STRICT_ALIGNMENT`

Define this macro to be the value 1 if instructions will fail to work if given data not on the nominal alignment. If instructions will merely go slower in that case, define this macro as 0.

`PCC_BITFIELD_TYPE_MATTERS`

Define this if you wish to imitate the way many other C compilers handle alignment of bitfields and the structures that contain them.

The behavior is that the type written for a bitfield (`int`, `short`, or other integer type) imposes an alignment for the entire structure, as if the structure really did contain an ordinary field of that type. In addition, the bitfield is placed within the structure so that it would fit within such a field, not crossing a boundary for it.

Thus, on most machines, a bitfield whose type is written as `int` would not cross a four-byte boundary, and would force four-byte alignment for the whole structure. (The alignment used may not be four bytes; it is controlled by the other alignment parameters.)

If the macro is defined, its definition should be a C expression; a nonzero value for the expression enables this behavior.

Note that if this macro is not defined, or its value is zero, some bitfields may cross more than one alignment boundary. The compiler can support such references if there are `insv', `extv', and `extzv' insns that can directly reference memory.

The other known way of making bitfields work is to define `STRUCTURE_SIZE_BOUNDARY` as large as `BIGGEST_ALIGNMENT`. Then every structure can be accessed with fullwords.

Unless the machine has bitfield instructions or you define `STRUCTURE_SIZE_BOUNDARY` that way, you must define `PCC_BITFIELD_TYPE_MATTERS` to have a nonzero value.

If your aim is to make GNU CC use the same conventions for laying out bitfields as are used by another compiler, here is how to investigate what the other compiler does. Compile and run this program:

```
struct foo1
{
```

```
  char x;
  char :0;
  char y;
};

struct foo2
{
  char x;
  int :0;
  char y;
};

main ()
{
  printf ("Size of foo1 is %d\n",
          sizeof (struct foo1));
  printf ("Size of foo2 is %d\n",
          sizeof (struct foo2));
  exit (0);
}
```

If this prints 2 and 5, then the compiler's behavior is what you would get from `PCC_BITFIELD_TYPE_MATTERS`.

`BITFIELD_NBYTES_LIMITED`

Like PCC_BITFIELD_TYPE_MATTERS except that its effect is limited to aligning a bitfield within the structure.

`ROUND_TYPE_SIZE (struct, size, align)`

Define this macro as an expression for the overall size of a structure (given by struct as a tree node) when the size computed from the fields is size and the alignment is align.

The default is to round size up to a multiple of align.

`ROUND_TYPE_ALIGN (struct, computed, specified)`

Define this macro as an expression for the alignment of a structure (given by struct as a tree node) if the alignment computed in the usual way is computed and the alignment explicitly specified was specified.

The default is to use specified if it is larger; otherwise, use the smaller of computed and `BIGGEST_ALIGNMENT`

`MAX_FIXED_MODE_SIZE`

An integer expression for the size in bits of the largest integer machine mode that should actually be used. All integer machine modes of this size or smaller can be used for structures and unions with the appropriate sizes. If this macro is undefined, `GET_MODE_BITSIZE (DImode)` is assumed.

`CHECK_FLOAT_VALUE (mode, value, overflow)`

A C statement to validate the value value (of type `double`) for mode mode. This means that y check whether value fits within the possible range of values for mode mode on this target mac The mode mode is always a mode of class `MODE_FLOAT`. overflow is nonzero if the value is already known to be out of range.

If value is not valid or if overflow is nonzero, you should set overflow to 1 and then assign some valid value to value. Allowing an invalid value to go through the compiler can produce incorrect assembler code which may even cause Unix assemblers to crash.

This macro need not be defined if there is no work for it to do.

`TARGET_FLOAT_FORMAT`

A code distinguishing the floating point format of the target machine. There are three defined values:

`IEEE_FLOAT_FORMAT`

This code indicates IEEE floating point. It is the default; there is no need to define this macro when the format is IEEE.

`VAX_FLOAT_FORMAT`

This code indicates the peculiar format used on the Vax.

`UNKNOWN_FLOAT_FORMAT`

This code indicates any other format.

The value of this macro is compared with `HOST_FLOAT_FORMAT` (see section The Configuration File) to determine whether the target machine has the same format as the host machine. If any other formats are actually in use on supported machines, new codes should be defined for them.

The ordering of the component words of floating point values stored in memory is controlled by `FLOAT_WORDS_BIG_ENDIAN` for the target machine and `HOST_FLOAT_WORDS_BIG_ENDIAN` for the host.

Layout of Source Language Data Types

These macros define the sizes and other characteristics of the standard basic data types used in programs being compiled. Unlike the macros in the previous section, these apply to specific features of C and related languages, rather than to fundamental aspects of storage layout.

`INT_TYPE_SIZE`

A C expression for the size in bits of the type `int` on the target machine. If you don't define this, the default is one word.

`MAX_INT_TYPE_SIZE`

Maximum number for the size in bits of the type `int` on the target machine. If this is undefined, the default is `INT_TYPE_SIZE`. Otherwise, it is the constant value that is the largest value that `INT_TYPE_SIZE` can have at run-time. This is used in `cpp`.

`SHORT_TYPE_SIZE`

A C expression for the size in bits of the type `short` on the target machine. If you don't defin this, the default is half a word. (If this would be less than one storage unit, it is rounded up to c unit.)

`LONG_TYPE_SIZE`

A C expression for the size in bits of the type `long` on the target machine. If you don't define this, the default is one word.

`MAX_LONG_TYPE_SIZE`

Maximum number for the size in bits of the type `long` on the target machine. If this is undefined, the default is `LONG_TYPE_SIZE`. Otherwise, it is the constant value that is the largest value that `LONG_TYPE_SIZE` can have at run-time. This is used in `cpp`.

`LONG_LONG_TYPE_SIZE`

A C expression for the size in bits of the type `long long` on the target machine. If you don't define this, the default is two words. If you want to support GNU Ada on your machine, the value of macro must be at least 64.

`CHAR_TYPE_SIZE`

A C expression for the size in bits of the type `char` on the target machine. If you don't define this, the default is one quarter of a word. (If this would be less than one storage unit, it is rounded up to one unit.)

`MAX_CHAR_TYPE_SIZE`

Maximum number for the size in bits of the type `char` on the target machine. If this is undefined, the default is `CHAR_TYPE_SIZE`. Otherwise, it is the constant value that is the largest value that `CHAR_TYPE_SIZE` can have at run-time. This is used in `cpp`.

`FLOAT_TYPE_SIZE`

A C expression for the size in bits of the type `float` on the target machine. If you don't define this, the default is one word.

`DOUBLE_TYPE_SIZE`

A C expression for the size in bits of the type `double` on the target machine. If you don't define this, the default is two words.

`LONG_DOUBLE_TYPE_SIZE`

A C expression for the size in bits of the type `long double` on the target machine. If you don't define this, the default is two words.

`DEFAULT_SIGNED_CHAR`

An expression whose value is 1 or 0, according to whether the type `char` should be signed or unsigned by default. The user can always override this default with the options `-fsigned-char' and `-funsigned-char'.

`DEFAULT_SHORT_ENUMS`

A C expression to determine whether to give an `enum` type only as many bytes as it takes to represent the range of possible values of that type. A nonzero value means to do that; a zero value means all `enum` types should be allocated like `int`.

If you don't define the macro, the default is 0.

`SIZE_TYPE`

A C expression for a string describing the name of the data type to use for size values. The typedef name `size_t` is defined using the contents of the string.

The string can contain more than one keyword. If so, separate them with spaces, and write first any length keyword, then `unsigned` if appropriate, and finally `int`. The string must exactly match one of the data type names defined in the function `init_decl_processing` in the file `` `c-decl.c' ``. You may not omit `int` or change the order--that would cause the compiler to crash on startup.

If you don't define this macro, the default is `"long unsigned int"`.

`PTRDIFF_TYPE`

A C expression for a string describing the name of the data type to use for the result of subtracting two pointers. The typedef name `ptrdiff_t` is defined using the contents of the string. See `SIZE_TYPE` above for more information.

If you don't define this macro, the default is `"long int"`.

`WCHAR_TYPE`

A C expression for a string describing the name of the data type to use for wide characters. The typedef name `wchar_t` is defined using the contents of the string. See `SIZE_TYPE` above for more information.

If you don't define this macro, the default is `"int"`.

`WCHAR_TYPE_SIZE`

A C expression for the size in bits of the data type for wide characters. This is used in `cpp`, which cannot make use of `WCHAR_TYPE`.

`MAX_WCHAR_TYPE_SIZE`

Maximum number for the size in bits of the data type for wide characters. If this is undefined, the default is `WCHAR_TYPE_SIZE`. Otherwise, it is the constant value that is the largest value that `WCHAR_TYPE_SIZE` can have at run-time. This is used in `cpp`.

`OBJC_INT_SELECTORS`

Define this macro if the type of Objective C selectors should be `int`.

If this macro is not defined, then selectors should have the type `struct objc_selector *`.

`OBJC_SELECTORS_WITHOUT_LABELS`

Define this macro if the compiler can group all the selectors together into a vector and use just one label at the beginning of the vector. Otherwise, the compiler must give each selector its own assembler label.

On certain machines, it is important to have a separate label for each selector because this enables the linker to eliminate duplicate selectors.

`TARGET_BELL`

A C constant expression for the integer value for escape sequence `\a'.

`TARGET_BS`

`TARGET_TAB`

`TARGET_NEWLINE`

C constant expressions for the integer values for escape sequences `\b', `\t' and `\n'.

`TARGET_VT`

`TARGET_FF`

`TARGET_CR`

C constant expressions for the integer values for escape sequences `\v', `\f' and `\r'.

Register Usage

This section explains how to describe what registers the target machine has, and how (in general) they can be used.

The description of which registers a specific instruction can use is done with register classes; see section Register Classes. For information on using registers to access a stack frame, see section Registers That Address the Stack Frame. For passing values in registers, see section Passing Arguments in Registers. For returning values in registers, see section How Scalar Function Values Are Returned.

Basic Characteristics of Registers

Registers have various characteristics.

`FIRST_PSEUDO_REGISTER`

Number of hardware registers known to the compiler. They receive numbers 0 through `FIRST_PSEUDO_REGISTER-1`; thus, the first pseudo register's number really is assigned the number `FIRST_PSEUDO_REGISTER`.

`FIXED_REGISTERS`

An initializer that says which registers are used for fixed purposes all throughout the compiled code and are therefore not available for general allocation. These would include the stack pointer, the frame pointer (except on machines where that can be used as a general register when no frame pointer is needed), the program counter on machines where that is considered one of the addressable registers, and any other numbered register with a standard use.

This information is expressed as a sequence of numbers, separated by commas and surrounded by braces. The nth number is 1 if register n is fixed, 0 otherwise.

The table initialized from this macro, and the table initialized by the following one, may be overridden at run time either automatically, by the actions of the macro `CONDITIONAL_REGISTER_USAGE`, or by the user with the command options `-ffixed-reg', `-fcall-used-reg' and `-fcall-saved-reg'.

`CALL_USED_REGISTERS`

Like `FIXED_REGISTERS` but has 1 for each register that is clobbered (in general) by function calls as well as for fixed registers. This macro therefore identifies the registers that are not

available for general allocation of values that must live across function calls.

If a register has 0 in `CALL_USED_REGISTERS`, the compiler automatically saves it on function entry and restores it on function exit, if the register is used within the function.

`CONDITIONAL_REGISTER_USAGE`

Zero or more C statements that may conditionally modify two variables `fixed_regs` and `call_used_regs` (both of type `char []`) after they have been initialized from the two preceding macros.

This is necessary in case the fixed or call-clobbered registers depend on target flags.

You need not define this macro if it has no work to do.

If the usage of an entire class of registers depends on the target flags, you may indicate this to GCC by using this macro to modify `fixed_regs` and `call_used_regs` to 1 for each of the registers in the classes which should not be used by GCC. Also define the macro `REG_CLASS_FROM_LETTER` to return `NO_REGS` if it is called with a letter for a class that shouldn't be used.

(However, if this class is not included in `GENERAL_REGS` and all of the insn patterns whose constraints permit this class are controlled by target switches, then GCC will automatically avoid using these registers when the target switches are opposed to them.)

`NON_SAVING_SETJMP`

If this macro is defined and has a nonzero value, it means that `setjmp` and related functions fail to save the registers, or that `longjmp` fails to restore them. To compensate, the compiler avoids putting variables in registers in functions that use `setjmp`.

`INCOMING_REGNO (out)`

Define this macro if the target machine has register windows. This C expression returns the register number as seen by the called function corresponding to the register number out as seen by the calling function. Return out if register number out is not an outbound register.

`OUTGOING_REGNO (in)`

Define this macro if the target machine has register windows. This C expression returns the register number as seen by the calling function corresponding to the register number in as seen by the called function. Return in if register number in is not an inbound register.

Order of Allocation of Registers

Registers are allocated in order.

`REG_ALLOC_ORDER`

If defined, an initializer for a vector of integers, containing the numbers of hard registers in the order in which GNU CC should prefer to use them (from most preferred to least).

If this macro is not defined, registers are used lowest numbered first (all else being equal).

One use of this macro is on machines where the highest numbered registers must always be saved

and the save-multiple-registers instruction supports only sequences of consecutive registers. O such machines, define `REG_ALLOC_ORDER` to be an initializer that lists the highest numbere allocatable register first.

`ORDER_REGS_FOR_LOCAL_ALLOC`

A C statement (sans semicolon) to choose the order in which to allocate hard registers for pseudo-registers local to a basic block.

Store the desired register order in the array `reg_alloc_order`. Element 0 should be the register to allocate first; element 1, the next register; and so on.

The macro body should not assume anything about the contents of `reg_alloc_order` before execution of the macro.

On most machines, it is not necessary to define this macro.

How Values Fit in Registers

This section discusses the macros that describe which kinds of values (specifically, which machine modes) each register can hold, and how many consecutive registers are needed for a given mode.

`HARD_REGNO_NREGS (regno, mode)`

A C expression for the number of consecutive hard registers, starting at register number regno, required to hold a value of mode mode.

On a machine where all registers are exactly one word, a suitable definition of this macro is

```
#define HARD_REGNO_NREGS(REGNO, MODE)            \
   ((GET_MODE_SIZE (MODE) + UNITS_PER_WORD - 1)  \
    / UNITS_PER_WORD))
```

`HARD_REGNO_MODE_OK (regno, mode)`

A C expression that is nonzero if it is permissible to store a value of mode mode in hard register number regno (or in several registers starting with that one). For a machine where all registers are equivalent, a suitable definition is

```
#define HARD_REGNO_MODE_OK(REGNO, MODE) 1
```

It is not necessary for this macro to check for the numbers of fixed registers, because the allocation mechanism considers them to be always occupied.

On some machines, double-precision values must be kept in even/odd register pairs. The way to implement that is to define this macro to reject odd register numbers for such modes.

The minimum requirement for a mode to be OK in a register is that the `movmode' instruction pattern support moves between the register and any other hard register for which the mode is OK; and that moving a value into the register and back out not alter it.

Since the same instruction used to move `SImode` will work for all narrower integer modes, it is

not necessary on any machine for `HARD_REGNO_MODE_OK` to distinguish between these mo provided you define patterns `movhi', etc., to take advantage of this. This is useful because of t interaction between `HARD_REGNO_MODE_OK` and `MODES_TIEABLE_P`; it is very desirable for all integer modes to be tieable.

Many machines have special registers for floating point arithmetic. Often people assume that floating point machine modes are allowed only in floating point registers. This is not true. Any registers that can hold integers can safely *hold* a floating point machine mode, whether or not floating arithmetic can be done on it in those registers. Integer move instructions can be used to move the values.

On some machines, though, the converse is true: fixed-point machine modes may not go in floating registers. This is true if the floating registers normalize any value stored in them, because storing a non-floating value there would garble it. In this case, `HARD_REGNO_MODE_OK` should reject fixed-point machine modes in floating registers. But if the floating registers do not automatically normalize, if you can store any bit pattern in one and retrieve it unchanged without a trap, then any machine mode may go in a floating register, so you can define this macro to say so.

The primary significance of special floating registers is rather that they are the registers acceptable in floating point arithmetic instructions. However, this is of no concern to `HARD_REGNO_MODE_OK`. You handle it by writing the proper constraints for those instructions.

On some machines, the floating registers are especially slow to access, so that it is better to store a value in a stack frame than in such a register if floating point arithmetic is not being done. As long as the floating registers are not in class `GENERAL_REGS`, they will not be used unless some pattern's constraint asks for one.

`MODES_TIEABLE_P (mode1, mode2)`

A C expression that is nonzero if it is desirable to choose register allocation so as to avoid move instructions between a value of mode mode1 and a value of mode mode2.

If `HARD_REGNO_MODE_OK (r, mode1)` and `HARD_REGNO_MODE_OK (r, mode2)` are ever different for any r, then `MODES_TIEABLE_P (mode1, mode2)` must be zero.

Handling Leaf Functions

On some machines, a leaf function (i.e., one which makes no calls) can run more efficiently if it does not make its own register window. Often this means it is required to receive its arguments in the registers where they are passed by the caller, instead of the registers where they would normally arrive.

The special treatment for leaf functions generally applies only when other conditions are met; for example, often they may use only those registers for its own variables and temporaries. We use the term "leaf function" to mean a function that is suitable for this special handling, so that functions with no calls are not necessarily "leaf functions".

GNU CC assigns register numbers before it knows whether the function is suitable for leaf function treatment. So it needs to renumber the registers in order to output a leaf function. The following macros accomplish this.

`LEAF_REGISTERS`

A C initializer for a vector, indexed by hard register number, which contains 1 for a register that is allowable in a candidate for leaf function treatment.

If leaf function treatment involves renumbering the registers, then the registers marked here should be the ones before renumbering--those that GNU CC would ordinarily allocate. The registers which will actually be used in the assembler code, after renumbering, should not be marked with 1 in this vector.

Define this macro only if the target machine offers a way to optimize the treatment of leaf functions.

`LEAF_REG_REMAP (regno)`

A C expression whose value is the register number to which regno should be renumbered, when a function is treated as a leaf function.

If regno is a register number which should not appear in a leaf function before renumbering, then the expression should yield -1, which will cause the compiler to abort.

Define this macro only if the target machine offers a way to optimize the treatment of leaf functions, and registers need to be renumbered to do this.

Normally, `FUNCTION_PROLOGUE` and `FUNCTION_EPILOGUE` must treat leaf functions specially. It can test the C variable `leaf_function` which is nonzero for leaf functions. (The variable `leaf_function` is defined only if `LEAF_REGISTERS` is defined.)

Registers That Form a Stack

There are special features to handle computers where some of the "registers" form a stack, as in the 80387 coprocessor for the 80386. Stack registers are normally written by pushing onto the stack, and are numbered relative to the top of the stack.

Currently, GNU CC can only handle one group of stack-like registers, and they must be consecutively numbered.

`STACK_REGS`

Define this if the machine has any stack-like registers.

`FIRST_STACK_REG`

The number of the first stack-like register. This one is the top of the stack.

`LAST_STACK_REG`

The number of the last stack-like register. This one is the bottom of the stack.

Obsolete Macros for Controlling Register Usage

These features do not work very well. They exist because they used to be required to generate correct code for the 80387 coprocessor of the 80386. They are no longer used by that machine description and may be removed in a later version of the compiler. Don't use them!

`OVERLAPPING_REGNO_P (regno)`

If defined, this is a C expression whose value is nonzero if hard register number regno is an overlapping register. This means a hard register which overlaps a hard register with a different number. (Such overlap is undesirable, but occasionally it allows a machine to be supported which otherwise could not be.) This macro must return nonzero for *all* the registers which overlap each other. GNU CC can use an overlapping register only in certain limited ways. It can be used for allocation within a basic block, and may be spilled for reloading; that is all.

If this macro is not defined, it means that none of the hard registers overlap each other. This is the usual situation.

`INSN_CLOBBERS_REGNO_P (insn, regno)`

If defined, this is a C expression whose value should be nonzero if the insn insn has the effect of mysteriously clobbering the contents of hard register number regno. By "mysterious" we mean that the insn's RTL expression doesn't describe such an effect.

If this macro is not defined, it means that no insn clobbers registers mysteriously. This is the usual situation; all else being equal, it is best for the RTL expression to show all the activity.

`PRESERVE_DEATH_INFO_REGNO_P (regno)`

If defined, this is a C expression whose value is nonzero if accurate `REG_DEAD` notes are needed for hard register number regno at the time of outputting the assembler code. When this is so, a few optimizations that take place after register allocation and could invalidate the death notes are not done when this register is involved.

You would arrange to preserve death info for a register when some of the code in the machine description which is executed to write the assembler code looks at the death notes. This is necessary only when the actual hardware feature which GNU CC thinks of as a register is not actually a register of the usual sort. (It might, for example, be a hardware stack.)

If this macro is not defined, it means that no death notes need to be preserved. This is the usual situation.

Register Classes

On many machines, the numbered registers are not all equivalent. For example, certain registers may not be allowed for indexed addressing; certain registers may not be allowed in some instructions. These machine restrictions are described to the compiler using register classes.

You define a number of register classes, giving each one a name and saying which of the registers belong to it. Then you can specify register classes that are allowed as operands to particular instruction patterns.

In general, each register will belong to several classes. In fact, one class must be named `ALL_REGS` and contain all the registers. Another class must be named `NO_REGS` and contain no registers. Often the union of two classes will be another class; however, this is not required.

One of the classes must be named `GENERAL_REGS`. There is nothing terribly special about the name, but the operand constraint letters `r' and `g' specify this class. If `GENERAL_REGS` is the same as

`ALL_REGS`, just define it as a macro which expands to `ALL_REGS`.

Order the classes so that if class x is contained in class y then x has a lower class number than y.

The way classes other than `GENERAL_REGS` are specified in operand constraints is through machine-dependent operand constraint letters. You can define such letters to correspond to various classes, then use them in operand constraints.

You should define a class for the union of two classes whenever some instruction allows both classes. For example, if an instruction allows either a floating point (coprocessor) register or a general register for a certain operand, you should define a class `FLOAT_OR_GENERAL_REGS` which includes both of them. Otherwise you will get suboptimal code.

You must also specify certain redundant information about the register classes: for each class, which classes contain it and which ones are contained in it; for each pair of classes, the largest class contained in their union.

When a value occupying several consecutive registers is expected in a certain class, all the registers used must belong to that class. Therefore, register classes cannot be used to enforce a requirement for a register pair to start with an even-numbered register. The way to specify this requirement is with `HARD_REGNO_MODE_OK`.

Register classes used for input-operands of bitwise-and or shift instructions have a special requirement: each such class must have, for each fixed-point machine mode, a subclass whose registers can transfer that mode to or from memory. For example, on some machines, the operations for single-byte values (`QImode`) are limited to certain registers. When this is so, each register class that is used in a bitwise-and or shift instruction must have a subclass consisting of registers from which single-byte values can be loaded or stored. This is so that `PREFERRED_RELOAD_CLASS` can always have a possible value to return.

`enum reg_class`

An enumeral type that must be defined with all the register class names as enumeral values. `NO_REGS` must be first. `ALL_REGS` must be the last register class, followed by one more enumeral value, `LIM_REG_CLASSES`, which is not a register class but rather tells how many classes there are.

Each register class has a number, which is the value of casting the class name to type `int`. The number serves as an index in many of the tables described below.

`N_REG_CLASSES`

The number of distinct register classes, defined as follows:

```
#define N_REG_CLASSES (int) LIM_REG_CLASSES
```

`REG_CLASS_NAMES`

An initializer containing the names of the register classes as C string constants. These names are used in writing some of the debugging dumps.

`REG_CLASS_CONTENTS`

An initializer containing the contents of the register classes, as integers which are bit masks. The

nth integer specifies the contents of class n. The way the integer mask is interpreted is that reg r is in the class if `mask & (1 << r)` is 1.

When the machine has more than 32 registers, an integer does not suffice. Then the integers are replaced by sub-initializers, braced groupings containing several integers. Each sub-initializer must be suitable as an initializer for the type `HARD_REG_SET` which is defined in `hard-reg-set.h`.

`REGNO_REG_CLASS (regno)`

A C expression whose value is a register class containing hard register regno. In general there is more than one such class; choose a class which is minimal, meaning that no smaller class also contains the register.

`BASE_REG_CLASS`

A macro whose definition is the name of the class to which a valid base register must belong. A base register is one used in an address which is the register value plus a displacement.

`INDEX_REG_CLASS`

A macro whose definition is the name of the class to which a valid index register must belong. An index register is one used in an address where its value is either multiplied by a scale factor or added to another register (as well as added to a displacement).

`REG_CLASS_FROM_LETTER (char)`

A C expression which defines the machine-dependent operand constraint letters for register classes. If char is such a letter, the value should be the register class corresponding to it. Otherwise, the value should be `NO_REGS`. The register letter `r', corresponding to class `GENERAL_REGS`, will not be passed to this macro; you do not need to handle it.

`REGNO_OK_FOR_BASE_P (num)`

A C expression which is nonzero if register number num is suitable for use as a base register in operand addresses. It may be either a suitable hard register or a pseudo register that has been allocated such a hard register.

`REGNO_OK_FOR_INDEX_P (num)`

A C expression which is nonzero if register number num is suitable for use as an index register in operand addresses. It may be either a suitable hard register or a pseudo register that has been allocated such a hard register.

The difference between an index register and a base register is that the index register may be scaled. If an address involves the sum of two registers, neither one of them scaled, then either one may be labeled the "base" and the other the "index"; but whichever labeling is used must fit the machine's constraints of which registers may serve in each capacity. The compiler will try both labelings, looking for one that is valid, and will reload one or both registers only if neither labeling works.

`PREFERRED_RELOAD_CLASS (x, class)`

A C expression that places additional restrictions on the register class to use when it is necessary to copy value x into a register in class class. The value is a register class; perhaps class, or perhaps another, smaller class. On many machines, the following definition is safe:

```
#define PREFERRED_RELOAD_CLASS(X,CLASS) CLASS
```

Sometimes returning a more restrictive class makes better code. For example, on the 68000, when x is an integer constant that is in range for a `moveq' instruction, the value of this macro is always `DATA_REGS` as long as class includes the data registers. Requiring a data register guarantees that a `moveq' will be used.

If x is a `const_double`, by returning `NO_REGS` you can force x into a memory constant. This is useful on certain machines where immediate floating values cannot be loaded into certain kinds of registers.

`PREFERRED_OUTPUT_RELOAD_CLASS (x, class)`

Like `PREFERRED_RELOAD_CLASS`, but for output reloads instead of input reloads. If you don't define this macro, the default is to use class, unchanged.

`LIMIT_RELOAD_CLASS (mode, class)`

A C expression that places additional restrictions on the register class to use when it is necessary to be able to hold a value of mode mode in a reload register for which class class would ordinarily be used.

Unlike `PREFERRED_RELOAD_CLASS`, this macro should be used when there are certain modes that simply can't go in certain reload classes.

The value is a register class; perhaps class, or perhaps another, smaller class.

Don't define this macro unless the target machine has limitations which require the macro to do something nontrivial.

`SECONDARY_RELOAD_CLASS (class, mode, x)`

`SECONDARY_INPUT_RELOAD_CLASS (class, mode, x)`

`SECONDARY_OUTPUT_RELOAD_CLASS (class, mode, x)`

Many machines have some registers that cannot be copied directly to or from memory or even from other types of registers. An example is the `MQ' register, which on most machines, can only be copied to or from general registers, but not memory. Some machines allow copying all registers to and from memory, but require a scratch register for stores to some memory locations (e.g., those with symbolic address on the RT, and those with certain symbolic address on the Sparc when compiling PIC). In some cases, both an intermediate and a scratch register are required.

You should define these macros to indicate to the reload phase that it may need to allocate at least one register for a reload in addition to the register to contain the data. Specifically, if copying x to a register class in mode requires an intermediate register, you should define `SECONDARY_INPUT_RELOAD_CLASS` to return the largest register class all of whose registers can be used as intermediate registers or scratch registers.

If copying a register class in mode to x requires an intermediate or scratch register, `SECONDARY_OUTPUT_RELOAD_CLASS` should be defined to return the largest register class required. If the requirements for input and output reloads are the same, the macro `SECONDARY_RELOAD_CLASS` should be used instead of defining both macros identically.

The values returned by these macros are often `GENERAL_REGS`. Return `NO_REGS` if no spare register is needed; i.e., if x can be directly copied to or from a register of class in mode without requiring a scratch register. Do not define this macro if it would always return `NO_REGS`.

If a scratch register is required (either with or without an intermediate register), you should define patterns for `reload_inm' or `reload_outm', as required (see section Standard Pattern Names For Generation. These patterns, which will normally be implemented with a `define_expand`, should be similar to the `movm' patterns, except that operand 2 is the scratch register.

Define constraints for the reload register and scratch register that contain a single register class. If the original reload register (whose class is class) can meet the constraint given in the pattern, the value returned by these macros is used for the class of the scratch register. Otherwise, two additional reload registers are required. Their classes are obtained from the constraints in the insn pattern.

x might be a pseudo-register or a `subreg` of a pseudo-register, which could either be in a hard register or in memory. Use `true_regnum` to find out; it will return -1 if the pseudo is in memory and the hard register number if it is in a register.

These macros should not be used in the case where a particular class of registers can only be copied to memory and not to another class of registers. In that case, secondary reload registers are not needed and would not be helpful. Instead, a stack location must be used to perform the copy and the `movm` pattern should use memory as a intermediate storage. This case often occurs between floating-point and general registers.

`SECONDARY_MEMORY_NEEDED (class1, class2, m)`

Certain machines have the property that some registers cannot be copied to some other registers without using memory. Define this macro on those machines to be a C expression that is non-zero if objects of mode m in registers of class1 can only be copied to registers of class class2 by storing a register of class1 into memory and loading that memory location into a register of class2.

Do not define this macro if its value would always be zero.

`SECONDARY_MEMORY_NEEDED_RTX (mode)`

Normally when `SECONDARY_MEMORY_NEEDED` is defined, the compiler allocates a stack slot for a memory location needed for register copies. If this macro is defined, the compiler instead uses the memory location defined by this macro.

Do not define this macro if you do not define `SECONDARY_MEMORY_NEEDED`.

`SECONDARY_MEMORY_NEEDED_MODE (mode)`

When the compiler needs a secondary memory location to copy between two registers of mode mode, it normally allocates sufficient memory to hold a quantity of `BITS_PER_WORD` bits and performs the store and load operations in a mode that many bits wide and whose class is the same as that of mode.

This is right thing to do on most machines because it ensures that all bits of the register are copied and prevents accesses to the registers in a narrower mode, which some machines prohibit for floating-point registers.

However, this default behavior is not correct on some machines, such as the DEC Alpha, that s short integers in floating-point registers differently than in integer registers. On those machines, the default widening will not work correctly and you must define this macro to suppress that widening in some cases. See the file `alpha.h' for details.

Do not define this macro if you do not define SECONDARY_MEMORY_NEEDED or if widening mode to a mode that is BITS_PER_WORD bits wide is correct for your machine.

SMALL_REGISTER_CLASSES

Normally the compiler avoids choosing registers that have been explicitly mentioned in the rtl as spill registers (these registers are normally those used to pass parameters and return values). However, some machines have so few registers of certain classes that there would not be enough registers to use as spill registers if this were done.

Define SMALL_REGISTER_CLASSES on these machines. When it is defined, the compiler allows registers explicitly used in the rtl to be used as spill registers but avoids extending the lifetime of these registers.

It is always safe to define this macro, but if you unnecessarily define it, you will reduce the amount of optimizations that can be performed in some cases. If you do not define this macro when it is required, the compiler will run out of spill registers and print a fatal error message. For most machines, you should not define this macro.

CLASS_LIKELY_SPILLED_P (class)

A C expression whose value is nonzero if pseudos that have been assigned to registers of class class would likely be spilled because registers of class are needed for spill registers.

The default value of this macro returns 1 if class has exactly one register and zero otherwise. On most machines, this default should be used. Only define this macro to some other expression if pseudo allocated by `local-alloc.c' end up in memory because their hard registers were needed for spill registers. If this macro returns nonzero for those classes, those pseudos will only be allocated by `global.c', which knows how to reallocate the pseudo to another register. If there would not be another register available for reallocation, you should not change the definition of this macro since the only effect of such a definition would be to slow down register allocation.

CLASS_MAX_NREGS (class, mode)

A C expression for the maximum number of consecutive registers of class class needed to hold a value of mode mode.

This is closely related to the macro HARD_REGNO_NREGS. In fact, the value of the macro CLASS_MAX_NREGS (class, mode) should be the maximum value of HARD_REGNO_NREGS (regno, mode) for all regno values in the class class.

This macro helps control the handling of multiple-word values in the reload pass.

CLASS_CANNOT_CHANGE_SIZE

If defined, a C expression for a class that contains registers which the compiler must always access in a mode that is the same size as the mode in which it loaded the register.

For the example, loading 32-bit integer or floating-point objects into floating-point registers on the

Alpha extends them to 64-bits. Therefore loading a 64-bit object and then storing it as a 32-bit object does not store the low-order 32-bits, as would be the case for a normal register. Therefo `alpha.h' defines this macro as `FLOAT_REGS`.

Three other special macros describe which operands fit which constraint letters.

`CONST_OK_FOR_LETTER_P (value, c)`

A C expression that defines the machine-dependent operand constraint letters that specify particular ranges of integer values. If c is one of those letters, the expression should check that value, an integer, is in the appropriate range and return 1 if so, 0 otherwise. If c is not one of those letters, the value should be 0 regardless of value.

`CONST_DOUBLE_OK_FOR_LETTER_P (value, c)`

A C expression that defines the machine-dependent operand constraint letters that specify particular ranges of `const_double` values.

If c is one of those letters, the expression should check that value, an RTX of code `const_double`, is in the appropriate range and return 1 if so, 0 otherwise. If c is not one of those letters, the value should be 0 regardless of value.

`const_double` is used for all floating-point constants and for `DImode` fixed-point constants. A given letter can accept either or both kinds of values. It can use `GET_MODE` to distinguish between these kinds.

`EXTRA_CONSTRAINT (value, c)`

A C expression that defines the optional machine-dependent constraint letters that can be used to segregate specific types of operands, usually memory references, for the target machine. Normally this macro will not be defined. If it is required for a particular target machine, it should return 1 if value corresponds to the operand type represented by the constraint letter c. If c is not defined as an extra constraint, the value returned should be 0 regardless of value.

For example, on the ROMP, load instructions cannot have their output in r0 if the memory reference contains a symbolic address. Constraint letter `Q' is defined as representing a memory address that does *not* contain a symbolic address. An alternative is specified with a `Q' constraint on the input and `r' on the output. The next alternative specifies `m' on the input and a register class that does not include r0 on the output.

Stack Layout and Calling Conventions

This describes the stack layout and calling conventions.

Basic Stack Layout

Here is the basic stack layout.

`STACK_GROWS_DOWNWARD`

Define this macro if pushing a word onto the stack moves the stack pointer to a smaller address.

When we say, "define this macro if ...," it means that the compiler checks this macro only with `#ifdef` so the precise definition used does not matter.

`FRAME_GROWS_DOWNWARD`

Define this macro if the addresses of local variable slots are at negative offsets from the frame pointer.

`ARGS_GROW_DOWNWARD`

Define this macro if successive arguments to a function occupy decreasing addresses on the stack.

`STARTING_FRAME_OFFSET`

Offset from the frame pointer to the first local variable slot to be allocated.

If `FRAME_GROWS_DOWNWARD`, find the next slot's offset by subtracting the first slot's length from `STARTING_FRAME_OFFSET`. Otherwise, it is found by adding the length of the first slot to the value `STARTING_FRAME_OFFSET`.

`STACK_POINTER_OFFSET`

Offset from the stack pointer register to the first location at which outgoing arguments are placed. If not specified, the default value of zero is used. This is the proper value for most machines.

If `ARGS_GROW_DOWNWARD`, this is the offset to the location above the first location at which outgoing arguments are placed.

`FIRST_PARM_OFFSET (fundecl)`

Offset from the argument pointer register to the first argument's address. On some machines it may depend on the data type of the function.

If `ARGS_GROW_DOWNWARD`, this is the offset to the location above the first argument's address.

`STACK_DYNAMIC_OFFSET (fundecl)`

Offset from the stack pointer register to an item dynamically allocated on the stack, e.g., by `alloca`.

The default value for this macro is `STACK_POINTER_OFFSET` plus the length of the outgoing arguments. The default is correct for most machines. See `` `function.c' `` for details.

`DYNAMIC_CHAIN_ADDRESS (frameaddr)`

A C expression whose value is RTL representing the address in a stack frame where the pointer to the caller's frame is stored. Assume that frameaddr is an RTL expression for the address of the stack frame itself.

If you don't define this macro, the default is to return the value of frameaddr---that is, the stack frame address is also the address of the stack word that points to the previous frame.

`SETUP_FRAME_ADDRESSES ()`

If defined, a C expression that produces the machine-specific code to setup the stack so that arbitrary frames can be accessed. For example, on the Sparc, we must flush all of the register windows to the stack before we can access arbitrary stack frames. This macro will seldom need to be defined.

`RETURN_ADDR_RTX (count, frameaddr)`

A C expression whose value is RTL representing the value of the return address for the frame count steps up from the current frame. frameaddr is the frame pointer of the count frame, or the frame pointer of the count - 1 frame if `RETURN_ADDR_IN_PREVIOUS_FRAME` is defined.

`RETURN_ADDR_IN_PREVIOUS_FRAME`

Define this if the return address of a particular stack frame is accessed from the frame pointer of the previous stack frame.

Registers That Address the Stack Frame

This discusses registers that address the stack frame.

`STACK_POINTER_REGNUM`

The register number of the stack pointer register, which must also be a fixed register according to `FIXED_REGISTERS`. On most machines, the hardware determines which register this is.

`FRAME_POINTER_REGNUM`

The register number of the frame pointer register, which is used to access automatic variables in the stack frame. On some machines, the hardware determines which register this is. On other machines, you can choose any register you wish for this purpose.

`HARD_FRAME_POINTER_REGNUM`

On some machines the offset between the frame pointer and starting offset of the automatic variables is not known until after register allocation has been done (for example, because the saved registers are between these two locations). On those machines, define `FRAME_POINTER_REGNUM` the number of a special, fixed register to be used internally until the offset is known, and define `HARD_FRAME_POINTER_REGNUM` to be actual the hard register number used for the frame pointer.

You should define this macro only in the very rare circumstances when it is not possible to calculate the offset between the frame pointer and the automatic variables until after register allocation has been completed. When this macro is defined, you must also indicate in your definition of `ELIMINABLE_REGS` how to eliminate `FRAME_POINTER_REGNUM` into either `HARD_FRAME_POINTER_REGNUM` or `STACK_POINTER_REGNUM`.

Do not define this macro if it would be the same as `FRAME_POINTER_REGNUM`.

`ARG_POINTER_REGNUM`

The register number of the arg pointer register, which is used to access the function's argument list. On some machines, this is the same as the frame pointer register. On some machines, the hardware determines which register this is. On other machines, you can choose any register you wish for this purpose. If this is not the same register as the frame pointer register, then you must mark it as a fixed register according to `FIXED_REGISTERS`, or arrange to be able to eliminate it (see section Eliminating Frame Pointer and Arg Pointer).

`STATIC_CHAIN_REGNUM`

`STATIC_CHAIN_INCOMING_REGNUM`

Register numbers used for passing a function's static chain pointer. If register windows are used, the register number as seen by the called function is `STATIC_CHAIN_INCOMING_REGNUM`,

while the register number as seen by the calling function is `STATIC_CHAIN_REGNUM`. If the registers are the same, `STATIC_CHAIN_INCOMING_REGNUM` need not be defined.

The static chain register need not be a fixed register.

If the static chain is passed in memory, these macros should not be defined; instead, the next two macros should be defined.

`STATIC_CHAIN`

`STATIC_CHAIN_INCOMING`

If the static chain is passed in memory, these macros provide rtx giving `mem` expressions that denote where they are stored. `STATIC_CHAIN` and `STATIC_CHAIN_INCOMING` give the locations as seen by the calling and called functions, respectively. Often the former will be at an offset from the stack pointer and the latter at an offset from the frame pointer.

The variables `stack_pointer_rtx`, `frame_pointer_rtx`, and `arg_pointer_rtx` will have been initialized prior to the use of these macros and should be used to refer to those items.

If the static chain is passed in a register, the two previous macros should be defined instead.

Eliminating Frame Pointer and Arg Pointer

This is about eliminating the frame pointer and arg pointer.

`FRAME_POINTER_REQUIRED`

A C expression which is nonzero if a function must have and use a frame pointer. This expression is evaluated in the reload pass. If its value is nonzero the function will have a frame pointer.

The expression can in principle examine the current function and decide according to the facts, but on most machines the constant 0 or the constant 1 suffices. Use 0 when the machine allows code to be generated with no frame pointer, and doing so saves some time or space. Use 1 when there is no possible advantage to avoiding a frame pointer.

In certain cases, the compiler does not know how to produce valid code without a frame pointer. The compiler recognizes those cases and automatically gives the function a frame pointer regardless of what `FRAME_POINTER_REQUIRED` says. You don't need to worry about them.

In a function that does not require a frame pointer, the frame pointer register can be allocated for ordinary usage, unless you mark it as a fixed register. See `FIXED_REGISTERS` for more information.

`INITIAL_FRAME_POINTER_OFFSET (depth-var)`

A C statement to store in the variable depth-var the difference between the frame pointer and the stack pointer values immediately after the function prologue. The value would be computed from information such as the result of `get_frame_size ()` and the tables of registers `regs_ever_live` and `call_used_regs`.

If `ELIMINABLE_REGS` is defined, this macro will be not be used and need not be defined. Otherwise, it must be defined even if `FRAME_POINTER_REQUIRED` is defined to always be true; in that case, you may set depth-var to anything.

`ELIMINABLE_REGS`

If defined, this macro specifies a table of register pairs used to eliminate unneeded registers that point into the stack frame. If it is not defined, the only elimination attempted by the compiler is to replace references to the frame pointer with references to the stack pointer.

The definition of this macro is a list of structure initializations, each of which specifies an original and replacement register.

On some machines, the position of the argument pointer is not known until the compilation is completed. In such a case, a separate hard register must be used for the argument pointer. This register can be eliminated by replacing it with either the frame pointer or the argument pointer, depending on whether or not the frame pointer has been eliminated.

In this case, you might specify:

```
#define ELIMINABLE_REGS  \
{{ARG_POINTER_REGNUM, STACK_POINTER_REGNUM}, \
 {ARG_POINTER_REGNUM, FRAME_POINTER_REGNUM}, \
 {FRAME_POINTER_REGNUM, STACK_POINTER_REGNUM}}
```

Note that the elimination of the argument pointer with the stack pointer is specified first since that is the preferred elimination.

`CAN_ELIMINATE (from-reg, to-reg)`

A C expression that returns non-zero if the compiler is allowed to try to replace register number from-reg with register number to-reg. This macro need only be defined if `ELIMINABLE_REGS` is defined, and will usually be the constant 1, since most of the cases preventing register elimination are things that the compiler already knows about.

`INITIAL_ELIMINATION_OFFSET (from-reg, to-reg, offset-var)`

This macro is similar to `INITIAL_FRAME_POINTER_OFFSET`. It specifies the initial difference between the specified pair of registers. This macro must be defined if `ELIMINABLE_REGS` is defined.

`LONGJMP_RESTORE_FROM_STACK`

Define this macro if the `longjmp` function restores registers from the stack frames, rather than from those saved specifically by `setjmp`. Certain quantities must not be kept in registers across a call to `setjmp` on such machines.

Passing Function Arguments on the Stack

The macros in this section control how arguments are passed on the stack. See the following section for other macros that control passing certain arguments in registers.

`PROMOTE_PROTOTYPES`

Define this macro if an argument declared in a prototype as an integral type smaller than `int` should actually be passed as an `int`. In addition to avoiding errors in certain cases of mismatch, it also makes for better code on certain machines.

`PUSH_ROUNDING (npushed)`

A C expression that is the number of bytes actually pushed onto the stack when an instruction attempts to push npushed bytes.

If the target machine does not have a push instruction, do not define this macro. That directs GNU CC to use an alternate strategy: to allocate the entire argument block and then store the arguments into it.

On some machines, the definition

```
#define PUSH_ROUNDING(BYTES) (BYTES)
```

will suffice. But on other machines, instructions that appear to push one byte actually push two bytes in an attempt to maintain alignment. Then the definition should be

```
#define PUSH_ROUNDING(BYTES) (((BYTES) + 1) & ~1)
```

`ACCUMULATE_OUTGOING_ARGS`

If defined, the maximum amount of space required for outgoing arguments will be computed and placed into the variable `current_function_outgoing_args_size`. No space will be pushed onto the stack for each call; instead, the function prologue should increase the stack frame size by this amount.

Defining both `PUSH_ROUNDING` and `ACCUMULATE_OUTGOING_ARGS` is not proper.

`REG_PARM_STACK_SPACE (fndecl)`

Define this macro if functions should assume that stack space has been allocated for arguments even when their values are passed in registers.

The value of this macro is the size, in bytes, of the area reserved for arguments passed in registers for the function represented by fndecl.

This space can be allocated by the caller, or be a part of the machine-dependent stack frame: `OUTGOING_REG_PARM_STACK_SPACE` says which.

`MAYBE_REG_PARM_STACK_SPACE`

`FINAL_REG_PARM_STACK_SPACE (const_size, var_size)`

Define these macros in addition to the one above if functions might allocate stack space for arguments even when their values are passed in registers. These should be used when the stack space allocated for arguments in registers is not a simple constant independent of the function declaration.

The value of the first macro is the size, in bytes, of the area that we should initially assume would be reserved for arguments passed in registers.

The value of the second macro is the actual size, in bytes, of the area that will be reserved for arguments passed in registers. This takes two arguments: an integer representing the number of bytes of fixed sized arguments on the stack, and a tree representing the number of bytes of variable sized arguments on the stack.

When these macros are defined, `REG_PARM_STACK_SPACE` will only be called for libcall functions, the current function, or for a function being called when it is known that such stack space must be allocated. In each case this value can be easily computed.

When deciding whether a called function needs such stack space, and how much space to reserve, GNU CC uses these two macros instead of `REG_PARM_STACK_SPACE`.

`OUTGOING_REG_PARM_STACK_SPACE`

Define this if it is the responsibility of the caller to allocate the area reserved for arguments passed in registers.

If `ACCUMULATE_OUTGOING_ARGS` is defined, this macro controls whether the space for these arguments counts in the value of `current_function_outgoing_args_size`.

`STACK_PARMS_IN_REG_PARM_AREA`

Define this macro if `REG_PARM_STACK_SPACE` is defined, but the stack parameters don't skip the area specified by it.

Normally, when a parameter is not passed in registers, it is placed on the stack beyond the `REG_PARM_STACK_SPACE` area. Defining this macro suppresses this behavior and causes the parameter to be passed on the stack in its natural location.

`RETURN_POPS_ARGS (fundecl, funtype, stack-size)`

A C expression that should indicate the number of bytes of its own arguments that a function pops on returning, or 0 if the function pops no arguments and the caller must therefore pop them all after the function returns.

fundecl is a C variable whose value is a tree node that describes the function in question. Normally it is a node of type `FUNCTION_DECL` that describes the declaration of the function. From this it is possible to obtain the DECL_MACHINE_ATTRIBUTES of the function.

funtype is a C variable whose value is a tree node that describes the function in question. Normally it is a node of type `FUNCTION_TYPE` that describes the data type of the function. From this it is possible to obtain the data types of the value and arguments (if known).

When a call to a library function is being considered, funtype will contain an identifier node for the library function. Thus, if you need to distinguish among various library functions, you can do so by their names. Note that "library function" in this context means a function used to perform arithmetic, whose name is known specially in the compiler and was not mentioned in the C code being compiled.

stack-size is the number of bytes of arguments passed on the stack. If a variable number of bytes is passed, it is zero, and argument popping will always be the responsibility of the calling function.

On the Vax, all functions always pop their arguments, so the definition of this macro is stack-size. On the 68000, using the standard calling convention, no functions pop their arguments, so the value of the macro is always 0 in this case. But an alternative calling convention is available in which functions that take a fixed number of arguments pop them but other functions (such as `printf`) pop nothing (the caller pops all). When this convention is in use, funtype is examined to determine whether a function takes a fixed number of arguments.

Passing Arguments in Registers

This section describes the macros which let you control how various types of arguments are passed in registers or how they are arranged in the stack.

`FUNCTION_ARG (cum, mode, type, named)`

A C expression that controls whether a function argument is passed in a register, and which register.

The arguments are cum, which summarizes all the previous arguments; mode, the machine mode of the argument; type, the data type of the argument as a tree node or 0 if that is not known (which happens for C support library functions); and named, which is 1 for an ordinary argument and 0 for nameless arguments that correspond to `...' in the called function's prototype.

The value of the expression should either be a `reg` RTX for the hard register in which to pass the argument, or zero to pass the argument on the stack.

For machines like the Vax and 68000, where normally all arguments are pushed, zero suffices as a definition.

The usual way to make the ANSI library `` `stdarg.h' `` work on a machine where some arguments are usually passed in registers, is to cause nameless arguments to be passed on the stack instead. This is done by making `FUNCTION_ARG` return 0 whenever named is 0.

You may use the macro `MUST_PASS_IN_STACK (mode, type)` in the definition of this macro to determine if this argument is of a type that must be passed in the stack. If `REG_PARM_STACK_SPACE` is not defined and `FUNCTION_ARG` returns non-zero for such an argument, the compiler will abort. If `REG_PARM_STACK_SPACE` is defined, the argument will be computed in the stack and then loaded into a register.

`FUNCTION_INCOMING_ARG (cum, mode, type, named)`

Define this macro if the target machine has "register windows", so that the register in which a function sees an arguments is not necessarily the same as the one in which the caller passed the argument.

For such machines, `FUNCTION_ARG` computes the register in which the caller passes the value, and `FUNCTION_INCOMING_ARG` should be defined in a similar fashion to tell the function being called where the arguments will arrive.

If `FUNCTION_INCOMING_ARG` is not defined, `FUNCTION_ARG` serves both purposes.

`FUNCTION_ARG_PARTIAL_NREGS (cum, mode, type, named)`

A C expression for the number of words, at the beginning of an argument, must be put in registers. The value must be zero for arguments that are passed entirely in registers or that are entirely pushed on the stack.

On some machines, certain arguments must be passed partially in registers and partially in memory. On these machines, typically the first n words of arguments are passed in registers, and the rest on the stack. If a multi-word argument (a `double` or a structure) crosses that boundary, its

first few words must be passed in registers and the rest must be pushed. This macro tells the compiler when this occurs, and how many of the words should go in registers.

`FUNCTION_ARG` for these arguments should return the first register to be used by the caller for this argument; likewise `FUNCTION_INCOMING_ARG`, for the called function.

`FUNCTION_ARG_PASS_BY_REFERENCE (cum, mode, type, named)`

A C expression that indicates when an argument must be passed by reference. If nonzero for an argument, a copy of that argument is made in memory and a pointer to the argument is passed instead of the argument itself. The pointer is passed in whatever way is appropriate for passing a pointer to that type.

On machines where `REG_PARM_STACK_SPACE` is not defined, a suitable definition of this macro might be

```
#define FUNCTION_ARG_PASS_BY_REFERENCE\
(CUM, MODE, TYPE, NAMED)  \
  MUST_PASS_IN_STACK (MODE, TYPE)
```

`FUNCTION_ARG_CALLEE_COPIES (cum, mode, type, named)`

If defined, a C expression that indicates when it is the called function's responsibility to make a copy of arguments passed by invisible reference. Normally, the caller makes a copy and passes the address of the copy to the routine being called. When FUNCTION_ARG_CALLEE_COPIES is defined and is nonzero, the caller does not make a copy. Instead, it passes a pointer to the "live" value. The called function must not modify this value. If it can be determined that the value won't be modified, it need not make a copy; otherwise a copy must be made.

`CUMULATIVE_ARGS`

A C type for declaring a variable that is used as the first argument of `FUNCTION_ARG` and other related values. For some target machines, the type `int` suffices and can hold the number of bytes of argument so far.

There is no need to record in `CUMULATIVE_ARGS` anything about the arguments that have been passed on the stack. The compiler has other variables to keep track of that. For target machines on which all arguments are passed on the stack, there is no need to store anything in `CUMULATIVE_ARGS`; however, the data structure must exist and should not be empty, so use `int`.

`INIT_CUMULATIVE_ARGS (cum, fntype, libname)`

A C statement (sans semicolon) for initializing the variable cum for the state at the beginning of the argument list. The variable has type `CUMULATIVE_ARGS`. The value of fntype is the tree node for the data type of the function which will receive the args, or 0 if the args are to a compiler support library function.

When processing a call to a compiler support library function, libname identifies which one. It is a `symbol_ref` rtx which contains the name of the function, as a string. libname is 0 when an ordinary C function call is being processed. Thus, each time this macro is called, either libname or fntype is nonzero, but never both of them at once.

`INIT_CUMULATIVE_INCOMING_ARGS (cum, fntype, libname)`

Like `INIT_CUMULATIVE_ARGS` but overrides it for the purposes of finding the arguments for the function being compiled. If this macro is undefined, `INIT_CUMULATIVE_ARGS` is used instead.

The value passed for libname is always 0, since library routines with special calling conventions are never compiled with GNU CC. The argument libname exists for symmetry with `INIT_CUMULATIVE_ARGS`.

`FUNCTION_ARG_ADVANCE (cum, mode, type, named)`

A C statement (sans semicolon) to update the summarizer variable cum to advance past an argument in the argument list. The values mode, type and named describe that argument. Once this is done, the variable cum is suitable for analyzing the *following* argument with `FUNCTION_ARG`, etc.

This macro need not do anything if the argument in question was passed on the stack. The compiler knows how to track the amount of stack space used for arguments without any special help.

`FUNCTION_ARG_PADDING (mode, type)`

If defined, a C expression which determines whether, and in which direction, to pad out an argument with extra space. The value should be of type `enum direction`: either `upward` to pad above the argument, `downward` to pad below, or `none` to inhibit padding.

The *amount* of padding is always just enough to reach the next multiple of `FUNCTION_ARG_BOUNDARY`; this macro does not control it.

This macro has a default definition which is right for most systems. For little-endian machines, the default is to pad upward. For big-endian machines, the default is to pad downward for an argument of constant size shorter than an `int`, and upward otherwise.

`FUNCTION_ARG_BOUNDARY (mode, type)`

If defined, a C expression that gives the alignment boundary, in bits, of an argument with the specified mode and type. If it is not defined, `PARM_BOUNDARY` is used for all arguments.

`FUNCTION_ARG_REGNO_P (regno)`

A C expression that is nonzero if regno is the number of a hard register in which function arguments are sometimes passed. This does *not* include implicit arguments such as the static chain and the structure-value address. On many machines, no registers can be used for this purpose since all function arguments are pushed on the stack.

How Scalar Function Values Are Returned

This section discusses the macros that control returning scalars as values--values that can fit in registers.

`TRADITIONAL_RETURN_FLOAT`

Define this macro if `-traditional' should not cause functions declared to return `float` to convert the value to `double`.

`FUNCTION_VALUE (valtype, func)`

A C expression to create an RTX representing the place where a function returns a value of da type valtype. valtype is a tree node representing a data type. Write `TYPE_MODE (valtype)` get the machine mode used to represent that type. On many machines, only the mode is relevant. (Actually, on most machines, scalar values are returned in the same place regardless of mode).

If `PROMOTE_FUNCTION_RETURN` is defined, you must apply the same promotion rules specified in `PROMOTE_MODE` if valtype is a scalar type.

If the precise function being called is known, func is a tree node (`FUNCTION_DECL`) for it; otherwise, func is a null pointer. This makes it possible to use a different value-returning convention for specific functions when all their calls are known.

`FUNCTION_VALUE` is not used for return vales with aggregate data types, because these are returned in another way. See `STRUCT_VALUE_REGNUM` and related macros, below.

`FUNCTION_OUTGOING_VALUE (valtype, func)`

Define this macro if the target machine has "register windows" so that the register in which a function returns its value is not the same as the one in which the caller sees the value.

For such machines, `FUNCTION_VALUE` computes the register in which the caller will see the value. `FUNCTION_OUTGOING_VALUE` should be defined in a similar fashion to tell the function where to put the value.

If `FUNCTION_OUTGOING_VALUE` is not defined, `FUNCTION_VALUE` serves both purposes.

`FUNCTION_OUTGOING_VALUE` is not used for return vales with aggregate data types, because these are returned in another way. See `STRUCT_VALUE_REGNUM` and related macros, below.

`LIBCALL_VALUE (mode)`

A C expression to create an RTX representing the place where a library function returns a value of mode mode. If the precise function being called is known, func is a tree node (`FUNCTION_DECL`) for it; otherwise, func is a null pointer. This makes it possible to use a different value-returning convention for specific functions when all their calls are known.

Note that "library function" in this context means a compiler support routine, used to perform arithmetic, whose name is known specially by the compiler and was not mentioned in the C code being compiled.

The definition of `LIBRARY_VALUE` need not be concerned aggregate data types, because none of the library functions returns such types.

`FUNCTION_VALUE_REGNO_P (regno)`

A C expression that is nonzero if regno is the number of a hard register in which the values of called function may come back.

A register whose use for returning values is limited to serving as the second of a pair (for a value of type `double`, say) need not be recognized by this macro. So for most machines, this definition suffices:

```
#define FUNCTION_VALUE_REGNO_P(N) ((N) == 0)
```

If the machine has register windows, so that the caller and the called function use different registers for the return value, this macro should recognize only the caller's register numbers.

`APPLY_RESULT_SIZE`

Define this macro if `untyped_call' and `untyped_return' need more space than is implied by `FUNCTION_VALUE_REGNO_P` for saving and restoring an arbitrary return value.

How Large Values Are Returned

When a function value's mode is `BLKmode` (and in some other cases), the value is not returned according to `FUNCTION_VALUE` (see section How Scalar Function Values Are Returned). Instead, the caller passes the address of a block of memory in which the value should be stored. This address is called the structure value address.

This section describes how to control returning structure values in memory.

`RETURN_IN_MEMORY (type)`

A C expression which can inhibit the returning of certain function values in registers, based on the type of value. A nonzero value says to return the function value in memory, just as large structures are always returned. Here type will be a C expression of type `tree`, representing the data type of the value.

Note that values of mode `BLKmode` must be explicitly handled by this macro. Also, the option `-fpcc-struct-return' takes effect regardless of this macro. On most systems, it is possible to leave the macro undefined; this causes a default definition to be used, whose value is the constant 1 for `BLKmode` values, and 0 otherwise.

Do not use this macro to indicate that structures and unions should always be returned in memory. You should instead use `DEFAULT_PCC_STRUCT_RETURN` to indicate this.

`DEFAULT_PCC_STRUCT_RETURN`

Define this macro to be 1 if all structure and union return values must be in memory. Since this results in slower code, this should be defined only if needed for compatibility with other compilers or with an ABI. If you define this macro to be 0, then the conventions used for structure and union return values are decided by the `RETURN_IN_MEMORY` macro.

If not defined, this defaults to the value 1.

`STRUCT_VALUE_REGNUM`

If the structure value address is passed in a register, then `STRUCT_VALUE_REGNUM` should be the number of that register.

`STRUCT_VALUE`

If the structure value address is not passed in a register, define `STRUCT_VALUE` as an expression returning an RTX for the place where the address is passed. If it returns 0, the address is passed as an "invisible" first argument.

`STRUCT_VALUE_INCOMING_REGNUM`

On some architectures the place where the structure value address is found by the called function is

not the same place that the caller put it. This can be due to register windows, or it could be bec the function prologue moves it to a different place.

If the incoming location of the structure value address is in a register, define this macro as the register number.

`STRUCT_VALUE_INCOMING`

If the incoming location is not a register, then you should define `STRUCT_VALUE_INCOMING` as an expression for an RTX for where the called function should find the value. If it should find the value on the stack, define this to create a `mem` which refers to the frame pointer. A definition of 0 means that the address is passed as an "invisible" first argument.

`PCC_STATIC_STRUCT_RETURN`

Define this macro if the usual system convention on the target machine for returning structures and unions is for the called function to return the address of a static variable containing the value.

Do not define this if the usual system convention is for the caller to pass an address to the subroutine.

This macro has effect in `-fpcc-struct-return' mode, but it does nothing when you use `-freg-struct-return' mode.

Caller-Saves Register Allocation

If you enable it, GNU CC can save registers around function calls. This makes it possible to use call-clobbered registers to hold variables that must live across calls.

`DEFAULT_CALLER_SAVES`

Define this macro if function calls on the target machine do not preserve any registers; in other words, if `CALL_USED_REGISTERS` has 1 for all registers. This macro enables `-fcaller-saves' by default. Eventually that option will be enabled by default on all machines and both the option and this macro will be eliminated.

`CALLER_SAVE_PROFITABLE (refs, calls)`

A C expression to determine whether it is worthwhile to consider placing a pseudo-register in a call-clobbered hard register and saving and restoring it around each function call. The expression should be 1 when this is worth doing, and 0 otherwise.

If you don't define this macro, a default is used which is good on most machines: `4 * calls < refs`.

Function Entry and Exit

This section describes the macros that output function entry (prologue) and exit (epilogue) code.

`FUNCTION_PROLOGUE (file, size)`

A C compound statement that outputs the assembler code for entry to a function. The prologue is responsible for setting up the stack frame, initializing the frame pointer register, saving registers that must be saved, and allocating size additional bytes of storage for the local variables. size is an

integer. file is a stdio stream to which the assembler code should be output.

The label for the beginning of the function need not be output by this macro. That has already been done when the macro is run.

To determine which registers to save, the macro can refer to the array `regs_ever_live`: element r is nonzero if hard register r is used anywhere within the function. This implies the function prologue should save register r, provided it is not one of the call-used registers. (`FUNCTION_EPILOGUE` must likewise use `regs_ever_live`.)

On machines that have "register windows", the function entry code does not save on the stack the registers that are in the windows, even if they are supposed to be preserved by function calls; instead it takes appropriate steps to "push" the register stack, if any non-call-used registers are used in the function.

On machines where functions may or may not have frame-pointers, the function entry code must vary accordingly; it must set up the frame pointer if one is wanted, and not otherwise. To determine whether a frame pointer is in wanted, the macro can refer to the variable `frame_pointer_needed`. The variable's value will be 1 at run time in a function that needs a frame pointer. See section Eliminating Frame Pointer and Arg Pointer.

The function entry code is responsible for allocating any stack space required for the function. This stack space consists of the regions listed below. In most cases, these regions are allocated in the order listed, with the last listed region closest to the top of the stack (the lowest address if `STACK_GROWS_DOWNWARD` is defined, and the highest address if it is not defined). You can use a different order for a machine if doing so is more convenient or required for compatibility reasons. Except in cases where required by standard or by a debugger, there is no reason why the stack layout used by GCC need agree with that used by other compilers for a machine.

A region of `current_function_pretend_args_size` bytes of uninitialized space just underneath the first argument arriving on the stack. (This may not be at the very start of the allocated stack region if the calling sequence has pushed anything else since pushing the stack arguments. But usually, on such machines, nothing else has been pushed yet, because the function prologue itself does all the pushing.) This region is used on machines where an argument may be passed partly in registers and partly in memory, and, in some cases to support the features in `` `varargs.h' `` and `` `stdargs.h' ``.

An area of memory used to save certain registers used by the function. The size of this area, which may also include space for such things as the return address and pointers to previous stack frames, is machine-specific and usually depends on which registers have been used in the function. Machines with register windows often do not require a save area.

A region of at least size bytes, possibly rounded up to an allocation boundary, to contain the local variables of the function. On some machines, this region and the save area may occur in the opposite order, with the save area closer to the top of the stack.

Optionally, when `ACCUMULATE_OUTGOING_ARGS` is defined, a region of `current_function_outgoing_args_size` bytes to be used for outgoing argument lists of the function. See section Passing Function Arguments on the Stack.

Normally, it is necessary for the macros `FUNCTION_PROLOGUE` and `FUNCTION_EPILOGUE` treat leaf functions specially. The C variable `leaf_function` is nonzero for such a function.

`EXIT_IGNORE_STACK`

Define this macro as a C expression that is nonzero if the return instruction or the function epilogue ignores the value of the stack pointer; in other words, if it is safe to delete an instruction to adjust the stack pointer before a return from the function.

Note that this macro's value is relevant only for functions for which frame pointers are maintained. It is never safe to delete a final stack adjustment in a function that has no frame pointer, and the compiler knows this regardless of `EXIT_IGNORE_STACK`.

`FUNCTION_EPILOGUE (file, size)`

A C compound statement that outputs the assembler code for exit from a function. The epilogue is responsible for restoring the saved registers and stack pointer to their values when the function was called, and returning control to the caller. This macro takes the same arguments as the macro `FUNCTION_PROLOGUE`, and the registers to restore are determined from `regs_ever_live` and `CALL_USED_REGISTERS` in the same way.

On some machines, there is a single instruction that does all the work of returning from the function. On these machines, give that instruction the name `return' and do not define the macro `FUNCTION_EPILOGUE` at all.

Do not define a pattern named `return' if you want the `FUNCTION_EPILOGUE` to be used. If you want the target switches to control whether return instructions or epilogues are used, define a `return' pattern with a validity condition that tests the target switches appropriately. If the `return' pattern's validity condition is false, epilogues will be used.

On machines where functions may or may not have frame-pointers, the function exit code must vary accordingly. Sometimes the code for these two cases is completely different. To determine whether a frame pointer is wanted, the macro can refer to the variable `frame_pointer_needed`. The variable's value will be 1 when compiling a function that needs a frame pointer.

Normally, `FUNCTION_PROLOGUE` and `FUNCTION_EPILOGUE` must treat leaf functions specially. The C variable `leaf_function` is nonzero for such a function. See section Handling Leaf Functions.

On some machines, some functions pop their arguments on exit while others leave that for the caller to do. For example, the 68020 when given `-mrtd' pops arguments in functions that take a fixed number of arguments.

Your definition of the macro `RETURN_POPS_ARGS` decides which functions pop their own arguments. `FUNCTION_EPILOGUE` needs to know what was decided. The variable that is called `current_function_pops_args` is the number of bytes of its arguments that a function should pop. See section How Scalar Function Values Are Returned.

`DELAY_SLOTS_FOR_EPILOGUE`

Define this macro if the function epilogue contains delay slots to which instructions from the rest

of the function can be "moved". The definition should be a C expression whose value is an int representing the number of delay slots there.

`ELIGIBLE_FOR_EPILOGUE_DELAY (insn, n)`

A C expression that returns 1 if insn can be placed in delay slot number n of the epilogue.

The argument n is an integer which identifies the delay slot now being considered (since different slots may have different rules of eligibility). It is never negative and is always less than the number of epilogue delay slots (what `DELAY_SLOTS_FOR_EPILOGUE` returns). If you reject a particular insn for a given delay slot, in principle, it may be reconsidered for a subsequent delay slot. Also, other insns may (at least in principle) be considered for the so far unfilled delay slot.

The insns accepted to fill the epilogue delay slots are put in an RTL list made with `insn_list` objects, stored in the variable `current_function_epilogue_delay_list`. The insn for the first delay slot comes first in the list. Your definition of the macro `FUNCTION_EPILOGUE` should fill the delay slots by outputting the insns in this list, usually by calling `final_scan_insn`.

You need not define this macro if you did not define `DELAY_SLOTS_FOR_EPILOGUE`.

Generating Code for Profiling

These macros will help you generate code for profiling.

`FUNCTION_PROFILER (file, labelno)`

A C statement or compound statement to output to file some assembler code to call the profiling subroutine `mcount`. Before calling, the assembler code must load the address of a counter variable into a register where `mcount` expects to find the address. The name of this variable is `LP' followed by the number labelno, so you would generate the name using `LP%d' in a `fprintf`.

The details of how the address should be passed to `mcount` are determined by your operating system environment, not by GNU CC. To figure them out, compile a small program for profiling using the system's installed C compiler and look at the assembler code that results.

`PROFILE_BEFORE_PROLOGUE`

Define this macro if the code for function profiling should come before the function prologue. Normally, the profiling code comes after.

`FUNCTION_BLOCK_PROFILER (file, labelno)`

A C statement or compound statement to output to file some assembler code to initialize basic-block profiling for the current object module. This code should call the subroutine `__bb_init_func` once per object module, passing it as its sole argument the address of a block allocated in the object module.

The name of the block is a local symbol made with this statement:

```
ASM_GENERATE_INTERNAL_LABEL (buffer, "LPBX", 0);
```

Of course, since you are writing the definition of `ASM_GENERATE_INTERNAL_LABEL` as well as that of this macro, you can take a short cut in the definition of this macro and use the name that you know will result.

The first word of this block is a flag which will be nonzero if the object module has already been initialized. So test this word first, and do not call `__bb_init_func` if the flag is nonzero.

`BLOCK_PROFILER (file, blockno)`

A C statement or compound statement to increment the count associated with the basic block number blockno. Basic blocks are numbered separately from zero within each compilation. The count associated with block number blockno is at index blockno in a vector of words; the name of this array is a local symbol made with this statement:

```
ASM_GENERATE_INTERNAL_LABEL (buffer, "LPBX", 2);
```

Of course, since you are writing the definition of `ASM_GENERATE_INTERNAL_LABEL` as well as that of this macro, you can take a short cut in the definition of this macro and use the name that you know will result.

`BLOCK_PROFILER_CODE`

A C function or functions which are needed in the library to support block profiling.

Implementing the Varargs Macros

GNU CC comes with an implementation of `` `varargs.h' `` and `` `stdarg.h' `` that work without change on machines that pass arguments on the stack. Other machines require their own implementations of varargs, and the two machine independent header files must have conditionals to include it.

ANSI `` `stdarg.h' `` differs from traditional `` `varargs.h' `` mainly in the calling convention for `va_start`. The traditional implementation takes just one argument, which is the variable in which to store the argument pointer. The ANSI implementation of `va_start` takes an additional second argument. The user is supposed to write the last named argument of the function here.

However, `va_start` should not use this argument. The way to find the end of the named arguments is with the built-in functions described below.

`__builtin_saveregs ()`

Use this built-in function to save the argument registers in memory so that the varargs mechanism can access them. Both ANSI and traditional versions of `va_start` must use `__builtin_saveregs`, unless you use `SETUP_INCOMING_VARARGS` (see below) instead.

On some machines, `__builtin_saveregs` is open-coded under the control of the macro `EXPAND_BUILTIN_SAVEREGS`. On other machines, it calls a routine written in assembler language, found in `` `libgcc2.c' ``.

Code generated for the call to `__builtin_saveregs` appears at the beginning of the function, as opposed to where the call to `__builtin_saveregs` is written, regardless of what the code is. This is because the registers must be saved before the function starts to use them for its own

purposes.

`__builtin_args_info (category)`

Use this built-in function to find the first anonymous arguments in registers.

In general, a machine may have several categories of registers used for arguments, each for a particular category of data types. (For example, on some machines, floating-point registers are used for floating-point arguments while other arguments are passed in the general registers.) To make non-varargs functions use the proper calling convention, you have defined the `CUMULATIVE_ARGS` data type to record how many registers in each category have been used so far

`__builtin_args_info` accesses the same data structure of type `CUMULATIVE_ARGS` after the ordinary argument layout is finished with it, with category specifying which word to access. Thus, the value indicates the first unused register in a given category.

Normally, you would use `__builtin_args_info` in the implementation of `va_start`, accessing each category just once and storing the value in the `va_list` object. This is because `va_list` will have to update the values, and there is no way to alter the values accessed by `__builtin_args_info`.

`__builtin_next_arg (lastarg)`

This is the equivalent of `__builtin_args_info`, for stack arguments. It returns the address of the first anonymous stack argument, as type `void *`. If `ARGS_GROW_DOWNWARD`, it returns the address of the location above the first anonymous stack argument. Use it in `va_start` to initialize the pointer for fetching arguments from the stack. Also use it in `va_start` to verify that the second parameter lastarg is the last named argument of the current function.

`__builtin_classify_type (object)`

Since each machine has its own conventions for which data types are passed in which kind of register, your implementation of `va_arg` has to embody these conventions. The easiest way to categorize the specified data type is to use `__builtin_classify_type` together with `sizeof` and `__alignof__`.

`__builtin_classify_type` ignores the value of object, considering only its data type. It returns an integer describing what kind of type that is--integer, floating, pointer, structure, and so on.

The file `` `typeclass.h' `` defines an enumeration that you can use to interpret the values of `__builtin_classify_type`.

These machine description macros help implement varargs:

`EXPAND_BUILTIN_SAVEREGS (args)`

If defined, is a C expression that produces the machine-specific code for a call to `__builtin_saveregs`. This code will be moved to the very beginning of the function, before any parameter access are made. The return value of this function should be an RTX that contains the value to use as the return of `__builtin_saveregs`.

The argument args is a `tree_list` containing the arguments that were passed to

`__builtin_saveregs`.

If this macro is not defined, the compiler will output an ordinary call to the library function `__builtin_saveregs'.

`SETUP_INCOMING_VARARGS (args_so_far, mode, type,`

pretend_args_size, second_time) This macro offers an alternative to using `__builtin_saveregs` and defining the macro `EXPAND_BUILTIN_SAVEREGS`. Use it to store the anonymous register arguments into the stack so that all the arguments appear to have been passed consecutively on the stack. Once this is done, you can use the standard implementation of varargs that works for machines that pass all their arguments on the stack.

The argument args_so_far is the `CUMULATIVE_ARGS` data structure, containing the values that obtain after processing of the named arguments. The arguments mode and type describe the last named argument--its machine mode and its data type as a tree node.

The macro implementation should do two things: first, push onto the stack all the argument registers *not* used for the named arguments, and second, store the size of the data thus pushed into the `int`-valued variable whose name is supplied as the argument pretend_args_size. The value that you store here will serve as additional offset for setting up the stack frame.

Because you must generate code to push the anonymous arguments at compile time without knowing their data types, `SETUP_INCOMING_VARARGS` is only useful on machines that have just a single category of argument register and use it uniformly for all data types.

If the argument second_time is nonzero, it means that the arguments of the function are being analyzed for the second time. This happens for an inline function, which is not actually compiled until the end of the source file. The macro `SETUP_INCOMING_VARARGS` should not generate any instructions in this case.

`STRICT_ARGUMENT_NAMING`

Define this macro if the location where a function argument is passed depends on whether or not it is a named argument.

This macro controls how the named argument to `FUNCTION_ARG` is set for varargs and stdarg functions. With this macro defined, the named argument is always true for named arguments, and false for unnamed arguments. If this is not defined, but `SETUP_INCOMING_VARARGS` is defined, then all arguments are treated as named. Otherwise, all named arguments except the last are treated as named.

Trampolines for Nested Functions

A trampoline is a small piece of code that is created at run time when the address of a nested function is taken. It normally resides on the stack, in the stack frame of the containing function. These macros tell GNU CC how to generate code to allocate and initialize a trampoline.

The instructions in the trampoline must do two things: load a constant address into the static chain register, and jump to the real address of the nested function. On CISC machines such as the m68k, this

requires two instructions, a move immediate and a jump. Then the two addresses exist in the trampol as word-long immediate operands. On RISC machines, it is often necessary to load each address into register in two parts. Then pieces of each address form separate immediate operands.

The code generated to initialize the trampoline must store the variable parts--the static chain value and the function address--into the immediate operands of the instructions. On a CISC machine, this is simply a matter of copying each address to a memory reference at the proper offset from the start of the trampoline. On a RISC machine, it may be necessary to take out pieces of the address and store them separately.

`TRAMPOLINE_TEMPLATE (file)`

A C statement to output, on the stream file, assembler code for a block of data that contains the constant parts of a trampoline. This code should not include a label--the label is taken care of automatically.

`TRAMPOLINE_SECTION`

The name of a subroutine to switch to the section in which the trampoline template is to be placed (see section Dividing the Output into Sections (Texts, Data, ...)). The default is a value of `readonly_data_section', which places the trampoline in the section containing read-only data.

`TRAMPOLINE_SIZE`

A C expression for the size in bytes of the trampoline, as an integer.

`TRAMPOLINE_ALIGNMENT`

Alignment required for trampolines, in bits.

If you don't define this macro, the value of `BIGGEST_ALIGNMENT` is used for aligning trampolines.

`INITIALIZE_TRAMPOLINE (addr, fnaddr, static_chain)`

A C statement to initialize the variable parts of a trampoline. addr is an RTX for the address of the trampoline; fnaddr is an RTX for the address of the nested function; static_chain is an RTX for the static chain value that should be passed to the function when it is called.

`ALLOCATE_TRAMPOLINE (fp)`

A C expression to allocate run-time space for a trampoline. The expression value should be an RTX representing a memory reference to the space for the trampoline.

If this macro is not defined, by default the trampoline is allocated as a stack slot. This default is right for most machines. The exceptions are machines where it is impossible to execute instructions in the stack area. On such machines, you may have to implement a separate stack, using this macro in conjunction with `FUNCTION_PROLOGUE` and `FUNCTION_EPILOGUE`.

fp points to a data structure, a `struct function`, which describes the compilation status of the immediate containing function of the function which the trampoline is for. Normally (when `ALLOCATE_TRAMPOLINE` is not defined), the stack slot for the trampoline is in the stack frame of this containing function. Other allocation strategies probably must do something analogous with this information.

Implementing trampolines is difficult on many machines because they have separate instruction and data

caches. Writing into a stack location fails to clear the memory in the instruction cache, so when the program jumps to that location, it executes the old contents.

Here are two possible solutions. One is to clear the relevant parts of the instruction cache whenever a trampoline is set up. The other is to make all trampolines identical, by having them jump to a standard subroutine. The former technique makes trampoline execution faster; the latter makes initialization faster.

To clear the instruction cache when a trampoline is initialized, define the following macros which describe the shape of the cache.

`INSN_CACHE_SIZE`

The total size in bytes of the cache.

`INSN_CACHE_LINE_WIDTH`

The length in bytes of each cache line. The cache is divided into cache lines which are disjoint slots, each holding a contiguous chunk of data fetched from memory. Each time data is brought into the cache, an entire line is read at once. The data loaded into a cache line is always aligned on a boundary equal to the line size.

`INSN_CACHE_DEPTH`

The number of alternative cache lines that can hold any particular memory location.

Alternatively, if the machine has system calls or instructions to clear the instruction cache directly, you can define the following macro.

`CLEAR_INSN_CACHE (BEG, END)`

If defined, expands to a C expression clearing the *instruction cache* in the specified interval. If it is not defined, and the macro INSN_CACHE_SIZE is defined, some generic code is generated to clear the cache. The definition of this macro would typically be a series of `asm` statements. Both BEG and END are both pointer expressions.

To use a standard subroutine, define the following macro. In addition, you must make sure that the instructions in a trampoline fill an entire cache line with identical instructions, or else ensure that the beginning of the trampoline code is always aligned at the same point in its cache line. Look in `` `m68k.h' `` as a guide.

`TRANSFER_FROM_TRAMPOLINE`

Define this macro if trampolines need a special subroutine to do their work. The macro should expand to a series of `asm` statements which will be compiled with GNU CC. They go in a library function named `__transfer_from_trampoline`.

If you need to avoid executing the ordinary prologue code of a compiled C function when you jump to the subroutine, you can do so by placing a special label of your own in the assembler code. Use one `asm` statement to generate an assembler label, and another to make the label global. Then trampolines can use that label to jump directly to your special assembler code.

Implicit Calls to Library Routines

Here is an explanation of implicit calls to library routines.

`MULSI3_LIBCALL`

A C string constant giving the name of the function to call for multiplication of one signed full-word by another. If you do not define this macro, the default name is used, which is `__mulsi3`, a function defined in `` `libgcc.a' ``.

`DIVSI3_LIBCALL`

A C string constant giving the name of the function to call for division of one signed full-word by another. If you do not define this macro, the default name is used, which is `__divsi3`, a function defined in `` `libgcc.a' ``.

`UDIVSI3_LIBCALL`

A C string constant giving the name of the function to call for division of one unsigned full-word by another. If you do not define this macro, the default name is used, which is `__udivsi3`, a function defined in `` `libgcc.a' ``.

`MODSI3_LIBCALL`

A C string constant giving the name of the function to call for the remainder in division of one signed full-word by another. If you do not define this macro, the default name is used, which is `__modsi3`, a function defined in `` `libgcc.a' ``.

`UMODSI3_LIBCALL`

A C string constant giving the name of the function to call for the remainder in division of one unsigned full-word by another. If you do not define this macro, the default name is used, which is `__umodsi3`, a function defined in `` `libgcc.a' ``.

`MULDI3_LIBCALL`

A C string constant giving the name of the function to call for multiplication of one signed double-word by another. If you do not define this macro, the default name is used, which is `__muldi3`, a function defined in `` `libgcc.a' ``.

`DIVDI3_LIBCALL`

A C string constant giving the name of the function to call for division of one signed double-word by another. If you do not define this macro, the default name is used, which is `__divdi3`, a function defined in `` `libgcc.a' ``.

`UDIVDI3_LIBCALL`

A C string constant giving the name of the function to call for division of one unsigned full-word by another. If you do not define this macro, the default name is used, which is `__udivdi3`, a function defined in `` `libgcc.a' ``.

`MODDI3_LIBCALL`

A C string constant giving the name of the function to call for the remainder in division of one signed double-word by another. If you do not define this macro, the default name is used, which is `__moddi3`, a function defined in `` `libgcc.a' ``.

`UMODDI3_LIBCALL`

A C string constant giving the name of the function to call for the remainder in division of one unsigned full-word by another. If you do not define this macro, the default name is used, which is `__umoddi3`, a function defined in `libgcc.a'.

`INIT_TARGET_OPTABS`

Define this macro as a C statement that declares additional library routines renames existing ones. `init_optabs` calls this macro after initializing all the normal library routines.

`TARGET_EDOM`

The value of `EDOM` on the target machine, as a C integer constant expression. If you don't define this macro, GNU CC does not attempt to deposit the value of `EDOM` into `errno` directly. Look in `/usr/include/errno.h' to find the value of `EDOM` on your system.

If you do not define `TARGET_EDOM`, then compiled code reports domain errors by calling the library function and letting it report the error. If mathematical functions on your system use `matherr` when there is an error, then you should leave `TARGET_EDOM` undefined so that `matherr` is used normally.

`GEN_ERRNO_RTX`

Define this macro as a C expression to create an rtl expression that refers to the global "variable" `errno`. (On certain systems, `errno` may not actually be a variable.) If you don't define this macro, a reasonable default is used.

`TARGET_MEM_FUNCTIONS`

Define this macro if GNU CC should generate calls to the System V (and ANSI C) library functions `memcpy` and `memset` rather than the BSD functions `bcopy` and `bzero`.

`LIBGCC_NEEDS_DOUBLE`

Define this macro if only `float` arguments cannot be passed to library routines (so they must be converted to `double`). This macro affects both how library calls are generated and how the library routines in `libgcc1.c' accept their arguments. It is useful on machines where floating and fixed point arguments are passed differently, such as the i860.

`FLOAT_ARG_TYPE`

Define this macro to override the type used by the library routines to pick up arguments of type `float`. (By default, they use a union of `float` and `int`.)

The obvious choice would be `float`---but that won't work with traditional C compilers that expect all arguments declared as `float` to arrive as `double`. To avoid this conversion, the library routines ask for the value as some other type and then treat it as a `float`.

On some systems, no other type will work for this. For these systems, you must use `LIBGCC_NEEDS_DOUBLE` instead, to force conversion of the values `double` before they are passed.

`FLOATIFY (passed-value)`

Define this macro to override the way library routines redesignate a `float` argument as a `float` instead of the type it was passed as. The default is an expression which takes the `float` field of the union.

`FLOAT_VALUE_TYPE`

Define this macro to override the type used by the library routines to return values that ought t have type `float`. (By default, they use `int`.)

The obvious choice would be `float`---but that won't work with traditional C compilers gratuitously convert values declared as `float` into `double`.

`INTIFY (float-value)`

Define this macro to override the way the value of a `float`-returning library routine should be packaged in order to return it. These functions are actually declared to return type `FLOAT_VALUE_TYPE` (normally `int`).

These values can't be returned as type `float` because traditional C compilers would gratuitously convert the value to a `double`.

A local variable named `intify` is always available when the macro `INTIFY` is used. It is a union of a `float` field named `f` and a field named `i` whose type is `FLOAT_VALUE_TYPE` or `int`.

If you don't define this macro, the default definition works by copying the value through that union.

`nongcc_SI_type`

Define this macro as the name of the data type corresponding to `SImode` in the system's own C compiler.

You need not define this macro if that type is `long int`, as it usually is.

`nongcc_word_type`

Define this macro as the name of the data type corresponding to the word_mode in the system's own C compiler.

You need not define this macro if that type is `long int`, as it usually is.

`perform_...`

Define these macros to supply explicit C statements to carry out various arithmetic operations on types `float` and `double` in the library routines in `` `libgcc1.c' ``. See that file for a full list of these macros and their arguments.

On most machines, you don't need to define any of these macros, because the C compiler that comes with the system takes care of doing them.

`NEXT_OBJC_RUNTIME`

Define this macro to generate code for Objective C message sending using the calling convention of the NeXT system. This calling convention involves passing the object, the selector and the method arguments all at once to the method-lookup library function.

The default calling convention passes just the object and the selector to the lookup function, which returns a pointer to the method.

Addressing Modes

This is about addressing modes.

`HAVE_POST_INCREMENT`

Define this macro if the machine supports post-increment addressing.

`HAVE_PRE_INCREMENT`

`HAVE_POST_DECREMENT`

`HAVE_PRE_DECREMENT`

Similar for other kinds of addressing.

`CONSTANT_ADDRESS_P (x)`

A C expression that is 1 if the RTX x is a constant which is a valid address. On most machines, this can be defined as `CONSTANT_P (x)`, but a few machines are more restrictive in which constant addresses are supported.

`CONSTANT_P` accepts integer-values expressions whose values are not explicitly known, such as `symbol_ref`, `label_ref`, and `high` expressions and `const` arithmetic expressions, in addition to `const_int` and `const_double` expressions.

`MAX_REGS_PER_ADDRESS`

A number, the maximum number of registers that can appear in a valid memory address. Note that it is up to you to specify a value equal to the maximum number that `GO_IF_LEGITIMATE_ADDRESS` would ever accept.

`GO_IF_LEGITIMATE_ADDRESS (mode, x, label)`

A C compound statement with a conditional `goto label;` executed if x (an RTX) is a legitimate memory address on the target machine for a memory operand of mode mode.

It usually pays to define several simpler macros to serve as subroutines for this one. Otherwise it may be too complicated to understand.

This macro must exist in two variants: a strict variant and a non-strict one. The strict variant is used in the reload pass. It must be defined so that any pseudo-register that has not been allocated a hard register is considered a memory reference. In contexts where some kind of register is required, a pseudo-register with no hard register must be rejected.

The non-strict variant is used in other passes. It must be defined to accept all pseudo-registers in every context where some kind of register is required.

Compiler source files that want to use the strict variant of this macro define the macro `REG_OK_STRICT`. You should use an `#ifdef REG_OK_STRICT` conditional to define the strict variant in that case and the non-strict variant otherwise.

Subroutines to check for acceptable registers for various purposes (one for base registers, one for index registers, and so on) are typically among the subroutines used to define `GO_IF_LEGITIMATE_ADDRESS`. Then only these subroutine macros need have two variants; the higher levels of macros may be the same whether strict or not.

Normally, constant addresses which are the sum of a `symbol_ref` and an integer are stored inside a `const` RTX to mark them as constant. Therefore, there is no need to recognize such sums specifically as legitimate addresses. Normally you would simply recognize any `const` as legitimate.

Usually `PRINT_OPERAND_ADDRESS` is not prepared to handle constant sums that are not marked with `const`. It assumes that a naked `plus` indicates indexing. If so, then you *must* reject such naked constant sums as illegitimate addresses, so that none of them will be given to `PRINT_OPERAND_ADDRESS`.

On some machines, whether a symbolic address is legitimate depends on the section that the address refers to. On these machines, define the macro `ENCODE_SECTION_INFO` to store the information into the `symbol_ref`, and then check for it here. When you see a `const`, you will have to look inside it to find the `symbol_ref` in order to determine the section. See section Defining the Output Assembler Language.

The best way to modify the name string is by adding text to the beginning, with suitable punctuation to prevent any ambiguity. Allocate the new name in `saveable_obstack`. You will have to modify `ASM_OUTPUT_LABELREF` to remove and decode the added text and output the name accordingly, and define `STRIP_NAME_ENCODING` to access the original name string.

You can check the information stored here into the `symbol_ref` in the definitions of the macros `GO_IF_LEGITIMATE_ADDRESS` and `PRINT_OPERAND_ADDRESS`.

`REG_OK_FOR_BASE_P (x)`

A C expression that is nonzero if x (assumed to be a `reg` RTX) is valid for use as a base register. For hard registers, it should always accept those which the hardware permits and reject the others. Whether the macro accepts or rejects pseudo registers must be controlled by `REG_OK_STRICT` as described above. This usually requires two variant definitions, of which `REG_OK_STRICT` controls the one actually used.

`REG_OK_FOR_INDEX_P (x)`

A C expression that is nonzero if x (assumed to be a `reg` RTX) is valid for use as an index register.

The difference between an index register and a base register is that the index register may be scaled. If an address involves the sum of two registers, neither one of them scaled, then either one may be labeled the "base" and the other the "index"; but whichever labeling is used must fit the machine's constraints of which registers may serve in each capacity. The compiler will try both labelings, looking for one that is valid, and will reload one or both registers only if neither labeling works.

`LEGITIMIZE_ADDRESS (x, oldx, mode, win)`

A C compound statement that attempts to replace x with a valid memory address for an operand of mode mode. win will be a C statement label elsewhere in the code; the macro definition may use

```
GO_IF_LEGITIMATE_ADDRESS (mode, x, win);
```

to avoid further processing if the address has become legitimate.

x will always be the result of a call to `break_out_memory_refs`, and oldx will be the operand that was given to that function to produce x.

The code generated by this macro should not alter the substructure of x. If it transforms x into a more legitimate form, it should assign x (which will always be a C variable) a new value.

It is not necessary for this macro to come up with a legitimate address. The compiler has standard ways of doing so in all cases. In fact, it is safe for this macro to do nothing. But often a machine-dependent strategy can generate better code.

`GO_IF_MODE_DEPENDENT_ADDRESS (addr, label)`

A C statement or compound statement with a conditional `goto label;` executed if memory address x (an RTX) can have different meanings depending on the machine mode of the memory reference it is used for or if the address is valid for some modes but not others.

Autoincrement and autodecrement addresses typically have mode-dependent effects because the amount of the increment or decrement is the size of the operand being addressed. Some machines have other mode-dependent addresses. Many RISC machines have no mode-dependent addresses.

You may assume that addr is a valid address for the machine.

`LEGITIMATE_CONSTANT_P (x)`

A C expression that is nonzero if x is a legitimate constant for an immediate operand on the target machine. You can assume that x satisfies `CONSTANT_P`, so you need not check this. In fact, `1' is a suitable definition for this macro on machines where anything `CONSTANT_P` is valid.

Condition Code Status

This describes the condition code status.

The file `` `conditions.h' `` defines a variable `cc_status` to describe how the condition code was computed (in case the interpretation of the condition code depends on the instruction that it was set by). This variable contains the RTL expressions on which the condition code is currently based, and several standard flags.

Sometimes additional machine-specific flags must be defined in the machine description header file. It can also add additional machine-specific information by defining `CC_STATUS_MDEP`.

`CC_STATUS_MDEP`

C code for a data type which is used for declaring the `mdep` component of `cc_status`. It defaults to `int`.

This macro is not used on machines that do not use `cc0`.

`CC_STATUS_MDEP_INIT`

A C expression to initialize the `mdep` field to "empty". The default definition does nothing, since most machines don't use the field anyway. If you want to use the field, you should probably define this macro to initialize it.

This macro is not used on machines that do not use `cc0`.

`NOTICE_UPDATE_CC (exp, insn)`

A C compound statement to set the components of `cc_status` appropriately for an insn insn whose body is exp. It is this macro's responsibility to recognize insns that set the condition code as a byproduct of other activity as well as those that explicitly set `(cc0)`.

This macro is not used on machines that do not use `cc0`.

If there are insns that do not set the condition code but do alter other machine registers, this macro must check to see whether they invalidate the expressions that the condition code is recorded as reflecting. For example, on the 68000, insns that store in address registers do not set the condition code, which means that usually `NOTICE_UPDATE_CC` can leave `cc_status` unaltered for such insns. But suppose that the previous insn set the condition code based on location `a4@(102)' and the current insn stores a new value in `a4'. Although the condition code is not changed by this, it will no longer be true that it reflects the contents of `a4@(102)'. Therefore, `NOTICE_UPDATE_CC` must alter `cc_status` in this case to say that nothing is known about the condition code value.

The definition of `NOTICE_UPDATE_CC` must be prepared to deal with the results of peephole optimization: insns whose patterns are `parallel` RTXs containing various `reg`, `mem` or constants which are just the operands. The RTL structure of these insns is not sufficient to indicate what the insns actually do. What `NOTICE_UPDATE_CC` should do when it sees one is just to run `CC_STATUS_INIT`.

A possible definition of `NOTICE_UPDATE_CC` is to call a function that looks at an attribute (see section Instruction Attributes) named, for example, `cc'. This avoids having detailed information about patterns in two places, the `md' file and in `NOTICE_UPDATE_CC`.

`EXTRA_CC_MODES`

A list of names to be used for additional modes for condition code values in registers (see section Defining Jump Instruction Patterns). These names are added to `enum machine_mode` and all have class `MODE_CC`. By convention, they should start with `CC' and end with `mode'.

You should only define this macro if your machine does not use `cc0` and only if additional modes are required.

`EXTRA_CC_NAMES`

A list of C strings giving the names for the modes listed in `EXTRA_CC_MODES`. For example, the Sparc defines this macro and `EXTRA_CC_MODES` as

```
#define EXTRA_CC_MODES CC_NOOVmode, CCFPmode, CCFPEmode
#define EXTRA_CC_NAMES "CC_NOOV", "CCFP", "CCFPE"
```

This macro is not required if `EXTRA_CC_MODES` is not defined.

`SELECT_CC_MODE (op, x, y)`

Returns a mode from class `MODE_CC` to be used when comparison operation code op is applied to rtx x and y. For example, on the Sparc, `SELECT_CC_MODE` is defined as (see see section

Defining Jump Instruction Patterns for a description of the reason for this definition)

```
#define SELECT_CC_MODE(OP,X,Y) \
  (GET_MODE_CLASS (GET_MODE (X)) == MODE_FLOAT          \
   ? ((OP == EQ || OP == NE) ? CCFPmode : CCFPEmode)    \
   : ((GET_CODE (X) == PLUS || GET_CODE (X) == MINUS    \
       || GET_CODE (X) == NEG) \
      ? CC_NOOVmode : CCmode))
```

You need not define this macro if `EXTRA_CC_MODES` is not defined.

`CANONICALIZE_COMPARISON (code, op0, op1)`

One some machines not all possible comparisons are defined, but you can convert an invalid comparison into a valid one. For example, the Alpha does not have a `GT` comparison, but you can use an `LT` comparison instead and swap the order of the operands.

On such machines, define this macro to be a C statement to do any required conversions. code is the initial comparison code and op0 and op1 are the left and right operands of the comparison, respectively. You should modify code, op0, and op1 as required.

GNU CC will not assume that the comparison resulting from this macro is valid but will see if the resulting insn matches a pattern in the `` `md' `` file.

You need not define this macro if it would never change the comparison code or operands.

`REVERSIBLE_CC_MODE (mode)`

A C expression whose value is one if it is always safe to reverse a comparison whose mode is mode. If `SELECT_CC_MODE` can ever return mode for a floating-point inequality comparison, then `REVERSIBLE_CC_MODE (mode)` must be zero.

You need not define this macro if it would always returns zero or if the floating-point format is anything other than `IEEE_FLOAT_FORMAT`. For example, here is the definition used on the Sparc, where floating-point inequality comparisons are always given `CCFPEmode`:

```
#define REVERSIBLE_CC_MODE(MODE)  ((MODE) != CCFPEmode)
```

Describing Relative Costs of Operations

These macros let you describe the relative speed of various operations on the target machine.

`CONST_COSTS (x, code, outer_code)`

A part of a C `switch` statement that describes the relative costs of constant RTL expressions. It must contain `case` labels for expression codes `const_int`, `const`, `symbol_ref`, `label_ref` and `const_double`. Each case must ultimately reach a `return` statement to return the relative cost of the use of that kind of constant value in an expression. The cost may depend on the precise value of the constant, which is available for examination in x, and the rtx code of the expression in which it is contained, found in outer_code.

code is the expression code--redundant, since it can be obtained with `GET_CODE (x)`.

`RTX_COSTS (x, code, outer_code)`

Like `CONST_COSTS` but applies to nonconstant RTL expressions. This can be used, for example, to indicate how costly a multiply instruction is. In writing this macro, you can use the construct `COSTS_N_INSNS (n)` to specify a cost equal to n fast instructions. outer_code is the code of the expression in which x is contained.

This macro is optional; do not define it if the default cost assumptions are adequate for the target machine.

`ADDRESS_COST (address)`

An expression giving the cost of an addressing mode that contains address. If not defined, the cost is computed from the address expression and the `CONST_COSTS` values.

For most CISC machines, the default cost is a good approximation of the true cost of the addressing mode. However, on RISC machines, all instructions normally have the same length and execution time. Hence all addresses will have equal costs.

In cases where more than one form of an address is known, the form with the lowest cost will be used. If multiple forms have the same, lowest, cost, the one that is the most complex will be used.

For example, suppose an address that is equal to the sum of a register and a constant is used twice in the same basic block. When this macro is not defined, the address will be computed in a register and memory references will be indirect through that register. On machines where the cost of the addressing mode containing the sum is no higher than that of a simple indirect reference, this will produce an additional instruction and possibly require an additional register. Proper specification of this macro eliminates this overhead for such machines.

Similar use of this macro is made in strength reduction of loops.

address need not be valid as an address. In such a case, the cost is not relevant and can be any value; invalid addresses need not be assigned a different cost.

On machines where an address involving more than one register is as cheap as an address computation involving only one register, defining `ADDRESS_COST` to reflect this can cause two registers to be live over a region of code where only one would have been if `ADDRESS_COST` were not defined in that manner. This effect should be considered in the definition of this macro. Equivalent costs should probably only be given to addresses with different numbers of registers on machines with lots of registers.

This macro will normally either not be defined or be defined as a constant.

`REGISTER_MOVE_COST (from, to)`

A C expression for the cost of moving data from a register in class from to one in class to. The classes are expressed using the enumeration values such as `GENERAL_REGS`. A value of 4 is the default; other values are interpreted relative to that.

It is not required that the cost always equal 2 when from is the same as to; on some machines it is expensive to move between registers if they are not general registers.

If reload sees an insn consisting of a single `set` between two hard registers, and if `REGISTER_MOVE_COST` applied to their classes returns a value of 2, reload does not check to ensure that the constraints of the insn are met. Setting a cost of other than 2 will allow reload to verify that the constraints are met. You should do this if the `movm' pattern's constraints do not allow such copying.

`MEMORY_MOVE_COST (m)`

A C expression for the cost of moving data of mode m between a register and memory. A value of 2 is the default; this cost is relative to those in `REGISTER_MOVE_COST`.

If moving between registers and memory is more expensive than between two registers, you should define this macro to express the relative cost.

`BRANCH_COST`

A C expression for the cost of a branch instruction. A value of 1 is the default; other values are interpreted relative to that.

Here are additional macros which do not specify precise relative costs, but only that certain actions are more expensive than GNU CC would ordinarily expect.

`SLOW_BYTE_ACCESS`

Define this macro as a C expression which is nonzero if accessing less than a word of memory (i.e. a `char` or a `short`) is no faster than accessing a word of memory, i.e., if such access require more than one instruction or if there is no difference in cost between byte and (aligned) word loads.

When this macro is not defined, the compiler will access a field by finding the smallest containing object; when it is defined, a fullword load will be used if alignment permits. Unless bytes accesses are faster than word accesses, using word accesses is preferable since it may eliminate subsequent memory access if subsequent accesses occur to other fields in the same word of the structure, but to different bytes.

`SLOW_ZERO_EXTEND`

Define this macro if zero-extension (of a `char` or `short` to an `int`) can be done faster if the destination is a register that is known to be zero.

If you define this macro, you must have instruction patterns that recognize RTL structures like this:

```
(set (strict_low_part (subreg:QI (reg:SI ...) 0)) ...)
```

and likewise for `HImode`.

`SLOW_UNALIGNED_ACCESS`

Define this macro to be the value 1 if unaligned accesses have a cost many times greater than aligned accesses, for example if they are emulated in a trap handler.

When this macro is non-zero, the compiler will act as if `STRICT_ALIGNMENT` were non-zero when generating code for block moves. This can cause significantly more instructions to be produced. Therefore, do not set this macro non-zero if unaligned accesses only add a cycle or two

to the time for a memory access.

If the value of this macro is always zero, it need not be defined.

`DONT_REDUCE_ADDR`

Define this macro to inhibit strength reduction of memory addresses. (On some machines, such strength reduction seems to do harm rather than good.)

`MOVE_RATIO`

The number of scalar move insns which should be generated instead of a string move insn or a library call. Increasing the value will always make code faster, but eventually incurs high cost in increased code size.

If you don't define this, a reasonable default is used.

`NO_FUNCTION_CSE`

Define this macro if it is as good or better to call a constant function address than to call an address kept in a register.

`NO_RECURSIVE_FUNCTION_CSE`

Define this macro if it is as good or better for a function to call itself with an explicit address than to call an address kept in a register.

`ADJUST_COST (insn, link, dep_insn, cost)`

A C statement (sans semicolon) to update the integer variable cost based on the relationship between insn that is dependent on dep_insn through the dependence link. The default is to make no adjustment to cost. This can be used for example to specify to the scheduler that an output- or anti-dependence does not incur the same cost as a data-dependence.

Dividing the Output into Sections (Texts, Data, ...)

An object file is divided into sections containing different types of data. In the most common case, there are three sections: the text section, which holds instructions and read-only data; the data section, which holds initialized writable data; and the bss section, which holds uninitialized data. Some systems have other kinds of sections.

The compiler must tell the assembler when to switch sections. These macros control what commands to output to tell the assembler this. You can also define additional sections.

`TEXT_SECTION_ASM_OP`

A C expression whose value is a string containing the assembler operation that should precede instructions and read-only data. Normally `".text"` is right.

`DATA_SECTION_ASM_OP`

A C expression whose value is a string containing the assembler operation to identify the following data as writable initialized data. Normally `".data"` is right.

`SHARED_SECTION_ASM_OP`

if defined, a C expression whose value is a string containing the assembler operation to identify the following data as shared data. If not defined, `DATA_SECTION_ASM_OP` will be used.

`INIT_SECTION_ASM_OP`

if defined, a C expression whose value is a string containing the assembler operation to identify the following data as initialization code. If not defined, GNU CC will assume such a section does not exist.

`EXTRA_SECTIONS`

A list of names for sections other than the standard two, which are `in_text` and `in_data`. You need not define this macro on a system with no other sections (that GCC needs to use).

`EXTRA_SECTION_FUNCTIONS`

One or more functions to be defined in `` `varasm.c' ``. These functions should do jobs analogous to those of `text_section` and `data_section`, for your additional sections. Do not define this macro if you do not define `EXTRA_SECTIONS`.

`READONLY_DATA_SECTION`

On most machines, read-only variables, constants, and jump tables are placed in the text section. If this is not the case on your machine, this macro should be defined to be the name of a function (either `data_section` or a function defined in `EXTRA_SECTIONS`) that switches to the section to be used for read-only items.

If these items should be placed in the text section, this macro should not be defined.

`SELECT_SECTION (exp, reloc)`

A C statement or statements to switch to the appropriate section for output of exp. You can assume that exp is either a `VAR_DECL` node or a constant of some sort. reloc indicates whether the initial value of exp requires link-time relocations. Select the section by calling `text_section` or one of the alternatives for other sections.

Do not define this macro if you put all read-only variables and constants in the read-only data section (usually the text section).

`SELECT_RTX_SECTION (mode, rtx)`

A C statement or statements to switch to the appropriate section for output of rtx in mode mode. You can assume that rtx is some kind of constant in RTL. The argument mode is redundant except in the case of a `const_int` rtx. Select the section by calling `text_section` or one of the alternatives for other sections.

Do not define this macro if you put all constants in the read-only data section.

`JUMP_TABLES_IN_TEXT_SECTION`

Define this macro if jump tables (for `tablejump` insns) should be output in the text section, along with the assembler instructions. Otherwise, the readonly data section is used.

This macro is irrelevant if there is no separate readonly data section.

`ENCODE_SECTION_INFO (decl)`

Define this macro if references to a symbol must be treated differently depending on something about the variable or function named by the symbol (such as what section it is in).

The macro definition, if any, is executed immediately after the rtl for decl has been created and stored in `DECL_RTL (decl)`. The value of the rtl will be a `mem` whose address is a

`symbol_ref`.

The usual thing for this macro to do is to record a flag in the `symbol_ref` (such as `SYMBOL_REF_FLAG`) or to store a modified name string in the `symbol_ref` (if one bit is not enough information).

`STRIP_NAME_ENCODING (var, sym_name)`

Decode sym_name and store the real name part in var, sans the characters that encode section info. Define this macro if `ENCODE_SECTION_INFO` alters the symbol's name string.

Position Independent Code

This section describes macros that help implement generation of position independent code. Simply defining these macros is not enough to generate valid PIC; you must also add support to the macros `GO_IF_LEGITIMATE_ADDRESS` and `PRINT_OPERAND_ADDRESS`, as well as `LEGITIMIZE_ADDRESS`. You must modify the definition of `movsi' to do something appropriate when the source operand contains a symbolic address. You may also need to alter the handling of switch statements so that they use relative addresses.

`PIC_OFFSET_TABLE_REGNUM`

The register number of the register used to address a table of static data addresses in memory. In some cases this register is defined by a processor's "application binary interface" (ABI). When this macro is defined, RTL is generated for this register once, as with the stack pointer and frame pointer registers. If this macro is not defined, it is up to the machine-dependent files to allocate such a register (if necessary).

`PIC_OFFSET_TABLE_REG_CALL_CLOBBERED`

Define this macro if the register defined by `PIC_OFFSET_TABLE_REGNUM` is clobbered by calls. Do not define this macro if `PPIC_OFFSET_TABLE_REGNUM` is not defined.

`FINALIZE_PIC`

By generating position-independent code, when two different programs (A and B) share a common library (libC.a), the text of the library can be shared whether or not the library is linked at the same address for both programs. In some of these environments, position-independent code requires not only the use of different addressing modes, but also special code to enable the use of these addressing modes.

The `FINALIZE_PIC` macro serves as a hook to emit these special codes once the function is being compiled into assembly code, but not before. (It is not done before, because in the case of compiling an inline function, it would lead to multiple PIC prologues being included in functions which used inline functions and were compiled to assembly language.)

`LEGITIMATE_PIC_OPERAND_P (x)`

A C expression that is nonzero if x is a legitimate immediate operand on the target machine when generating position independent code. You can assume that x satisfies `CONSTANT_P`, so you need not check this. You can also assume flag_pic is true, so you need not check it either. You need not define this macro if all constants (including `SYMBOL_REF`) can be immediate operands when generating position independent code.

Defining the Output Assembler Language

This section describes macros whose principal purpose is to describe how to write instructions in assembler language--rather than what the instructions do.

The Overall Framework of an Assembler File

This describes the overall framework of an assembler file.

`ASM_FILE_START (stream)`

A C expression which outputs to the stdio stream stream some appropriate text to go at the start of an assembler file.

Normally this macro is defined to output a line containing `#NO_APP', which is a comment that has no effect on most assemblers but tells the GNU assembler that it can save time by not checking for certain assembler constructs.

On systems that use SDB, it is necessary to output certain commands; see `attasm.h'.

`ASM_FILE_END (stream)`

A C expression which outputs to the stdio stream stream some appropriate text to go at the end of an assembler file.

If this macro is not defined, the default is to output nothing special at the end of the file. Most systems don't require any definition.

On systems that use SDB, it is necessary to output certain commands; see `attasm.h'.

`ASM_IDENTIFY_GCC (file)`

A C statement to output assembler commands which will identify the object file as having been compiled with GNU CC (or another GNU compiler).

If you don't define this macro, the string `gcc_compiled.:' is output. This string is calculated to define a symbol which, on BSD systems, will never be defined for any other reason. GDB checks for the presence of this symbol when reading the symbol table of an executable.

On non-BSD systems, you must arrange communication with GDB in some other fashion. If GDB is not used on your system, you can define this macro with an empty body.

`ASM_COMMENT_START`

A C string constant describing how to begin a comment in the target assembler language. The compiler assumes that the comment will end at the end of the line.

`ASM_APP_ON`

A C string constant for text to be output before each `asm` statement or group of consecutive ones. Normally this is `"#APP"`, which is a comment that has no effect on most assemblers but tells the GNU assembler that it must check the lines that follow for all valid assembler constructs.

`ASM_APP_OFF`

A C string constant for text to be output after each `asm` statement or group of consecutive one. Normally this is `"#NO_APP"`, which tells the GNU assembler to resume making the time-sav assumptions that are valid for ordinary compiler output.

`ASM_OUTPUT_SOURCE_FILENAME (stream, name)`

A C statement to output COFF information or DWARF debugging information which indicates that filename name is the current source file to the stdio stream stream.

This macro need not be defined if the standard form of output for the file format in use is appropriate.

`ASM_OUTPUT_SOURCE_LINE (stream, line)`

A C statement to output DBX or SDB debugging information before code for line number line of the current source file to the stdio stream stream.

This macro need not be defined if the standard form of debugging information for the debugger in use is appropriate.

`ASM_OUTPUT_IDENT (stream, string)`

A C statement to output something to the assembler file to handle a `#ident' directive containing the text string. If this macro is not defined, nothing is output for a `#ident' directive.

`ASM_OUTPUT_SECTION_NAME (stream, decl, name)`

A C statement to output something to the assembler file to switch to section name for object decl which is either a `FUNCTION_DECL`, a `VAR_DECL` or `NULL_TREE`. Some target formats do not support arbitrary sections. Do not define this macro in such cases.

At present this macro is only used to support section attributes. When this macro is undefined, section attributes are disabled.

`OBJC_PROLOGUE`

A C statement to output any assembler statements which are required to precede any Objective C object definitions or message sending. The statement is executed only when compiling an Objective C program.

Output of Data

This describes data output.

`ASM_OUTPUT_LONG_DOUBLE (stream, value)`

`ASM_OUTPUT_DOUBLE (stream, value)`

`ASM_OUTPUT_FLOAT (stream, value)`

`ASM_OUTPUT_THREE_QUARTER_FLOAT (stream, value)`

`ASM_OUTPUT_SHORT_FLOAT (stream, value)`

`ASM_OUTPUT_BYTE_FLOAT (stream, value)`

A C statement to output to the stdio stream stream an assembler instruction to assemble a floating-point constant of `TFmode`, `DFmode`, `SFmode`, `TQFmode`, `HFmode`, or `QFmode`, respectively, whose value is value. value will be a C expression of type `REAL_VALUE_TYPE`.

Macros such as `REAL_VALUE_TO_TARGET_DOUBLE` are useful for writing these definitions.

`ASM_OUTPUT_QUADRUPLE_INT (stream, exp)`

`ASM_OUTPUT_DOUBLE_INT (stream, exp)`

`ASM_OUTPUT_INT (stream, exp)`

`ASM_OUTPUT_SHORT (stream, exp)`

`ASM_OUTPUT_CHAR (stream, exp)`

A C statement to output to the stdio stream stream an assembler instruction to assemble an integer of 16, 8, 4, 2 or 1 bytes, respectively, whose value is value. The argument exp will be an RTL expression which represents a constant value. Use `output_addr_const (stream, exp)' to output this value as an assembler expression.

For sizes larger than `UNITS_PER_WORD`, if the action of a macro would be identical to repeatedly calling the macro corresponding to a size of `UNITS_PER_WORD`, once for each word, you need not define the macro.

`ASM_OUTPUT_BYTE (stream, value)`

A C statement to output to the stdio stream stream an assembler instruction to assemble a single byte containing the number value.

`ASM_BYTE_OP`

A C string constant giving the pseudo-op to use for a sequence of single-byte constants. If this macro is not defined, the default is `"byte"`.

`ASM_OUTPUT_ASCII (stream, ptr, len)`

A C statement to output to the stdio stream stream an assembler instruction to assemble a string constant containing the len bytes at ptr. ptr will be a C expression of type `char *` and len a C expression of type `int`.

If the assembler has a `.ascii` pseudo-op as found in the Berkeley Unix assembler, do not define the macro `ASM_OUTPUT_ASCII`.

`ASM_OUTPUT_POOL_PROLOGUE (file funname fundecl size)`

A C statement to output assembler commands to define the start of the constant pool for a function. funname is a string giving the name of the function. Should the return type of the function be required, it can be obtained via fundecl. size is the size, in bytes, of the constant pool that will be written immediately after this call.

If no constant-pool prefix is required, the usual case, this macro need not be defined.

`ASM_OUTPUT_SPECIAL_POOL_ENTRY (file, x, mode, align, labelno, jumpto)`

A C statement (with or without semicolon) to output a constant in the constant pool, if it needs special treatment. (This macro need not do anything for RTL expressions that can be output normally.)

The argument file is the standard I/O stream to output the assembler code on. x is the RTL expression for the constant to output, and mode is the machine mode (in case x is a `const_int'). align is the required alignment for the value x; you should output an assembler directive to force this much alignment.

The argument labelno is a number to use in an internal label for the address of this pool entry. The definition of this macro is responsible for outputting the label definition at the proper place. Here is how to do this:

```
ASM_OUTPUT_INTERNAL_LABEL (file, "LC", labelno);
```

When you output a pool entry specially, you should end with a `goto` to the label jumpto. This will prevent the same pool entry from being output a second time in the usual manner.

You need not define this macro if it would do nothing.

`IS_ASM_LOGICAL_LINE_SEPARATOR (C)`

Define this macro as a C expression which is nonzero if C is used as a logical line separator by the assembler.

If you do not define this macro, the default is that only the character `;' is treated as a logical line separator.

`ASM_OPEN_PAREN`

`ASM_CLOSE_PAREN`

These macros are defined as C string constant, describing the syntax in the assembler for grouping arithmetic expressions. The following definitions are correct for most assemblers:

```
#define ASM_OPEN_PAREN "("
#define ASM_CLOSE_PAREN ")"
```

These macros are provided by `real.h' for writing the definitions of `ASM_OUTPUT_DOUBLE` and the like:

`REAL_VALUE_TO_TARGET_SINGLE (x, l)`

`REAL_VALUE_TO_TARGET_DOUBLE (x, l)`

`REAL_VALUE_TO_TARGET_LONG_DOUBLE (x, l)`

These translate x, of type `REAL_VALUE_TYPE`, to the target's floating point representation, and store its bit pattern in the array of `long int` whose address is l. The number of elements in the output array is determined by the size of the desired target floating point data type: 32 bits of it go in each `long int` array element. Each array element holds 32 bits of the result, even if `long int` is wider than 32 bits on the host machine.

The array element values are designed so that you can print them out using `fprintf` in the order they should appear in the target machine's memory.

`REAL_VALUE_TO_DECIMAL (x, format, string)`

This macro converts x, of type `REAL_VALUE_TYPE`, to a decimal number and stores it as a string into string. You must pass, as string, the address of a long enough block of space to hold the result.

The argument format is a `printf`-specification that serves as a suggestion for how to format the output string.

Output of Uninitialized Variables

Each of the macros in this section is used to do the whole job of outputting a single uninitialized variable.

`ASM_OUTPUT_COMMON (stream, name, size, rounded)`

A C statement (sans semicolon) to output to the stdio stream stream the assembler definition of a common-label named name whose size is size bytes. The variable rounded is the size rounded up to whatever alignment the caller wants.

Use the expression `assemble_name (stream, name)` to output the name itself; before and after that, output the additional assembler syntax for defining the name, and a newline.

This macro controls how the assembler definitions of uninitialized global variables are output.

`ASM_OUTPUT_ALIGNED_COMMON (stream, name, size, alignment)`

Like `ASM_OUTPUT_COMMON` except takes the required alignment as a separate, explicit argument. If you define this macro, it is used in place of `ASM_OUTPUT_COMMON`, and gives you more flexibility in handling the required alignment of the variable. The alignment is specified as the number of bits.

`ASM_OUTPUT_SHARED_COMMON (stream, name, size, rounded)`

If defined, it is similar to `ASM_OUTPUT_COMMON`, except that it is used when name is shared. If not defined, `ASM_OUTPUT_COMMON` will be used.

`ASM_OUTPUT_LOCAL (stream, name, size, rounded)`

A C statement (sans semicolon) to output to the stdio stream stream the assembler definition of a local-common-label named name whose size is size bytes. The variable rounded is the size rounded up to whatever alignment the caller wants.

Use the expression `assemble_name (stream, name)` to output the name itself; before and after that, output the additional assembler syntax for defining the name, and a newline.

This macro controls how the assembler definitions of uninitialized static variables are output.

`ASM_OUTPUT_ALIGNED_LOCAL (stream, name, size, alignment)`

Like `ASM_OUTPUT_LOCAL` except takes the required alignment as a separate, explicit argument. If you define this macro, it is used in place of `ASM_OUTPUT_LOCAL`, and gives you more flexibility in handling the required alignment of the variable. The alignment is specified as the number of bits.

`ASM_OUTPUT_SHARED_LOCAL (stream, name, size, rounded)`

If defined, it is similar to `ASM_OUTPUT_LOCAL`, except that it is used when name is shared. If not defined, `ASM_OUTPUT_LOCAL` will be used.

Output and Generation of Labels

This is about outputting labels.

`ASM_OUTPUT_LABEL (stream, name)`

A C statement (sans semicolon) to output to the stdio stream stream the assembler definition of a

label named name. Use the expression `assemble_name (stream, name)` to output the name itself; before and after that, output the additional assembler syntax for defining the name, and a newline.

`ASM_DECLARE_FUNCTION_NAME (stream, name, decl)`

A C statement (sans semicolon) to output to the stdio stream stream any text necessary for declaring the name name of a function which is being defined. This macro is responsible for outputting the label definition (perhaps using `ASM_OUTPUT_LABEL`). The argument decl is the `FUNCTION_DECL` tree node representing the function.

If this macro is not defined, then the function name is defined in the usual manner as a label (by means of `ASM_OUTPUT_LABEL`).

`ASM_DECLARE_FUNCTION_SIZE (stream, name, decl)`

A C statement (sans semicolon) to output to the stdio stream stream any text necessary for declaring the size of a function which is being defined. The argument name is the name of the function. The argument decl is the `FUNCTION_DECL` tree node representing the function.

If this macro is not defined, then the function size is not defined.

`ASM_DECLARE_OBJECT_NAME (stream, name, decl)`

A C statement (sans semicolon) to output to the stdio stream stream any text necessary for declaring the name name of an initialized variable which is being defined. This macro must output the label definition (perhaps using `ASM_OUTPUT_LABEL`). The argument decl is the `VAR_DECL` tree node representing the variable.

If this macro is not defined, then the variable name is defined in the usual manner as a label (by means of `ASM_OUTPUT_LABEL`).

`ASM_FINISH_DECLARE_OBJECT (stream, decl, toplevel, atend)`

A C statement (sans semicolon) to finish up declaring a variable name once the compiler has processed its initializer fully and thus has had a chance to determine the size of an array when controlled by an initializer. This is used on systems where it's necessary to declare something about the size of the object.

If you don't define this macro, that is equivalent to defining it to do nothing.

`ASM_GLOBALIZE_LABEL (stream, name)`

A C statement (sans semicolon) to output to the stdio stream stream some commands that will make the label name global; that is, available for reference from other files. Use the expression `assemble_name (stream, name)` to output the name itself; before and after that, output the additional assembler syntax for making that name global, and a newline.

`ASM_WEAKEN_LABEL`

A C statement (sans semicolon) to output to the stdio stream stream some commands that will make the label name weak; that is, available for reference from other files but only used if no other definition is available. Use the expression `assemble_name (stream, name)` to output the name itself; before and after that, output the additional assembler syntax for making that name weak, and a newline.

If you don't define this macro, GNU CC will not support weak symbols and you should not de the SUPPORTS_WEAK macro.

SUPPORTS_WEAK

A C expression which evaluates to true if the target supports weak symbols.

If you don't define this macro, `defaults.h' provides a default definition. If ASM_WEAKEN_LABEL is defined, the default definition is `1'; otherwise, it is `0'. Define this macro if you want to control weak symbol support with a compiler flag such as `-melf'.

ASM_OUTPUT_EXTERNAL (stream, decl, name)

A C statement (sans semicolon) to output to the stdio stream stream any text necessary for declaring the name of an external symbol named name which is referenced in this compilation but not defined. The value of decl is the tree node for the declaration.

This macro need not be defined if it does not need to output anything. The GNU assembler and most Unix assemblers don't require anything.

ASM_OUTPUT_EXTERNAL_LIBCALL (stream, symref)

A C statement (sans semicolon) to output on stream an assembler pseudo-op to declare a library function name external. The name of the library function is given by symref, which has type rtx and is a symbol_ref.

This macro need not be defined if it does not need to output anything. The GNU assembler and most Unix assemblers don't require anything.

ASM_OUTPUT_LABELREF (stream, name)

A C statement (sans semicolon) to output to the stdio stream stream a reference in assembler syntax to a label named name. This should add `_' to the front of the name, if that is customary on your operating system, as it is in most Berkeley Unix systems. This macro is used in assemble_name.

ASM_OUTPUT_INTERNAL_LABEL (stream, prefix, num)

A C statement to output to the stdio stream stream a label whose name is made from the string prefix and the number num.

It is absolutely essential that these labels be distinct from the labels used for user-level functions and variables. Otherwise, certain programs will have name conflicts with internal labels.

It is desirable to exclude internal labels from the symbol table of the object file. Most assemblers have a naming convention for labels that should be excluded; on many systems, the letter `L' at the beginning of a label has this effect. You should find out what convention your system uses, and follow it.

The usual definition of this macro is as follows:

```
fprintf (stream, "L%s%d:\n", prefix, num)
```

ASM_GENERATE_INTERNAL_LABEL (string, prefix, num)

A C statement to store into the string string a label whose name is made from the string prefix and

the number num.

This string, when output subsequently by `assemble_name`, should produce the output that `ASM_OUTPUT_INTERNAL_LABEL` would produce with the same prefix and num.

If the string begins with `*', then `assemble_name` will output the rest of the string unchanged. It is often convenient for `ASM_GENERATE_INTERNAL_LABEL` to use `*' in this way. If the string doesn't start with `*', then `ASM_OUTPUT_LABELREF` gets to output the string, and may change it. (Of course, `ASM_OUTPUT_LABELREF` is also part of your machine description, so you should know what it does on your machine.)

`ASM_FORMAT_PRIVATE_NAME (outvar, name, number)`

A C expression to assign to outvar (which is a variable of type `char *`) a newly allocated string made from the string name and the number number, with some suitable punctuation added. Use `alloca` to get space for the string.

The string will be used as an argument to `ASM_OUTPUT_LABELREF` to produce an assembler label for an internal static variable whose name is name. Therefore, the string must be such as to result in valid assembler code. The argument number is different each time this macro is executed; it prevents conflicts between similarly-named internal static variables in different scopes.

Ideally this string should not be a valid C identifier, to prevent any conflict with the user's own symbols. Most assemblers allow periods or percent signs in assembler symbols; putting at least one of these between the name and the number will suffice.

`ASM_OUTPUT_DEF (stream, name, value)`

A C statement to output to the stdio stream stream assembler code which defines (equates) the symbol name to have the value value.

If SET_ASM_OP is defined, a default definition is provided which is correct for most systems.

`OBJC_GEN_METHOD_LABEL (buf, is_inst, class_name, cat_name, sel_name)`

Define this macro to override the default assembler names used for Objective C methods.

The default name is a unique method number followed by the name of the class (e.g. `_1_Foo'). For methods in categories, the name of the category is also included in the assembler name (e.g. `_1_Foo_Bar').

These names are safe on most systems, but make debugging difficult since the method's selector is not present in the name. Therefore, particular systems define other ways of computing names.

buf is an expression of type `char *` which gives you a buffer in which to store the name; its length is as long as class_name, cat_name and sel_name put together, plus 50 characters extra.

The argument is_inst specifies whether the method is an instance method or a class method; class_name is the name of the class; cat_name is the name of the category (or NULL if the method is not in a category); and sel_name is the name of the selector.

On systems where the assembler can handle quoted names, you can use this macro to provide more human-readable names.

How Initialization Functions Are Handled

The compiled code for certain languages includes constructors (also called initialization routines)---functions to initialize data in the program when the program is started. These functions need to be called before the program is "started"---that is to say, before `main` is called.

Compiling some languages generates destructors (also called termination routines) that should be called when the program terminates.

To make the initialization and termination functions work, the compiler must output something in the assembler code to cause those functions to be called at the appropriate time. When you port the compiler to a new system, you need to specify how to do this.

There are two major ways that GCC currently supports the execution of initialization and termination functions. Each way has two variants. Much of the structure is common to all four variations.

The linker must build two lists of these functions--a list of initialization functions, called `__CTOR_LIST__`, and a list of termination functions, called `__DTOR_LIST__`.

Each list always begins with an ignored function pointer (which may hold 0, -1, or a count of the function pointers after it, depending on the environment). This is followed by a series of zero or more function pointers to constructors (or destructors), followed by a function pointer containing zero.

Depending on the operating system and its executable file format, either `` `crtstuff.c' `` or `` `libgcc2.c' `` traverses these lists at startup time and exit time. Constructors are called in reverse order of the list; destructors in forward order.

The best way to handle static constructors works only for object file formats which provide arbitrarily-named sections. A section is set aside for a list of constructors, and another for a list of destructors. Traditionally these are called `.ctors' and `.dtors'. Each object file that defines an initialization function also puts a word in the constructor section to point to that function. The linker accumulates all these words into one contiguous `.ctors' section. Termination functions are handled similarly.

To use this method, you need appropriate definitions of the macros `ASM_OUTPUT_CONSTRUCTOR` and `ASM_OUTPUT_DESTRUCTOR`. Usually you can get them by including `` `svr4.h' ``.

When arbitrary sections are available, there are two variants, depending upon how the code in `` `crtstuff.c' `` is called. On systems that support an init section which is executed at program startup, parts of `` `crtstuff.c' `` are compiled into that section. The program is linked by the `gcc` driver like this:

```
ld -o output_file crtbegin.o ... crtend.o -lgcc
```

The head of a function (`__do_global_ctors`) appears in the init section of `` `crtbegin.o' ``; the remainder of the function appears in the init section of `` `crtend.o' ``. The linker will pull these two parts of the section together, making a whole function. If any of the user's object files linked into the middle of it contribute code, then that code will be executed as part of the body of `__do_global_ctors`.

To use this variant, you must define the `INIT_SECTION_ASM_OP` macro properly.

If no init section is available, do not define `INIT_SECTION_ASM_OP`. Then `__do_global_ctors` is built into the text section like all other functions, and resides in `` `libgcc.a' ``. When GCC compiles any function called `main`, it inserts a procedure call to `__main` as the first executable code after the function prologue. The `__main` function, also defined in `` `libgcc2.c' ``, simply calls `` `__do_global_ctors' ``.

In file formats that don't support arbitrary sections, there are again two variants. In the simplest variant, the GNU linker (GNU `ld`) and an `a.out' format must be used. In this case, `ASM_OUTPUT_CONSTRUCTOR` is defined to produce a `.stabs` entry of type `N_SETT', referencing the name `__CTOR_LIST__`, and with the address of the void function containing the initialization code as its value. The GNU linker recognizes this as a request to add the value to a "set"; the values are accumulated, and are eventually placed in the executable as a vector in the format described above, with a leading (ignored) count and a trailing zero element. `ASM_OUTPUT_DESTRUCTOR` is handled similarly. Since no init section is available, the absence of `INIT_SECTION_ASM_OP` causes the compilation of `main` to call `__main` as above, starting the initialization process.

The last variant uses neither arbitrary sections nor the GNU linker. This is preferable when you want to do dynamic linking and when using file formats which the GNU linker does not support, such as `ECOFF'. In this case, `ASM_OUTPUT_CONSTRUCTOR` does not produce an `N_SETT` symbol; initialization and termination functions are recognized simply by their names. This requires an extra program in the linkage step, called `collect2`. This program pretends to be the linker, for use with GNU CC; it does its job by running the ordinary linker, but also arranges to include the vectors of initialization and termination functions. These functions are called via `__main` as described above.

Choosing among these configuration options has been simplified by a set of operating-system-dependent files in the `` `config' `` subdirectory. These files define all of the relevant parameters. Usually it is sufficient to include one into your specific machine-dependent configuration file. These files are:

`` `aoutos.h' ``
: For operating systems using the `a.out' format.

`` `next.h' ``
: For operating systems using the `MachO' format.

`` `svr3.h' ``
: For System V Release 3 and similar systems using `COFF' format.

`` `svr4.h' ``
: For System V Release 4 and similar systems using `ELF' format.

`` `vms.h' ``
: For the VMS operating system.

Macros Controlling Initialization Routines

Here are the macros that control how the compiler handles initialization and termination functions:

`INIT_SECTION_ASM_OP`

If defined, a C string constant for the assembler operation to identify the following data as initialization code. If not defined, GNU CC will assume such a section does not exist. When you are using special sections for initialization and termination functions, this macro also controls how `` `crtstuff.c' `` and `` `libgcc2.c' `` arrange to run the initialization functions.

`HAS_INIT_SECTION`

If defined, `main` will not call `__main` as described above. This macro should be defined for systems that control the contents of the init section on a symbol-by-symbol basis, such as OSF/1, and should not be defined explicitly for systems that support `INIT_SECTION_ASM_OP`.

`LD_INIT_SWITCH`

If defined, a C string constant for a switch that tells the linker that the following symbol is an initialization routine.

`LD_FINI_SWITCH`

If defined, a C string constant for a switch that tells the linker that the following symbol is a finalization routine.

`INVOKE__main`

If defined, `main` will call `__main` despite the presence of `INIT_SECTION_ASM_OP`. This macro should be defined for systems where the init section is not actually run automatically, but is still useful for collecting the lists of constructors and destructors.

`ASM_OUTPUT_CONSTRUCTOR (stream, name)`

Define this macro as a C statement to output on the stream stream the assembler code to arrange to call the function named name at initialization time.

Assume that name is the name of a C function generated automatically by the compiler. This function takes no arguments. Use the function `assemble_name` to output the name name; this performs any system-specific syntactic transformations such as adding an underscore.

If you don't define this macro, nothing special is output to arrange to call the function. This is correct when the function will be called in some other manner--for example, by means of the `collect2` program, which looks through the symbol table to find these functions by their names.

`ASM_OUTPUT_DESTRUCTOR (stream, name)`

This is like `ASM_OUTPUT_CONSTRUCTOR` but used for termination functions rather than initialization functions.

If your system uses `collect2` as the means of processing constructors, then that program normally uses `nm` to scan an object file for constructor functions to be called. On certain kinds of systems, you can define these macros to make `collect2` work faster (and, in some cases, make it work at all):

`OBJECT_FORMAT_COFF`

Define this macro if the system uses COFF (Common Object File Format) object files, so that

`collect2` can assume this format and scan object files directly for dynamic constructor/destructor functions.

`OBJECT_FORMAT_ROSE`

Define this macro if the system uses ROSE format object files, so that `collect2` can assume this format and scan object files directly for dynamic constructor/destructor functions.

These macros are effective only in a native compiler; `collect2` as part of a cross compiler always uses `nm` for the target machine.

`REAL_NM_FILE_NAME`

Define this macro as a C string constant containing the file name to use to execute `nm`. The default is to search the path normally for `nm`.

If your system supports shared libraries and has a program to list the dynamic dependencies of a given library or executable, you can define these macros to enable support for running initialization and termination functions in shared libraries:

`LDD_SUFFIX`

Define this macro to a C string constant containing the name of the program which lists dynamic dependencies, like `"ldd"` under SunOS 4.

`PARSE_LDD_OUTPUT (PTR)`

Define this macro to be C code that extracts filenames from the output of the program denoted by `LDD_SUFFIX`. PTR is a variable of type `char *` that points to the beginning of a line of output from `LDD_SUFFIX`. If the line lists a dynamic dependency, the code must advance PTR to the beginning of the filename on that line. Otherwise, it must set PTR to `NULL`.

Output of Assembler Instructions

This describes assembler instruction output.

`REGISTER_NAMES`

A C initializer containing the assembler's names for the machine registers, each one as a C string constant. This is what translates register numbers in the compiler into assembler language.

`ADDITIONAL_REGISTER_NAMES`

If defined, a C initializer for an array of structures containing a name and a register number. This macro defines additional names for hard registers, thus allowing the `asm` option in declarations to refer to registers using alternate names.

`ASM_OUTPUT_OPCODE (stream, ptr)`

Define this macro if you are using an unusual assembler that requires different names for the machine instructions.

The definition is a C statement or statements which output an assembler instruction opcode to the stdio stream stream. The macro-operand ptr is a variable of type `char *` which points to the opcode name in its "internal" form--the form that is written in the machine description. The definition should output the opcode name to stream, performing any translation you desire, and increment the variable ptr to point at the end of the opcode so that it will not be output twice.

In fact, your macro definition may process less than the entire opcode name, or more than the opcode name; but if you want to process text that includes `%'-sequences to substitute operands, you must take care of the substitution yourself. Just be sure to increment ptr over whatever text should not be output normally.

If you need to look at the operand values, they can be found as the elements of `recog_operand`.

If the macro definition does nothing, the instruction is output in the usual way.

`FINAL_PRESCAN_INSN (insn, opvec, noperands)`

If defined, a C statement to be executed just prior to the output of assembler code for insn, to modify the extracted operands so they will be output differently.

Here the argument opvec is the vector containing the operands extracted from insn, and noperands is the number of elements of the vector which contain meaningful data for this insn. The contents of this vector are what will be used to convert the insn template into assembler code, so you can change the assembler output by changing the contents of the vector.

This macro is useful when various assembler syntaxes share a single file of instruction patterns; by defining this macro differently, you can cause a large class of instructions to be output differently (such as with rearranged operands). Naturally, variations in assembler syntax affecting individual insn patterns ought to be handled by writing conditional output routines in those patterns.

If this macro is not defined, it is equivalent to a null statement.

`PRINT_OPERAND (stream, x, code)`

A C compound statement to output to stdio stream stream the assembler syntax for an instruction operand x. x is an RTL expression.

code is a value that can be used to specify one of several ways of printing the operand. It is used when identical operands must be printed differently depending on the context. code comes from the `%' specification that was used to request printing of the operand. If the specification was just `%digit' then code is 0; if the specification was `%ltr digit' then code is the ASCII code for ltr.

If x is a register, this macro should print the register's name. The names can be found in an array `reg_names` whose type is `char *[]`. `reg_names` is initialized from `REGISTER_NAMES`.

When the machine description has a specification `%punct' (a `%' followed by a punctuation character), this macro is called with a null pointer for x and the punctuation character for code.

`PRINT_OPERAND_PUNCT_VALID_P (code)`

A C expression which evaluates to true if code is a valid punctuation character for use in the `PRINT_OPERAND` macro. If `PRINT_OPERAND_PUNCT_VALID_P` is not defined, it means that no punctuation characters (except for the standard one, `%') are used in this way.

`PRINT_OPERAND_ADDRESS (stream, x)`

A C compound statement to output to stdio stream stream the assembler syntax for an instruction operand that is a memory reference whose address is x. x is an RTL expression.

On some machines, the syntax for a symbolic address depends on the section that the address refers to. On these machines, define the macro `ENCODE_SECTION_INFO` to store the

information into the `symbol_ref`, and then check for it here. See section Defining the Outpu Assembler Language.

`DBR_OUTPUT_SEQEND(file)`

A C statement, to be executed after all slot-filler instructions have been output. If necessary, call `dbr_sequence_length` to determine the number of slots filled in a sequence (zero if not currently outputting a sequence), to decide how many no-ops to output, or whatever.

Don't define this macro if it has nothing to do, but it is helpful in reading assembly output if the extent of the delay sequence is made explicit (e.g. with white space).

Note that output routines for instructions with delay slots must be prepared to deal with not being output as part of a sequence (i.e. when the scheduling pass is not run, or when no slot fillers could be found.) The variable `final_sequence` is null when not processing a sequence, otherwise it contains the `sequence` rtx being output.

`REGISTER_PREFIX`

`LOCAL_LABEL_PREFIX`

`USER_LABEL_PREFIX`

`IMMEDIATE_PREFIX`

If defined, C string expressions to be used for the `%R', `%L', `%U', and `%I' options of `asm_fprintf` (see `final.c'). These are useful when a single `md' file must support multiple assembler formats. In that case, the various `tm.h' files can define these macros differently.

`ASSEMBLER_DIALECT`

If your target supports multiple dialects of assembler language (such as different opcodes), define this macro as a C expression that gives the numeric index of the assembler language dialect to use, with zero as the first variant.

If this macro is defined, you may use `{option0|option1|option2...}' constructs in the output templates of patterns (see section Output Templates and Operand Substitution) or in the first argument of `asm_fprintf`. This construct outputs `option0', `option1' or `option2', etc., if the value of `ASSEMBLER_DIALECT` is zero, one or two, etc. Any special characters within these strings retain their usual meaning.

If you do not define this macro, the characters `{', `|' and `}' do not have any special meaning when used in templates or operands to `asm_fprintf`.

Define the macros `REGISTER_PREFIX`, `LOCAL_LABEL_PREFIX`, `USER_LABEL_PREFIX` and `IMMEDIATE_PREFIX` if you can express the variations in assemble language syntax with that mechanism. Define `ASSEMBLER_DIALECT` and use the `{option0|option1}' syntax if the syntax variant are larger and involve such things as different opcodes or operand order.

`ASM_OUTPUT_REG_PUSH (stream, regno)`

A C expression to output to stream some assembler code which will push hard register number regno onto the stack. The code need not be optimal, since this macro is used only when profiling.

`ASM_OUTPUT_REG_POP (stream, regno)`

A C expression to output to stream some assembler code which will pop hard register number regno off of the stack. The code need not be optimal, since this macro is used only when profil

Output of Dispatch Tables

This concerns dispatch tables.

`ASM_OUTPUT_ADDR_DIFF_ELT (stream, value, rel)`

This macro should be provided on machines where the addresses in a dispatch table are relative to the table's own address.

The definition should be a C statement to output to the stdio stream stream an assembler pseudo-instruction to generate a difference between two labels. value and rel are the numbers of two internal labels. The definitions of these labels are output using `ASM_OUTPUT_INTERNAL_LABEL`, and they must be printed in the same way here. For example,

```
fprintf (stream, "\t.word L%d-L%d\n",
         value, rel)
```

`ASM_OUTPUT_ADDR_VEC_ELT (stream, value)`

This macro should be provided on machines where the addresses in a dispatch table are absolute.

The definition should be a C statement to output to the stdio stream stream an assembler pseudo-instruction to generate a reference to a label. value is the number of an internal label whose definition is output using `ASM_OUTPUT_INTERNAL_LABEL`. For example,

```
fprintf (stream, "\t.word L%d\n", value)
```

`ASM_OUTPUT_CASE_LABEL (stream, prefix, num, table)`

Define this if the label before a jump-table needs to be output specially. The first three arguments are the same as for `ASM_OUTPUT_INTERNAL_LABEL`; the fourth argument is the jump-table which follows (a `jump_insn` containing an `addr_vec` or `addr_diff_vec`).

This feature is used on system V to output a `swbeg` statement for the table.

If this macro is not defined, these labels are output with `ASM_OUTPUT_INTERNAL_LABEL`.

`ASM_OUTPUT_CASE_END (stream, num, table)`

Define this if something special must be output at the end of a jump-table. The definition should be a C statement to be executed after the assembler code for the table is written. It should write the appropriate code to stdio stream stream. The argument table is the jump-table insn, and num is the label-number of the preceding label.

If this macro is not defined, nothing special is output at the end of the jump-table.

Assembler Commands for Alignment

This describes commands for alignment.

`ASM_OUTPUT_ALIGN_CODE (file)`

A C expression to output text to align the location counter in the way that is desirable at a point in the code that is reached only by jumping.

This macro need not be defined if you don't want any special alignment to be done at such a time. Most machine descriptions do not currently define the macro.

`ASM_OUTPUT_LOOP_ALIGN (file)`

A C expression to output text to align the location counter in the way that is desirable at the beginning of a loop.

This macro need not be defined if you don't want any special alignment to be done at such a time. Most machine descriptions do not currently define the macro.

`ASM_OUTPUT_SKIP (stream, nbytes)`

A C statement to output to the stdio stream stream an assembler instruction to advance the location counter by nbytes bytes. Those bytes should be zero when loaded. nbytes will be a C expression of type `int`.

`ASM_NO_SKIP_IN_TEXT`

Define this macro if `ASM_OUTPUT_SKIP` should not be used in the text section because it fails put zeros in the bytes that are skipped. This is true on many Unix systems, where the pseudo--op to skip bytes produces no-op instructions rather than zeros when used in the text section.

`ASM_OUTPUT_ALIGN (stream, power)`

A C statement to output to the stdio stream stream an assembler command to advance the location counter to a multiple of 2 to the power bytes. power will be a C expression of type `int`.

Controlling Debugging Information Format

This describes how to specify debugging information.

Macros Affecting All Debugging Formats

These macros affect all debugging formats.

`DBX_REGISTER_NUMBER (regno)`

A C expression that returns the DBX register number for the compiler register number regno. In simple cases, the value of this expression may be regno itself. But sometimes there are some registers that the compiler knows about and DBX does not, or vice versa. In such cases, some register may need to have one number in the compiler and another for DBX.

If two registers have consecutive numbers inside GNU CC, and they can be used as a pair to hold a multiword value, then they *must* have consecutive numbers after renumbering with

`DBX_REGISTER_NUMBER`. Otherwise, debuggers will be unable to access such a pair, because they expect register pairs to be consecutive in their own numbering scheme.

If you find yourself defining `DBX_REGISTER_NUMBER` in way that does not preserve register pairs, then what you must do instead is redefine the actual register numbering scheme.

`DEBUGGER_AUTO_OFFSET (x)`

A C expression that returns the integer offset value for an automatic variable having address x (an RTL expression). The default computation assumes that x is based on the frame-pointer and gives the offset from the frame-pointer. This is required for targets that produce debugging output for DBX or COFF-style debugging output for SDB and allow the frame-pointer to be eliminated when the `-g' options is used.

`DEBUGGER_ARG_OFFSET (offset, x)`

A C expression that returns the integer offset value for an argument having address x (an RTL expression). The nominal offset is offset.

`PREFERRED_DEBUGGING_TYPE`

A C expression that returns the type of debugging output GNU CC produces when the user specifies `-g' or `-ggdb'. Define this if you have arranged for GNU CC to support more than one format of debugging output. Currently, the allowable values are `DBX_DEBUG`, `SDB_DEBUG`, `DWARF_DEBUG`, and `XCOFF_DEBUG`.

The value of this macro only affects the default debugging output; the user can always get a specific type of output by using `-gstabs', `-gcoff', `-gdwarf', or `-gxcoff'.

Specific Options for DBX Output

These are specific options for DBX output.

`DBX_DEBUGGING_INFO`

Define this macro if GNU CC should produce debugging output for DBX in response to the `-g' option.

`XCOFF_DEBUGGING_INFO`

Define this macro if GNU CC should produce XCOFF format debugging output in response to the `-g' option. This is a variant of DBX format.

`DEFAULT_GDB_EXTENSIONS`

Define this macro to control whether GNU CC should by default generate GDB's extended version of DBX debugging information (assuming DBX-format debugging information is enabled at all). If you don't define the macro, the default is 1: always generate the extended information if there is any occasion to.

`DEBUG_SYMS_TEXT`

Define this macro if all `.stabs` commands should be output while in the text section.

`ASM_STABS_OP`

A C string constant naming the assembler pseudo op to use instead of `.stabs` to define an ordinary debugging symbol. If you don't define this macro, `.stabs` is used. This macro applies

only to DBX debugging information format.

`ASM_STABD_OP`

A C string constant naming the assembler pseudo op to use instead of `.stabd` to define a debugging symbol whose value is the current location. If you don't define this macro, `.stabd` is used. This macro applies only to DBX debugging information format.

`ASM_STABN_OP`

A C string constant naming the assembler pseudo op to use instead of `.stabn` to define a debugging symbol with no name. If you don't define this macro, `.stabn` is used. This macro applies only to DBX debugging information format.

`DBX_NO_XREFS`

Define this macro if DBX on your system does not support the construct `xstagname'. On some systems, this construct is used to describe a forward reference to a structure named tagname. On other systems, this construct is not supported at all.

`DBX_CONTIN_LENGTH`

A symbol name in DBX-format debugging information is normally continued (split into two separate `.stabs` directives) when it exceeds a certain length (by default, 80 characters). On some operating systems, DBX requires this splitting; on others, splitting must not be done. You can inhibit splitting by defining this macro with the value zero. You can override the default splitting-length by defining this macro as an expression for the length you desire.

`DBX_CONTIN_CHAR`

Normally continuation is indicated by adding a `\' character to the end of a `.stabs` string when a continuation follows. To use a different character instead, define this macro as a character constant for the character you want to use. Do not define this macro if backslash is correct for your system.

`DBX_STATIC_STAB_DATA_SECTION`

Define this macro if it is necessary to go to the data section before outputting the `.stabs' pseudo-op for a non-global static variable.

`DBX_TYPE_DECL_STABS_CODE`

The value to use in the "code" field of the `.stabs` directive for a typedef. The default is `N_LSYM`.

`DBX_STATIC_CONST_VAR_CODE`

The value to use in the "code" field of the `.stabs` directive for a static variable located in the text section. DBX format does not provide any "right" way to do this. The default is `N_FUN`.

`DBX_REGPARM_STABS_CODE`

The value to use in the "code" field of the `.stabs` directive for a parameter passed in registers. DBX format does not provide any "right" way to do this. The default is `N_RSYM`.

`DBX_REGPARM_STABS_LETTER`

The letter to use in DBX symbol data to identify a symbol as a parameter passed in registers. DBX format does not customarily provide any way to do this. The default is `'P'`.

`DBX_MEMPARM_STABS_LETTER`

The letter to use in DBX symbol data to identify a symbol as a stack parameter. The default is

'p'.

`DBX_FUNCTION_FIRST`

Define this macro if the DBX information for a function and its arguments should precede the assembler code for the function. Normally, in DBX format, the debugging information entirely follows the assembler code.

`DBX_LBRAC_FIRST`

Define this macro if the `N_LBRAC` symbol for a block should precede the debugging information for variables and functions defined in that block. Normally, in DBX format, the `N_LBRAC` symbol comes first.

`DBX_BLOCKS_FUNCTION_RELATIVE`

Define this macro if the value of a symbol describing the scope of a block (`N_LBRAC` or `N_RBRAC`) should be relative to the start of the enclosing function. Normally, GNU C uses an absolute address.

Open-Ended Hooks for DBX Format

These are hooks for DBX format.

`DBX_OUTPUT_LBRAC (stream, name)`

Define this macro to say how to output to stream the debugging information for the start of a scope level for variable names. The argument name is the name of an assembler symbol (for use with `assemble_name`) whose value is the address where the scope begins.

`DBX_OUTPUT_RBRAC (stream, name)`

Like `DBX_OUTPUT_LBRAC`, but for the end of a scope level.

`DBX_OUTPUT_ENUM (stream, type)`

Define this macro if the target machine requires special handling to output an enumeration type. The definition should be a C statement (sans semicolon) to output the appropriate information to stream for the type type.

`DBX_OUTPUT_FUNCTION_END (stream, function)`

Define this macro if the target machine requires special output at the end of the debugging information for a function. The definition should be a C statement (sans semicolon) to output the appropriate information to stream. function is the `FUNCTION_DECL` node for the function.

`DBX_OUTPUT_STANDARD_TYPES (syms)`

Define this macro if you need to control the order of output of the standard data types at the beginning of compilation. The argument syms is a `tree` which is a chain of all the predefined global symbols, including names of data types.

Normally, DBX output starts with definitions of the types for integers and characters, followed by all the other predefined types of the particular language in no particular order.

On some machines, it is necessary to output different particular types first. To do this, define `DBX_OUTPUT_STANDARD_TYPES` to output those symbols in the necessary order. Any predefined types that you don't explicitly output will be output afterward in no particular order.

Be careful not to define this macro so that it works only for C. There are no global variables to access most of the built-in types, because another language may have another set of types. The way to output a particular type is to look through syms to see if you can find it. Here is an example:

```
{
  tree decl;
  for (decl = syms; decl; decl = TREE_CHAIN (decl))
    if (!strcmp (IDENTIFIER_POINTER (DECL_NAME (decl)),
                 "long int"))
      dbxout_symbol (decl);
  ...
}
```

This does nothing if the expected type does not exist.

See the function `init_decl_processing` in `c-decl.c' to find the names to use for all the built-in C types.

Here is another way of finding a particular type:

```
{
  tree decl;
  for (decl = syms; decl; decl = TREE_CHAIN (decl))
    if (TREE_CODE (decl) == TYPE_DECL
        && (TREE_CODE (TREE_TYPE (decl))
            == INTEGER_CST)
        && TYPE_PRECISION (TREE_TYPE (decl)) == 16
        && TYPE_UNSIGNED (TREE_TYPE (decl)))
      /* This must be unsigned short.  */
      dbxout_symbol (decl);
  ...
}
```

File Names in DBX Format

This describes file names in DBX format.

`DBX_WORKING_DIRECTORY`

Define this if DBX wants to have the current directory recorded in each object file.

Note that the working directory is always recorded if GDB extensions are enabled.

`DBX_OUTPUT_MAIN_SOURCE_FILENAME (stream, name)`

A C statement to output DBX debugging information to the stdio stream stream which indicates that file name is the main source file--the file specified as the input file for compilation. This macro is called only once, at the beginning of compilation.

This macro need not be defined if the standard form of output for DBX debugging information appropriate.

`DBX_OUTPUT_MAIN_SOURCE_DIRECTORY (stream, name)`

A C statement to output DBX debugging information to the stdio stream stream which indicates that the current directory during compilation is named name.

This macro need not be defined if the standard form of output for DBX debugging information is appropriate.

`DBX_OUTPUT_MAIN_SOURCE_FILE_END (stream, name)`

A C statement to output DBX debugging information at the end of compilation of the main source file name.

If you don't define this macro, nothing special is output at the end of compilation, which is correct for most machines.

`DBX_OUTPUT_SOURCE_FILENAME (stream, name)`

A C statement to output DBX debugging information to the stdio stream stream which indicates that file name is the current source file. This output is generated each time input shifts to a different source file as a result of `#include', the end of an included file, or a `#line' command.

This macro need not be defined if the standard form of output for DBX debugging information is appropriate.

Macros for SDB and DWARF Output

Here are macros for SDB and DWARF output.

`SDB_DEBUGGING_INFO`

Define this macro if GNU CC should produce COFF-style debugging output for SDB in response to the `-g' option.

`DWARF_DEBUGGING_INFO`

Define this macro if GNU CC should produce dwarf format debugging output in response to the `-g' option.

`PUT_SDB_...`

Define these macros to override the assembler syntax for the special SDB assembler directives. See `sdbout.c' for a list of these macros and their arguments. If the standard syntax is used, you need not define them yourself.

`SDB_DELIM`

Some assemblers do not support a semicolon as a delimiter, even between SDB assembler directives. In that case, define this macro to be the delimiter to use (usually `\n'). It is not necessary to define a new set of `PUT_SDB_op` macros if this is the only change required.

`SDB_GENERATE_FAKE`

Define this macro to override the usual method of constructing a dummy name for anonymous structure and union types. See `sdbout.c' for more information.

`SDB_ALLOW_UNKNOWN_REFERENCES`

Define this macro to allow references to unknown structure, union, or enumeration tags to be emitted. Standard COFF does not allow handling of unknown references, MIPS ECOFF has support for it.

`SDB_ALLOW_FORWARD_REFERENCES`

Define this macro to allow references to structure, union, or enumeration tags that have not yet been seen to be handled. Some assemblers choke if forward tags are used, while some require it.

Cross Compilation and Floating Point

While all modern machines use 2's complement representation for integers, there are a variety of representations for floating point numbers. This means that in a cross-compiler the representation of floating point numbers in the compiled program may be different from that used in the machine doing the compilation.

Because different representation systems may offer different amounts of range and precision, the cross compiler cannot safely use the host machine's floating point arithmetic. Therefore, floating point constants must be represented in the target machine's format. This means that the cross compiler cannot use `atof` to parse a floating point constant; it must have its own special routine to use instead. Also, constant folding must emulate the target machine's arithmetic (or must not be done at all).

The macros in the following table should be defined only if you are cross compiling between different floating point formats.

Otherwise, don't define them. Then default definitions will be set up which use `double` as the data type, `==` to test for equality, etc.

You don't need to worry about how many times you use an operand of any of these macros. The compiler never uses operands which have side effects.

`REAL_VALUE_TYPE`

A macro for the C data type to be used to hold a floating point value in the target machine's format. Typically this would be a `struct` containing an array of `int`.

`REAL_VALUES_EQUAL (x, y)`

A macro for a C expression which compares for equality the two values, x and y, both of type `REAL_VALUE_TYPE`.

`REAL_VALUES_LESS (x, y)`

A macro for a C expression which tests whether x is less than y, both values being of type `REAL_VALUE_TYPE` and interpreted as floating point numbers in the target machine's representation.

`REAL_VALUE_LDEXP (x, scale)`

A macro for a C expression which performs the standard library function `ldexp`, but using the target machine's floating point representation. Both x and the value of the expression have type `REAL_VALUE_TYPE`. The second argument, scale, is an integer.

`REAL_VALUE_FIX (x)`

A macro whose definition is a C expression to convert the target-machine floating point value x to a signed integer. x has type `REAL_VALUE_TYPE`.

`REAL_VALUE_UNSIGNED_FIX (x)`

A macro whose definition is a C expression to convert the target-machine floating point value x to an unsigned integer. x has type `REAL_VALUE_TYPE`.

`REAL_VALUE_RNDZINT (x)`

A macro whose definition is a C expression to round the target-machine floating point value x towards zero to an integer value (but still as a floating point number). x has type `REAL_VALUE_TYPE`, and so does the value.

`REAL_VALUE_UNSIGNED_RNDZINT (x)`

A macro whose definition is a C expression to round the target-machine floating point value x towards zero to an unsigned integer value (but still represented as a floating point number). x has type `REAL_VALUE_TYPE`, and so does the value.

`REAL_VALUE_ATOF (string, mode)`

A macro for a C expression which converts string, an expression of type `char *`, into a floating point number in the target machine's representation for mode mode. The value has type `REAL_VALUE_TYPE`.

`REAL_INFINITY`

Define this macro if infinity is a possible floating point value, and therefore division by 0 is legitimate.

`REAL_VALUE_ISINF (x)`

A macro for a C expression which determines whether x, a floating point value, is infinity. The value has type `int`. By default, this is defined to call `isinf`.

`REAL_VALUE_ISNAN (x)`

A macro for a C expression which determines whether x, a floating point value, is a "nan" (not-a-number). The value has type `int`. By default, this is defined to call `isnan`.

Define the following additional macros if you want to make floating point constant folding work while cross compiling. If you don't define them, cross compilation is still possible, but constant folding will not happen for floating point values.

`REAL_ARITHMETIC (output, code, x, y)`

A macro for a C statement which calculates an arithmetic operation of the two floating point values x and y, both of type `REAL_VALUE_TYPE` in the target machine's representation, to produce a result of the same type and representation which is stored in output (which will be a variable).

The operation to be performed is specified by code, a tree code which will always be one of the following: `PLUS_EXPR`, `MINUS_EXPR`, `MULT_EXPR`, `RDIV_EXPR`, `MAX_EXPR`, `MIN_EXPR`.

The expansion of this macro is responsible for checking for overflow. If overflow happens, the macro expansion should execute the statement `return 0;`, which indicates the inability to

perform the arithmetic operation requested.

`REAL_VALUE_NEGATE (x)`

A macro for a C expression which returns the negative of the floating point value x. Both x and the value of the expression have type `REAL_VALUE_TYPE` and are in the target machine's floating point representation.

There is no way for this macro to report overflow, since overflow can't happen in the negation operation.

`REAL_VALUE_TRUNCATE (mode, x)`

A macro for a C expression which converts the floating point value x to mode mode.

Both x and the value of the expression are in the target machine's floating point representation and have type `REAL_VALUE_TYPE`. However, the value should have an appropriate bit pattern to be output properly as a floating constant whose precision accords with mode mode.

There is no way for this macro to report overflow.

`REAL_VALUE_TO_INT (low, high, x)`

A macro for a C expression which converts a floating point value x into a double-precision integer which is then stored into low and high, two variables of type int.

`REAL_VALUE_FROM_INT (x, low, high)`

A macro for a C expression which converts a double-precision integer found in low and high, two variables of type int, into a floating point value which is then stored into x.

Miscellaneous Parameters

Here are several miscellaneous parameters.

`PREDICATE_CODES`

Define this if you have defined special-purpose predicates in the file `` `machine.c' ``. This macro is called within an initializer of an array of structures. The first field in the structure is the name of a predicate and the second field is an array of rtl codes. For each predicate, list all rtl codes that can be in expressions matched by the predicate. The list should have a trailing comma. Here is an example of two entries in the list for a typical RISC machine:

```
#define PREDICATE_CODES \
  {"gen_reg_rtx_operand", {SUBREG, REG}},  \
  {"reg_or_short_cint_operand", {SUBREG, REG, CONST_INT}},
```

Defining this macro does not affect the generated code (however, incorrect definitions that omit an rtl code that may be matched by the predicate can cause the compiler to malfunction). Instead, it allows the table built by `` `genrecog' `` to be more compact and efficient, thus speeding up the compiler. The most important predicates to include in the list specified by this macro are thoses used in the most insn patterns.

`CASE_VECTOR_MODE`

An alias for a machine mode name. This is the machine mode that elements of a jump-table sh have.

`CASE_VECTOR_PC_RELATIVE`

Define this macro if jump-tables should contain relative addresses.

`CASE_DROPS_THROUGH`

Define this if control falls through a `case` insn when the index value is out of range. This means the specified default-label is actually ignored by the `case` insn proper.

`CASE_VALUES_THRESHOLD`

Define this to be the smallest number of different values for which it is best to use a jump-table instead of a tree of conditional branches. The default is four for machines with a `casesi` instruction and five otherwise. This is best for most machines.

`WORD_REGISTER_OPERATIONS`

Define this macro if operations between registers with integral mode smaller than a word are always performed on the entire register. Most RISC machines have this property and most CISC machines do not.

`LOAD_EXTEND_OP (mode)`

Define this macro to be a C expression indicating when insns that read memory in mode, an integral mode narrower than a word, set the bits outside of mode to be either the sign-extension or the zero-extension of the data read. Return `SIGN_EXTEND` for values of mode for which the insn sign-extends, `ZERO_EXTEND` for which it zero-extends, and `NIL` for other modes.

This macro is not called with mode non-integral or with a width greater than or equal to `BITS_PER_WORD`, so you may return any value in this case. Do not define this macro if it would always return `NIL`. On machines where this macro is defined, you will normally define it as the constant `SIGN_EXTEND` or `ZERO_EXTEND`.

`IMPLICIT_FIX_EXPR`

An alias for a tree code that should be used by default for conversion of floating point values to fixed point. Normally, `FIX_ROUND_EXPR` is used.

`FIXUNS_TRUNC_LIKE_FIX_TRUNC`

Define this macro if the same instructions that convert a floating point number to a signed fixed point number also convert validly to an unsigned one.

`EASY_DIV_EXPR`

An alias for a tree code that is the easiest kind of division to compile code for in the general case. It may be `TRUNC_DIV_EXPR`, `FLOOR_DIV_EXPR`, `CEIL_DIV_EXPR` or `ROUND_DIV_EXPR`. These four division operators differ in how they round the result to an integer. `EASY_DIV_EXPR` is used when it is permissible to use any of those kinds of division and the choice should be made on the basis of efficiency.

`MOVE_MAX`

The maximum number of bytes that a single instruction can move quickly from memory to memory.

`MAX_MOVE_MAX`

The maximum number of bytes that a single instruction can move quickly from memory to memory. If this is undefined, the default is `MOVE_MAX`. Otherwise, it is the constant value that the largest value that `MOVE_MAX` can have at run-time.

`SHIFT_COUNT_TRUNCATED`

A C expression that is nonzero if on this machine the number of bits actually used for the count of a shift operation is equal to the number of bits needed to represent the size of the object being shifted. When this macro is non-zero, the compiler will assume that it is safe to omit a sign-extend, zero-extend, and certain bitwise `and' instructions that truncates the count of a shift operation. On machines that have instructions that act on bitfields at variable positions, which may include `bit test' instructions, a nonzero `SHIFT_COUNT_TRUNCATED` also enables deletion of truncations of the values that serve as arguments to bitfield instructions.

If both types of instructions truncate the count (for shifts) and position (for bitfield operations), or if no variable-position bitfield instructions exist, you should define this macro.

However, on some machines, such as the 80386 and the 680x0, truncation only applies to shift operations and not the (real or pretended) bitfield operations. Define `SHIFT_COUNT_TRUNCATED` to be zero on such machines. Instead, add patterns to the `md' file that include the implied truncation of the shift instructions.

You need not define this macro if it would always have the value of zero.

`TRULY_NOOP_TRUNCATION (outprec, inprec)`

A C expression which is nonzero if on this machine it is safe to "convert" an integer of inprec bits to one of outprec bits (where outprec is smaller than inprec) by merely operating on it as if it had only outprec bits.

On many machines, this expression can be 1.

When `TRULY_NOOP_TRUNCATION` returns 1 for a pair of sizes for modes for which `MODES_TIEABLE_P` is 0, suboptimal code can result. If this is the case, making `TRULY_NOOP_TRUNCATION` return 0 in such cases may improve things.

`STORE_FLAG_VALUE`

A C expression describing the value returned by a comparison operator with an integral mode and stored by a store-flag instruction (`scond') when the condition is true. This description must apply to *all* the `scond' patterns and all the comparison operators whose results have a `MODE_INT` mode.

A value of 1 or -1 means that the instruction implementing the comparison operator returns exactly 1 or -1 when the comparison is true and 0 when the comparison is false. Otherwise, the value indicates which bits of the result are guaranteed to be 1 when the comparison is true. This value is interpreted in the mode of the comparison operation, which is given by the mode of the first operand in the `scond' pattern. Either the low bit or the sign bit of `STORE_FLAG_VALUE` be on. Presently, only those bits are used by the compiler.

If `STORE_FLAG_VALUE` is neither 1 or -1, the compiler will generate code that depends only on the specified bits. It can also replace comparison operators with equivalent operations if they cause the required bits to be set, even if the remaining bits are undefined. For example, on a machine whose comparison operators return an `SImode` value and where `STORE_FLAG_VALUE` is

defined as `0x80000000', saying that just the sign bit is relevant, the expression

```
(ne:SI (and:SI x (const_int power-of-2)) (const_int 0))
```

can be converted to

```
(ashift:SI x (const_int n))
```

where n is the appropriate shift count to move the bit being tested into the sign bit.

There is no way to describe a machine that always sets the low-order bit for a true value, but does not guarantee the value of any other bits, but we do not know of any machine that has such an instruction. If you are trying to port GNU CC to such a machine, include an instruction to perform a logical-and of the result with 1 in the pattern for the comparison operators and let us know (see section How to Report Bugs).

Often, a machine will have multiple instructions that obtain a value from a comparison (or the condition codes). Here are rules to guide the choice of value for `STORE_FLAG_VALUE`, and hence the instructions to be used:

> Use the shortest sequence that yields a valid definition for `STORE_FLAG_VALUE`. It is more efficient for the compiler to "normalize" the value (convert it to, e.g., 1 or 0) than for the comparison operators to do so because there may be opportunities to combine the normalization with other operations.
>
> For equal-length sequences, use a value of 1 or -1, with -1 being slightly preferred on machines with expensive jumps and 1 preferred on other machines.
>
> As a second choice, choose a value of `0x80000001' if instructions exist that set both the sign and low-order bits but do not define the others.
>
> Otherwise, use a value of `0x80000000'.

Many machines can produce both the value chosen for `STORE_FLAG_VALUE` and its negation in the same number of instructions. On those machines, you should also define a pattern for those cases, e.g., one matching

```
(set A (neg:m (ne:m B C)))
```

Some machines can also perform `and` or `plus` operations on condition code values with less instructions than the corresponding `scond' insn followed by `and` or `plus`. On those machines, define the appropriate patterns. Use the names `incscc` and `decscc`, respectively, for the the patterns which perform `plus` or `minus` operations on condition code values. See `` `rs6000.md' `` for some examples. The GNU Superoptizer can be used to find such instruction sequences on other machines.

You need not define `STORE_FLAG_VALUE` if the machine has no store-flag instructions.

`FLOAT_STORE_FLAG_VALUE`

A C expression that gives a non-zero floating point value that is returned when comparison operators with floating-point results are true. Define this macro on machine that have comparison

operations that return floating-point values. If there are no such operations, do not define this macro.

`Pmode`

An alias for the machine mode for pointers. On most machines, define this to be the integer mode corresponding to the width of a hardware pointer; `SImode` on 32-bit machine or `DImode` on 64-bit machines. On some machines you must define this to be one of the partial integer modes, such as `PSImode`.

The width of `Pmode` must be at least as large as the value of `POINTER_SIZE`. If it is not equal, you must define the macro `POINTERS_EXTEND_UNSIGNED` to specify how pointers are extended to `Pmode`.

`FUNCTION_MODE`

An alias for the machine mode used for memory references to functions being called, in `call` RTL expressions. On most machines this should be `QImode`.

`INTEGRATE_THRESHOLD (decl)`

A C expression for the maximum number of instructions above which the function decl should not be inlined. decl is a `FUNCTION_DECL` node.

The default definition of this macro is 64 plus 8 times the number of arguments that the function accepts. Some people think a larger threshold should be used on RISC machines.

`SCCS_DIRECTIVE`

Define this if the preprocessor should ignore `#sccs` directives and print no error message.

`NO_IMPLICIT_EXTERN_C`

Define this macro if the system header files support C++ as well as C. This macro inhibits the usual method of using system header files in C++, which is to pretend that the file's contents are enclosed in `extern "C" {...}'.

`HANDLE_PRAGMA (stream)`

Define this macro if you want to implement any pragmas. If defined, it should be a C statement to be executed when `#pragma` is seen. The argument stream is the stdio input stream from which the source text can be read.

It is generally a bad idea to implement new uses of `#pragma`. The only reason to define this macro is for compatibility with other compilers that do support `#pragma` for the sake of any user programs which already use it.

`VALID_MACHINE_DECL_ATTRIBUTE (decl, attributes, identifier, args)`

If defined, a C expression whose value is nonzero if identifier with arguments args is a valid machine specific attribute for decl. The attributes in attributes have previously been assigned to decl.

`VALID_MACHINE_TYPE_ATTRIBUTE (type, attributes, identifier, args)`

If defined, a C expression whose value is nonzero if identifier with arguments args is a valid machine specific attribute for type. The attributes in attributes have previously been assigned to type.

`COMP_TYPE_ATTRIBUTES (type1, type2)`

If defined, a C expression whose value is zero if the attributes on type1 and type2 are incompatible, one if they are compatible, and two if they are nearly compatible (which causes a warning to be generated).

`SET_DEFAULT_TYPE_ATTRIBUTES (type)`

If defined, a C statement that assigns default attributes to newly defined type.

`DOLLARS_IN_IDENTIFIERS`

Define this macro to control use of the character `$' in identifier names. The value should be 0, 1, or 2. 0 means `$' is not allowed by default; 1 means it is allowed by default if `-traditional' is used; 2 means it is allowed by default provided `-ansi' is not used. 1 is the default; there is no need to define this macro in that case.

`NO_DOLLAR_IN_LABEL`

Define this macro if the assembler does not accept the character `$' in label names. By default constructors and destructors in G++ have `$' in the identifiers. If this macro is defined, `.' is used instead.

`NO_DOT_IN_LABEL`

Define this macro if the assembler does not accept the character `.' in label names. By default constructors and destructors in G++ have names that use `.'. If this macro is defined, these names are rewritten to avoid `.'.

`DEFAULT_MAIN_RETURN`

Define this macro if the target system expects every program's `main` function to return a standard "success" value by default (if no other value is explicitly returned).

The definition should be a C statement (sans semicolon) to generate the appropriate rtl instructions. It is used only when compiling the end of `main`.

`HAVE_ATEXIT`

Define this if the target system supports the function `atexit` from the ANSI C standard. If this is not defined, and `INIT_SECTION_ASM_OP` is not defined, a default `exit` function will be provided to support C++.

`EXIT_BODY`

Define this if your `exit` function needs to do something besides calling an external function `_cleanup` before terminating with `_exit`. The `EXIT_BODY` macro is only needed if netiher `HAVE_ATEXIT` nor `INIT_SECTION_ASM_OP` are defined.

`INSN_SETS_ARE_DELAYED (insn)`

Define this macro as a C expression that is nonzero if it is safe for the delay slot scheduler to place instructions in the delay slot of insn, even if they appear to use a resource set or clobbered in insn. insn is always a `jump_insn` or an `insn`; GNU CC knows that every `call_insn` has this behavior. On machines where some `insn` or `jump_insn` is really a function call and hence has this behavior, you should define this macro.

You need not define this macro if it would always return zero.

`INSN_REFERENCES_ARE_DELAYED (insn)`

Define this macro as a C expression that is nonzero if it is safe for the delay slot scheduler to place instructions in the delay slot of insn, even if they appear to set or clobber a resource referenced in insn. insn is always a `jump_insn` or an `insn`. On machines where some `insn` or `jump_insn` is really a function call and its operands are registers whose use is actually in the subroutine it calls, you should define this macro. Doing so allows the delay slot scheduler to move instructions which copy arguments into the argument registers into the delay slot of insn.

You need not define this macro if it would always return zero.

`MACHINE_DEPENDENT_REORG (insn)`

In rare cases, correct code generation requires extra machine dependent processing between the second jump optimization pass and delayed branch scheduling. On those machines, define this macro as a C statement to act on the code starting at insn.

Go to the previous, next section.

Go to the previous, next section.

The Configuration File

The configuration file `xm-machine.h' contains macro definitions that describe the machine and system on which the compiler is running, unlike the definitions in `machine.h', which describe the machine for which the compiler is producing output. Most of the values in `xm-machine.h' are actually the same on all machines that GNU CC runs on, so large parts of all configuration files are identical. But there are some macros that vary:

`USG`

Define this macro if the host system is System V.

`VMS`

Define this macro if the host system is VMS.

`FATAL_EXIT_CODE`

A C expression for the status code to be returned when the compiler exits after serious errors.

`SUCCESS_EXIT_CODE`

A C expression for the status code to be returned when the compiler exits without serious errors.

`HOST_WORDS_BIG_ENDIAN`

Defined if the host machine stores words of multi-word values in big-endian order. (GNU CC does not depend on the host byte ordering within a word.)

`HOST_FLOAT_WORDS_BIG_ENDIAN`

Define this macro to be 1 if the host machine stores `DFmode`, `XFmode` or `TFmode` floating point numbers in memory with the word containing the sign bit at the lowest address; otherwise, define it to be zero.

This macro need not be defined if the ordering is the same as for multi-word integers.

`HOST_FLOAT_FORMAT`

A numeric code distinguishing the floating point format for the host machine. See `TARGET_FLOAT_FORMAT` in section Storage Layout for the alternatives and default.

`HOST_BITS_PER_CHAR`

A C expression for the number of bits in `char` on the host machine.

`HOST_BITS_PER_SHORT`

A C expression for the number of bits in `short` on the host machine.

`HOST_BITS_PER_INT`

A C expression for the number of bits in `int` on the host machine.

`HOST_BITS_PER_LONG`

A C expression for the number of bits in `long` on the host machine.

`ONLY_INT_FIELDS`

Define this macro to indicate that the host compiler only supports `int` bit fields, rather than other integral types, including `enum`, as do most C compilers.

`OBSTACK_CHUNK_SIZE`

A C expression for the size of ordinary obstack chunks. If you don't define this, a usually-reasonable default is used.

`OBSTACK_CHUNK_ALLOC`

The function used to allocate obstack chunks. If you don't define this, `xmalloc` is used.

`OBSTACK_CHUNK_FREE`

The function used to free obstack chunks. If you don't define this, `free` is used.

`USE_C_ALLOCA`

Define this macro to indicate that the compiler is running with the `alloca` implemented in C. This version of `alloca` can be found in the file `` `alloca.c' ``; to use it, you must also alter the `` `Makefile' `` variable `ALLOCA`. (This is done automatically for the systems on which we know it is needed.)

If you do define this macro, you should probably do it as follows:

```
#ifndef __GNUC__
#define USE_C_ALLOCA
#else
#define alloca __builtin_alloca
#endif
```

so that when the compiler is compiled with GNU CC it uses the more efficient built-in `alloca` function.

`FUNCTION_CONVERSION_BUG`

Define this macro to indicate that the host compiler does not properly handle converting a function value to a pointer-to-function when it is used in an expression.

`HAVE_VPRINTF`

Define this if the library function `vprintf` is available on your system.

`MULTIBYTE_CHARS`

Define this macro to enable support for multibyte characters in the input to GNU CC. This requires that the host system support the ANSI C library functions for converting multibyte characters to wide characters.

`HAVE_PUTENV`

Define this if the library function `putenv` is available on your system.

`POSIX`

Define this if your system is POSIX.1 compliant.

`NO_SYS_SIGLIST`

Define this if your system *does not* provide the variable `sys_siglist`.

`DONT_DECLARE_SYS_SIGLIST`

Define this if your system has the variable `sys_siglist`, and there is already a declaration in the system header files.

`USE_PROTOTYPES`

Define this to be 1 if you know that the host compiler supports prototypes, even if it doesn't define __STDC__, or define it to be 0 if you do not want any prototypes used in compiling GNU CC. If `USE_PROTOTYPES' is not defined, it will be determined automatically whether your compiler supports prototypes by checking if `__STDC__' is defined.

`NO_MD_PROTOTYPES`

Define this if you wish suppression of prototypes generated from the machine description file, but to use other prototypes within GNU CC. If `USE_PROTOTYPES' is defined to be 0, or the host compiler does not support prototypes, this macro has no effect.

`MD_CALL_PROTOTYPES`

Define this if you wish to generate prototypes for the `gen_call` or `gen_call_value` functions generated from the machine description file. If `USE_PROTOTYPES' is defined to be 0, or the host compiler does not support prototypes, or `NO_MD_PROTOTYPES' is defined, this macro has no effect. As soon as all of the machine descriptions are modified to have the appropriate number of arguments, this macro will be removed.

Some systems do provide this variable, but with a different name such as `_sys_siglist`. On these systems, you can define `sys_siglist` as a macro which expands into the name actually provided.

`NO_STAB_H`

Define this if your system does not have the include file `` `stab.h' ``. If `USG' is defined, `NO_STAB_H' is assumed.

`PATH_SEPARATOR`

Define this macro to be a C character constant representing the character used to separate components in paths. The default value is. the colon character

`DIR_SEPARATOR`

If your system uses some character other than slash to separate directory names within a file specification, define this macro to be a C character constant specifying that character. When GNU CC displays file names, the character you specify will be used. GNU CC will test for both slash and the character you specify when parsing filenames.

`OBJECT_SUFFIX`

Define this macro to be a C string representing the suffix for object files on your machine. If you do not define this macro, GNU CC will use `.o' as the suffix for object files.

`EXECUTABLE_SUFFIX`

Define this macro to be a C string representing the suffix for executable files on your machine. If you do not define this macro, GNU CC will use the null string as the suffix for object files.

`COLLECT_EXPORT_LIST`

If defined, `collect2` will scan the individual object files specified on its command line and create an export list for the linker. Define this macro for systems like AIX, where the linker

discards object files that are not referenced from `main` and uses export lists.

In addition, configuration files for system V define `bcopy`, `bzero` and `bcmp` as aliases. Some files define `alloca` as a macro when compiled with GNU CC, in order to take advantage of the benefit of GNU CC's built-in `alloca`.

Using and Porting GNU CC

(1)

Prior to release 2 of the compiler, there was a separate g++ compiler. That version was based on GNU CC, but not integrated with it. Versions of g++ with a `1.xx' version number--for example, g++ version 1.37 or 1.42--are much less reliable than the versions integrated with GCC 2. Moreover, combining G++ `1.xx' with a version 2 GCC will simply not work.

(2)

The analogous feature in Fortran is called an assigned goto, but that name seems inappropriate in C, where one can do more than simply store label addresses in label variables.

(3)

A file's basename was the name stripped of all leading path information and of trailing suffixes, such as `.h' or `.C' or `.cc'.

Debugging with GDB

The GNU Source-Level Debugger

Seventh Edition, for GDB version 4.18

February 1999

Richard M. Stallman and Roland H. Pesch

This file describes GDB, the GNU symbolic debugger.

This is the Seventh Edition, February 1999, for GDB Version 4.18.

This document was generated on 20 May 1999 using the texi2html translator version 1.51a.

Go to the first, previous, next, last section, table of contents.

Summary of GDB

The purpose of a debugger such as GDB is to allow you to see what is going on "inside" another program while it executes--or what another program was doing at the moment it crashed.

GDB can do four main kinds of things (plus other things in support of these) to help you catch bugs in the act:

- Start your program, specifying anything that might affect its behavior.
- Make your program stop on specified conditions.
- Examine what has happened, when your program has stopped.
- Change things in your program, so you can experiment with correcting the effects of one bug and go on to learn about another.

You can use GDB to debug programs written in C or C++. For more information, see section C and C++.

Support for Modula-2 and Chill is partial. For information on Modula-2, see section Modula-2. There is no further documentation on Chill yet.

Debugging Pascal programs which use sets, subranges, file variables, or nested functions does not currently work. GDB does not support entering expressions, printing values, or similar features using Pascal syntax.

GDB can be used to debug programs written in Fortran, although it does not yet support entering expressions, printing values, or similar features using Fortran syntax. It may be necessary to refer to some variables with a trailing underscore.

Free software

GDB is **free software**, protected by the GNU General Public License (GPL). The GPL gives you the freedom to copy or adapt a licensed program--but every person getting a copy also gets with it the freedom to modify that copy (which means that they must get access to the source code), and the freedom to distribute further copies. Typical software companies use copyrights to limit your freedoms; the Free Software Foundation uses the GPL to preserve these freedoms.

Fundamentally, the General Public License is a license which says that you have these freedoms and that you cannot take these freedoms away from anyone else.

Contributors to GDB

Richard Stallman was the original author of GDB, and of many other GNU programs. Many others have contributed to its development. This section attempts to credit major contributors. One of the virtues of free software is that everyone is free to contribute to it; with regret, we cannot actually acknowledge everyone here. The file `ChangeLog' in the GDB distribution approximates a blow-by-blow account.

Changes much prior to version 2.0 are lost in the mists of time.

> *Plea:* Additions to this section are particularly welcome. If you or your friends (or enemies, to be evenhanded) have been unfairly omitted from this list, we would like to add your names!

So that they may not regard their many labors as thankless, we particularly thank those who shepherded GDB through major releases: Jim Blandy (release 4.18); Jason Molenda (release 4.17); Stan Shebs (release 4.14); Fred Fish (releases 4.16, 4.15, 4.13, 4.12, 4.11, 4.10, and 4.9); Stu Grossman and John Gilmore (releases 4.8, 4.7, 4.6, 4.5, and 4.4); John Gilmore (releases 4.3, 4.2, 4.1, 4.0, and 3.9); Jim Kingdon (releases 3.5, 3.4, and 3.3); and Randy Smith (releases 3.2, 3.1, and 3.0).

Richard Stallman, assisted at various times by Peter TerMaat, Chris Hanson, and Richard Mlynarik, handled releases through 2.8.

Michael Tiemann is the author of most of the GNU C++ support in GDB, with significant additional contributions from Per Bothner. James Clark wrote the GNU C++ demangler. Early work on C++ was by Peter TerMaat (who also did much general update work leading to release 3.0).

GDB 4 uses the BFD subroutine library to examine multiple object-file formats; BFD was a joint project of David V. Henkel-Wallace, Rich Pixley, Steve Chamberlain, and John Gilmore.

David Johnson wrote the original COFF support; Pace Willison did the original support for encapsulated COFF.

Brent Benson of Harris Computer Systems contributed DWARF 2 support.

Adam de Boor and Bradley Davis contributed the ISI Optimum V support. Per Bothner, Noboyuki Hikichi, and Alessandro Forin contributed MIPS support. Jean-Daniel Fekete contributed Sun 386i support. Chris Hanson improved the HP9000 support. Noboyuki Hikichi and Tomoyuki Hasei contributed Sony/News OS 3 support. David Johnson contributed Encore Umax support. Jyrki Kuoppala contributed Altos 3068 support. Jeff Law contributed HP PA and SOM support. Keith Packard contributed NS32K support. Doug Rabson contributed Acorn Risc Machine support. Bob Rusk contributed Harris Nighthawk CX-UX support. Chris Smith contributed Convex support (and Fortran debugging). Jonathan Stone contributed Pyramid support. Michael Tiemann contributed SPARC support. Tim Tucker contributed support for the Gould NP1 and Gould Powernode. Pace Willison contributed Intel 386 support. Jay Vosburgh contributed Symmetry support.

Andreas Schwab contributed M68K Linux support.

Rich Schaefer and Peter Schauer helped with support of SunOS shared libraries.

Jay Fenlason and Roland McGrath ensured that GDB and GAS agree about several machine instruction sets.

Patrick Duval, Ted Goldstein, Vikram Koka and Glenn Engel helped develop remote debugging. Intel Corporation, Wind River Systems, AMD, and ARM contributed remote debugging modules for the i960, VxWorks, A29K UDI, and RDI targets, respectively.

Brian Fox is the author of the readline libraries providing command-line editing and command history.

Andrew Beers of SUNY Buffalo wrote the language-switching code, the Modula-2 support, and contributed the Languages chapter of this manual.

Fred Fish wrote most of the support for Unix System Vr4. He also enhanced the command-completion support to cover C++ overloaded symbols.

Hitachi America, Ltd. sponsored the support for H8/300, H8/500, and Super-H processors.

NEC sponsored the support for the v850, Vr4xxx, and Vr5xxx processors.

Mitsubishi sponsored the support for D10V, D30V, and M32R/D processors.

Toshiba sponsored the support for the TX39 Mips processor.

Matsushita sponsored the support for the MN10200 and MN10300 processors.

Fujitsu sponsored the support for SPARClite and FR30 processors

Kung Hsu, Jeff Law, and Rick Sladkey added support for hardware watchpoints.

Michael Snyder added support for tracepoints.

Stu Grossman wrote gdbserver.

Jim Kingdon, Peter Schauer, Ian Taylor, and Stu Grossman made nearly innumerable bug fixes and cleanups throughout GDB.

The following people at the Hewlett-Packard Company contributed support for the PA-RISC 2.0 architecture, HP-UX 10.20, 10.30, and 11.0 (narrow mode), HP's implementation of kernel threads, HP's aC++ compiler, and the terminal user interface: Ben Krepp, Richard Title, John Bishop, Susan Macchia, Kathy Mann, Satish Pai, India Paul, Steve Rehrauer, and Elena Zannoni. Kim Haase provided HP-specific information in this manual.

Cygnus Solutions has sponsored GDB maintenance and much of its development since 1991. Cygnus engineers who have worked on GDB fulltime include Mark Alexander, Jim Blandy, Per Bothner, Edith Epstein, Chris Faylor, Fred Fish, Martin Hunt, Jim Ingham, John Gilmore, Stu Grossman, Kung Hsu, Jim Kingdon, John Metzler, Fernando Nasser, Geoffrey Noer, Dawn Perchik, Rich Pixley, Zdenek Radouch, Keith Seitz, Stan Shebs, David Taylor, and Elena Zannoni. In addition, Dave Brolley, Ian Carmichael, Steve Chamberlain, Nick Clifton, JT Conklin, Stan Cox, DJ Delorie, Ulrich Drepper, Frank Eigler, Doug Evans, Sean Fagan, David Henkel-Wallace, Richard Henderson, Jeff Holcomb, Jeff Law, Jim Lemke, Tom Lord, Bob Manson, Michael Meissner, Jason Merrill, Catherine Moore, Drew Moseley, Ken Raeburn, Gavin Romig-Koch, Rob Savoye, Jamie Smith, Mike Stump, Ian Taylor, Angela Thomas, Michael Tiemann, Tom Tromey, Ron Unrau, Jim Wilson, and David Zuhn have made contributions both

large and small.

A Sample GDB Session

You can use this manual at your leisure to read all about GDB. However, a handful of commands are enough to get started using the debugger. This chapter illustrates those commands.

In this sample session, we emphasize user input like this: **input**, to make it easier to pick out from the surrounding output.

One of the preliminary versions of GNU `m4` (a generic macro processor) exhibits the following bug: sometimes, when we change its quote strings from the default, the commands used to capture one macro definition within another stop working. In the following short `m4` session, we define a macro `foo` which expands to `0000`; we then use the `m4` built-in `defn` to define `bar` as the same thing. However, when we change the open quote string to `<QUOTE>` and the close quote string to `<UNQUOTE>`, the same procedure fails to define a new synonym `baz`:

```
$ cd gnu/m4
$ ./m4
define(foo,0000)

foo
0000
define(bar,defn(`foo'))

bar
0000
changequote(<QUOTE>,<UNQUOTE>)

define(baz,defn(<QUOTE>foo<UNQUOTE>))
baz
C-d
m4: End of input: 0: fatal error: EOF in string
```

Let us use GDB to try to see what is going on.

```
$ gdb m4
GDB is free software and you are welcome to distribute copies
 of it under certain conditions; type "show copying" to see
 the conditions.
There is absolutely no warranty for GDB; type "show warranty"
 for details.
```

```
GDB 4.18, Copyright 1999 Free Software Foundation, Inc...
(gdb)
```

GDB reads only enough symbol data to know where to find the rest when needed; as a result, the first prompt comes up very quickly. We now tell GDB to use a narrower display width than usual, so that examples fit in this manual.

```
(gdb) set width 70
```

We need to see how the `m4` built-in `changequote` works. Having looked at the source, we know the relevant subroutine is `m4_changequote`, so we set a breakpoint there with the GDB `break` command.

```
(gdb) break m4_changequote
Breakpoint 1 at 0x62f4: file builtin.c, line 879.
```

Using the `run` command, we start `m4` running under GDB control; as long as control does not reach the `m4_changequote` subroutine, the program runs as usual:

```
(gdb) run
Starting program: /work/Editorial/gdb/gnu/m4/m4
define(foo,0000)

foo
0000
```

To trigger the breakpoint, we call `changequote`. GDB suspends execution of `m4`, displaying information about the context where it stops.

```
changequote(<QUOTE>,<UNQUOTE>)

Breakpoint 1, m4_changequote (argc=3, argv=0x33c70)
    at builtin.c:879
879         if (bad_argc(TOKEN_DATA_TEXT(argv[0]),argc,1,3))
```

Now we use the command `n` (`next`) to advance execution to the next line of the current function.

```
(gdb) n
882         set_quotes((argc >= 2) ? TOKEN_DATA_TEXT(argv[1])\
 : nil,
```

`set_quotes` looks like a promising subroutine. We can go into it by using the command `s` (`step`) instead of `next`. `step` goes to the next line to be executed in *any* subroutine, so it steps into `set_quotes`.

```
(gdb) s
```

```
set_quotes (lq=0x34c78 "<QUOTE>", rq=0x34c88 "<UNQUOTE>")
    at input.c:530
530         if (lquote != def_lquote)
```

The display that shows the subroutine where `m4` is now suspended (and its arguments) is called a stack frame display. It shows a summary of the stack. We can use the `backtrace` command (which can also be spelled `bt`), to see where we are in the stack as a whole: the `backtrace` command displays a stack frame for each active subroutine.

```
(gdb) bt
#0  set_quotes (lq=0x34c78 "<QUOTE>", rq=0x34c88 "<UNQUOTE>")
    at input.c:530
#1  0x6344 in m4_changequote (argc=3, argv=0x33c70)
    at builtin.c:882
#2  0x8174 in expand_macro (sym=0x33320) at macro.c:242
#3  0x7a88 in expand_token (obs=0x0, t=209696, td=0xf7fffa30)
    at macro.c:71
#4  0x79dc in expand_input () at macro.c:40
#5  0x2930 in main (argc=0, argv=0xf7fffb20) at m4.c:195
```

We step through a few more lines to see what happens. The first two times, we can use `s'; the next two times we use `n` to avoid falling into the `xstrdup` subroutine.

```
(gdb) s
0x3b5c  532         if (rquote != def_rquote)
(gdb) s
0x3b80  535         lquote = (lq == nil || *lq == '\0') ?  \
def_lquote : xstrdup(lq);
(gdb) n
536         rquote = (rq == nil || *rq == '\0') ? def_rquote\
 : xstrdup(rq);
(gdb) n
538         len_lquote = strlen(rquote);
```

The last line displayed looks a little odd; we can examine the variables `lquote` and `rquote` to see if they are in fact the new left and right quotes we specified. We use the command `p` (`print`) to see their values.

```
(gdb) p lquote
$1 = 0x35d40 "<QUOTE>"
(gdb) p rquote
$2 = 0x35d50 "<UNQUOTE>"
```

`lquote` and `rquote` are indeed the new left and right quotes. To look at some context, we can display ten lines of source surrounding the current line with the `l` (`list`) command.

```
(gdb) l
533             xfree(rquote);
534
535         lquote = (lq == nil || *lq == '\0') ? def_lquote\
 : xstrdup (lq);
536         rquote = (rq == nil || *rq == '\0') ? def_rquote\
 : xstrdup (rq);
537
538         len_lquote = strlen(rquote);
539         len_rquote = strlen(lquote);
540     }
541
542     void
```

Let us step past the two lines that set `len_lquote` and `len_rquote`, and then examine the values of those variables.

```
(gdb) n
539         len_rquote = strlen(lquote);
(gdb) n
540     }
(gdb) p len_lquote
$3 = 9
(gdb) p len_rquote
$4 = 7
```

That certainly looks wrong, assuming `len_lquote` and `len_rquote` are meant to be the lengths of `lquote` and `rquote` respectively. We can set them to better values using the `p` command, since it can print the value of any expression--and that expression can include subroutine calls and assignments.

```
(gdb) p len_lquote=strlen(lquote)
$5 = 7
(gdb) p len_rquote=strlen(rquote)
$6 = 9
```

Is that enough to fix the problem of using the new quotes with the `m4` built-in `defn`? We can allow `m4` to continue executing with the `c` (`continue`) command, and then try the example that caused trouble initially:

```
(gdb) c
Continuing.

define(baz,defn(<QUOTE>foo<UNQUOTE>))

baz
0000
```

Success! The new quotes now work just as well as the default ones. The problem seems to have been the two typos defining the wrong lengths. We allow `m4` exit by giving it an EOF as input:

```
C-d
Program exited normally.
```

The message `Program exited normally.' is from GDB; it indicates `m4` has finished executing. We can end our GDB session with the GDB `quit` command.

```
(gdb) quit
```

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Getting In and Out of GDB

This chapter discusses how to start GDB, and how to get out of it. The essentials are:

- type `gdb' to start GDB.
- type quit or C-d to exit.

Invoking GDB

Invoke GDB by running the program `gdb`. Once started, GDB reads commands from the terminal until you tell it to exit.

You can also run `gdb` with a variety of arguments and options, to specify more of your debugging environment at the outset.

The command-line options described here are designed to cover a variety of situations; in some environments, some of these options may effectively be unavailable.

The most usual way to start GDB is with one argument, specifying an executable program:

```
gdb program
```

You can also start with both an executable program and a core file specified:

```
gdb program core
```

You can, instead, specify a process ID as a second argument, if you want to debug a running process:

```
gdb program 1234
```

would attach GDB to process `1234` (unless you also have a file named `` `1234' ``; GDB does check for a core file first).

Taking advantage of the second command-line argument requires a fairly complete operating system; when you use GDB as a remote debugger attached to a bare board, there may not be any notion of "process", and there is often no way to get a core dump.

You can run `gdb` without printing the front material, which describes GDB's non-warranty, by specifying `-silent`:

```
gdb -silent
```

You can further control how GDB starts up by using command-line options. GDB itself can remind you

of the options available.

Type

```
gdb -help
```

to display all available options and briefly describe their use (`gdb -h' is a shorter equivalent).

All options and command line arguments you give are processed in sequential order. The order makes a difference when the `-x' option is used.

Choosing files

When GDB starts, it reads any arguments other than options as specifying an executable file and core file (or process ID). This is the same as if the arguments were specified by the `-se' and `-c' options respectively. (GDB reads the first argument that does not have an associated option flag as equivalent to the `-se' option followed by that argument; and the second argument that does not have an associated option flag, if any, as equivalent to the `-c' option followed by that argument.)

Many options have both long and short forms; both are shown in the following list. GDB also recognizes the long forms if you truncate them, so long as enough of the option is present to be unambiguous. (If you prefer, you can flag option arguments with `--' rather than `-', though we illustrate the more usual convention.)

`-symbols file`

`-s file`

Read symbol table from file file.

`-exec file`

`-e file`

Use file file as the executable file to execute when appropriate, and for examining pure data in conjunction with a core dump.

`-se file`

Read symbol table from file file and use it as the executable file.

`-core file`

`-c file`

Use file file as a core dump to examine.

`-c number`

Connect to process ID number, as with the `attach` command (unless there is a file in core-dump format named number, in which case `-c' specifies that file as a core dump to read).

`-command file`

`-x file`

Execute GDB commands from file file. See section Command files.

`-directory directory`

`-d directory`

Add directory to the path to search for source files.

`-m`

`-mapped`

Warning: this option depends on operating system facilities that are not supported on all systems. If memory-mapped files are available on your system through the `mmap` system call, you can use this option to have GDB write the symbols from your program into a reusable file in the current directory. If the program you are debugging is called `` `/tmp/fred' ``, the mapped symbol file is `` `./fred.syms' ``. Future GDB debugging sessions notice the presence of this file, and can quickly map in symbol information from it, rather than reading the symbol table from the executable program. The `` `.syms' `` file is specific to the host machine where GDB is run. It holds an exact image of the internal GDB symbol table. It cannot be shared across multiple host platforms.

`-r`

`-readnow`

Read each symbol file's entire symbol table immediately, rather than the default, which is to read it incrementally as it is needed. This makes startup slower, but makes future operations faster.

The `-mapped` and `-readnow` options are typically combined in order to build a `` `.syms' `` file that contains complete symbol information. (See section Commands to specify files, for information on `` `.syms' `` files.) A simple GDB invocation to do nothing but build a `` `.syms' `` file for future use is:

```
gdb -batch -nx -mapped -readnow programname
```

Choosing modes

You can run GDB in various alternative modes--for example, in batch mode or quiet mode.

`-nx`

`-n`

Do not execute commands from any initialization files (normally called `` `.gdbinit' ``, or `` `gdb.ini' `` on PCs). Normally, the commands in these files are executed after all the command options and arguments have been processed. See section Command files.

`-quiet`

`-q`

"Quiet". Do not print the introductory and copyright messages. These messages are also suppressed in batch mode.

`-batch`

Run in batch mode. Exit with status `0` after processing all the command files specified with `-x' (and all commands from initialization files, if not inhibited with `-n'). Exit with nonzero status if an error occurs in executing the GDB commands in the command files. Batch mode may be useful for running GDB as a filter, for example to download and run a program on another computer; in

order to make this more useful, the message

```
Program exited normally.
```

(which is ordinarily issued whenever a program running under GDB control terminates) is not issued when running in batch mode.

`-cd directory`

Run GDB using directory as its working directory, instead of the current directory.

`-fullname`

`-f`

GNU Emacs sets this option when it runs GDB as a subprocess. It tells GDB to output the full file name and line number in a standard, recognizable fashion each time a stack frame is displayed (which includes each time your program stops). This recognizable format looks like two `\032' characters, followed by the file name, line number and character position separated by colons, and a newline. The Emacs-to-GDB interface program uses the two `\032' characters as a signal to display the source code for the frame.

`-b bps`

Set the line speed (baud rate or bits per second) of any serial interface used by GDB for remote debugging.

`-tty device`

Run using device for your program's standard input and output.

Quitting GDB

`quit`

To exit GDB, use the `quit` command (abbreviated `q`), or type an end-of-file character (usually C-d). If you do not supply expression, GDB will terminate normally; otherwise it will terminate using the result of expression as the error code.

An interrupt (often C-c) does not exit from GDB, but rather terminates the action of any GDB command that is in progress and returns to GDB command level. It is safe to type the interrupt character at any time because GDB does not allow it to take effect until a time when it is safe.

If you have been using GDB to control an attached process or device, you can release it with the `detach` command (see section Debugging an already-running process).

Shell commands

If you need to execute occasional shell commands during your debugging session, there is no need to leave or suspend GDB; you can just use the `shell` command.

`shell command string`

Invoke a standard shell to execute command string. If it exists, the environment variable `SHELL`

determines which shell to run. Otherwise GDB uses `/bin/sh`.

The utility `make` is often needed in development environments. You do not have to use the `shell` command for this purpose in GDB:

`make make-args`

Execute the `make` program with the specified arguments. This is equivalent to `shell make make-args'.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

GDB Commands

You can abbreviate a GDB command to the first few letters of the command name, if that abbreviation is unambiguous; and you can repeat certain GDB commands by typing just RET. You can also use the TAB key to get GDB to fill out the rest of a word in a command (or to show you the alternatives available, if there is more than one possibility).

Command syntax

A GDB command is a single line of input. There is no limit on how long it can be. It starts with a command name, which is followed by arguments whose meaning depends on the command name. For example, the command `step` accepts an argument which is the number of times to step, as in `step 5'. You can also use the `step` command with no arguments. Some command names do not allow any arguments.

GDB command names may always be truncated if that abbreviation is unambiguous. Other possible command abbreviations are listed in the documentation for individual commands. In some cases, even ambiguous abbreviations are allowed; for example, `s` is specially defined as equivalent to `step` even though there are other commands whose names start with `s`. You can test abbreviations by using them as arguments to the `help` command.

A blank line as input to GDB (typing just RET) means to repeat the previous command. Certain commands (for example, `run`) will not repeat this way; these are commands whose unintentional repetition might cause trouble and which you are unlikely to want to repeat.

The `list` and `x` commands, when you repeat them with RET, construct new arguments rather than repeating exactly as typed. This permits easy scanning of source or memory.

GDB can also use RET in another way: to partition lengthy output, in a way similar to the common utility `more` (see section Screen size). Since it is easy to press one RET too many in this situation, GDB disables command repetition after any command that generates this sort of display.

Any text from a # to the end of the line is a comment; it does nothing. This is useful mainly in command files (see section Command files).

Command completion

GDB can fill in the rest of a word in a command for you, if there is only one possibility; it can also show you what the valid possibilities are for the next word in a command, at any time. This works for GDB commands, GDB subcommands, and the names of symbols in your program.

Press the TAB key whenever you want GDB to fill out the rest of a word. If there is only one possibi GDB fills in the word, and waits for you to finish the command (or press RET to enter it). For examp if you type

```
(gdb) info bre TAB
```

GDB fills in the rest of the word `breakpoints', since that is the only `info` subcommand beginning with `bre':

```
(gdb) info breakpoints
```

You can either press RET at this point, to run the `info breakpoints` command, or backspace and enter something else, if `breakpoints' does not look like the command you expected. (If you were sure you wanted `info breakpoints` in the first place, you might as well just type RET immediately after `info bre', to exploit command abbreviations rather than command completion).

If there is more than one possibility for the next word when you press TAB, GDB sounds a bell. You can either supply more characters and try again, or just press TAB a second time; GDB displays all the possible completions for that word. For example, you might want to set a breakpoint on a subroutine whose name begins with `make_', but when you type b make_TAB GDB just sounds the bell. Typing TAB again displays all the function names in your program that begin with those characters, for example:

```
(gdb) b make_ TAB
GDB sounds bell; press TAB again, to see:
make_a_section_from_file     make_environ
make_abs_section             make_function_type
make_blockvector             make_pointer_type
make_cleanup                 make_reference_type
make_command                 make_symbol_completion_list
(gdb) b make_
```

After displaying the available possibilities, GDB copies your partial input (`b make_' in the example) so you can finish the command.

If you just want to see the list of alternatives in the first place, you can press M-? rather than pressing TAB twice. M-? means META ?. You can type this either by holding down a key designated as the META shift on your keyboard (if there is one) while typing ?, or as ESC followed by ?.

Sometimes the string you need, while logically a "word", may contain parentheses or other characters that GDB normally excludes from its notion of a word. To permit word completion to work in this situation, you may enclose words in `'` (single quote marks) in GDB commands.

The most likely situation where you might need this is in typing the name of a C++ function. This is because C++ allows function overloading (multiple definitions of the same function, distinguished by argument type). For example, when you want to set a breakpoint you may need to distinguish whether you mean the version of `name` that takes an `int` parameter, `name(int)`, or the version that takes a

`float` parameter, `name(float)`. To use the word-completion facilities in this situation, type a single quote `'` at the beginning of the function name. This alerts GDB that it may need to consider more information than usual when you press TAB or M-? to request word completion:

```
(gdb) b 'bubble( M-?
bubble(double,double)    bubble(int,int)
(gdb) b 'bubble(
```

In some cases, GDB can tell that completing a name requires using quotes. When this happens, GDB inserts the quote for you (while completing as much as it can) if you do not type the quote in the first place:

```
(gdb) b bub TAB
GDB alters your input line to the following, and rings a bell:
(gdb) b 'bubble(
```

In general, GDB can tell that a quote is needed (and inserts it) if you have not yet started typing the argument list when you ask for completion on an overloaded symbol.

For more information about overloaded functions, see section C++ expressions. You can use the command `set overload-resolution off` to disable overload resolution; see section GDB features for C++.

Getting help

You can always ask GDB itself for information on its commands, using the command `help`.

`help`

`h`

> You can use `help` (abbreviated `h`) with no arguments to display a short list of named classes of commands:
>
> ```
> (gdb) help
> List of classes of commands:
>
> running -- Running the program
> stack -- Examining the stack
> data -- Examining data
> breakpoints -- Making program stop at certain points
> files -- Specifying and examining files
> status -- Status inquiries
> support -- Support facilities
> user-defined -- User-defined commands
> aliases -- Aliases of other commands
> obscure -- Obscure features
> ```

```
Type "help" followed by a class name for a list of
commands in that class.
Type "help" followed by command name for full
documentation.
Command name abbreviations are allowed if unambiguous.
(gdb)
```

`help class`

Using one of the general help classes as an argument, you can get a list of the individual commands in that class. For example, here is the help display for the class `status`:

```
(gdb) help status
Status inquiries.

List of commands:

show -- Generic command for showing things set
 with "set"
info -- Generic command for printing status

Type "help" followed by command name for full
documentation.
Command name abbreviations are allowed if unambiguous.
(gdb)
```

`help command`

With a command name as `help` argument, GDB displays a short paragraph on how to use that command.

`complete args`

The `complete args` command lists all the possible completions for the beginning of a command. Use args to specify the beginning of the command you want completed. For example:

```
complete i
```

results in:

```
info
inspect
ignore
```

This is intended for use by GNU Emacs.

In addition to `help`, you can use the GDB commands `info` and `show` to inquire about the state of your program, or the state of GDB itself. Each command supports many topics of inquiry; this manual introduces each of them in the appropriate context. The listings under `info` and under `show` in the Index point to all the sub-commands. See section Index.

`info`

This command (abbreviated `i`) is for describing the state of your program. For example, you can list the arguments given to your program with `info args`, list the registers currently in use with `info registers`, or list the breakpoints you have set with `info breakpoints`. You can get a complete list of the `info` sub-commands with `help info`.

`set`

You can assign the result of an expression to an environment variable with `set`. For example, you can set the GDB prompt to a $-sign with `set prompt $`.

`show`

In contrast to `info`, `show` is for describing the state of GDB itself. You can change most of the things you can `show`, by using the related command `set`; for example, you can control what number system is used for displays with `set radix`, or simply inquire which is currently in use with `show radix`. To display all the settable parameters and their current values, you can use `show` with no arguments; you may also use `info set`. Both commands produce the same display.

Here are three miscellaneous `show` subcommands, all of which are exceptional in lacking corresponding `set` commands:

`show version`

Show what version of GDB is running. You should include this information in GDB bug-reports. If multiple versions of GDB are in use at your site, you may occasionally want to determine which version of GDB you are running; as GDB evolves, new commands are introduced, and old ones may wither away. The version number is also announced when you start GDB.

`show copying`

Display information about permission for copying GDB.

`show warranty`

Display the GNU "NO WARRANTY" statement.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Running Programs Under GDB

When you run a program under GDB, you must first generate debugging information when you compile it. You may start GDB with its arguments, if any, in an environment of your choice. You may redirect your program's input and output, debug an already running process, or kill a child process.

Compiling for debugging

In order to debug a program effectively, you need to generate debugging information when you compile it. This debugging information is stored in the object file; it describes the data type of each variable or function and the correspondence between source line numbers and addresses in the executable code.

To request debugging information, specify the `-g' option when you run the compiler.

Many C compilers are unable to handle the `-g' and `-O' options together. Using those compilers, you cannot generate optimized executables containing debugging information.

GCC, the GNU C compiler, supports `-g' with or without `-O', making it possible to debug optimized code. We recommend that you *always* use `-g' whenever you compile a program. You may think your program is correct, but there is no sense in pushing your luck.

When you debug a program compiled with `-g -O', remember that the optimizer is rearranging your code; the debugger shows you what is really there. Do not be too surprised when the execution path does not exactly match your source file! An extreme example: if you define a variable, but never use it, GDB never sees that variable--because the compiler optimizes it out of existence.

Some things do not work as well with `-g -O' as with just `-g', particularly on machines with instruction scheduling. If in doubt, recompile with `-g' alone, and if this fixes the problem, please report it to us as a bug (including a test case!).

Older versions of the GNU C compiler permitted a variant option `-gg' for debugging information. GDB no longer supports this format; if your GNU C compiler has this option, do not use it.

Starting your program

`run`
`r`

Use the `run` command to start your program under GDB. You must first specify the program name (except on VxWorks) with an argument to GDB (see section Getting In and Out of GDB), or by using the `file` or `exec-file` command (see section Commands to specify files).

If you are running your program in an execution environment that supports processes, `run` creates an inferior process and makes that process run your program. (In environments without processes, `run` jumps to the start of your program.)

The execution of a program is affected by certain information it receives from its superior. GDB provides ways to specify this information, which you must do *before* starting your program. (You can change it after starting your program, but such changes only affect your program the next time you start it.) This information may be divided into four categories:

The *arguments.*

> Specify the arguments to give your program as the arguments of the `run` command. If a shell is available on your target, the shell is used to pass the arguments, so that you may use normal conventions (such as wildcard expansion or variable substitution) in describing the arguments. In Unix systems, you can control which shell is used with the `SHELL` environment variable. See section Your program's arguments.

The *environment.*

> Your program normally inherits its environment from GDB, but you can use the GDB commands `set environment` and `unset environment` to change parts of the environment that affect your program. See section Your program's environment.

The *working directory.*

> Your program inherits its working directory from GDB. You can set the GDB working directory with the `cd` command in GDB. See section Your program's working directory.

The *standard input and output.*

> Your program normally uses the same device for standard input and standard output as GDB is using. You can redirect input and output in the `run` command line, or you can use the `tty` command to set a different device for your program. See section Your program's input and output.
>
> *Warning:* While input and output redirection work, you cannot use pipes to pass the output of the program you are debugging to another program; if you attempt this, GDB is likely to wind up debugging the wrong program.

When you issue the `run` command, your program begins to execute immediately. See section Stopping and Continuing, for discussion of how to arrange for your program to stop. Once your program has stopped, you may call functions in your program, using the `print` or `call` commands. See section Examining Data.

If the modification time of your symbol file has changed since the last time GDB read its symbols, GDB discards its symbol table, and reads it again. When it does this, GDB tries to retain your current breakpoints.

Your program's arguments

The arguments to your program can be specified by the arguments of the `run` command. They are passed to a shell, which expands wildcard characters and performs redirection of I/O, and thence to your program. Your `SHELL` environment variable (if it exists) specifies what shell GDB uses. If you do not

define `SHELL`, GDB uses `/bin/sh`.

`run` with no arguments uses the same arguments used by the previous `run`, or those set by the `set args` command.

`set args`

Specify the arguments to be used the next time your program is run. If `set args` has no arguments, `run` executes your program with no arguments. Once you have run your program with arguments, using `set args` before the next `run` is the only way to run it again without arguments.

`show args`

Show the arguments to give your program when it is started.

Your program's environment

The **environment** consists of a set of environment variables and their values. Environment variables conventionally record such things as your user name, your home directory, your terminal type, and your search path for programs to run. Usually you set up environment variables with the shell and they are inherited by all the other programs you run. When debugging, it can be useful to try running your program with a modified environment without having to start GDB over again.

`path directory`

Add directory to the front of the `PATH` environment variable (the search path for executables), for both GDB and your program. You may specify several directory names, separated by `:' or whitespace. If directory is already in the path, it is moved to the front, so it is searched sooner. You can use the string `$cwd' to refer to whatever is the current working directory at the time GDB searches the path. If you use `.' instead, it refers to the directory where you executed the `path` command. GDB replaces `.' in the directory argument (with the current path) before adding directory to the search path.

`show paths`

Display the list of search paths for executables (the `PATH` environment variable).

`show environment [varname]`

Print the value of environment variable varname to be given to your program when it starts. If you do not supply varname, print the names and values of all environment variables to be given to your program. You can abbreviate `environment` as `env`.

`set environment varname [=] value`

Set environment variable varname to value. The value changes for your program only, not for GDB itself. value may be any string; the values of environment variables are just strings, and any interpretation is supplied by your program itself. The value parameter is optional; if it is eliminated, the variable is set to a null value. For example, this command:

```
set env USER = foo
```

tells a Unix program, when subsequently run, that its user is named `foo'. (The spaces around `=' are used for clarity here; they are not actually required.)

`unset environment varname`

Remove variable varname from the environment to be passed to your program. This is different from `set env varname ='; `unset environment` removes the variable from the environment, rather than assigning it an empty value.

Warning: GDB runs your program using the shell indicated by your `SHELL` environment variable if it exists (or `/bin/sh` if not). If your `SHELL` variable names a shell that runs an initialization file--such as `` `.cshrc' `` for C-shell, or `` `.bashrc' `` for BASH--any variables you set in that file affect your program. You may wish to move setting of environment variables to files that are only run when you sign on, such as `` `.login' `` or `` `.profile' ``.

Your program's working directory

Each time you start your program with `run`, it inherits its working directory from the current working directory of GDB. The GDB working directory is initially whatever it inherited from its parent process (typically the shell), but you can specify a new working directory in GDB with the `cd` command.

The GDB working directory also serves as a default for the commands that specify files for GDB to operate on. See section Commands to specify files.

`cd directory`

Set the GDB working directory to directory.

`pwd`

Print the GDB working directory.

Your program's input and output

By default, the program you run under GDB does input and output to the same terminal that GDB uses. GDB switches the terminal to its own terminal modes to interact with you, but it records the terminal modes your program was using and switches back to them when you continue running your program.

`info terminal`

Displays information recorded by GDB about the terminal modes your program is using.

You can redirect your program's input and/or output using shell redirection with the `run` command. For example,

```
run > outfile
```

starts your program, diverting its output to the file `` `outfile' ``.

Another way to specify where your program should do input and output is with the `tty` command. This command accepts a file name as argument, and causes this file to be the default for future `run` commands. It also resets the controlling terminal for the child process, for future `run` commands. For example,

`tty /dev/ttyb`

directs that processes started with subsequent `run` commands default to do input and output on the terminal `/dev/ttyb' and have that as their controlling terminal.

An explicit redirection in `run` overrides the `tty` command's effect on the input/output device, but not its effect on the controlling terminal.

When you use the `tty` command or redirect input in the `run` command, only the input *for your program* is affected. The input for GDB still comes from your terminal.

Debugging an already-running process

`attach process-id`

> This command attaches to a running process--one that was started outside GDB. (`info files` shows your active targets.) The command takes as argument a process ID. The usual way to find out the process-id of a Unix process is with the `ps` utility, or with the `jobs -l' shell command. `attach` does not repeat if you press RET a second time after executing the command.

To use `attach`, your program must be running in an environment which supports processes; for example, `attach` does not work for programs on bare-board targets that lack an operating system. You must also have permission to send the process a signal.

When you use `attach`, the debugger finds the program running in the process first by looking in the current working directory, then (if the program is not found) by using the source file search path (see section Specifying source directories). You can also use the `file` command to load the program. See section Commands to specify files.

The first thing GDB does after arranging to debug the specified process is to stop it. You can examine and modify an attached process with all the GDB commands that are ordinarily available when you start processes with `run`. You can insert breakpoints; you can step and continue; you can modify storage. If you would rather the process continue running, you may use the `continue` command after attaching GDB to the process.

`detach`

> When you have finished debugging the attached process, you can use the `detach` command to release it from GDB control. Detaching the process continues its execution. After the `detach` command, that process and GDB become completely independent once more, and you are ready to `attach` another process or start one with `run`. `detach` does not repeat if you press RET again after executing the command.

If you exit GDB or use the `run` command while you have an attached process, you kill that process. By default, GDB asks for confirmation if you try to do either of these things; you can control whether or not you need to confirm by using the `set confirm` command (see section Optional warnings and messages).

TOC

Killing the child process

`kill`

Kill the child process in which your program is running under GDB.

This command is useful if you wish to debug a core dump instead of a running process. GDB ignores any core dump file while your program is running.

On some operating systems, a program cannot be executed outside GDB while you have breakpoints set on it inside GDB. You can use the `kill` command in this situation to permit running your program outside the debugger.

The `kill` command is also useful if you wish to recompile and relink your program, since on many systems it is impossible to modify an executable file while it is running in a process. In this case, when you next type `run`, GDB notices that the file has changed, and reads the symbol table again (while trying to preserve your current breakpoint settings).

Additional process information

Some operating systems provide a facility called `/proc' that can be used to examine the image of a running process using file-system subroutines. If GDB is configured for an operating system with this facility, the command `info proc` is available to report on several kinds of information about the process running your program. `info proc` works only on SVR4 systems that support `procfs`.

`info proc`

Summarize available information about the process.

`info proc mappings`

Report on the address ranges accessible in the program, with information on whether your program may read, write, or execute each range.

`info proc times`

Starting time, user CPU time, and system CPU time for your program and its children.

`info proc id`

Report on the process IDs related to your program: its own process ID, the ID of its parent, the process group ID, and the session ID.

`info proc status`

General information on the state of the process. If the process is stopped, this report includes the reason for stopping, and any signal received.

`info proc all`

Show all the above information about the process.

Debugging programs with multiple threads

In some operating systems, such as HP-UX and Solaris, a single program may have more than one **thread** of execution. The precise semantics of threads differ from one operating system to another, but in general the threads of a single program are akin to multiple processes--except that they share one address space (that is, they can all examine and modify the same variables). On the other hand, each thread has its own registers and execution stack, and perhaps private memory.

GDB provides these facilities for debugging multi-thread programs:

- automatic notification of new threads
- `thread threadno', a command to switch among threads
- `info threads', a command to inquire about existing threads
- `thread apply [threadno] [all] args', a command to apply a command to a list of threads
- thread-specific breakpoints

  Warning: These facilities are not yet available on every GDB configuration where the operating system supports threads. If your GDB does not support threads, these commands have no effect. For example, a system without thread support shows no output from `info threads', and always rejects the `thread` command, like this:

```
(gdb) info threads
(gdb) thread 1
Thread ID 1 not known.  Use the "info threads" command to
see the IDs of currently known threads.
```

The GDB thread debugging facility allows you to observe all threads while your program runs--but whenever GDB takes control, one thread in particular is always the focus of debugging. This thread is called the **current thread**. Debugging commands show program information from the perspective of the current thread.

Whenever GDB detects a new thread in your program, it displays the target system's identification for the thread with a message in the form `[New systag]'. systag is a thread identifier whose form varies depending on the particular system. For example, on LynxOS, you might see

```
[New process 35 thread 27]
```

when GDB notices a new thread. In contrast, on an SGI system, the systag is simply something like `process 368', with no further qualifier.

For debugging purposes, GDB associates its own thread number--always a single integer--with each thread in your program.

`info threads`

Display a summary of all threads currently in your program. GDB displays for each thread (in this order):

1. the thread number assigned by GDB
2. the target system's thread identifier (systag)
3. the current stack frame summary for that thread

An asterisk `*' to the left of the GDB thread number indicates the current thread. For example,

```
(gdb) info threads
  3 process 35 thread 27  0x34e5 in sigpause ()
  2 process 35 thread 23  0x34e5 in sigpause ()
* 1 process 35 thread 13  main (argc=1, argv=0x7ffffff8)
    at threadtest.c:68
```

`thread threadno`

Make thread number threadno the current thread. The command argument threadno is the internal GDB thread number, as shown in the first field of the `info threads' display. GDB responds by displaying the system identifier of the thread you selected, and its current stack frame summary:

```
(gdb) thread 2
[Switching to process 35 thread 23]
0x34e5 in sigpause ()
```

As with the `[New ...]' message, the form of the text after `Switching to' depends on your system's conventions for identifying threads.

`thread apply [threadno] [all] args`

The `thread apply` command allows you to apply a command to one or more threads. Specify the numbers of the threads that you want affected with the command argument threadno. threadno is the internal GDB thread number, as shown in the first field of the `info threads' display. To apply a command to all threads, use `thread apply all` args.

Whenever GDB stops your program, due to a breakpoint or a signal, it automatically selects the thread where that breakpoint or signal happened. GDB alerts you to the context switch with a message of the form `[Switching to systag]' to identify the thread.

See section Stopping and starting multi-thread programs, for more information about how GDB behaves when you stop and start programs with multiple threads.

See section Setting watchpoints, for information about watchpoints in programs with multiple threads.

Debugging programs with multiple processes

GDB has no special support for debugging programs which create additional processes using the `fork` function. When a program forks, GDB will continue to debug the parent process and the child process will run unimpeded. If you have set a breakpoint in any code which the child then executes, the child will get a `SIGTRAP` signal which (unless it catches the signal) will cause it to terminate.

However, if you want to debug the child process there is a workaround which isn't too painful. Put a call

to `sleep` in the code which the child process executes after the fork. It may be useful to sleep only i certain environment variable is set, or a certain file exists, so that the delay need not occur when you don't want to run GDB on the child. While the child is sleeping, use the `ps` program to get its process ID. Then tell GDB (a new invocation of GDB if you are also debugging the parent process) to attach to the child process (see section Debugging an already-running process). From that point on you can debug the child process just like any other process which you attached to.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Stopping and Continuing

The principal purposes of using a debugger are so that you can stop your program before it terminates; or so that, if your program runs into trouble, you can investigate and find out why.

Inside GDB, your program may stop for any of several reasons, such as a signal, a breakpoint, or reaching a new line after a GDB command such as `step`. You may then examine and change variables, set new breakpoints or remove old ones, and then continue execution. Usually, the messages shown by GDB provide ample explanation of the status of your program--but you can also explicitly request this information at any time.

`info program`

Display information about the status of your program: whether it is running or not, what process it is, and why it stopped.

Breakpoints, watchpoints, and catchpoints

A **breakpoint** makes your program stop whenever a certain point in the program is reached. For each breakpoint, you can add conditions to control in finer detail whether your program stops. You can set breakpoints with the `break` command and its variants (see section Setting breakpoints), to specify the place where your program should stop by line number, function name or exact address in the program.

In HP-UX, SunOS 4.x, SVR4, and Alpha OSF/1 configurations, you can set breakpoints in shared libraries before the executable is run. There is a minor limitation on HP-UX systems: you must wait until the executable is run in order to set breakpoints in shared library routines that are not called directly by the program (for example, routines that are arguments in a `pthread_create` call).

A **watchpoint** is a special breakpoint that stops your program when the value of an expression changes. You must use a different command to set watchpoints (see section Setting watchpoints), but aside from that, you can manage a watchpoint like any other breakpoint: you enable, disable, and delete both breakpoints and watchpoints using the same commands.

You can arrange to have values from your program displayed automatically whenever GDB stops at a breakpoint. See section Automatic display.

A **catchpoint** is another special breakpoint that stops your program when a certain kind of event occurs, such as the throwing of a C++ exception or the loading of a library. As with watchpoints, you use a different command to set a catchpoint (see section Setting catchpoints), but aside from that, you can manage a catchpoint like any other breakpoint. (To stop when your program receives a signal, use the `handle` command; see section Signals.)

GDB assigns a number to each breakpoint, watchpoint, or catchpoint when you create it; these numbers

are successive integers starting with one. In many of the commands for controlling various features of breakpoints you use the breakpoint number to say which breakpoint you want to change. Each breakpoint may be **enabled** or **disabled**; if disabled, it has no effect on your program until you enable it again.

Setting breakpoints

Breakpoints are set with the `break` command (abbreviated `b`). The debugger convenience variable `$bpnum' records the number of the breakpoints you've set most recently; see section Convenience variables, for a discussion of what you can do with convenience variables.

You have several ways to say where the breakpoint should go.

`break function`

Set a breakpoint at entry to function function. When using source languages that permit overloading of symbols, such as C++, function may refer to more than one possible place to break. See section Breakpoint menus, for a discussion of that situation.

`break +offset`

`break -offset`

Set a breakpoint some number of lines forward or back from the position at which execution stopped in the currently selected frame.

`break linenum`

Set a breakpoint at line linenum in the current source file. That file is the last file whose source text was printed. This breakpoint stops your program just before it executes any of the code on that line.

`break filename:linenum`

Set a breakpoint at line linenum in source file filename.

`break filename:function`

Set a breakpoint at entry to function function found in file filename. Specifying a file name as well as a function name is superfluous except when multiple files contain similarly named functions.

`break *address`

Set a breakpoint at address address. You can use this to set breakpoints in parts of your program which do not have debugging information or source files.

`break`

When called without any arguments, `break` sets a breakpoint at the next instruction to be executed in the selected stack frame (see section Examining the Stack). In any selected frame but the innermost, this makes your program stop as soon as control returns to that frame. This is similar to the effect of a `finish` command in the frame inside the selected frame--except that `finish` does not leave an active breakpoint. If you use `break` without an argument in the innermost frame, GDB stops the next time it reaches the current location; this may be useful inside loops. GDB normally ignores breakpoints when it resumes execution, until at least one instruction has been executed. If it did not do this, you would be unable to proceed past a breakpoint without first disabling the breakpoint. This rule applies whether or not the breakpoint already existed when

your program stopped.

`break ... if cond`

Set a breakpoint with condition cond; evaluate the expression cond each time the breakpoint is reached, and stop only if the value is nonzero--that is, if cond evaluates as true. `...' stands for one of the possible arguments described above (or no argument) specifying where to break. See section Break conditions, for more information on breakpoint conditions.

`tbreak args`

Set a breakpoint enabled only for one stop. args are the same as for the `break` command, and the breakpoint is set in the same way, but the breakpoint is automatically deleted after the first time your program stops there. See section Disabling breakpoints.

`hbreak args`

Set a hardware-assisted breakpoint. args are the same as for the `break` command and the breakpoint is set in the same way, but the breakpoint requires hardware support and some target hardware may not have this support. The main purpose of this is EPROM/ROM code debugging, so you can set a breakpoint at an instruction without changing the instruction. This can be used with the new trap-generation provided by SPARClite DSU. DSU will generate traps when a program accesses some data or instruction address that is assigned to the debug registers. However the hardware breakpoint registers can only take two data breakpoints, and GDB will reject this command if more than two are used. Delete or disable unused hardware breakpoints before setting new ones. See section Break conditions.

`thbreak args`

Set a hardware-assisted breakpoint enabled only for one stop. args are the same as for the `hbreak` command and the breakpoint is set in the same way. However, like the `tbreak` command, the breakpoint is automatically deleted after the first time your program stops there. Also, like the `hbreak` command, the breakpoint requires hardware support and some target hardware may not have this support. See section Disabling breakpoints. Also See section Break conditions.

`rbreak regex`

Set breakpoints on all functions matching the regular expression regex. This command sets an unconditional breakpoint on all matches, printing a list of all breakpoints it set. Once these breakpoints are set, they are treated just like the breakpoints set with the `break` command. You can delete them, disable them, or make them conditional the same way as any other breakpoint. When debugging C++ programs, `rbreak` is useful for setting breakpoints on overloaded functions that are not members of any special classes.

`info breakpoints [n]`

`info break [n]`

`info watchpoints [n]`

Print a table of all breakpoints, watchpoints, and catchpoints set and not deleted, with the following columns for each breakpoint:

Breakpoint Numbers

Type

Breakpoint, watchpoint, or catchpoint.

Disposition

Whether the breakpoint is marked to be disabled or deleted when hit.

Enabled or Disabled

Enabled breakpoints are marked with `y'. `n' marks breakpoints that are not enabled.

Address

Where the breakpoint is in your program, as a memory address

What

Where the breakpoint is in the source for your program, as a file and line number.

If a breakpoint is conditional, `info break` shows the condition on the line following the affected breakpoint; breakpoint commands, if any, are listed after that. `info break` with a breakpoint number n as argument lists only that breakpoint. The convenience variable `$_` and the default examining-address for the `x` command are set to the address of the last breakpoint listed (see section Examining memory). `info break` displays a count of the number of times the breakpoint has been hit. This is especially useful in conjunction with the `ignore` command. You can ignore a large number of breakpoint hits, look at the breakpoint info to see how many times the breakpoint was hit, and then run again, ignoring one less than that number. This will get you quickly to the last hit of that breakpoint.

GDB allows you to set any number of breakpoints at the same place in your program. There is nothing silly or meaningless about this. When the breakpoints are conditional, this is even useful (see section Break conditions).

GDB itself sometimes sets breakpoints in your program for special purposes, such as proper handling of `longjmp` (in C programs). These internal breakpoints are assigned negative numbers, starting with `-1`; `info breakpoints' does not display them.

You can see these breakpoints with the GDB maintenance command `maint info breakpoints'.

`maint info breakpoints`

Using the same format as `info breakpoints', display both the breakpoints you've set explicitly, and those GDB is using for internal purposes. Internal breakpoints are shown with negative breakpoint numbers. The type column identifies what kind of breakpoint is shown:

`breakpoint`

Normal, explicitly set breakpoint.

`watchpoint`

Normal, explicitly set watchpoint.

`longjmp`

Internal breakpoint, used to handle correctly stepping through `longjmp` calls.

`longjmp resume`

Internal breakpoint at the target of a `longjmp`.

`until`

Temporary internal breakpoint used by the GDB `until` command.

`finish`

Temporary internal breakpoint used by the GDB `finish` command.

Setting watchpoints

You can use a watchpoint to stop execution whenever the value of an expression changes, without having to predict a particular place where this may happen.

Depending on your system, watchpoints may be implemented in software or hardware. GDB does software watchpointing by single-stepping your program and testing the variable's value each time, which is hundreds of times slower than normal execution. (But this may still be worth it, to catch errors where you have no clue what part of your program is the culprit.)

On some systems, such as HP-UX and Linux, GDB includes support for hardware watchpoints, which do not slow down the running of your program.

`watch expr`

Set a watchpoint for an expression. GDB will break when expr is written into by the program and its value changes.

`rwatch expr`

Set a watchpoint that will break when watch expr is read by the program. If you use both watchpoints, both must be set with the `rwatch` command.

`awatch expr`

Set a watchpoint that will break when args is read and written into by the program. If you use both watchpoints, both must be set with the `awatch` command.

`info watchpoints`

This command prints a list of watchpoints, breakpoints, and catchpoints; it is the same as `info break`.

GDB sets a **hardware watchpoint** if possible. Hardware watchpoints execute very quickly, and the debugger reports a change in value at the exact instruction where the change occurs. If GDB cannot set a hardware watchpoint, it sets a software watchpoint, which executes more slowly and reports the change in value at the next statement, not the instruction, after the change occurs.

When you issue the `watch` command, GDB reports

```
Hardware watchpoint num: expr
```

if it was able to set a hardware watchpoint.

The SPARClite DSU will generate traps when a program accesses some data or instruction address that is assigned to the debug registers. For the data addresses, DSU facilitates the `watch` command. However the hardware breakpoint registers can only take two data watchpoints, and both watchpoints must be the same kind. For example, you can set two watchpoints with `watch` commands, two with `rwatch` commands, **or** two with `awatch` commands, but you cannot set one watchpoint with one command and the other with a different command. GDB will reject the command if you try to mix watchpoints. Delete

or disable unused watchpoint commands before setting new ones.

If you call a function interactively using `print` or `call`, any watchpoints you have set will be inactive until GDB reaches another kind of breakpoint or the call completes.

> *Warning:* In multi-thread programs, watchpoints have only limited usefulness. With the current watchpoint implementation, GDB can only watch the value of an expression *in a single thread*. If you are confident that the expression can only change due to the current thread's activity (and if you are also confident that no other thread can become current), then you can use watchpoints as usual. However, GDB may not notice when a non-current thread's activity changes the expression.

Setting catchpoints

You can use **catchpoints** to cause the debugger to stop for certain kinds of program events, such as C++ exceptions or the loading of a shared library. Use the `catch` command to set a catchpoint.

`catch event`

Stop when event occurs. event can be any of the following:

`throw`

The throwing of a C++ exception.

`catch`

The catching of a C++ exception.

`exec`

A call to `exec`. This is currently only available for HP-UX.

`fork`

A call to `fork`. This is currently only available for HP-UX.

`vfork`

A call to `vfork`. This is currently only available for HP-UX.

`load`

`load libname`

The dynamic loading of any shared library, or the loading of the library libname. This is currently only available for HP-UX.

`unload`

`unload libname`

The unloading of any dynamically loaded shared library, or the unloading of the library libname. This is currently only available for HP-UX.

`tcatch event`

Set a catchpoint that is enabled only for one stop. The catchpoint is automatically deleted after the first time the event is caught.

Use the `info break` command to list the current catchpoints.

There are currently some limitations to C++ exception handling (`catch throw` and `catch cat` in GDB:

- If you call a function interactively, GDB normally returns control to you when the function has finished executing. If the call raises an exception, however, the call may bypass the mechanism that returns control to you and cause your program either to abort or to simply continue running until it hits a breakpoint, catches a signal that GDB is listening for, or exits. This is the case even if you set a catchpoint for the exception; catchpoints on exceptions are disabled within interactive calls.
- You cannot raise an exception interactively.
- You cannot install an exception handler interactively.

Sometimes `catch` is not the best way to debug exception handling: if you need to know exactly where an exception is raised, it is better to stop *before* the exception handler is called, since that way you can see the stack before any unwinding takes place. If you set a breakpoint in an exception handler instead, it may not be easy to find out where the exception was raised.

To stop just before an exception handler is called, you need some knowledge of the implementation. In the case of GNU C++, exceptions are raised by calling a library function named `__raise_exception` which has the following ANSI C interface:

```
/* addr is where the exception identifier is stored.
   ID is the exception identifier.  */
void __raise_exception (void **addr, void *id);
```

To make the debugger catch all exceptions before any stack unwinding takes place, set a breakpoint on `__raise_exception` (see section Breakpoints, watchpoints, and catchpoints).

With a conditional breakpoint (see section Break conditions) that depends on the value of id, you can stop your program when a specific exception is raised. You can use multiple conditional breakpoints to stop your program when any of a number of exceptions are raised.

Deleting breakpoints

It is often necessary to eliminate a breakpoint, watchpoint, or catchpoint once it has done its job and you no longer want your program to stop there. This is called **deleting** the breakpoint. A breakpoint that has been deleted no longer exists; it is forgotten.

With the `clear` command you can delete breakpoints according to where they are in your program. With the `delete` command you can delete individual breakpoints, watchpoints, or catchpoints by specifying their breakpoint numbers.

It is not necessary to delete a breakpoint to proceed past it. GDB automatically ignores breakpoints on the first instruction to be executed when you continue execution without changing the execution address.

`clear`

Delete any breakpoints at the next instruction to be executed in the selected stack frame (see section Selecting a frame). When the innermost frame is selected, this is a good way to delete a

breakpoint where your program just stopped.

`clear function`

`clear filename:function`

Delete any breakpoints set at entry to the function function.

`clear linenum`

`clear filename:linenum`

Delete any breakpoints set at or within the code of the specified line.

`delete [breakpoints] [bnums...]`

Delete the breakpoints, watchpoints, or catchpoints of the numbers specified as arguments. If no argument is specified, delete all breakpoints (GDB asks confirmation, unless you have `set confirm off`). You can abbreviate this command as `d`.

Disabling breakpoints

Rather than deleting a breakpoint, watchpoint, or catchpoint, you might prefer to **disable** it. This makes the breakpoint inoperative as if it had been deleted, but remembers the information on the breakpoint so that you can **enable** it again later.

You disable and enable breakpoints, watchpoints, and catchpoints with the `enable` and `disable` commands, optionally specifying one or more breakpoint numbers as arguments. Use `info break` or `info watch` to print a list of breakpoints, watchpoints, and catchpoints if you do not know which numbers to use.

A breakpoint, watchpoint, or catchpoint can have any of four different states of enablement:

- Enabled. The breakpoint stops your program. A breakpoint set with the `break` command starts out in this state.
- Disabled. The breakpoint has no effect on your program.
- Enabled once. The breakpoint stops your program, but then becomes disabled. A breakpoint set with the `tbreak` command starts out in this state.
- Enabled for deletion. The breakpoint stops your program, but immediately after it does so it is deleted permanently.

You can use the following commands to enable or disable breakpoints, watchpoints, and catchpoints:

`disable [breakpoints] [bnums...]`

Disable the specified breakpoints--or all breakpoints, if none are listed. A disabled breakpoint has no effect but is not forgotten. All options such as ignore-counts, conditions and commands are remembered in case the breakpoint is enabled again later. You may abbreviate `disable` as `dis`.

`enable [breakpoints] [bnums...]`

Enable the specified breakpoints (or all defined breakpoints). They become effective once again in stopping your program.

`enable [breakpoints] once bnums...`

Enable the specified breakpoints temporarily. GDB disables any of these breakpoints immediately

after stopping your program.

`enable [breakpoints] delete bnums...`

Enable the specified breakpoints to work once, then die. GDB deletes any of these breakpoints as soon as your program stops there.

Except for a breakpoint set with `tbreak` (see section Setting breakpoints), breakpoints that you set are initially enabled; subsequently, they become disabled or enabled only when you use one of the commands above. (The command `until` can set and delete a breakpoint of its own, but it does not change the state of your other breakpoints; see section Continuing and stepping.)

Break conditions

The simplest sort of breakpoint breaks every time your program reaches a specified place. You can also specify a **condition** for a breakpoint. A condition is just a Boolean expression in your programming language (see section Expressions). A breakpoint with a condition evaluates the expression each time your program reaches it, and your program stops only if the condition is *true*.

This is the converse of using assertions for program validation; in that situation, you want to stop when the assertion is violated--that is, when the condition is false. In C, if you want to test an assertion expressed by the condition assert, you should set the condition `! assert' on the appropriate breakpoint.

Conditions are also accepted for watchpoints; you may not need them, since a watchpoint is inspecting the value of an expression anyhow--but it might be simpler, say, to just set a watchpoint on a variable name, and specify a condition that tests whether the new value is an interesting one.

Break conditions can have side effects, and may even call functions in your program. This can be useful, for example, to activate functions that log program progress, or to use your own print functions to format special data structures. The effects are completely predictable unless there is another enabled breakpoint at the same address. (In that case, GDB might see the other breakpoint first and stop your program without checking the condition of this one.) Note that breakpoint commands are usually more convenient and flexible for the purpose of performing side effects when a breakpoint is reached (see section Breakpoint command lists).

Break conditions can be specified when a breakpoint is set, by using `if' in the arguments to the `break` command. See section Setting breakpoints. They can also be changed at any time with the `condition` command. The `watch` command does not recognize the `if` keyword; `condition` is the only way to impose a further condition on a watchpoint.

`condition bnum expression`

Specify expression as the break condition for breakpoint, watchpoint, or catchpoint number bnum. After you set a condition, breakpoint bnum stops your program only if the value of expression is true (nonzero, in C). When you use `condition`, GDB checks expression immediately for syntactic correctness, and to determine whether symbols in it have referents in the context of your breakpoint. GDB does not actually evaluate expression at the time the `condition` command is given, however. See section Expressions.

`condition bnum`

Remove the condition from breakpoint number bnum. It becomes an ordinary unconditional breakpoint.

A special case of a breakpoint condition is to stop only when the breakpoint has been reached a certain number of times. This is so useful that there is a special way to do it, using the **ignore count** of the breakpoint. Every breakpoint has an ignore count, which is an integer. Most of the time, the ignore count is zero, and therefore has no effect. But if your program reaches a breakpoint whose ignore count is positive, then instead of stopping, it just decrements the ignore count by one and continues. As a result, if the ignore count value is n, the breakpoint does not stop the next n times your program reaches it.

`ignore bnum count`

Set the ignore count of breakpoint number bnum to count. The next count times the breakpoint is reached, your program's execution does not stop; other than to decrement the ignore count, GDB takes no action. To make the breakpoint stop the next time it is reached, specify a count of zero. When you use `continue` to resume execution of your program from a breakpoint, you can specify an ignore count directly as an argument to `continue`, rather than using `ignore`. See section Continuing and stepping. If a breakpoint has a positive ignore count and a condition, the condition is not checked. Once the ignore count reaches zero, GDB resumes checking the condition. You could achieve the effect of the ignore count with a condition such as `$foo-- <= 0' using a debugger convenience variable that is decremented each time. See section Convenience variables.

Ignore counts apply to breakpoints, watchpoints, and catchpoints.

Breakpoint command lists

You can give any breakpoint (or watchpoint or catchpoint) a series of commands to execute when your program stops due to that breakpoint. For example, you might want to print the values of certain expressions, or enable other breakpoints.

```
commands [bnum]
... command-list ...
end
```

Specify a list of commands for breakpoint number bnum. The commands themselves appear on the following lines. Type a line containing just `end` to terminate the commands. To remove all commands from a breakpoint, type `commands` and follow it immediately with `end`; that is, give no commands. With no bnum argument, `commands` refers to the last breakpoint, watchpoint, or catchpoint set (not to the breakpoint most recently encountered).

Pressing RET as a means of repeating the last GDB command is disabled within a command-list.

You can use breakpoint commands to start your program up again. Simply use the `continue` command, or `step`, or any other command that resumes execution.

Any other commands in the command list, after a command that resumes execution, are ignored. This is because any time you resume execution (even with a simple `next` or `step`), you may encounter another breakpoint--which could have its own command list, leading to ambiguities about which list to execute.

If the first command you specify in a command list is `silent`, the usual message about stopping at a breakpoint is not printed. This may be desirable for breakpoints that are to print a specific message and then continue. If none of the remaining commands print anything, you see no sign that the breakpoint was reached. `silent` is meaningful only at the beginning of a breakpoint command list.

The commands `echo`, `output`, and `printf` allow you to print precisely controlled output, and are often useful in silent breakpoints. See section Commands for controlled output.

For example, here is how you could use breakpoint commands to print the value of `x` at entry to `foo` whenever `x` is positive.

```
break foo if x>0
commands
silent
printf "x is %d\n",x
cont
end
```

One application for breakpoint commands is to compensate for one bug so you can test for another. Put a breakpoint just after the erroneous line of code, give it a condition to detect the case in which something erroneous has been done, and give it commands to assign correct values to any variables that need them. End with the `continue` command so that your program does not stop, and start with the `silent` command so that no output is produced. Here is an example:

```
break 403
commands
silent
set x = y + 4
cont
end
```

Breakpoint menus

Some programming languages (notably C++) permit a single function name to be defined several times, for application in different contexts. This is called **overloading**. When a function name is overloaded, `break function' is not enough to tell GDB where you want a breakpoint. If you realize this is a problem, you can use something like `break function(types)' to specify which particular version of the function you want. Otherwise, GDB offers you a menu of numbered choices for different possible breakpoints, and waits for your selection with the prompt `>'. The first two options are always `[0] cancel' and `[1] all'. Typing 1 sets a breakpoint at each definition of function, and typing 0 aborts the `break` command without setting any new breakpoints.

For example, the following session excerpt shows an attempt to set a breakpoint at the overloaded symbol `String::after`. We choose three particular definitions of that function name:

```
(gdb) b String::after
```

```
[0] cancel
[1] all
[2] file:String.cc; line number:867
[3] file:String.cc; line number:860
[4] file:String.cc; line number:875
[5] file:String.cc; line number:853
[6] file:String.cc; line number:846
[7] file:String.cc; line number:735
> 2 4 6
Breakpoint 1 at 0xb26c: file String.cc, line 867.
Breakpoint 2 at 0xb344: file String.cc, line 875.
Breakpoint 3 at 0xafcc: file String.cc, line 846.
Multiple breakpoints were set.
Use the "delete" command to delete unwanted
 breakpoints.
(gdb)
```

Continuing and stepping

Continuing means resuming program execution until your program completes normally. In contrast, **stepping** means executing just one more "step" of your program, where "step" may mean either one line of source code, or one machine instruction (depending on what particular command you use). Either when continuing or when stepping, your program may stop even sooner, due to a breakpoint or a signal. (If due to a signal, you may want to use `handle`, or use `signal 0' to resume execution. See section Signals.)

`continue [ignore-count]`

`c [ignore-count]`

`fg [ignore-count]`

> Resume program execution, at the address where your program last stopped; any breakpoints set at that address are bypassed. The optional argument ignore-count allows you to specify a further number of times to ignore a breakpoint at this location; its effect is like that of `ignore` (see section Break conditions). The argument ignore-count is meaningful only when your program stopped due to a breakpoint. At other times, the argument to `continue` is ignored. The synonyms `c` and `fg` are provided purely for convenience, and have exactly the same behavior as `continue`.

To resume execution at a different place, you can use `return` (see section Returning from a function) to go back to the calling function; or `jump` (see section Continuing at a different address) to go to an arbitrary location in your program.

A typical technique for using stepping is to set a breakpoint (see section Breakpoints, watchpoints, and catchpoints) at the beginning of the function or the section of your program where a problem is believed to lie, run your program until it stops at that breakpoint, and then step through the suspect area, examining the variables that are interesting, until you see the problem happen.

`step`

Continue running your program until control reaches a different source line, then stop it and return control to GDB. This command is abbreviated `s`.

> *Warning:* If you use the `step` command while control is within a function that was compiled without debugging information, execution proceeds until control reaches a function that does have debugging information. Likewise, it will not step into a function which is compiled without debugging information. To step through functions without debugging information, use the `stepi` command, described below.

The `step` command now only stops at the first instruction of a source line. This prevents the multiple stops that used to occur in switch statements, for loops, etc. `step` continues to stop if a function that has debugging information is called within the line. Also, the `step` command now only enters a subroutine if there is line number information for the subroutine. Otherwise it acts like the `next` command. This avoids problems when using `cc -gl` on MIPS machines. Previously, `step` entered subroutines if there was any debugging information about the routine.

`step count`

Continue running as in `step`, but do so count times. If a breakpoint is reached, or a signal not related to stepping occurs before count steps, stepping stops right away.

`next [count]`

Continue to the next source line in the current (innermost) stack frame. This is similar to `step`, but function calls that appear within the line of code are executed without stopping. Execution stops when control reaches a different line of code at the original stack level that was executing when you gave the `next` command. This command is abbreviated `n`. An argument count is a repeat count, as for `step`. The `next` command now only stops at the first instruction of a source line. This prevents the multiple stops that used to occur in switch statements, for loops, etc.

`finish`

Continue running until just after function in the selected stack frame returns. Print the returned value (if any). Contrast this with the `return` command (see section Returning from a function).

`until`

`u`

Continue running until a source line past the current line, in the current stack frame, is reached. This command is used to avoid single stepping through a loop more than once. It is like the `next` command, except that when `until` encounters a jump, it automatically continues execution until the program counter is greater than the address of the jump. This means that when you reach the end of a loop after single stepping though it, `until` makes your program continue execution until it exits the loop. In contrast, a `next` command at the end of a loop simply steps back to the beginning of the loop, which forces you to step through the next iteration. `until` always stops your program if it attempts to exit the current stack frame. `until` may produce somewhat counterintuitive results if the order of machine code does not match the order of the source lines. For example, in the following excerpt from a debugging session, the `f` (`frame`) command shows that execution is stopped at line `206`; yet when we use `until`, we get to line `195`:

```
(gdb) f
```

```
#0  main (argc=4, argv=0xf7fffae8) at m4.c:206
206                 expand_input();
(gdb) until
195             for ( ; argc > 0; NEXTARG) {
```

This happened because, for execution efficiency, the compiler had generated code for the loop closure test at the end, rather than the start, of the loop--even though the test in a C `for`-loop is written before the body of the loop. The `until` command appeared to step back to the beginning of the loop when it advanced to this expression; however, it has not really gone to an earlier statement--not in terms of the actual machine code. `until` with no argument works by means of single instruction stepping, and hence is slower than `until` with an argument.

`until location`

`u location`

Continue running your program until either the specified location is reached, or the current stack frame returns. location is any of the forms of argument acceptable to `break` (see section Setting breakpoints). This form of the command uses breakpoints, and hence is quicker than `until` without an argument.

`stepi`

`si`

Execute one machine instruction, then stop and return to the debugger. It is often useful to do `display/i $pc' when stepping by machine instructions. This makes GDB automatically display the next instruction to be executed, each time your program stops. See section Automatic display. An argument is a repeat count, as in `step`.

`nexti`

`ni`

Execute one machine instruction, but if it is a function call, proceed until the function returns. An argument is a repeat count, as in `next`.

Signals

A signal is an asynchronous event that can happen in a program. The operating system defines the possible kinds of signals, and gives each kind a name and a number. For example, in Unix `SIGINT` is the signal a program gets when you type an interrupt (often C-c); `SIGSEGV` is the signal a program gets from referencing a place in memory far away from all the areas in use; `SIGALRM` occurs when the alarm clock timer goes off (which happens only if your program has requested an alarm).

Some signals, including `SIGALRM`, are a normal part of the functioning of your program. Others, such as `SIGSEGV`, indicate errors; these signals are **fatal** (kill your program immediately) if the program has not specified in advance some other way to handle the signal. `SIGINT` does not indicate an error in your program, but it is normally fatal so it can carry out the purpose of the interrupt: to kill the program.

GDB has the ability to detect any occurrence of a signal in your program. You can tell GDB in advance what to do for each kind of signal.

Normally, GDB is set up to ignore non-erroneous signals like `SIGALRM` (so as not to interfere with t role in the functioning of your program) but to stop your program immediately whenever an error sig happens. You can change these settings with the `handle` command.

`info signals`

Print a table of all the kinds of signals and how GDB has been told to handle each one. You can use this to see the signal numbers of all the defined types of signals. `info handle` is the new alias for `info signals`.

`handle signal keywords...`

Change the way GDB handles signal signal. signal can be the number of a signal or its name (with or without the `SIG' at the beginning). The keywords say what change to make.

The keywords allowed by the `handle` command can be abbreviated. Their full names are:

`nostop`

GDB should not stop your program when this signal happens. It may still print a message telling you that the signal has come in.

`stop`

GDB should stop your program when this signal happens. This implies the `print` keyword as well.

`print`

GDB should print a message when this signal happens.

`noprint`

GDB should not mention the occurrence of the signal at all. This implies the `nostop` keyword as well.

`pass`

GDB should allow your program to see this signal; your program can handle the signal, or else it may terminate if the signal is fatal and not handled.

`nopass`

GDB should not allow your program to see this signal.

When a signal stops your program, the signal is not visible until you continue. Your program sees the signal then, if `pass` is in effect for the signal in question *at that time*. In other words, after GDB reports a signal, you can use the `handle` command with `pass` or `nopass` to control whether your program sees that signal when you continue.

You can also use the `signal` command to prevent your program from seeing a signal, or cause it to see a signal it normally would not see, or to give it any signal at any time. For example, if your program stopped due to some sort of memory reference error, you might store correct values into the erroneous variables and continue, hoping to see more execution; but your program would probably terminate immediately as a result of the fatal signal once it saw the signal. To prevent this, you can continue with `signal 0'. See section Giving your program a signal.

Stopping and starting multi-thread programs

When your program has multiple threads (see section Debugging programs with multiple threads), you can choose whether to set breakpoints on all threads, or on a particular thread.

`break linespec thread threadno`

`break linespec thread threadno if ...`

linespec specifies source lines; there are several ways of writing them, but the effect is always to specify some source line. Use the qualifier `thread threadno' with a breakpoint command to specify that you only want GDB to stop the program when a particular thread reaches this breakpoint. threadno is one of the numeric thread identifiers assigned by GDB, shown in the first column of the `info threads' display. If you do not specify `thread threadno' when you set a breakpoint, the breakpoint applies to *all* threads of your program. You can use the `thread` qualifier on conditional breakpoints as well; in this case, place `thread threadno' before the breakpoint condition, like this:

```
(gdb) break frik.c:13 thread 28 if bartab > lim
```

Whenever your program stops under GDB for any reason, *all* threads of execution stop, not just the current thread. This allows you to examine the overall state of the program, including switching between threads, without worrying that things may change underfoot.

Conversely, whenever you restart the program, *all* threads start executing. *This is true even when single-stepping* with commands like `step` or `next`.

In particular, GDB cannot single-step all threads in lockstep. Since thread scheduling is up to your debugging target's operating system (not controlled by GDB), other threads may execute more than one statement while the current thread completes a single step. Moreover, in general other threads stop in the middle of a statement, rather than at a clean statement boundary, when the program stops.

You might even find your program stopped in another thread after continuing or even single-stepping. This happens whenever some other thread runs into a breakpoint, a signal, or an exception before the first thread completes whatever you requested.

On some OSes, you can lock the OS scheduler and thus allow only a single thread to run.

`set scheduler-locking mode`

Set the scheduler locking mode. If it is `off`, then there is no locking and any thread may run at any time. If `on`, then only the current thread may run when the inferior is resumed. The `step` mode optimizes for single-stepping. It stops other threads from "seizing the prompt" by preempting the current thread while you are stepping. Other threads will only rarely (or never) get a chance to run when you step. They are more likely to run when you "next" over a function call, and they are completely free to run when you use commands like "continue", "until", or "finish". However, unless another thread hits a breakpoint during its timeslice, they will never steal the GDB prompt away from the thread that you are debugging.

`show scheduler-locking`

Display the current scheduler locking mode.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Examining the Stack

When your program has stopped, the first thing you need to know is where it stopped and how it got there.

Each time your program performs a function call, information about the call is generated. That information includes the location of the call in your program, the arguments of the call, and the local variables of the function being called. The information is saved in a block of data called a **stack frame**. The stack frames are allocated in a region of memory called the **call stack**.

When your program stops, the GDB commands for examining the stack allow you to see all of this information.

One of the stack frames is **selected** by GDB and many GDB commands refer implicitly to the selected frame. In particular, whenever you ask GDB for the value of a variable in your program, the value is found in the selected frame. There are special GDB commands to select whichever frame you are interested in. See section Selecting a frame.

When your program stops, GDB automatically selects the currently executing frame and describes it briefly, similar to the `frame` command (see section Information about a frame).

Stack frames

The call stack is divided up into contiguous pieces called **stack frames**, or **frames** for short; each frame is the data associated with one call to one function. The frame contains the arguments given to the function, the function's local variables, and the address at which the function is executing.

When your program is started, the stack has only one frame, that of the function `main`. This is called the **initial** frame or the **outermost** frame. Each time a function is called, a new frame is made. Each time a function returns, the frame for that function invocation is eliminated. If a function is recursive, there can be many frames for the same function. The frame for the function in which execution is actually occurring is called the **innermost** frame. This is the most recently created of all the stack frames that still exist.

Inside your program, stack frames are identified by their addresses. A stack frame consists of many bytes, each of which has its own address; each kind of computer has a convention for choosing one byte whose address serves as the address of the frame. Usually this address is kept in a register called the **frame pointer register** while execution is going on in that frame.

GDB assigns numbers to all existing stack frames, starting with zero for the innermost frame, one for the frame that called it, and so on upward. These numbers do not really exist in your program; they are assigned by GDB to give you a way of designating stack frames in GDB commands.

Some compilers provide a way to compile functions so that they operate without stack frames. (For example, the `gcc` option `-fomit-frame-pointer' generates functions without a frame.) This is occasionally done with heavily used library functions to save the frame setup time. GDB has limited facilities for dealing with these function invocations. If the innermost function invocation has no stack frame, GDB nevertheless regards it as though it had a separate frame, which is numbered zero as usual, allowing correct tracing of the function call chain. However, GDB has no provision for frameless functions elsewhere in the stack.

`frame args`

The `frame` command allows you to move from one stack frame to another, and to print the stack frame you select. args may be either the address of the frame or the stack frame number. Without an argument, `frame` prints the current stack frame.

`select-frame`

The `select-frame` command allows you to move from one stack frame to another without printing the frame. This is the silent version of `frame`.

Backtraces

A backtrace is a summary of how your program got where it is. It shows one line per frame, for many frames, starting with the currently executing frame (frame zero), followed by its caller (frame one), and on up the stack.

`backtrace`

`bt`

Print a backtrace of the entire stack: one line per frame for all frames in the stack. You can stop the backtrace at any time by typing the system interrupt character, normally C-c.

`backtrace n`

`bt n`

Similar, but print only the innermost n frames.

`backtrace -n`

`bt -n`

Similar, but print only the outermost n frames.

The names `where` and `info stack` (abbreviated `info s`) are additional aliases for `backtrace`.

Each line in the backtrace shows the frame number and the function name. The program counter value is also shown--unless you use `set print address off`. The backtrace also shows the source file name and line number, as well as the arguments to the function. The program counter value is omitted if it is at the beginning of the code for that line number.

Here is an example of a backtrace. It was made with the command `bt 3', so it shows the innermost three frames.

```
#0  m4_traceon (obs=0x24eb0, argc=1, argv=0x2b8c8)
```

```
    at builtin.c:993
#1  0x6e38 in expand_macro (sym=0x2b600) at macro.c:242
#2  0x6840 in expand_token (obs=0x0, t=177664, td=0xf7fffb08)
    at macro.c:71
(More stack frames follow...)
```

The display for frame zero does not begin with a program counter value, indicating that your program has stopped at the beginning of the code for line `993` of `builtin.c`.

Selecting a frame

Most commands for examining the stack and other data in your program work on whichever stack frame is selected at the moment. Here are the commands for selecting a stack frame; all of them finish by printing a brief description of the stack frame just selected.

`frame n`

`f n`

Select frame number n. Recall that frame zero is the innermost (currently executing) frame, frame one is the frame that called the innermost one, and so on. The highest-numbered frame is the one for `main`.

`frame addr`

`f addr`

Select the frame at address addr. This is useful mainly if the chaining of stack frames has been damaged by a bug, making it impossible for GDB to assign numbers properly to all frames. In addition, this can be useful when your program has multiple stacks and switches between them. On the SPARC architecture, `frame` needs two addresses to select an arbitrary frame: a frame pointer and a stack pointer. On the MIPS and Alpha architecture, it needs two addresses: a stack pointer and a program counter. On the 29k architecture, it needs three addresses: a register stack pointer, a program counter, and a memory stack pointer.

`up n`

Move n frames up the stack. For positive numbers n, this advances toward the outermost frame, to higher frame numbers, to frames that have existed longer. n defaults to one.

`down n`

Move n frames down the stack. For positive numbers n, this advances toward the innermost frame, to lower frame numbers, to frames that were created more recently. n defaults to one. You may abbreviate `down` as `do`.

All of these commands end by printing two lines of output describing the frame. The first line shows the frame number, the function name, the arguments, and the source file and line number of execution in that frame. The second line shows the text of that source line.

For example:

```
(gdb) up
```

```
#1  0x22f0 in main (argc=1, argv=0xf7fffbf4, env=0xf7fffbfc)
    at env.c:10
10              read_input_file (argv[i]);
```

After such a printout, the `list` command with no arguments prints ten lines centered on the point of execution in the frame. See section Printing source lines.

`up-silently n`

`down-silently n`

These two commands are variants of `up` and `down`, respectively; they differ in that they do their work silently, without causing display of the new frame. They are intended primarily for use in GDB command scripts, where the output might be unnecessary and distracting.

Information about a frame

There are several other commands to print information about the selected stack frame.

`frame`

`f`

When used without any argument, this command does not change which frame is selected, but prints a brief description of the currently selected stack frame. It can be abbreviated `f`. With an argument, this command is used to select a stack frame. See section Selecting a frame.

`info frame`

`info f`

This command prints a verbose description of the selected stack frame, including:

- the address of the frame
- the address of the next frame down (called by this frame)
- the address of the next frame up (caller of this frame)
- the language in which the source code corresponding to this frame is written
- the address of the frame's arguments
- the program counter saved in it (the address of execution in the caller frame)
- which registers were saved in the frame

The verbose description is useful when something has gone wrong that has made the stack format fail to fit the usual conventions.

`info frame addr`

`info f addr`

Print a verbose description of the frame at address addr, without selecting that frame. The selected frame remains unchanged by this command. This requires the same kind of address (more than one for some architectures) that you specify in the `frame` command. See section Selecting a frame.

`info args`

Print the arguments of the selected frame, each on a separate line.

`info locals`

Print the local variables of the selected frame, each on a separate line. These are all variables (declared either static or automatic) accessible at the point of execution of the selected frame.

`info catch`

Print a list of all the exception handlers that are active in the current stack frame at the current point of execution. To see other exception handlers, visit the associated frame (using the `up`, `down`, or `frame` commands); then type `info catch`. See section Setting catchpoints.

MIPS/Alpha machines and the function stack

Alpha- and MIPS-based computers use an unusual stack frame, which sometimes requires GDB to search backward in the object code to find the beginning of a function.

To improve response time (especially for embedded applications, where GDB may be restricted to a slow serial line for this search) you may want to limit the size of this search, using one of these commands:

`set heuristic-fence-post limit`

Restrict GDB to examining at most limit bytes in its search for the beginning of a function. A value of 0 (the default) means there is no limit. However, except for 0, the larger the limit the more bytes `heuristic-fence-post` must search and therefore the longer it takes to run.

`show heuristic-fence-post`

Display the current limit.

These commands are available *only* when GDB is configured for debugging programs on Alpha or MIPS processors.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Examining Source Files

GDB can print parts of your program's source, since the debugging information recorded in the program tells GDB what source files were used to build it. When your program stops, GDB spontaneously prints the line where it stopped. Likewise, when you select a stack frame (see section Selecting a frame), GDB prints the line where execution in that frame has stopped. You can print other portions of source files by explicit command.

If you use GDB through its GNU Emacs interface, you may prefer to use Emacs facilities to view source; see section Using GDB under GNU Emacs.

Printing source lines

To print lines from a source file, use the `list` command (abbreviated `l`). By default, ten lines are printed. There are several ways to specify what part of the file you want to print.

Here are the forms of the `list` command most commonly used:

`list linenum`

Print lines centered around line number linenum in the current source file.

`list function`

Print lines centered around the beginning of function function.

`list`

Print more lines. If the last lines printed were printed with a `list` command, this prints lines following the last lines printed; however, if the last line printed was a solitary line printed as part of displaying a stack frame (see section Examining the Stack), this prints lines centered around that line.

`list -`

Print lines just before the lines last printed.

By default, GDB prints ten source lines with any of these forms of the `list` command. You can change this using `set listsize`:

`set listsize count`

Make the `list` command display count source lines (unless the `list` argument explicitly specifies some other number).

`show listsize`

Display the number of lines that `list` prints.

Repeating a `list` command with RET discards the argument, so it is equivalent to typing just `list`.

This is more useful than listing the same lines again. An exception is made for an argument of `-'; that argument is preserved in repetition so that each repetition moves up in the source file.

In general, the `list` command expects you to supply zero, one or two **linespecs**. Linespecs specify source lines; there are several ways of writing them but the effect is always to specify some source line. Here is a complete description of the possible arguments for `list`:

`list linespec`

Print lines centered around the line specified by linespec.

`list first,last`

Print lines from first to last. Both arguments are linespecs.

`list ,last`

Print lines ending with last.

`list first,`

Print lines starting with first.

`list +`

Print lines just after the lines last printed.

`list -`

Print lines just before the lines last printed.

`list`

As described in the preceding table.

Here are the ways of specifying a single source line--all the kinds of linespec.

`number`

Specifies line number of the current source file. When a `list` command has two linespecs, this refers to the same source file as the first linespec.

`+offset`

Specifies the line offset lines after the last line printed. When used as the second linespec in a `list` command that has two, this specifies the line offset lines down from the first linespec.

`-offset`

Specifies the line offset lines before the last line printed.

`filename:number`

Specifies line number in the source file filename.

`function`

Specifies the line that begins the body of the function function. For example: in C, this is the line with the open brace.

`filename:function`

Specifies the line of the open-brace that begins the body of the function function in the file filename. You only need the file name with a function name to avoid ambiguity when there are identically named functions in different source files.

`*address`

Specifies the line containing the program address address. address may be any expression.

Searching source files

There are two commands for searching through the current source file for a regular expression.

`forward-search regexp`

`search regexp`

The command `forward-search regexp' checks each line, starting with the one following the last line listed, for a match for regexp. It lists the line that is found. You can use the synonym `search regexp' or abbreviate the command name as `fo`.

`reverse-search regexp`

The command `reverse-search regexp' checks each line, starting with the one before the last line listed and going backward, for a match for regexp. It lists the line that is found. You can abbreviate this command as `rev`.

Specifying source directories

Executable programs sometimes do not record the directories of the source files from which they were compiled, just the names. Even when they do, the directories could be moved between the compilation and your debugging session. GDB has a list of directories to search for source files; this is called the **source path**. Each time GDB wants a source file, it tries all the directories in the list, in the order they are present in the list, until it finds a file with the desired name. Note that the executable search path is *not* used for this purpose. Neither is the current working directory, unless it happens to be in the source path.

If GDB cannot find a source file in the source path, and the object program records a directory, GDB tries that directory too. If the source path is empty, and there is no record of the compilation directory, GDB looks in the current directory as a last resort.

Whenever you reset or rearrange the source path, GDB clears out any information it has cached about where source files are found and where each line is in the file.

When you start GDB, its source path is empty. To add other directories, use the `directory` command.

`directory dirname ...`

`dir dirname ...`

Add directory dirname to the front of the source path. Several directory names may be given to this command, separated by `:' or whitespace. You may specify a directory that is already in the source path; this moves it forward, so GDB searches it sooner. You can use the string `$cdir' to refer to the compilation directory (if one is recorded), and `$cwd' to refer to the current working directory. `$cwd' is not the same as `.'---the former tracks the current working directory as it changes during your GDB session, while the latter is immediately expanded to the current directory at the time you add an entry to the source path.

`directory`

Reset the source path to empty again. This requires confirmation.

`show directories`

Print the source path: show which directories it contains.

If your source path is cluttered with directories that are no longer of interest, GDB may sometimes cause confusion by finding the wrong versions of source. You can correct the situation as follows:

1. Use `directory` with no argument to reset the source path to empty.
2. Use `directory` with suitable arguments to reinstall the directories you want in the source path. You can add all the directories in one command.

Source and machine code

You can use the command `info line` to map source lines to program addresses (and vice versa), and the command `disassemble` to display a range of addresses as machine instructions. When run under GNU Emacs mode, the `info line` command now causes the arrow to point to the line specified. Also, `info line` prints addresses in symbolic form as well as hex.

`info line linespec`

Print the starting and ending addresses of the compiled code for source line linespec. You can specify source lines in any of the ways understood by the `list` command (see section Printing source lines).

For example, we can use `info line` to discover the location of the object code for the first line of function `m4_changequote`:

```
(gdb) info line m4_changecom
Line 895 of "builtin.c" starts at pc 0x634c and ends at 0x6350.
```

We can also inquire (using `*addr` as the form for linespec) what source line covers a particular address:

```
(gdb) info line *0x63ff
Line 926 of "builtin.c" starts at pc 0x63e4 and ends at 0x6404.
```

After `info line`, the default address for the `x` command is changed to the starting address of the line, so that `x/i' is sufficient to begin examining the machine code (see section Examining memory). Also, this address is saved as the value of the convenience variable `$_` (see section Convenience variables).

`disassemble`

This specialized command dumps a range of memory as machine instructions. The default memory range is the function surrounding the program counter of the selected frame. A single argument to this command is a program counter value; GDB dumps the function surrounding this value. Two arguments specify a range of addresses (first inclusive, second exclusive) to dump.

The following example shows the disassembly of a range of addresses of HP PA-RISC 2.0 code:

```
(gdb) disas 0x32c4 0x32e4
Dump of assembler code from 0x32c4 to 0x32e4:
0x32c4 <main+204>:      addil 0,dp
0x32c8 <main+208>:      ldw 0x22c(sr0,r1),r26
0x32cc <main+212>:      ldil 0x3000,r31
0x32d0 <main+216>:      ble 0x3f8(sr4,r31)
0x32d4 <main+220>:      ldo 0(r31),rp
0x32d8 <main+224>:      addil -0x800,dp
0x32dc <main+228>:      ldo 0x588(r1),r26
0x32e0 <main+232>:      ldil 0x3000,r31
End of assembler dump.
```

Some architectures have more than one commonly-used set of instruction mnemonics or other syntax.

`set assembly-language instruction-set`

> Select the instruction set to use when disassembling the program via the `disassemble` or `x/i` commands. Currently this command is only defined for the Intel x86 family. You can set instruction-set to either `i386` or `i8086`. The default is `i386`.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Examining Data

The usual way to examine data in your program is with the `print` command (abbreviated `p`), or its synonym `inspect`. It evaluates and prints the value of an expression of the language your program is written in (see section Using GDB with Different Languages).

`print exp`

`print /f exp`

> exp is an expression (in the source language). By default the value of exp is printed in a format appropriate to its data type; you can choose a different format by specifying `/f', where f is a letter specifying the format; see section Output formats.

`print`

`print /f`

> If you omit exp, GDB displays the last value again (from the **value history**; see section Value history). This allows you to conveniently inspect the same value in an alternative format.

A more low-level way of examining data is with the `x` command. It examines data in memory at a specified address and prints it in a specified format. See section Examining memory.

If you are interested in information about types, or about how the fields of a struct or class are declared, use the `ptype exp` command rather than `print`. See section Examining the Symbol Table.

Expressions

`print` and many other GDB commands accept an expression and compute its value. Any kind of constant, variable or operator defined by the programming language you are using is valid in an expression in GDB. This includes conditional expressions, function calls, casts and string constants. It unfortunately does not include symbols defined by preprocessor `#define` commands.

GDB now supports array constants in expressions input by the user. The syntax is {element, element...}. For example, you can now use the command `print {1, 2, 3}` to build up an array in memory that is malloc'd in the target program.

Because C is so widespread, most of the expressions shown in examples in this manual are in C. See section Using GDB with Different Languages, for information on how to use expressions in other languages.

In this section, we discuss operators that you can use in GDB expressions regardless of your programming language.

Casts are supported in all languages, not just in C, because it is so useful to cast a number into a pointer

in order to examine a structure at that address in memory.

GDB supports these operators, in addition to those common to programming languages:

`@`

`@' is a binary operator for treating parts of memory as arrays. See section Artificial arrays, for more information.

`::`

`::' allows you to specify a variable in terms of the file or function where it is defined. See section Program variables.

`{type} addr`

Refers to an object of type type stored at address addr in memory. addr may be any expression whose value is an integer or pointer (but parentheses are required around binary operators, just as in a cast). This construct is allowed regardless of what kind of data is normally supposed to reside at addr.

Program variables

The most common kind of expression to use is the name of a variable in your program.

Variables in expressions are understood in the selected stack frame (see section Selecting a frame); they must be either:

- global (or file-static)

or

- visible according to the scope rules of the programming language from the point of execution in that frame

This means that in the function

```
foo (a)
     int a;
{
  bar (a);
  {
    int b = test ();
    bar (b);
  }
}
```

you can examine and use the variable `a` whenever your program is executing within the function `foo`, but you can only use or examine the variable `b` while your program is executing inside the block where `b` is declared.

There is an exception: you can refer to a variable or function whose scope is a single source file even if

the current execution point is not in this file. But it is possible to have more than one such variable or function with the same name (in different source files). If that happens, referring to that name has unpredictable effects. If you wish, you can specify a static variable in a particular function or file, using the colon-colon notation:

```
file::variable
function::variable
```

Here file or function is the name of the context for the static variable. In the case of file names, you can use quotes to make sure GDB parses the file name as a single word--for example, to print a global value of `x` defined in `` `f2.c' ``:

```
(gdb) p 'f2.c'::x
```

This use of `::' is very rarely in conflict with the very similar use of the same notation in C++. GDB also supports use of the C++ scope resolution operator in GDB expressions.

> *Warning:* Occasionally, a local variable may appear to have the wrong value at certain points in a function--just after entry to a new scope, and just before exit.

You may see this problem when you are stepping by machine instructions. This is because, on most machines, it takes more than one instruction to set up a stack frame (including local variable definitions); if you are stepping by machine instructions, variables may appear to have the wrong values until the stack frame is completely built. On exit, it usually also takes more than one machine instruction to destroy a stack frame; after you begin stepping through that group of instructions, local variable definitions may be gone.

This may also happen when the compiler does significant optimizations. To be sure of always seeing accurate values, turn off all optimization when compiling.

Artificial arrays

It is often useful to print out several successive objects of the same type in memory; a section of an array, or an array of dynamically determined size for which only a pointer exists in the program.

You can do this by referring to a contiguous span of memory as an **artificial array**, using the binary operator `@'. The left operand of `@' should be the first element of the desired array and be an individual object. The right operand should be the desired length of the array. The result is an array value whose elements are all of the type of the left argument. The first element is actually the left argument; the second element comes from bytes of memory immediately following those that hold the first element, and so on. Here is an example. If a program says

```
int *array = (int *) malloc (len * sizeof (int));
```

you can print the contents of `array` with

```
p *array@len
```

The left operand of `@' must reside in memory. Array values made with `@' in this way behave just like other arrays in terms of subscripting, and are coerced to pointers when used in expressions. Artificial arrays most often appear in expressions via the value history (see section Value history), after printing one out.

Another way to create an artificial array is to use a cast. This re-interprets a value as if it were an array. The value need not be in memory:

```
(gdb) p/x (short[2])0x12345678
$1 = {0x1234, 0x5678}
```

As a convenience, if you leave the array length out (as in `(type)[])value') gdb calculates the size to fill the value (as `sizeof(value)/sizeof(type)':

```
(gdb) p/x (short[])0x12345678
$2 = {0x1234, 0x5678}
```

Sometimes the artificial array mechanism is not quite enough; in moderately complex data structures, the elements of interest may not actually be adjacent--for example, if you are interested in the values of pointers in an array. One useful work-around in this situation is to use a convenience variable (see section Convenience variables) as a counter in an expression that prints the first interesting value, and then repeat that expression via RET. For instance, suppose you have an array `dtab` of pointers to structures, and you are interested in the values of a field `fv` in each structure. Here is an example of what you might type:

```
set $i = 0
p dtab[$i++]->fv
RET
RET
...
```

Output formats

By default, GDB prints a value according to its data type. Sometimes this is not what you want. For example, you might want to print a number in hex, or a pointer in decimal. Or you might want to view data in memory at a certain address as a character string or as an instruction. To do these things, specify an **output format** when you print a value.

The simplest use of output formats is to say how to print a value already computed. This is done by starting the arguments of the `print` command with a slash and a format letter. The format letters supported are:

`x`

Regard the bits of the value as an integer, and print the integer in hexadecimal.

`d`

Print as integer in signed decimal.

`u`

Print as integer in unsigned decimal.

`o`

Print as integer in octal.

`t`

Print as integer in binary. The letter `t' stands for "two". (1)

`a`

Print as an address, both absolute in hexadecimal and as an offset from the nearest preceding symbol. You can use this format used to discover where (in what function) an unknown address is located:

```
(gdb) p/a 0x54320
$3 = 0x54320 <_initialize_vx+396>
```

`c`

Regard as an integer and print it as a character constant.

`f`

Regard the bits of the value as a floating point number and print using typical floating point syntax.

For example, to print the program counter in hex (see section Registers), type

```
p/x $pc
```

Note that no space is required before the slash; this is because command names in GDB cannot contain a slash.

To reprint the last value in the value history with a different format, you can use the `print` command with just a format and no expression. For example, `p/x' reprints the last value in hex.

Examining memory

You can use the command `x` (for "examine") to examine memory in any of several formats, independently of your program's data types.

`x/nfu addr`

`x addr`

`x`

Use the `x` command to examine memory.

n, f, and u are all optional parameters that specify how much memory to display and how to format it;

addr is an expression giving the address where you want to start displaying memory. If you use defau for nfu, you need not type the slash `/'. Several commands set convenient defaults for addr.

n, the repeat count

The repeat count is a decimal integer; the default is 1. It specifies how much memory (counting by units u) to display.

f, the display format

The display format is one of the formats used by `print`, `s' (null-terminated string), or `i' (machine instruction). The default is `x' (hexadecimal) initially. The default changes each time you use either `x` or `print`.

u, the unit size

The unit size is any of

`b`

Bytes.

`h`

Halfwords (two bytes).

`w`

Words (four bytes). This is the initial default.

`g`

Giant words (eight bytes).

Each time you specify a unit size with `x`, that size becomes the default unit the next time you use `x`. (For the `s' and `i' formats, the unit size is ignored and is normally not written.)

addr, starting display address

addr is the address where you want GDB to begin displaying memory. The expression need not have a pointer value (though it may); it is always interpreted as an integer address of a byte of memory. See section Expressions, for more information on expressions. The default for addr is usually just after the last address examined--but several other commands also set the default address: `info breakpoints` (to the address of the last breakpoint listed), `info line` (to the starting address of a line), and `print` (if you use it to display a value from memory).

For example, `x/3uh 0x54320' is a request to display three halfwords (`h`) of memory, formatted as unsigned decimal integers (`u'), starting at address `0x54320`. `x/4xw $sp' prints the four words (`w') of memory above the stack pointer (here, `$sp'; see section Registers) in hexadecimal (`x').

Since the letters indicating unit sizes are all distinct from the letters specifying output formats, you do not have to remember whether unit size or format comes first; either order works. The output specifications `4xw' and `4wx' mean exactly the same thing. (However, the count n must come first; `wx4' does not work.)

Even though the unit size u is ignored for the formats `s' and `i', you might still want to use a count n; for example, `3i' specifies that you want to see three machine instructions, including any operands. The command `disassemble` gives an alternative way of inspecting machine instructions; see section Source and machine code.

All the defaults for the arguments to `x` are designed to make it easy to continue scanning memory wi minimal specifications each time you use `x`. For example, after you have inspected three machine instructions with `x/3i addr', you can inspect the next seven with just `x/7'. If you use RET to repeat the x command, the repeat count n is used again; the other arguments default as for successive uses of `x`.

The addresses and contents printed by the `x` command are not saved in the value history because there is often too much of them and they would get in the way. Instead, GDB makes these values available for subsequent use in expressions as values of the convenience variables `$_` and `$__`. After an `x` command, the last address examined is available for use in expressions in the convenience variable `$_`. The contents of that address, as examined, are available in the convenience variable `$__`.

If the `x` command has a repeat count, the address and contents saved are from the last memory unit printed; this is not the same as the last address printed if several units were printed on the last line of output.

Automatic display

If you find that you want to print the value of an expression frequently (to see how it changes), you might want to add it to the **automatic display list** so that GDB prints its value each time your program stops. Each expression added to the list is given a number to identify it; to remove an expression from the list, you specify that number. The automatic display looks like this:

```
2: foo = 38
3: bar[5] = (struct hack *) 0x3804
```

This display shows item numbers, expressions and their current values. As with displays you request manually using `x` or `print`, you can specify the output format you prefer; in fact, `display` decides whether to use `print` or `x` depending on how elaborate your format specification is--it uses `x` if you specify a unit size, or one of the two formats (`i' and `s') that are only supported by `x`; otherwise it uses `print`.

`display exp`

Add the expression exp to the list of expressions to display each time your program stops. See section Expressions. `display` does not repeat if you press RET again after using it.

`display/fmt exp`

For fmt specifying only a display format and not a size or count, add the expression exp to the auto-display list but arrange to display it each time in the specified format fmt. See section Output formats.

`display/fmt addr`

For fmt `i' or `s', or including a unit-size or a number of units, add the expression addr as a memory address to be examined each time your program stops. Examining means in effect doing `x/fmt addr'. See section Examining memory.

For example, `display/i $pc' can be helpful, to see the machine instruction about to be executed each time execution stops (`$pc' is a common name for the program counter; see section Registers).

`undisplay dnums...`
`delete display dnums...`

Remove item numbers dnums from the list of expressions to display. `undisplay` does not repeat if you press RET after using it. (Otherwise you would just get the error `No display number ...'.)

`disable display dnums...`

Disable the display of item numbers dnums. A disabled display item is not printed automatically, but is not forgotten. It may be enabled again later.

`enable display dnums...`

Enable display of item numbers dnums. It becomes effective once again in auto display of its expression, until you specify otherwise.

`display`

Display the current values of the expressions on the list, just as is done when your program stops.

`info display`

Print the list of expressions previously set up to display automatically, each one with its item number, but without showing the values. This includes disabled expressions, which are marked as such. It also includes expressions which would not be displayed right now because they refer to automatic variables not currently available.

If a display expression refers to local variables, then it does not make sense outside the lexical context for which it was set up. Such an expression is disabled when execution enters a context where one of its variables is not defined. For example, if you give the command `display last_char` while inside a function with an argument `last_char`, GDB displays this argument while your program continues to stop inside that function. When it stops elsewhere--where there is no variable `last_char`---the display is disabled automatically. The next time your program stops where `last_char` is meaningful, you can enable the display expression once again.

Print settings

GDB provides the following ways to control how arrays, structures, and symbols are printed.

These settings are useful for debugging programs in any language:

`set print address`
`set print address on`

GDB prints memory addresses showing the location of stack traces, structure values, pointer values, breakpoints, and so forth, even when it also displays the contents of those addresses. The default is `on`. For example, this is what a stack frame display looks like with `set print address on`:

```
(gdb) f
#0  set_quotes (lq=0x34c78 "<<", rq=0x34c88 ">>")
    at input.c:530
530         if (lquote != def_lquote)
```

`set print address off`

Do not print addresses when displaying their contents. For example, this is the same stack frame displayed with `set print address off`:

```
(gdb) set print addr off
(gdb) f
#0  set_quotes (lq="<<", rq=">>") at input.c:530
530         if (lquote != def_lquote)
```

You can use `set print address off' to eliminate all machine dependent displays from the GDB interface. For example, with `print address off`, you should get the same text for backtraces on all machines--whether or not they involve pointer arguments.

`show print address`

Show whether or not addresses are to be printed.

When GDB prints a symbolic address, it normally prints the closest earlier symbol plus an offset. If that symbol does not uniquely identify the address (for example, it is a name whose scope is a single source file), you may need to clarify. One way to do this is with `info line`, for example `info line *0x4537'. Alternately, you can set GDB to print the source file and line number when it prints a symbolic address:

`set print symbol-filename on`

Tell GDB to print the source file name and line number of a symbol in the symbolic form of an address.

`set print symbol-filename off`

Do not print source file name and line number of a symbol. This is the default.

`show print symbol-filename`

Show whether or not GDB will print the source file name and line number of a symbol in the symbolic form of an address.

Another situation where it is helpful to show symbol filenames and line numbers is when disassembling code; GDB shows you the line number and source file that corresponds to each instruction.

Also, you may wish to see the symbolic form only if the address being printed is reasonably close to the closest earlier symbol:

`set print max-symbolic-offset max-offset`

Tell GDB to only display the symbolic form of an address if the offset between the closest earlier symbol and the address is less than max-offset. The default is 0, which tells GDB to always print the symbolic form of an address if any symbol precedes it.

`show print max-symbolic-offset`

Ask how large the maximum offset is that GDB prints in a symbolic address.

If you have a pointer and you are not sure where it points, try `set print symbol-filename on'. Then you can determine the name and source file location of the variable where it points, using `p/a pointer'. This interprets the address in symbolic form. For example, here GDB shows that a variable `ptt` points at another variable `t`, defined in `hi2.c':

```
(gdb) set print symbol-filename on
(gdb) p/a ptt
$4 = 0xe008 <t in hi2.c>
```

Warning: For pointers that point to a local variable, `p/a' does not show the symbol name and filename of the referent, even with the appropriate `set print` options turned on.

Other settings control how different kinds of objects are printed:

`set print array`

`set print array on`

Pretty print arrays. This format is more convenient to read, but uses more space. The default is off.

`set print array off`

Return to compressed format for arrays.

`show print array`

Show whether compressed or pretty format is selected for displaying arrays.

`set print elements number-of-elements`

Set a limit on how many elements of an array GDB will print. If GDB is printing a large array, it stops printing after it has printed the number of elements set by the `set print elements` command. This limit also applies to the display of strings. Setting number-of-elements to zero means that the printing is unlimited.

`show print elements`

Display the number of elements of a large array that GDB will print. If the number is 0, then the printing is unlimited.

`set print null-stop`

Cause GDB to stop printing the characters of an array when the first NULL is encountered. This is useful when large arrays actually contain only short strings.

`set print pretty on`

Cause GDB to print structures in an indented format with one member per line, like this:

```
$1 = {
  next = 0x0,
  flags = {
    sweet = 1,
    sour = 1
  },
  meat = 0x54 "Pork"
}
```

`set print pretty off`

Cause GDB to print structures in a compact format, like this:

```
$1 = {next = 0x0, flags = {sweet = 1, sour = 1}, \
meat = 0x54 "Pork"}
```

This is the default format.

`show print pretty`

Show which format GDB is using to print structures.

`set print sevenbit-strings on`

Print using only seven-bit characters; if this option is set, GDB displays any eight-bit characters (in strings or character values) using the notation \nnn. This setting is best if you are working in English (ASCII) and you use the high-order bit of characters as a marker or "meta" bit.

`set print sevenbit-strings off`

Print full eight-bit characters. This allows the use of more international character sets, and is the default.

`show print sevenbit-strings`

Show whether or not GDB is printing only seven-bit characters.

`set print union on`

Tell GDB to print unions which are contained in structures. This is the default setting.

`set print union off`

Tell GDB not to print unions which are contained in structures.

`show print union`

Ask GDB whether or not it will print unions which are contained in structures. For example, given the declarations

```
typedef enum {Tree, Bug} Species;
typedef enum {Big_tree, Acorn, Seedling} Tree_forms;
typedef enum {Caterpillar, Cocoon, Butterfly}
              Bug_forms;

struct thing {
  Species it;
  union {
    Tree_forms tree;
    Bug_forms bug;
  } form;
};

struct thing foo = {Tree, {Acorn}};
```

with `set print union on` in effect `p foo' would print

```
$1 = {it = Tree, form = {tree = Acorn, bug = Cocoon}}
```

and with `set print union off` in effect it would print

```
$1 = {it = Tree, form = {...}}
```

These settings are of interest when debugging C++ programs:

`set print demangle`

`set print demangle on`

Print C++ names in their source form rather than in the encoded ("mangled") form passed to the assembler and linker for type-safe linkage. The default is `on'.

`show print demangle`

Show whether C++ names are printed in mangled or demangled form.

`set print asm-demangle`

`set print asm-demangle on`

Print C++ names in their source form rather than their mangled form, even in assembler code printouts such as instruction disassemblies. The default is off.

`show print asm-demangle`

Show whether C++ names in assembly listings are printed in mangled or demangled form.

`set demangle-style style`

Choose among several encoding schemes used by different compilers to represent C++ names. The choices for style are currently:

`auto`

Allow GDB to choose a decoding style by inspecting your program.

`gnu`

Decode based on the GNU C++ compiler (`g++`) encoding algorithm. This is the default.

`hp`

Decode based on the HP ANSI C++ (`aCC`) encoding algorithm.

`lucid`

Decode based on the Lucid C++ compiler (`lcc`) encoding algorithm.

`arm`

Decode using the algorithm in the C++ Annotated Reference Manual. **Warning:** this setting alone is not sufficient to allow debugging `cfront`-generated executables. GDB would require further enhancement to permit that.

If you omit style, you will see a list of possible formats.

`show demangle-style`

Display the encoding style currently in use for decoding C++ symbols.

`set print object`

`set print object on`

When displaying a pointer to an object, identify the *actual* (derived) type of the object rather than the *declared* type, using the virtual function table.

`set print object off`

Display only the declared type of objects, without reference to the virtual function table. This is the default setting.

`show print object`

Show whether actual, or declared, object types are displayed.

`set print static-members`

`set print static-members on`

Print static members when displaying a C++ object. The default is on.

`set print static-members off`

Do not print static members when displaying a C++ object.

`show print static-members`

Show whether C++ static members are printed, or not.

`set print vtbl`

`set print vtbl on`

Pretty print C++ virtual function tables. The default is off.

`set print vtbl off`

Do not pretty print C++ virtual function tables.

`show print vtbl`

Show whether C++ virtual function tables are pretty printed, or not.

Value history

Values printed by the `print` command are saved in the GDB **value history**. This allows you to refer to them in other expressions. Values are kept until the symbol table is re-read or discarded (for example with the `file` or `symbol-file` commands). When the symbol table changes, the value history is discarded, since the values may contain pointers back to the types defined in the symbol table.

The values printed are given **history numbers** by which you can refer to them. These are successive integers starting with one. `print` shows you the history number assigned to a value by printing `$num = ' before the value; here num is the history number.

To refer to any previous value, use `$' followed by the value's history number. The way `print` labels its output is designed to remind you of this. Just `$` refers to the most recent value in the history, and `$$` refers to the value before that. `$$n` refers to the nth value from the end; `$$2` is the value just prior to `$$`, `$$1` is equivalent to `$$`, and `$$0` is equivalent to `$`.

For example, suppose you have just printed a pointer to a structure and want to see the contents of the structure. It suffices to type

```
p *$
```

If you have a chain of structures where the component `next` points to the next one, you can print the contents of the next one with this:

```
p *$.next
```

You can print successive links in the chain by repeating this command--which you can do by just typing RET.

Note that the history records values, not expressions. If the value of `x` is 4 and you type these commands:

```
print x
set x=5
```

then the value recorded in the value history by the `print` command remains 4 even though the value of `x` has changed.

`show values`

Print the last ten values in the value history, with their item numbers. This is like `p $$9' repeated ten times, except that `show values` does not change the history.

`show values n`

Print ten history values centered on history item number n.

`show values +`

Print ten history values just after the values last printed. If no more values are available, `show values +` produces no display.

Pressing RET to repeat `show values n` has exactly the same effect as `show values +'.

Convenience variables

GDB provides **convenience variables** that you can use within GDB to hold on to a value and refer to it later. These variables exist entirely within GDB; they are not part of your program, and setting a convenience variable has no direct effect on further execution of your program. That is why you can use them freely.

Convenience variables are prefixed with `$'. Any name preceded by `$' can be used for a convenience variable, unless it is one of the predefined machine-specific register names (see section Registers). (Value history references, in contrast, are *numbers* preceded by `$'. See section Value history.)

You can save a value in a convenience variable with an assignment expression, just as you would set a variable in your program. For example:

```
set $foo = *object_ptr
```

would save in `$foo` the value contained in the object pointed to by `object_ptr`.

Using a convenience variable for the first time creates it, but its value is `void` until you assign a new value. You can alter the value with another assignment at any time.

Convenience variables have no fixed types. You can assign a convenience variable any type of value,

including structures and arrays, even if that variable already has a value of a different type. The convenience variable, when used as an expression, has the type of its current value.

`show convenience`

Print a list of convenience variables used so far, and their values. Abbreviated `show con`.

One of the ways to use a convenience variable is as a counter to be incremented or a pointer to be advanced. For example, to print a field from successive elements of an array of structures:

```
set $i = 0
print bar[$i++]->contents
```

Repeat that command by typing RET.

Some convenience variables are created automatically by GDB and given values likely to be useful.

`$_`

The variable `$_` is automatically set by the `x` command to the last address examined (see section Examining memory). Other commands which provide a default address for `x` to examine also set `$_` to that address; these commands include `info line` and `info breakpoint`. The type of `$_` is `void *` except when set by the `x` command, in which case it is a pointer to the type of `$__`.

`$__`

The variable `$__` is automatically set by the `x` command to the value found in the last address examined. Its type is chosen to match the format in which the data was printed.

`$_exitcode`

The variable `$_exitcode` is automatically set to the exit code when the program being debugged terminates.

Registers

You can refer to machine register contents, in expressions, as variables with names starting with `$'. The names of registers are different for each machine; use `info registers` to see the names used on your machine.

`info registers`

Print the names and values of all registers except floating-point registers (in the selected stack frame).

`info all-registers`

Print the names and values of all registers, including floating-point registers.

`info registers regname ...`

Print the **relativized** value of each specified register regname. As discussed in detail below, register values are normally relative to the selected stack frame. regname may be any register name valid on the machine you are using, with or without the initial `$'.

GDB has four "standard" register names that are available (in expressions) on most machines--whenever

they do not conflict with an architecture's canonical mnemonics for registers. The register names `$pc` and `$sp` are used for the program counter register and the stack pointer. `$fp` is used for a register that contains a pointer to the current stack frame, and `$ps` is used for a register that contains the processor status. For example, you could print the program counter in hex with

```
p/x $pc
```

or print the instruction to be executed next with

```
x/i $pc
```

or add four to the stack pointer(2) with

```
set $sp += 4
```

Whenever possible, these four standard register names are available on your machine even though the machine has different canonical mnemonics, so long as there is no conflict. The `info registers` command shows the canonical names. For example, on the SPARC, `info registers` displays the processor status register as `$psr` but you can also refer to it as `$ps`.

GDB always considers the contents of an ordinary register as an integer when the register is examined in this way. Some machines have special registers which can hold nothing but floating point; these registers are considered to have floating point values. There is no way to refer to the contents of an ordinary register as floating point value (although you can *print* it as a floating point value with `print/f $regname').

Some registers have distinct "raw" and "virtual" data formats. This means that the data format in which the register contents are saved by the operating system is not the same one that your program normally sees. For example, the registers of the 68881 floating point coprocessor are always saved in "extended" (raw) format, but all C programs expect to work with "double" (virtual) format. In such cases, GDB normally works with the virtual format only (the format that makes sense for your program), but the `info registers` command prints the data in both formats.

Normally, register values are relative to the selected stack frame (see section Selecting a frame). This means that you get the value that the register would contain if all stack frames farther in were exited and their saved registers restored. In order to see the true contents of hardware registers, you must select the innermost frame (with `frame 0').

However, GDB must deduce where registers are saved, from the machine code generated by your compiler. If some registers are not saved, or if GDB is unable to locate the saved registers, the selected stack frame makes no difference.

`set rstack_high_address address`

> On AMD 29000 family processors, registers are saved in a separate "register stack". There is no way for GDB to determine the extent of this stack. Normally, GDB just assumes that the stack is "large enough". This may result in GDB referencing memory locations that do not exist. If necessary, you can get around this problem by specifying the ending address of the register stack with the `set rstack_high_address` command. The argument should be an address, which

TOC

you probably want to precede with `0x' to specify in hexadecimal.

`show rstack_high_address`

Display the current limit of the register stack, on AMD 29000 family processors.

Floating point hardware

Depending on the configuration, GDB may be able to give you more information about the status of the floating point hardware.

`info float`

Display hardware-dependent information about the floating point unit. The exact contents and layout vary depending on the floating point chip. Currently, `info float' is supported on the ARM and x86 machines.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Using GDB with Different Languages

Although programming languages generally have common aspects, they are rarely expressed in the same manner. For instance, in ANSI C, dereferencing a pointer `p` is accomplished by `*p`, but in Modula-2, it is accomplished by `p^`. Values can also be represented (and displayed) differently. Hex numbers in C appear as `0x1ae', while in Modula-2 they appear as `1AEH'.

Language-specific information is built into GDB for some languages, allowing you to express operations like the above in your program's native language, and allowing GDB to output values in a manner consistent with the syntax of your program's native language. The language you use to build expressions is called the **working language**.

Switching between source languages

There are two ways to control the working language--either have GDB set it automatically, or select it manually yourself. You can use the `set language` command for either purpose. On startup, GDB defaults to setting the language automatically. The working language is used to determine how expressions you type are interpreted, how values are printed, etc.

In addition to the working language, every source file that GDB knows about has its own working language. For some object file formats, the compiler might indicate which language a particular source file is in. However, most of the time GDB infers the language from the name of the file. The language of a source file controls whether C++ names are demangled--this way `backtrace` can show each frame appropriately for its own language. There is no way to set the language of a source file from within GDB.

This is most commonly a problem when you use a program, such as `cfront` or `f2c`, that generates C but is written in another language. In that case, make the program use `#line` directives in its C output; that way GDB will know the correct language of the source code of the original program, and will display that source code, not the generated C code.

List of filename extensions and languages

If a source file name ends in one of the following extensions, then GDB infers that its language is the one indicated.

`.c'`
: C source file

`.C'`

`.cc'`

`.cp'`

`.cpp'
`.cxx'
`.c++'
: C++ source file

`.f'
`.F'
: Fortran source file

`.ch'
`.c186'
`.c286'
: CHILL source file.

`.mod'
: Modula-2 source file

`.s'
`.S'
: Assembler source file. This actually behaves almost like C, but GDB does not skip over function prologues when stepping.

In addition, you may set the language associated with a filename extension. See section Displaying the language.

Setting the working language

If you allow GDB to set the language automatically, expressions are interpreted the same way in your debugging session and your program.

If you wish, you may set the language manually. To do this, issue the command `set language lang', where lang is the name of a language, such as `c` or `modula-2`. For a list of the supported languages, type `set language'.

Setting the language manually prevents GDB from updating the working language automatically. This can lead to confusion if you try to debug a program when the working language is not the same as the source language, when an expression is acceptable to both languages--but means different things. For instance, if the current source file were written in C, and GDB was parsing Modula-2, a command such as:

```
print a = b + c
```

might not have the effect you intended. In C, this means to add `b` and `c` and place the result in `a`. The result printed would be the value of `a`. In Modula-2, this means to compare `a` to the result of `b+c`, yielding a `BOOLEAN` value.

Having GDB infer the source language

To have GDB set the working language automatically, use `set language local' or `set language auto'. GDB then infers the working language. That is, when your program stops in a frame (usually by encountering a breakpoint), GDB sets the working language to the language recorded for the function in that frame. If the language for a frame is unknown (that is, if the function or block corresponding to the frame was defined in a source file that does not have a recognized extension), the current working language is not changed, and GDB issues a warning.

This may not seem necessary for most programs, which are written entirely in one source language. However, program modules and libraries written in one source language can be used by a main program written in a different source language. Using `set language auto' in this case frees you from having to set the working language manually.

Displaying the language

The following commands help you find out which language is the working language, and also what language source files were written in.

`show language`

Display the current working language. This is the language you can use with commands such as `print` to build and compute expressions that may involve variables in your program.

`info frame`

Display the source language for this frame. This language becomes the working language if you use an identifier from this frame. See section Information about a frame, to identify the other information listed here.

`info source`

Display the source language of this source file. See section Examining the Symbol Table, to identify the other information listed here.

In unusual circumstances, you may have source files with extensions not in the standard list. You can then set the extension associated with a language explicitly:

`set extension-language .ext language`

Set source files with extension .ext to be assumed to be in the source language language.

`info extensions`

List all the filename extensions and the associated languages.

Type and range checking

Warning: In this release, the GDB commands for type and range checking are included, but they do not yet have any effect. This section documents the intended facilities.

Some languages are designed to guard you against making seemingly common errors through a series of

compile- and run-time checks. These include checking the type of arguments to functions and operat and making sure mathematical overflows are caught at run time. Checks such as these help to ensure program's correctness once it has been compiled by eliminating type mismatches, and providing active checks for range errors when your program is running.

GDB can check for conditions like the above if you wish. Although GDB does not check the statements in your program, it can check expressions entered directly into GDB for evaluation via the `print` command, for example. As with the working language, GDB can also decide whether or not to check automatically based on your program's source language. See section Supported languages, for the default settings of supported languages.

An overview of type checking

Some languages, such as Modula-2, are strongly typed, meaning that the arguments to operators and functions have to be of the correct type, otherwise an error occurs. These checks prevent type mismatch errors from ever causing any run-time problems. For example,

```
1 + 2 => 3
but
error--> 1 + 2.3
```

The second example fails because the `CARDINAL` 1 is not type-compatible with the `REAL` 2.3.

For the expressions you use in GDB commands, you can tell the GDB type checker to skip checking; to treat any mismatches as errors and abandon the expression; or to only issue warnings when type mismatches occur, but evaluate the expression anyway. When you choose the last of these, GDB evaluates expressions like the second example above, but also issues a warning.

Even if you turn type checking off, there may be other reasons related to type that prevent GDB from evaluating an expression. For instance, GDB does not know how to add an `int` and a `struct foo`. These particular type errors have nothing to do with the language in use, and usually arise from expressions, such as the one described above, which make little sense to evaluate anyway.

Each language defines to what degree it is strict about type. For instance, both Modula-2 and C require the arguments to arithmetical operators to be numbers. In C, enumerated types and pointers can be represented as numbers, so that they are valid arguments to mathematical operators. See section Supported languages, for further details on specific languages.

GDB provides some additional commands for controlling the type checker:

`set check type auto`

Set type checking on or off based on the current working language. See section Supported languages, for the default settings for each language.

`set check type on`

`set check type off`

Set type checking on or off, overriding the default setting for the current working language. Issue a warning if the setting does not match the language default. If any type mismatches occur in

evaluating an expression while typechecking is on, GDB prints a message and aborts evaluatic the expression.

`set check type warn`

Cause the type checker to issue warnings, but to always attempt to evaluate the expression. Evaluating the expression may still be impossible for other reasons. For example, GDB cannot add numbers and structures.

`show type`

Show the current setting of the type checker, and whether or not GDB is setting it automatically.

An overview of range checking

In some languages (such as Modula-2), it is an error to exceed the bounds of a type; this is enforced with run-time checks. Such range checking is meant to ensure program correctness by making sure computations do not overflow, or indices on an array element access do not exceed the bounds of the array.

For expressions you use in GDB commands, you can tell GDB to treat range errors in one of three ways: ignore them, always treat them as errors and abandon the expression, or issue warnings but evaluate the expression anyway.

A range error can result from numerical overflow, from exceeding an array index bound, or when you type a constant that is not a member of any type. Some languages, however, do not treat overflows as an error. In many implementations of C, mathematical overflow causes the result to "wrap around" to lower values--for example, if m is the largest integer value, and s is the smallest, then

```
m + 1 => s
```

This, too, is specific to individual languages, and in some cases specific to individual compilers or machines. See section Supported languages, for further details on specific languages.

GDB provides some additional commands for controlling the range checker:

`set check range auto`

Set range checking on or off based on the current working language. See section Supported languages, for the default settings for each language.

`set check range on`

`set check range off`

Set range checking on or off, overriding the default setting for the current working language. A warning is issued if the setting does not match the language default. If a range error occurs, then a message is printed and evaluation of the expression is aborted.

`set check range warn`

Output messages when the GDB range checker detects a range error, but attempt to evaluate the expression anyway. Evaluating the expression may still be impossible for other reasons, such as accessing memory that the process does not own (a typical example from many Unix systems).

`show range`

Show the current setting of the range checker, and whether or not it is being set automatically by GDB.

Supported languages

GDB supports C, C++, Fortran, Chill, assembly, and Modula-2. Some GDB features may be used in expressions regardless of the language you use: the GDB `@` and `::` operators, and the `{type}addr' construct (see section Expressions) can be used with the constructs of any supported language.

The following sections detail to what degree each source language is supported by GDB. These sections are not meant to be language tutorials or references, but serve only as a reference guide to what the GDB expression parser accepts, and what input and output formats should look like for different languages. There are many good books written on each of these languages; please look to these for a language reference or tutorial.

C and C++

Since C and C++ are so closely related, many features of GDB apply to both languages. Whenever this is the case, we discuss those languages together.

The C++ debugging facilities are jointly implemented by the C++ compiler and GDB. Therefore, to debug your C++ code effectively, you must compile your C++ programs with a supported C++ compiler, such as GNU `g++`, or the HP ANSI C++ compiler (`aCC`).

For best results when using GNU C++, use the stabs debugging format. You can select that format explicitly with the `g++` command-line options `-gstabs' or `-gstabs+'. See section `Options for Debugging Your Program or GNU CC' in Using GNU CC, for more information.

C and C++ operators

Operators must be defined on values of specific types. For instance, `+` is defined on numbers, but not on structures. Operators are often defined on groups of types.

For the purposes of C and C++, the following definitions hold:

- *Integral types* include `int` with any of its storage-class specifiers; `char`; and `enum`.
- *Floating-point types* include `float` and `double`.
- *Pointer types* include all types defined as `(type *)`.
- *Scalar types* include all of the above.

The following operators are supported. They are listed here in order of increasing precedence:

`,`

The comma or sequencing operator. Expressions in a comma-separated list are evaluated from left to right, with the result of the entire expression being the last expression evaluated.

`=`

Assignment. The value of an assignment expression is the value assigned. Defined on scalar types.

`op=`

Used in an expression of the form `a op= b`, and translated to `a = a op b`. `op=` and `=` have the same precendence. op is any one of the operators `|`, `^`, `&`, `<<`, `>>`, `+`, `-`, `*`, `/`, `%`.

`?:`

The ternary operator. `a ? b : c` can be thought of as: if a then b else c. a should be of an integral type.

`||`

Logical OR. Defined on integral types.

`&&`

Logical AND. Defined on integral types.

`|`

Bitwise OR. Defined on integral types.

`^`

Bitwise exclusive-OR. Defined on integral types.

`&`

Bitwise AND. Defined on integral types.

`==, !=`

Equality and inequality. Defined on scalar types. The value of these expressions is 0 for false and non-zero for true.

`<, >, <=, >=`

Less than, greater than, less than or equal, greater than or equal. Defined on scalar types. The value of these expressions is 0 for false and non-zero for true.

`<<, >>`

left shift, and right shift. Defined on integral types.

`@`

The GDB "artificial array" operator (see section Expressions).

`+, -`

Addition and subtraction. Defined on integral types, floating-point types and pointer types.

`*, /, %`

Multiplication, division, and modulus. Multiplication and division are defined on integral and floating-point types. Modulus is defined on integral types.

`++, --`

Increment and decrement. When appearing before a variable, the operation is performed before the variable is used in an expression; when appearing after it, the variable's value is used before the operation takes place.

`*`

Pointer dereferencing. Defined on pointer types. Same precedence as `++`.

`&`

Address operator. Defined on variables. Same precedence as `++`. For debugging C++, GDB implements a use of `&' beyond what is allowed in the C++ language itself: you can use `&(&ref)' (or, if you prefer, simply `&&ref') to examine the address where a C++ reference variable (declared with `&ref') is stored.

`-`

Negative. Defined on integral and floating-point types. Same precedence as `++`.

`!`

Logical negation. Defined on integral types. Same precedence as `++`.

`~`

Bitwise complement operator. Defined on integral types. Same precedence as `++`.

`., ->`

Structure member, and pointer-to-structure member. For convenience, GDB regards the two as equivalent, choosing whether to dereference a pointer based on the stored type information. Defined on `struct` and `union` data.

`[]`

Array indexing. `a[i]` is defined as `*(a+i)`. Same precedence as `->`.

`()`

Function parameter list. Same precedence as `->`.

`::`

C++ scope resolution operator. Defined on `struct`, `union`, and `class` types.

`::`

Doubled colons also represent the GDB scope operator (see section Expressions). Same precedence as `::`, above.

C and C++ constants

GDB allows you to express the constants of C and C++ in the following ways:

- Integer constants are a sequence of digits. Octal constants are specified by a leading `0' (i.e. zero), and hexadecimal constants by a leading `0x' or `0X'. Constants may also end with a letter `l', specifying that the constant should be treated as a `long` value.
- Floating point constants are a sequence of digits, followed by a decimal point, followed by a sequence of digits, and optionally followed by an exponent. An exponent is of the form: `e[[+]|-]nnn', where nnn is another sequence of digits. The `+' is optional for positive exponents.
- Enumerated constants consist of enumerated identifiers, or their integral equivalents.
- Character constants are a single character surrounded by single quotes (`'`), or a number--the ordinal value of the corresponding character (usually its ASCII value). Within quotes, the single character may be represented by a letter or by **escape sequences**, which are of the form `\nnn', where nnn is the octal representation of the character's ordinal value; or of the form `\x', where `x'

is a predefined special character--for example, `\n' for newline.

- String constants are a sequence of character constants surrounded by double quotes (").
- Pointer constants are an integral value. You can also write pointers to constants using the C operator `&'.
- Array constants are comma-separated lists surrounded by braces `{' and `}'; for example, `{1,2,3}' is a three-element array of integers, `{{1,2}, {3,4}, {5,6}}' is a three-by-two array, and `{&"hi", &"there", &"fred"}' is a three-element array of pointers.

C++ expressions

GDB expression handling can interpret most C++ expressions.

Warning: GDB can only debug C++ code if you use the proper compiler. Typically, C++ debugging depends on the use of additional debugging information in the symbol table, and thus requires special support. In particular, if your compiler generates a.out, MIPS ECOFF, RS/6000 XCOFF, or ELF with stabs extensions to the symbol table, these facilities are all available. (With GNU CC, you can use the `-gstabs' option to request stabs debugging extensions explicitly.) Where the object code format is standard COFF or DWARF in ELF, on the other hand, most of the C++ support in GDB does *not* work.

1. Member function calls are allowed; you can use expressions like

   ```
   count = aml->GetOriginal(x, y)
   ```

2. While a member function is active (in the selected stack frame), your expressions have the same namespace available as the member function; that is, GDB allows implicit references to the class instance pointer `this` following the same rules as C++.
3. You can call overloaded functions; GDB resolves the function call to the right definition, with one restriction--you must use arguments of the type required by the function that you want to call. GDB does not perform conversions requiring constructors or user-defined type operators.
4. GDB understands variables declared as C++ references; you can use them in expressions just as you do in C++ source--they are automatically dereferenced. In the parameter list shown when GDB displays a frame, the values of reference variables are not displayed (unlike other variables); this avoids clutter, since references are often used for large structures. The *address* of a reference variable is always shown, unless you have specified `set print address off'.
5. GDB supports the C++ name resolution operator `::`---your expressions can use it just as expressions in your program do. Since one scope may be defined in another, you can use `::` repeatedly if necessary, for example in an expression like `scope1::scope2::name'. GDB also allows resolving name scope by reference to source files, in both C and C++ debugging (see section Program variables).

C and C++ defaults

If you allow GDB to set type and range checking automatically, they both default to `off` whenever the working language changes to C or C++. This happens regardless of whether you or GDB selects the working language.

If you allow GDB to set the language automatically, it recognizes source files whose names end with `.c', `.C', or `.cc', etc, and when GDB enters code compiled from one of these files, it sets the working language to C or C++. See section Having GDB infer the source language, for further details.

C and C++ type and range checks

By default, when GDB parses C or C++ expressions, type checking is not used. However, if you turn type checking on, GDB considers two variables type equivalent if:

- The two variables are structured and have the same structure, union, or enumerated tag.
- The two variables have the same type name, or types that have been declared equivalent through `typedef`.

Range checking, if turned on, is done on mathematical operations. Array indices are not checked, since they are often used to index a pointer that is not itself an array.

GDB and C

The `set print union` and `show print union` commands apply to the `union` type. When set to `on', any `union` that is inside a `struct` or `class` is also printed. Otherwise, it appears as `{...}'.

The @ operator aids in the debugging of dynamic arrays, formed with pointers and a memory allocation function. See section Expressions.

GDB features for C++

Some GDB commands are particularly useful with C++, and some are designed specifically for use with C++. Here is a summary:

`breakpoint menus`

When you want a breakpoint in a function whose name is overloaded, GDB breakpoint menus help you specify which function definition you want. See section Breakpoint menus.

`rbreak regex`

Setting breakpoints using regular expressions is helpful for setting breakpoints on overloaded functions that are not members of any special classes. See section Setting breakpoints.

`catch throw`

`catch catch`

Debug C++ exception handling using these commands. See section Setting catchpoints.

`ptype typename`

Print inheritance relationships as well as other information for type typename. See section Examining the Symbol Table.

`set print demangle`

`show print demangle`

`set print asm-demangle`

`show print asm-demangle`

Control whether C++ symbols display in their source form, both when displaying code as C++ source and when displaying disassemblies. See section Print settings.

`set print object`

`show print object`

Choose whether to print derived (actual) or declared types of objects. See section Print settings.

`set print vtbl`

`show print vtbl`

Control the format for printing virtual function tables. See section Print settings.

`Overloaded symbol names`

You can specify a particular definition of an overloaded symbol, using the same notation that is used to declare such symbols in C++: type `symbol(types)` rather than just symbol. You can also use the GDB command-line word completion facilities to list the available choices, or to finish the type list for you. See section Command completion, for details on how to do this.

Modula-2

The extensions made to GDB to support Modula-2 only support output from the GNU Modula-2 compiler (which is currently being developed). Other Modula-2 compilers are not currently supported, and attempting to debug executables produced by them is most likely to give an error as GDB reads in the executable's symbol table.

Operators

Operators must be defined on values of specific types. For instance, `+` is defined on numbers, but not on structures. Operators are often defined on groups of types. For the purposes of Modula-2, the following definitions hold:

- *Integral types* consist of `INTEGER`, `CARDINAL`, and their subranges.
- *Character types* consist of `CHAR` and its subranges.
- *Floating-point types* consist of `REAL`.
- *Pointer types* consist of anything declared as `POINTER TO type`.
- *Scalar types* consist of all of the above.
- *Set types* consist of `SET` and `BITSET` types.
- *Boolean types* consist of `BOOLEAN`.

The following operators are supported, and appear in order of increasing precedence:

`,`

Function argument or array index separator.

`:=`

Assignment. The value of var `:=` value is value.

`<, >`

Less than, greater than on integral, floating-point, or enumerated types.

`<=, >=`

Less than, greater than, less than or equal to, greater than or equal to on integral, floating-point and enumerated types, or set inclusion on set types. Same precedence as `<`.

`=, <>, #`

Equality and two ways of expressing inequality, valid on scalar types. Same precedence as `<`. In GDB scripts, only `<>` is available for inequality, since # conflicts with the script comment character.

`IN`

Set membership. Defined on set types and the types of their members. Same precedence as `<`.

`OR`

Boolean disjunction. Defined on boolean types.

`AND, &`

Boolean conjuction. Defined on boolean types.

`@`

The GDB "artificial array" operator (see section Expressions).

`+, -`

Addition and subtraction on integral and floating-point types, or union and difference on set types.

`*`

Multiplication on integral and floating-point types, or set intersection on set types.

`/`

Division on floating-point types, or symmetric set difference on set types. Same precedence as `*`.

`DIV, MOD`

Integer division and remainder. Defined on integral types. Same precedence as `*`.

`-`

Negative. Defined on `INTEGER` and `REAL` data.

`^`

Pointer dereferencing. Defined on pointer types.

`NOT`

Boolean negation. Defined on boolean types. Same precedence as `^`.

`.`

`RECORD` field selector. Defined on `RECORD` data. Same precedence as `^`.

`[]`

Array indexing. Defined on `ARRAY` data. Same precedence as `^`.

`()`

Procedure argument list. Defined on `PROCEDURE` objects. Same precedence as `^`.

`::, .`

GDB and Modula-2 scope operators.

Warning: Sets and their operations are not yet supported, so GDB treats the use of the operator `IN`, or the use of operators `+`, `-`, `*`, `/`, `=`, , `<>`, #, `<=`, and `>=` on sets as an error.

Built-in functions and procedures

Modula-2 also makes available several built-in procedures and functions. In describing these, the following metavariables are used:

a

represents an `ARRAY` variable.

c

represents a `CHAR` constant or variable.

i

represents a variable or constant of integral type.

m

represents an identifier that belongs to a set. Generally used in the same function with the metavariable s. The type of s should be `SET OF mtype` (where mtype is the type of m).

n

represents a variable or constant of integral or floating-point type.

r

represents a variable or constant of floating-point type.

t

represents a type.

v

represents a variable.

x

represents a variable or constant of one of many types. See the explanation of the function for details.

All Modula-2 built-in procedures also return a result, described below.

`ABS(n)`

Returns the absolute value of n.

`CAP(c)`

If c is a lower case letter, it returns its upper case equivalent, otherwise it returns its argument

`CHR(i)`

Returns the character whose ordinal value is i.

`DEC(v)`

Decrements the value in the variable v. Returns the new value.

`DEC(v,i)`
: Decrements the value in the variable v by i. Returns the new value.

`EXCL(m,s)`
: Removes the element m from the set s. Returns the new set.

`FLOAT(i)`
: Returns the floating point equivalent of the integer i.

`HIGH(a)`
: Returns the index of the last member of a.

`INC(v)`
: Increments the value in the variable v. Returns the new value.

`INC(v,i)`
: Increments the value in the variable v by i. Returns the new value.

`INCL(m,s)`
: Adds the element m to the set s if it is not already there. Returns the new set.

`MAX(t)`
: Returns the maximum value of the type t.

`MIN(t)`
: Returns the minimum value of the type t.

`ODD(i)`
: Returns boolean TRUE if i is an odd number.

`ORD(x)`
: Returns the ordinal value of its argument. For example, the ordinal value of a character is its ASCII value (on machines supporting the ASCII character set). x must be of an ordered type, which include integral, character and enumerated types.

`SIZE(x)`
: Returns the size of its argument. x can be a variable or a type.

`TRUNC(r)`
: Returns the integral part of r.

`VAL(t,i)`
: Returns the member of the type t whose ordinal value is i.

Warning: Sets and their operations are not yet supported, so GDB treats the use of procedures `INCL` and `EXCL` as an error.

Constants

GDB allows you to express the constants of Modula-2 in the following ways:

- Integer constants are simply a sequence of digits. When used in an expression, a constant is interpreted to be type-compatible with the rest of the expression. Hexadecimal integers are

specified by a trailing `H', and octal integers by a trailing `B'.

- Floating point constants appear as a sequence of digits, followed by a decimal point and another sequence of digits. An optional exponent can then be specified, in the form `E[+|-]nnn', where `[+|-]nnn' is the desired exponent. All of the digits of the floating point constant must be valid decimal (base 10) digits.
- Character constants consist of a single character enclosed by a pair of like quotes, either single (') or double ("). They may also be expressed by their ordinal value (their ASCII value, usually) followed by a `C'.
- String constants consist of a sequence of characters enclosed by a pair of like quotes, either single (') or double ("). Escape sequences in the style of C are also allowed. See section C and C++ constants, for a brief explanation of escape sequences.
- Enumerated constants consist of an enumerated identifier.
- Boolean constants consist of the identifiers TRUE and FALSE.
- Pointer constants consist of integral values only.
- Set constants are not yet supported.

Modula-2 defaults

If type and range checking are set automatically by GDB, they both default to `on` whenever the working language changes to Modula-2. This happens regardless of whether you, or GDB, selected the working language.

If you allow GDB to set the language automatically, then entering code compiled from a file whose name ends with `` `.mod' `` sets the working language to Modula-2. See section Having GDB infer the source language, for further details.

Deviations from standard Modula-2

A few changes have been made to make Modula-2 programs easier to debug. This is done primarily via loosening its type strictness:

- Unlike in standard Modula-2, pointer constants can be formed by integers. This allows you to modify pointer variables during debugging. (In standard Modula-2, the actual address contained in a pointer variable is hidden from you; it can only be modified through direct assignment to another pointer variable or expression that returned a pointer.)
- C escape sequences can be used in strings and characters to represent non-printable characters. GDB prints out strings with these escape sequences embedded. Single non-printable characters are printed using the `CHR(nnn)' format.
- The assignment operator (`:=`) returns the value of its right-hand argument.
- All built-in procedures both modify *and* return their argument.

Modula-2 type and range checks

Warning: in this release, GDB does not yet perform type or range checking.

GDB considers two Modula-2 variables type equivalent if:

- They are of types that have been declared equivalent via a `TYPE t1 = t2` statement
- They have been declared on the same line. (Note: This is true of the GNU Modula-2 compiler, but it may not be true of other compilers.)

As long as type checking is enabled, any attempt to combine variables whose types are not equivalent is an error.

Range checking is done on all mathematical operations, assignment, array index bounds, and all built-in functions and procedures.

The scope operators `::` and `.`

There are a few subtle differences between the Modula-2 scope operator (`.`) and the GDB scope operator (`::`). The two have similar syntax:

```
module . id
scope :: id
```

where scope is the name of a module or a procedure, module the name of a module, and id is any declared identifier within your program, except another module.

Using the `::` operator makes GDB search the scope specified by scope for the identifier id. If it is not found in the specified scope, then GDB searches all scopes enclosing the one specified by scope.

Using the `.` operator makes GDB search the current scope for the identifier specified by id that was imported from the definition module specified by module. With this operator, it is an error if the identifier id was not imported from definition module module, or if id is not an identifier in module.

GDB and Modula-2

Some GDB commands have little use when debugging Modula-2 programs. Five subcommands of `set print` and `show print` apply specifically to C and C++: `vtbl', `demangle', `asm-demangle', `object', and `union'. The first four apply to C++, and the last to the C `union` type, which has no direct analogue in Modula-2.

The @ operator (see section Expressions), while available while using any language, is not useful with Modula-2. Its intent is to aid the debugging of **dynamic arrays**, which cannot be created in Modula-2 as they can in C or C++. However, because an address can be specified by an integral constant, the construct `{type}adrexp' is still useful. (see section Expressions)

In GDB scripts, the Modula-2 inequality operator # is interpreted as the beginning of a comment. Use <> instead.

Examining the Symbol Table

The commands described in this section allow you to inquire about the symbols (names of variables, functions and types) defined in your program. This information is inherent in the text of your program and does not change as your program executes. GDB finds it in your program's symbol table, in the file indicated when you started GDB (see section Choosing files), or by one of the file-management commands (see section Commands to specify files).

Occasionally, you may need to refer to symbols that contain unusual characters, which GDB ordinarily treats as word delimiters. The most frequent case is in referring to static variables in other source files (see section Program variables). File names are recorded in object files as debugging symbols, but GDB would ordinarily parse a typical file name, like `foo.c', as the three words `foo' `.' `c'. To allow GDB to recognize `foo.c' as a single symbol, enclose it in single quotes; for example,

```
p 'foo.c'::x
```

looks up the value of `x` in the scope of the file `foo.c'.

`info address symbol`

Describe where the data for symbol is stored. For a register variable, this says which register it is kept in. For a non-register local variable, this prints the stack-frame offset at which the variable is always stored. Note the contrast with `print &symbol', which does not work at all for a register variable, and for a stack local variable prints the exact address of the current instantiation of the variable.

`whatis exp`

Print the data type of expression exp. exp is not actually evaluated, and any side-effecting operations (such as assignments or function calls) inside it do not take place. See section Expressions.

`whatis`

Print the data type of `$`, the last value in the value history.

`ptype typename`

Print a description of data type typename. typename may be the name of a type, or for C code it may have the form `class class-name', `struct struct-tag', `union union-tag' or `enum enum-tag'.

`ptype exp`

`ptype`

Print a description of the type of expression exp. `ptype` differs from `whatis` by printing a detailed description, instead of just the name of the type. For example, for this variable declaration:

```
struct complex {double real; double imag;} v;
```

the two commands give this output:

```
(gdb) whatis v
type = struct complex
(gdb) ptype v
type = struct complex {
    double real;
    double imag;
}
```

As with `whatis`, using `ptype` without an argument refers to the type of `$`, the last value in the value history.

`info types regexp`

`info types`

Print a brief description of all types whose name matches regexp (or all types in your program, if you supply no argument). Each complete typename is matched as though it were a complete line; thus, `i type value' gives information on all types in your program whose name includes the string `value`, but `i type ^value$' gives information only on types whose complete name is `value`. This command differs from `ptype` in two ways: first, like `whatis`, it does not print a detailed description; second, it lists all source files where a type is defined.

`info source`

Show the name of the current source file--that is, the source file for the function containing the current point of execution--and the language it was written in.

`info sources`

Print the names of all source files in your program for which there is debugging information, organized into two lists: files whose symbols have already been read, and files whose symbols will be read when needed.

`info functions`

Print the names and data types of all defined functions.

`info functions regexp`

Print the names and data types of all defined functions whose names contain a match for regular expression regexp. Thus, `info fun step' finds all functions whose names include `step`; `info fun ^step' finds those whose names start with `step`.

`info variables`

Print the names and data types of all variables that are declared outside of functions (i.e., excluding local variables).

`info variables regexp`

Print the names and data types of all variables (except for local variables) whose names contain a match for regular expression regexp. Some systems allow individual object files that make up your program to be replaced without stopping and restarting your program. For example, in VxWorks you can simply recompile a defective object file and keep on running. If you are running on one of

these systems, you can allow GDB to reload the symbols for automatically relinked modules:

`set symbol-reloading on`

Replace symbol definitions for the corresponding source file when an object file with a particular name is seen again.

`set symbol-reloading off`

Do not replace symbol definitions when re-encountering object files of the same name. This is the default state; if you are not running on a system that permits automatically relinking modules, you should leave `symbol-reloading` off, since otherwise GDB may discard symbols when linking large programs, that may contain several modules (from different directories or libraries) with the same name.

`show symbol-reloading`

Show the current `on` or `off` setting.

`maint print symbols filename`

`maint print psymbols filename`

`maint print msymbols filename`

Write a dump of debugging symbol data into the file filename. These commands are used to debug the GDB symbol-reading code. Only symbols with debugging data are included. If you use `maint print symbols', GDB includes all the symbols for which it has already collected full details: that is, filename reflects symbols for only those files whose symbols GDB has read. You can use the command `info sources` to find out which files these are. If you use `maint print psymbols' instead, the dump shows information about symbols that GDB only knows partially--that is, symbols defined in files that GDB has skimmed, but not yet read completely. Finally, `maint print msymbols' dumps just the minimal symbol information required for each object file from which GDB has read some symbols. See section Commands to specify files, for a discussion of how GDB reads symbols (in the description of `symbol-file`).

Altering Execution

Once you think you have found an error in your program, you might want to find out for certain whether correcting the apparent error would lead to correct results in the rest of the run. You can find the answer by experiment, using the GDB features for altering execution of the program.

For example, you can store new values into variables or memory locations, give your program a signal, restart it at a different address, or even return prematurely from a function.

Assignment to variables

To alter the value of a variable, evaluate an assignment expression. See section Expressions. For example,

```
print x=4
```

stores the value 4 into the variable `x`, and then prints the value of the assignment expression (which is 4). See section Using GDB with Different Languages, for more information on operators in supported languages.

If you are not interested in seeing the value of the assignment, use the `set` command instead of the `print` command. `set` is really the same as `print` except that the expression's value is not printed and is not put in the value history (see section Value history). The expression is evaluated only for its effects.

If the beginning of the argument string of the `set` command appears identical to a `set` subcommand, use the `set variable` command instead of just `set`. This command is identical to `set` except for its lack of subcommands. For example, if your program has a variable `width`, you get an error if you try to set a new value with just `set width=13', because GDB has the command `set width`:

```
(gdb) whatis width
type = double
(gdb) p width
$4 = 13
(gdb) set width=47
Invalid syntax in expression.
```

The invalid expression, of course, is `=47'. In order to actually set the program's variable `width`, use

```
(gdb) set var width=47
```

GDB allows more implicit conversions in assignments than C; you can freely store an integer value into

a pointer variable or vice versa, and you can convert any structure to any other structure that is the sa length or shorter.

To store values into arbitrary places in memory, use the `{...}' construct to generate a value of specified type at a specified address (see section Expressions). For example, `{int}0x83040` refers to memory location `0x83040` as an integer (which implies a certain size and representation in memory), and

```
set {int}0x83040 = 4
```

stores the value 4 into that memory location.

Continuing at a different address

Ordinarily, when you continue your program, you do so at the place where it stopped, with the `continue` command. You can instead continue at an address of your own choosing, with the following commands:

`jump linespec`

Resume execution at line linespec. Execution stops again immediately if there is a breakpoint there. See section Printing source lines, for a description of the different forms of linespec. It is common practice to use the `tbreak` command in conjunction with `jump`. See section Setting breakpoints. The `jump` command does not change the current stack frame, or the stack pointer, or the contents of any memory location or any register other than the program counter. If line linespec is in a different function from the one currently executing, the results may be bizarre if the two functions expect different patterns of arguments or of local variables. For this reason, the `jump` command requests confirmation if the specified line is not in the function currently executing. However, even bizarre results are predictable if you are well acquainted with the machine-language code of your program.

`jump *address`

Resume execution at the instruction at address address.

You can get much the same effect as the `jump` command by storing a new value into the register `$pc`. The difference is that this does not start your program running; it only changes the address of where it *will* run when you continue. For example,

```
set $pc = 0x485
```

makes the next `continue` command or stepping command execute at address `0x485`, rather than at the address where your program stopped. See section Continuing and stepping.

The most common occasion to use the `jump` command is to back up--perhaps with more breakpoints set--over a portion of a program that has already executed, in order to examine its execution in more detail.

Giving your program a signal

`signal signal`

> Resume execution where your program stopped, but immediately give it the signal signal. signal can be the name or the number of a signal. For example, on many systems `signal 2` and `signal SIGINT` are both ways of sending an interrupt signal. Alternatively, if signal is zero, continue execution without giving a signal. This is useful when your program stopped on account of a signal and would ordinary see the signal when resumed with the `continue` command; `signal 0' causes it to resume without a signal. `signal` does not repeat when you press RET a second time after executing the command.

Invoking the `signal` command is not the same as invoking the `kill` utility from the shell. Sending a signal with `kill` causes GDB to decide what to do with the signal depending on the signal handling tables (see section Signals). The `signal` command passes the signal directly to your program.

Returning from a function

`return`

`return expression`

> You can cancel execution of a function call with the `return` command. If you give an expression argument, its value is used as the function's return value.

When you use `return`, GDB discards the selected stack frame (and all frames within it). You can think of this as making the discarded frame return prematurely. If you wish to specify a value to be returned, give that value as the argument to `return`.

This pops the selected stack frame (see section Selecting a frame), and any other frames inside of it, leaving its caller as the innermost remaining frame. That frame becomes selected. The specified value is stored in the registers used for returning values of functions.

The `return` command does not resume execution; it leaves the program stopped in the state that would exist if the function had just returned. In contrast, the `finish` command (see section Continuing and stepping) resumes execution until the selected stack frame returns naturally.

Calling program functions

`call expr`

> Evaluate the expression expr without displaying `void` returned values.

You can use this variant of the `print` command if you want to execute a function from your program, but without cluttering the output with `void` returned values. If the result is not void, it is printed and saved in the value history.

For the A29K, a user-controlled variable `call_scratch_address`, specifies the location of a

scratch area to be used when GDB calls a function in the target. This is necessary because the usual method of putting the scratch area on the stack does not work in systems that have separate instructio and data spaces.

Patching programs

By default, GDB opens the file containing your program's executable code (or the corefile) read-only. This prevents accidental alterations to machine code; but it also prevents you from intentionally patching your program's binary.

If you'd like to be able to patch the binary, you can specify that explicitly with the `set write` command. For example, you might want to turn on internal debugging flags, or even to make emergency repairs.

`set write on`

`set write off`

If you specify `set write on', GDB opens executable and core files for both reading and writing; if you specify `set write off' (the default), GDB opens them read-only. If you have already loaded a file, you must load it again (using the `exec-file` or `core-file` command) after changing `set write`, for your new setting to take effect.

`show write`

Display whether executable files and core files are opened for writing as well as reading.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

GDB Files

GDB needs to know the file name of the program to be debugged, both in order to read its symbol table and in order to start your program. To debug a core dump of a previous run, you must also tell GDB the name of the core dump file.

Commands to specify files

You may want to specify executable and core dump file names. The usual way to do this is at start-up time, using the arguments to GDB's start-up commands (see section Getting In and Out of GDB).

Occasionally it is necessary to change to a different file during a GDB session. Or you may run GDB and forget to specify a file you want to use. In these situations the GDB commands to specify new files are useful.

`file filename`

Use filename as the program to be debugged. It is read for its symbols and for the contents of pure memory. It is also the program executed when you use the `run` command. If you do not specify a directory and the file is not found in the GDB working directory, GDB uses the environment variable `PATH` as a list of directories to search, just as the shell does when looking for a program to run. You can change the value of this variable, for both GDB and your program, using the `path` command. On systems with memory-mapped files, an auxiliary file `` `filename.syms' `` may hold symbol table information for filename. If so, GDB maps in the symbol table from `` `filename.syms' ``, starting up more quickly. See the descriptions of the file options `-mapped' and `-readnow' (available on the command line, and with the commands `file`, `symbol-file`, or `add-symbol-file`, described below), for more information.

`file`

`file` with no argument makes GDB discard any information it has on both executable file and the symbol table.

`exec-file [ filename ]`

Specify that the program to be run (but not the symbol table) is found in filename. GDB searches the environment variable `PATH` if necessary to locate your program. Omitting filename means to discard information on the executable file.

`symbol-file [ filename ]`

Read symbol table information from file filename. `PATH` is searched when necessary. Use the `file` command to get both symbol table and program to run from the same file. `symbol-file` with no argument clears out GDB information on your program's symbol table. The `symbol-file` command causes GDB to forget the contents of its convenience variables, the value history, and all breakpoints and auto-display expressions. This is because they may contain

pointers to the internal data recording symbols and data types, which are part of the old symbol table data being discarded inside GDB. `symbol-file` does not repeat if you press RET again after executing it once. When GDB is configured for a particular environment, it understands debugging information in whatever format is the standard generated for that environment; you may use either a GNU compiler, or other compilers that adhere to the local conventions. Best results are usually obtained from GNU compilers; for example, using `gcc` you can generate debugging information for optimized code. For most kinds of object files, with the exception of old SVR3 systems using COFF, the `symbol-file` command does not normally read the symbol table in full right away. Instead, it scans the symbol table quickly to find which source files and which symbols are present. The details are read later, one source file at a time, as they are needed. The purpose of this two-stage reading strategy is to make GDB start up faster. For the most part, it is invisible except for occasional pauses while the symbol table details for a particular source file are being read. (The `set verbose` command can turn these pauses into messages if desired. See section Optional warnings and messages.) We have not implemented the two-stage strategy for COFF yet. When the symbol table is stored in COFF format, `symbol-file` reads the symbol table data in full right away. Note that "stabs-in-COFF" still does the two-stage strategy, since the debug info is actually in stabs format.

`symbol-file filename [ -readnow ] [ -mapped ]`

`file filename [ -readnow ] [ -mapped ]`

You can override the GDB two-stage strategy for reading symbol tables by using the `-readnow' option with any of the commands that load symbol table information, if you want to be sure GDB has the entire symbol table available. If memory-mapped files are available on your system through the `mmap` system call, you can use another option, `-mapped', to cause GDB to write the symbols for your program into a reusable file. Future GDB debugging sessions map in symbol information from this auxiliary symbol file (if the program has not changed), rather than spending time reading the symbol table from the executable program. Using the `-mapped' option has the same effect as starting GDB with the `-mapped' command-line option. You can use both options together, to make sure the auxiliary symbol file has all the symbol information for your program. The auxiliary symbol file for a program called myprog is called `myprog.syms'. Once this file exists (so long as it is newer than the corresponding executable), GDB always attempts to use it when you debug myprog; no special options or commands are needed. The `.syms' file is specific to the host machine where you run GDB. It holds an exact image of the internal GDB symbol table. It cannot be shared across multiple host platforms.

`core-file [ filename ]`

Specify the whereabouts of a core dump file to be used as the "contents of memory". Traditionally, core files contain only some parts of the address space of the process that generated them; GDB can access the executable file itself for other parts. `core-file` with no argument specifies that no core file is to be used. Note that the core file is ignored when your program is actually running under GDB. So, if you have been running your program and you wish to debug a core file instead, you must kill the subprocess in which the program is running. To do this, use the `kill` command (see section Killing the child process).

`add-symbol-file filename address`

`add-symbol-file filename address [ -readnow ] [ -mapped ]`

The `add-symbol-file` command reads additional symbol table information from the file filename. You would use this command when filename has been dynamically loaded (by some other means) into the program that is running. address should be the memory address at which the file has been loaded; GDB cannot figure this out for itself. You can specify address as an expression. The symbol table of the file filename is added to the symbol table originally read with the `symbol-file` command. You can use the `add-symbol-file` command any number of times; the new symbol data thus read keeps adding to the old. To discard all old symbol data instead, use the `symbol-file` command. `add-symbol-file` does not repeat if you press RET after using it. You can use the `-mapped' and `-readnow' options just as with the `symbol-file` command, to change how GDB manages the symbol table information for filename.

`add-shared-symbol-file`

The `add-shared-symbol-file` command can be used only under Harris' CXUX operating system for the Motorola 88k. GDB automatically looks for shared libraries, however if GDB does not find yours, you can run `add-shared-symbol-file`. It takes no arguments.

`section`

The `section` command changes the base address of section SECTION of the exec file to ADDR. This can be used if the exec file does not contain section addresses, (such as in the a.out format), or when the addresses specified in the file itself are wrong. Each section must be changed separately. The "info files" command lists all the sections and their addresses.

`info files`

`info target`

`info files` and `info target` are synonymous; both print the current target (see section Specifying a Debugging Target), including the names of the executable and core dump files currently in use by GDB, and the files from which symbols were loaded. The command `help target` lists all possible targets rather than current ones.

All file-specifying commands allow both absolute and relative file names as arguments. GDB always converts the file name to an absolute file name and remembers it that way.

GDB supports HP-UX, SunOS, SVr4, Irix 5, and IBM RS/6000 shared libraries. GDB automatically loads symbol definitions from shared libraries when you use the `run` command, or when you examine a core file. (Before you issue the `run` command, GDB does not understand references to a function in a shared library, however--unless you are debugging a core file).

`info share`

`info sharedlibrary`

Print the names of the shared libraries which are currently loaded.

`sharedlibrary regex`

`share regex`

Load shared object library symbols for files matching a Unix regular expression. As with files loaded automatically, it only loads shared libraries required by your program for a core file or after typing `run`. If regex is omitted all shared libraries required by your program are loaded.

Errors reading symbol files

While reading a symbol file, GDB occasionally encounters problems, such as symbol types it does not recognize, or known bugs in compiler output. By default, GDB does not notify you of such problems, since they are relatively common and primarily of interest to people debugging compilers. If you are interested in seeing information about ill-constructed symbol tables, you can either ask GDB to print only one message about each such type of problem, no matter how many times the problem occurs; or you can ask GDB to print more messages, to see how many times the problems occur, with the `set complaints` command (see section Optional warnings and messages).

The messages currently printed, and their meanings, include:

`inner block not inside outer block in symbol`

> The symbol information shows where symbol scopes begin and end (such as at the start of a function or a block of statements). This error indicates that an inner scope block is not fully contained in its outer scope blocks. GDB circumvents the problem by treating the inner block as if it had the same scope as the outer block. In the error message, symbol may be shown as "`(don't know)`" if the outer block is not a function.

`block at address out of order`

> The symbol information for symbol scope blocks should occur in order of increasing addresses. This error indicates that it does not do so. GDB does not circumvent this problem, and has trouble locating symbols in the source file whose symbols it is reading. (You can often determine what source file is affected by specifying `set verbose on`. See section Optional warnings and messages.)

`bad block start address patched`

> The symbol information for a symbol scope block has a start address smaller than the address of the preceding source line. This is known to occur in the SunOS 4.1.1 (and earlier) C compiler. GDB circumvents the problem by treating the symbol scope block as starting on the previous source line.

`bad string table offset in symbol n`

> Symbol number n contains a pointer into the string table which is larger than the size of the string table. GDB circumvents the problem by considering the symbol to have the name `foo`, which may cause other problems if many symbols end up with this name.

`unknown symbol type 0xnn`

> The symbol information contains new data types that GDB does not yet know how to read. `0xnn` is the symbol type of the misunderstood information, in hexadecimal. GDB circumvents the error by ignoring this symbol information. This usually allows you to debug your program, though certain symbols are not accessible. If you encounter such a problem and feel like debugging it, you can debug `gdb` with itself, breakpoint on `complain`, then go up to the function `read_dbx_symtab` and examine `*bufp` to see the symbol.

`stub type has NULL name`

> GDB could not find the full definition for a struct or class.

`const/volatile indicator missing (ok if using g++ v1.x), got...`

The symbol information for a C++ member function is missing some information that recent versions of the compiler should have output for it.

`info mismatch between compiler and debugger`

GDB could not parse a type specification output by the compiler.

Go to the first, previous, next, last section, table of contents.

Specifying a Debugging Target

A **target** is the execution environment occupied by your program. Often, GDB runs in the same host environment as your program; in that case, the debugging target is specified as a side effect when you use the `file` or `core` commands. When you need more flexibility--for example, running GDB on a physically separate host, or controlling a standalone system over a serial port or a realtime system over a TCP/IP connection--you can use the `target` command to specify one of the target types configured for GDB (see section Commands for managing targets).

Active targets

There are three classes of targets: processes, core files, and executable files. GDB can work concurrently on up to three active targets, one in each class. This allows you to (for example) start a process and inspect its activity without abandoning your work on a core file.

For example, if you execute `gdb a.out', then the executable file `a.out` is the only active target. If you designate a core file as well--presumably from a prior run that crashed and coredumped--then GDB has two active targets and uses them in tandem, looking first in the corefile target, then in the executable file, to satisfy requests for memory addresses. (Typically, these two classes of target are complementary, since core files contain only a program's read-write memory--variables and so on--plus machine status, while executable files contain only the program text and initialized data.)

When you type `run`, your executable file becomes an active process target as well. When a process target is active, all GDB commands requesting memory addresses refer to that target; addresses in an active core file or executable file target are obscured while the process target is active.

Use the `core-file` and `exec-file` commands to select a new core file or executable target (see section Commands to specify files). To specify as a target a process that is already running, use the `attach` command (see section Debugging an already-running process).

Commands for managing targets

`target type parameters`

Connects the GDB host environment to a target machine or process. A target is typically a protocol for talking to debugging facilities. You use the argument type to specify the type or protocol of the target machine. Further parameters are interpreted by the target protocol, but typically include things like device names or host names to connect with, process numbers, and baud rates. The `target` command does not repeat if you press RET again after executing the command.

`help target`

Displays the names of all targets available. To display targets currently selected, use either `info target` or `info files` (see section Commands to specify files).

`help target name`

Describe a particular target, including any parameters necessary to select it.

`set gnutarget args`

GDB uses its own library BFD to read your files. GDB knows whether it is reading an **executable**, a **core**, or a **.o** file; however, you can specify the file format with the `set gnutarget` command. Unlike most `target` commands, with `gnutarget` the `target` refers to a program, not a machine. *Warning:* To specify a file format with `set gnutarget`, you must know the actual BFD name. See section Commands to specify files.

`show gnutarget`

Use the `show gnutarget` command to display what file format `gnutarget` is set to read. If you have not set `gnutarget`, GDB will determine the file format for each file automatically, and `show gnutarget` displays `The current BDF target is "auto"'.

Here are some common targets (available, or not, depending on the GDB configuration):

`target exec program`

An executable file. `target exec program' is the same as `exec-file program'.

`target core filename`

A core dump file. `target core filename' is the same as `core-file filename'.

`target remote dev`

Remote serial target in GDB-specific protocol. The argument dev specifies what serial device to use for the connection (e.g. `` `/dev/ttya' ``). See section Remote debugging. `target remote` now supports the `load` command. This is only useful if you have some other way of getting the stub to the target system, and you can put it somewhere in memory where it won't get clobbered by the download.

`target sim`

CPU simulator. See section Simulated CPU target.

The following targets are all CPU-specific, and only available for specific configurations.

`target abug dev`

ABug ROM monitor for M68K.

`target adapt dev`

Adapt monitor for A29K.

`target amd-eb dev speed PROG`

Remote PC-resident AMD EB29K board, attached over serial lines. dev is the serial device, as for `target remote`; speed allows you to specify the linespeed; and PROG is the name of the program to be debugged, as it appears to DOS on the PC. See section The EBMON protocol for AMD29K.

`target array dev`

Array Tech LSI33K RAID controller board.

`target bug dev`

BUG monitor, running on a MVME187 (m88k) board.

`target cpu32bug dev`

CPU32BUG monitor, running on a CPU32 (M68K) board.

`target dbug dev`

dBUG ROM monitor for Motorola ColdFire.

`target ddb dev`

NEC's DDB monitor for Mips Vr4300.

`target dink32 dev`

DINK32 ROM monitor for PowerPC.

`target e7000 dev`

E7000 emulator for Hitachi H8 and SH.

`target es1800 dev`

ES-1800 emulator for M68K.

`target est dev`

EST-300 ICE monitor, running on a CPU32 (M68K) board.

`target hms dev`

A Hitachi SH, H8/300, or H8/500 board, attached via serial line to your host. Use special commands `device` and `speed` to control the serial line and the communications speed used. See section GDB and Hitachi microprocessors.

`target lsi dev`

LSI ROM monitor for Mips.

`target m32r dev`

Mitsubishi M32R/D ROM monitor.

`target mips dev`

IDT/SIM ROM monitor for Mips.

`target mon960 dev`

MON960 monitor for Intel i960.

`target nindy devicename`

An Intel 960 board controlled by a Nindy Monitor. devicename is the name of the serial device to use for the connection, e.g. `` `/dev/ttya' ``. See section GDB with a remote i960 (Nindy).

`target nrom dev`

NetROM ROM emulator. This target only supports downloading.

`target op50n dev`

OP50N monitor, running on an OKI HPPA board.

`target pmon dev`

PMON ROM monitor for Mips.

`target ppcbug dev`

`target ppcbug1 dev`

PPCBUG ROM monitor for PowerPC.

`target r3900 dev`

Densan DVE-R3900 ROM monitor for Toshiba R3900 Mips.

`target rdi dev`

ARM Angel monitor, via RDI library interface.

`target rdp dev`

ARM Demon monitor.

`target rom68k dev`

ROM 68K monitor, running on an M68K IDP board.

`target rombug dev`

ROMBUG ROM monitor for OS/9000.

`target sds dev`

SDS monitor, running on a PowerPC board (such as Motorola's ADS).

`target sparclite dev`

Fujitsu sparclite boards, used only for the purpose of loading. You must use an additional command to debug the program. For example: target remote dev using GDB standard remote protocol.

`target sh3 dev`

`target sh3e dev`

Hitachi SH-3 and SH-3E target systems.

`target st2000 dev speed`

A Tandem ST2000 phone switch, running Tandem's STDBUG protocol. dev is the name of the device attached to the ST2000 serial line; speed is the communication line speed. The arguments are not used if GDB is configured to connect to the ST2000 using TCP or Telnet. See section GDB with a Tandem ST2000.

`target udi keyword`

Remote AMD29K target, using the AMD UDI protocol. The keyword argument specifies which 29K board or simulator to use. See section The UDI protocol for AMD29K.

`target vxworks machinename`

A VxWorks system, attached via TCP/IP. The argument machinename is the target system's machine name or IP address. See section GDB and VxWorks.

`target w89k dev`

W89K monitor, running on a Winbond HPPA board.

Different targets are available on different configurations of GDB; your configuration may have more or

fewer targets.

Many remote targets require you to download the executable's code once you've successfully established a connection.

`load filename`

Depending on what remote debugging facilities are configured into GDB, the `load` command may be available. Where it exists, it is meant to make filename (an executable) available for debugging on the remote system--by downloading, or dynamic linking, for example. `load` also records the filename symbol table in GDB, like the `add-symbol-file` command. If your GDB does not have a `load` command, attempting to execute it gets the error message "`You can't do that when your target is ...`" The file is loaded at whatever address is specified in the executable. For some object file formats, you can specify the load address when you link the program; for other formats, like a.out, the object file format specifies a fixed address. On VxWorks, `load` links filename dynamically on the current target system as well as adding its symbols in GDB. With the Nindy interface to an Intel 960 board, `load` downloads filename to the 960 as well as adding its symbols in GDB. When you select remote debugging to a Hitachi SH, H8/300, or H8/500 board (see section GDB and Hitachi microprocessors), the `load` command downloads your program to the Hitachi board and also opens it as the current executable target for GDB on your host (like the `file` command). `load` does not repeat if you press RET again after using it.

Choosing target byte order

Some types of processors, such as the MIPS, PowerPC, and Hitachi SH, offer the ability to run either big-endian or little-endian byte orders. Usually the executable or symbol will include a bit to designate the endian-ness, and you will not need to worry about which to use. However, you may still find it useful to adjust GDB's idea of processor endian-ness manually.

`set endian big`

Instruct GDB to assume the target is big-endian.

`set endian little`

Instruct GDB to assume the target is little-endian.

`set endian auto`

Instruct GDB to use the byte order associated with the executable.

`show endian`

Display GDB's current idea of the target byte order.

Note that these commands merely adjust interpretation of symbolic data on the host, and that they have absolutely no effect on the target system.

Remote debugging

If you are trying to debug a program running on a machine that cannot run GDB in the usual way, it is often useful to use remote debugging. For example, you might use remote debugging on an operating system kernel, or on a small system which does not have a general purpose operating system powerful enough to run a full-featured debugger.

Some configurations of GDB have special serial or TCP/IP interfaces to make this work with particular debugging targets. In addition, GDB comes with a generic serial protocol (specific to GDB, but not specific to any particular target system) which you can use if you write the remote stubs--the code that runs on the remote system to communicate with GDB.

Other remote targets may be available in your configuration of GDB; use `help target` to list them.

The GDB remote serial protocol

To debug a program running on another machine (the debugging **target** machine), you must first arrange for all the usual prerequisites for the program to run by itself. For example, for a C program, you need:

1. A startup routine to set up the C runtime environment; these usually have a name like `` `crt0' ``. The startup routine may be supplied by your hardware supplier, or you may have to write your own.
2. You probably need a C subroutine library to support your program's subroutine calls, notably managing input and output.
3. A way of getting your program to the other machine--for example, a download program. These are often supplied by the hardware manufacturer, but you may have to write your own from hardware documentation.

The next step is to arrange for your program to use a serial port to communicate with the machine where GDB is running (the **host** machine). In general terms, the scheme looks like this:

On the host,

GDB already understands how to use this protocol; when everything else is set up, you can simply use the `target remote' command (see section Specifying a Debugging Target).

On the target,

you must link with your program a few special-purpose subroutines that implement the GDB remote serial protocol. The file containing these subroutines is called a **debugging stub**. On certain remote targets, you can use an auxiliary program `gdbserver` instead of linking a stub into your program. See section Using the `gdbserver` program, for details.

The debugging stub is specific to the architecture of the remote machine; for example, use `` `sparc-stub.c' `` to debug programs on SPARC boards.

These working remote stubs are distributed with GDB:

`i386-stub.c`

For Intel 386 and compatible architectures.

`m68k-stub.c`
: For Motorola 680x0 architectures.

`sh-stub.c`
: For Hitachi SH architectures.

`sparc-stub.c`
: For SPARC architectures.

`sparcl-stub.c`
: For Fujitsu SPARCLITE architectures.

The `README' file in the GDB distribution may list other recently added stubs.

What the stub can do for you

The debugging stub for your architecture supplies these three subroutines:

`set_debug_traps`
: This routine arranges for `handle_exception` to run when your program stops. You must call this subroutine explicitly near the beginning of your program.

`handle_exception`
: This is the central workhorse, but your program never calls it explicitly--the setup code arranges for `handle_exception` to run when a trap is triggered. `handle_exception` takes control when your program stops during execution (for example, on a breakpoint), and mediates communications with GDB on the host machine. This is where the communications protocol is implemented; `handle_exception` acts as the GDB representative on the target machine; it begins by sending summary information on the state of your program, then continues to execute, retrieving and transmitting any information GDB needs, until you execute a GDB command that makes your program resume; at that point, `handle_exception` returns control to your own code on the target machine.

`breakpoint`
: Use this auxiliary subroutine to make your program contain a breakpoint. Depending on the particular situation, this may be the only way for GDB to get control. For instance, if your target machine has some sort of interrupt button, you won't need to call this; pressing the interrupt button transfers control to `handle_exception`---in effect, to GDB. On some machines, simply receiving characters on the serial port may also trigger a trap; again, in that situation, you don't need to call `breakpoint` from your own program--simply running `target remote' from the host GDB session gets control. Call `breakpoint` if none of these is true, or if you simply want to make certain your program stops at a predetermined point for the start of your debugging session.

What you must do for the stub

The debugging stubs that come with GDB are set up for a particular chip architecture, but they have no information about the rest of your debugging target machine.

First of all you need to tell the stub how to communicate with the serial port.

`int getDebugChar()`

Write this subroutine to read a single character from the serial port. It may be identical to `getchar` for your target system; a different name is used to allow you to distinguish the two if you wish.

`void putDebugChar(int)`

Write this subroutine to write a single character to the serial port. It may be identical to `putchar` for your target system; a different name is used to allow you to distinguish the two if you wish.

If you want GDB to be able to stop your program while it is running, you need to use an interrupt-driven serial driver, and arrange for it to stop when it receives a `^C` (`\003', the control-C character). That is the character which GDB uses to tell the remote system to stop.

Getting the debugging target to return the proper status to GDB probably requires changes to the standard stub; one quick and dirty way is to just execute a breakpoint instruction (the "dirty" part is that GDB reports a `SIGTRAP` instead of a `SIGINT`).

Other routines you need to supply are:

`void exceptionHandler (int exception_number, void *exception_address)`

Write this function to install exception_address in the exception handling tables. You need to do this because the stub does not have any way of knowing what the exception handling tables on your target system are like (for example, the processor's table might be in ROM, containing entries which point to a table in RAM). exception_number is the exception number which should be changed; its meaning is architecture-dependent (for example, different numbers might represent divide by zero, misaligned access, etc). When this exception occurs, control should be transferred directly to exception_address, and the processor state (stack, registers, and so on) should be just as it is when a processor exception occurs. So if you want to use a jump instruction to reach exception_address, it should be a simple jump, not a jump to subroutine. For the 386, exception_address should be installed as an interrupt gate so that interrupts are masked while the handler runs. The gate should be at privilege level 0 (the most privileged level). The SPARC and 68k stubs are able to mask interrup themselves without help from `exceptionHandler`.

`void flush_i_cache()`

(sparc and sparclite only) Write this subroutine to flush the instruction cache, if any, on your target machine. If there is no instruction cache, this subroutine may be a no-op. On target machines that have instruction caches, GDB requires this function to make certain that the state of your program is stable.

You must also make sure this library routine is available:

`void *memset(void *, int, int)`

This is the standard library function `memset` that sets an area of memory to a known value. If you have one of the free versions of `libc.a`, `memset` can be found there; otherwise, you must either obtain it from your hardware manufacturer, or write your own.

If you do not use the GNU C compiler, you may need other standard library subroutines as well; this varies from one stub to another, but in general the stubs are likely to use any of the common library subroutines which `gcc` generates as inline code.

Putting it all together

In summary, when your program is ready to debug, you must follow these steps.

1. Make sure you have the supporting low-level routines (see section What you must do for the stub):

   ```
   getDebugChar, putDebugChar,
   flush_i_cache, memset, exceptionHandler.
   ```

2. Insert these lines near the top of your program:

   ```
   set_debug_traps();
   breakpoint();
   ```

3. For the 680x0 stub only, you need to provide a variable called `exceptionHook`. Normally you just use:

   ```
   void (*exceptionHook)() = 0;
   ```

   but if before calling `set_debug_traps`, you set it to point to a function in your program, that function is called when `GDB` continues after stopping on a trap (for example, bus error). The function indicated by `exceptionHook` is called with one parameter: an `int` which is the exception number.

4. Compile and link together: your program, the GDB debugging stub for your target architecture, and the supporting subroutines.
5. Make sure you have a serial connection between your target machine and the GDB host, and identify the serial port on the host.
6. Download your program to your target machine (or get it there by whatever means the manufacturer provides), and start it.
7. To start remote debugging, run GDB on the host machine, and specify as an executable file the program that is running in the remote machine. This tells GDB how to find your program's symbols and the contents of its pure text. Then establish communication using the `target remote` command. Its argument specifies how to communicate with the target machine--either via a devicename attached to a direct serial line, or a TCP port (usually to a terminal server which in turn has a serial line to the target). For example, to use a serial line connected to the device named `` `/dev/ttyb' ``:

   ```
   target remote /dev/ttyb
   ```

   To use a TCP connection, use an argument of the form `host:port`. For example, to connect to port 2828 on a terminal server named `manyfarms`:

   ```
   target remote manyfarms:2828
   ```

Now you can use all the usual commands to examine and change data and to step and continue the remote program.

To resume the remote program and stop debugging it, use the `detach` command.

Whenever GDB is waiting for the remote program, if you type the interrupt character (often C-C), GDB attempts to stop the program. This may or may not succeed, depending in part on the hardware and the serial drivers the remote system uses. If you type the interrupt character once again, GDB displays this prompt:

```
Interrupted while waiting for the program.
Give up (and stop debugging it)?  (y or n)
```

If you type y, GDB abandons the remote debugging session. (If you decide you want to try again later, you can use `target remote' again to connect once more.) If you type n, GDB goes back to waiting.

Communication protocol

The stub files provided with GDB implement the target side of the communication protocol, and the GDB side is implemented in the GDB source file `remote.c'. Normally, you can simply allow these subroutines to communicate, and ignore the details. (If you're implementing your own stub file, you can still ignore the details: start with one of the existing stub files. `sparc-stub.c' is the best organized, and therefore the easiest to read.)

However, there may be occasions when you need to know something about the protocol--for example, if there is only one serial port to your target machine, you might want your program to do something special if it recognizes a packet meant for GDB.

All GDB commands and responses (other than acknowledgements, which are single characters) are sent as a packet which includes a checksum. A packet is introduced with the character `$', and ends with the character `#' followed by a two-digit checksum:

```
$packet info#checksum
```

checksum is computed as the modulo 256 sum of the packet info characters.

When either the host or the target machine receives a packet, the first response expected is an acknowledgement: a single character, either `+' (to indicate the package was received correctly) or `-' (to request retransmission).

The host (GDB) sends commands, and the target (the debugging stub incorporated in your program) sends data in response. The target also sends data when your program stops.

Command packets are distinguished by their first character, which identifies the kind of command.

These are some of the commands currently supported (for a complete list of commands, look in `gdb/remote.c'):

`g`

Requests the values of CPU registers.

`G`

Sets the values of CPU registers.

`maddr,count`

Read count bytes at location addr.

`Maddr,count:...`

Write count bytes at location addr.

`c`

`caddr`

Resume execution at the current address (or at addr if supplied).

`s`

`saddr`

Step the target program for one instruction, from either the current program counter or from addr if supplied.

`k`

Kill the target program.

`?`

Report the most recent signal. To allow you to take advantage of the GDB signal handling commands, one of the functions of the debugging stub is to report CPU traps as the corresponding POSIX signal values.

`T`

Allows the remote stub to send only the registers that GDB needs to make a quick decision about single-stepping or conditional breakpoints. This eliminates the need to fetch the entire register set for each instruction being stepped through. GDB now implements a write-through cache for registers and only re-reads the registers if the target has run.

If you have trouble with the serial connection, you can use the command `set remotedebug`. This makes GDB report on all packets sent back and forth across the serial line to the remote machine. The packet-debugging information is printed on the GDB standard output stream. `set remotedebug off` turns it off, and `show remotedebug` shows you its current state.

Using the `gdbserver` program

`gdbserver` is a control program for Unix-like systems, which allows you to connect your program with a remote GDB via `target remote`---but without linking in the usual debugging stub.

`gdbserver` is not a complete replacement for the debugging stubs, because it requires essentially the same operating-system facilities that GDB itself does. In fact, a system that can run `gdbserver` to connect to a remote GDB could also run GDB locally! `gdbserver` is sometimes useful nevertheless, because it is a much smaller program than GDB itself. It is also easier to port than all of GDB, so you may be able to get started more quickly on a new system by using `gdbserver`. Finally, if you develop code for real-time systems, you may find that the tradeoffs involved in real-time operation make it more convenient to do as much development work as possible on another system, for example by cross-compiling. You can use `gdbserver` to make a similar choice for debugging.

GDB and `gdbserver` communicate via either a serial line or a TCP connection, using the standard GDB remote serial protocol.

On the target machine,

you need to have a copy of the program you want to debug. `gdbserver` does not need your program's symbol table, so you can strip the program if necessary to save space. GDB on the host system does all the symbol handling. To use the server, you must tell it how to communicate with GDB; the name of your program; and the arguments for your program. The syntax is:

```
target> gdbserver comm program [ args ... ]
```

comm is either a device name (to use a serial line) or a TCP hostname and portnumber. For example, to debug Emacs with the argument `foo.txt' and communicate with GDB over the serial port `/dev/com1':

```
target> gdbserver /dev/com1 emacs foo.txt
```

`gdbserver` waits passively for the host GDB to communicate with it. To use a TCP connection instead of a serial line:

```
target> gdbserver host:2345 emacs foo.txt
```

The only difference from the previous example is the first argument, specifying that you are communicating with the host GDB via TCP. The `host:2345' argument means that `gdbserver` is to expect a TCP connection from machine `host' to local TCP port 2345. (Currently, the `host' part is ignored.) You can choose any number you want for the port number as long as it does not conflict with any TCP ports already in use on the target system (for example, `23` is reserved for `telnet`).(3) You must use the same port number with the host GDB `target remote` command.

On the GDB host machine,

you need an unstripped copy of your program, since GDB needs symbols and debugging information. Start up GDB as usual, using the name of the local copy of your program as the first argument. (You may also need the `--baud' option if the serial line is running at anything other than 9600 bps.) After that, use `target remote` to establish communications with `gdbserver`. Its argument is either a device name (usually a serial device, like `/dev/ttyb'), or a TCP port descriptor in the form `host:PORT`. For example:

```
(gdb) target remote /dev/ttyb
```

communicates with the server via serial line `/dev/ttyb', and

```
(gdb) target remote the-target:2345
```

communicates via a TCP connection to port 2345 on host `the-target'. For TCP connections, you must start up `gdbserver` prior to using the `target remote` command. Otherwise you may get an error whose text depends on the host system, but which usually looks something like `Connection refused'.

Using the `gdbserve.nlm` program

`gdbserve.nlm` is a control program for NetWare systems, which allows you to connect your program with a remote GDB via `target remote`.

GDB and `gdbserve.nlm` communicate via a serial line, using the standard GDB remote serial protocol.

On the target machine,

you need to have a copy of the program you want to debug. `gdbserve.nlm` does not need your program's symbol table, so you can strip the program if necessary to save space. GDB on the host system does all the symbol handling. To use the server, you must tell it how to communicate with GDB; the name of your program; and the arguments for your program. The syntax is:

```
load gdbserve [ BOARD=board ] [ PORT=port ]
              [ BAUD=baud ] program [ args ... ]
```

board and port specify the serial line; baud specifies the baud rate used by the connection. port and node default to 0, baud defaults to 9600 bps. For example, to debug Emacs with the argument `foo.txt'and communicate with GDB over serial port number 2 or board 1 using a 19200 bps connection:

```
load gdbserve BOARD=1 PORT=2 BAUD=19200 emacs foo.txt
```

On the GDB host machine,

you need an unstripped copy of your program, since GDB needs symbols and debugging information. Start up GDB as usual, using the name of the local copy of your program as the first argument. (You may also need the `--baud' option if the serial line is running at anything other than 9600 bps. After that, use `target remote` to establish communications with `gdbserve.nlm`. Its argument is a device name (usually a serial device, like `` `/dev/ttyb' ``). For example:

```
(gdb) target remote /dev/ttyb
```

communications with the server via serial line `` `/dev/ttyb' ``.

GDB with a remote i960 (Nindy)

Nindy is a ROM Monitor program for Intel 960 target systems. When GDB is configured to control a remote Intel 960 using Nindy, you can tell GDB how to connect to the 960 in several ways:

- Through command line options specifying serial port, version of the Nindy protocol, and communications speed;
- By responding to a prompt on startup;
- By using the `target` command at any point during your GDB session. See section Commands for managing targets.

Startup with Nindy

If you simply start `gdb` without using any command-line options, you are prompted for what serial port to use, *before* you reach the ordinary GDB prompt:

```
Attach /dev/ttyNN -- specify NN, or "quit" to quit:
```

Respond to the prompt with whatever suffix (after `/dev/tty') identifies the serial port you want to use. You can, if you choose, simply start up with no Nindy connection by responding to the prompt with an empty line. If you do this and later wish to attach to Nindy, use `target` (see section Commands for managing targets).

Options for Nindy

These are the startup options for beginning your GDB session with a Nindy-960 board attached:

`-r port`

Specify the serial port name of a serial interface to be used to connect to the target system. This option is only available when GDB is configured for the Intel 960 target architecture. You may specify port as any of: a full pathname (e.g. `-r /dev/ttya'), a device name in `/dev' (e.g. `-r ttya'), or simply the unique suffix for a specific `tty` (e.g. `-r a').

`-O`

(An uppercase letter "O", not a zero.) Specify that GDB should use the "old" Nindy monitor protocol to connect to the target system. This option is only available when GDB is configured for the Intel 960 target architecture.

Warning: if you specify `-O', but are actually trying to connect to a target system that expects the newer protocol, the connection fails, appearing to be a speed mismatch. GDB repeatedly attempts to reconnect at several different line speeds. You can abort this process with an interrupt.

`-brk`

Specify that GDB should first send a BREAK signal to the target system, in an attempt to reset it, before connecting to a Nindy target.

Warning: Many target systems do not have the hardware that this requires; it only works with a few boards.

The standard `-b' option controls the line speed used on the serial port.

Nindy reset command

`reset`

For a Nindy target, this command sends a "break" to the remote target system; this is only useful if the target has been equipped with a circuit to perform a hard reset (or some other interesting action) when a break is detected.

The UDI protocol for AMD29K

GDB supports AMD's UDI ("Universal Debugger Interface") protocol for debugging the a29k processor family. To use this configuration with AMD targets running the MiniMON monitor, you need the program `MONTIP`, available from AMD at no charge. You can also use GDB with the UDI-conformant a29k simulator program `ISSTIP`, also available from AMD.

`target udi keyword`

> Select the UDI interface to a remote a29k board or simulator, where keyword is an entry in the AMD configuration file `` `udi_soc' ``. This file contains keyword entries which specify parameters used to connect to a29k targets. If the `` `udi_soc' `` file is not in your working directory, you must set the environment variable `UDICONF' to its pathname.

The EBMON protocol for AMD29K

AMD distributes a 29K development board meant to fit in a PC, together with a DOS-hosted monitor program called `EBMON`. As a shorthand term, this development system is called the "EB29K". To use GDB from a Unix system to run programs on the EB29K board, you must first connect a serial cable between the PC (which hosts the EB29K board) and a serial port on the Unix system. In the following, we assume you've hooked the cable between the PC's `` `COM1' `` port and `` `/dev/ttya' `` on the Unix system.

Communications setup

The next step is to set up the PC's port, by doing something like this in DOS on the PC:

```
C:\> MODE com1:9600,n,8,1,none
```

This example--run on an MS DOS 4.0 system--sets the PC port to 9600 bps, no parity, eight data bits, one stop bit, and no "retry" action; you must match the communications parameters when establishing the Unix end of the connection as well.

To give control of the PC to the Unix side of the serial line, type the following at the DOS console:

```
C:\> CTTY com1
```

(Later, if you wish to return control to the DOS console, you can use the command `CTTY con`---but you must send it over the device that had control, in our example over the `` `COM1' `` serial line).

From the Unix host, use a communications program such as `tip` or `cu` to communicate with the PC; for example,

```
cu -s 9600 -l /dev/ttya
```

The `cu` options shown specify, respectively, the linespeed and the serial port to use. If you use `tip` instead, your command line may look something like the following:

```
tip -9600 /dev/ttya
```

Your system may require a different name where we show `/dev/ttya' as the argument to `tip'. The communications parameters, including which port to use, are associated with the `tip' argument in the "remote" descriptions file--normally the system table `/etc/remote'.

Using the `tip' or `cu' connection, change the DOS working directory to the directory containing a copy of your 29K program, then start the PC program `EBMON' (an EB29K control program supplied with your board by AMD). You should see an initial display from `EBMON' similar to the one that follows, ending with the `EBMON' prompt `#'---

```
C:\> G:

G:\> CD \usr\joe\work29k

G:\USR\JOE\WORK29K> EBMON
Am29000 PC Coprocessor Board Monitor, version 3.0-18
Copyright 1990 Advanced Micro Devices, Inc.
Written by Gibbons and Associates, Inc.

Enter '?' or 'H' for help

PC Coprocessor Type   = EB29K
I/O Base              = 0x208
Memory Base           = 0xd0000

Data Memory Size      = 2048KB
Available I-RAM Range = 0x8000 to 0x1fffff
Available D-RAM Range = 0x80002000 to 0x801fffff

PageSize              = 0x400
Register Stack Size   = 0x800
Memory Stack Size     = 0x1800

CPU PRL               = 0x3
Am29027 Available     = No
Byte Write Available  = Yes

# ~.
```

Then exit the `cu' or `tip' program (done in the example by typing `~.' at the `EBMON' prompt). `EBMON' keeps running, ready for GDB to take over.

For this example, we've assumed what is probably the most convenient way to make sure the same 29K program is on both the PC and the Unix system: a PC/NFS connection that establishes "drive `G:'" on the PC as a file system on the Unix host. If you do not have PC/NFS or something similar connecting the two systems, you must arrange some other way--perhaps floppy-disk transfer--of getting the 29K

program from the Unix system to the PC; GDB does *not* download it over the serial line.

EB29K cross-debugging

Finally, `cd` to the directory containing an image of your 29K program on the Unix system, and start GDB---specifying as argument the name of your 29K program:

```
cd /usr/joe/work29k
gdb myfoo
```

Now you can use the `target` command:

```
target amd-eb /dev/ttya 9600 MYFOO
```

In this example, we've assumed your program is in a file called `` `myfoo' ``. Note that the filename given as the last argument to `target amd-eb` should be the name of the program as it appears to DOS. In our example this is simply `MYFOO`, but in general it can include a DOS path, and depending on your transfer mechanism may not resemble the name on the Unix side.

At this point, you can set any breakpoints you wish; when you are ready to see your program run on the 29K board, use the GDB command `run`.

To stop debugging the remote program, use the GDB `detach` command.

To return control of the PC to its console, use `tip` or `cu` once again, after your GDB session has concluded, to attach to `EBMON`. You can then type the command `q` to shut down `EBMON`, returning control to the DOS command-line interpreter. Type `CTTY con` to return command input to the main DOS console, and type ~. to leave `tip` or `cu`.

Remote log

The `target amd-eb` command creates a file `` `eb.log' `` in the current working directory, to help debug problems with the connection. `` `eb.log' `` records all the output from `EBMON`, including echoes of the commands sent to it. Running `tail -f' on this file in another window often helps to understand trouble with `EBMON`, or unexpected events on the PC side of the connection.

GDB with a Tandem ST2000

To connect your ST2000 to the host system, see the manufacturer's manual. Once the ST2000 is physically attached, you can run:

```
target st2000 dev speed
```

to establish it as your debugging environment. dev is normally the name of a serial device, such as `` `/dev/ttya' ``, connected to the ST2000 via a serial line. You can instead specify dev as a TCP connection (for example, to a serial line attached via a terminal concentrator) using the syntax `hostname:portnumber`.

The `load` and `attach` commands are *not* defined for this target; you must load your program into the ST2000 as you normally would for standalone operation. GDB reads debugging information (such as symbols) from a separate, debugging version of the program available on your host computer.

These auxiliary GDB commands are available to help you with the ST2000 environment:

`st2000 command`

Send a command to the STDBUG monitor. See the manufacturer's manual for available commands.

`connect`

Connect the controlling terminal to the STDBUG command monitor. When you are done interacting with STDBUG, typing either of two character sequences gets you back to the GDB command prompt: RET~. (Return, followed by tilde and period) or RET~C-d (Return, followed by tilde and control-D).

GDB and VxWorks

GDB enables developers to spawn and debug tasks running on networked VxWorks targets from a Unix host. Already-running tasks spawned from the VxWorks shell can also be debugged. GDB uses code that runs on both the Unix host and on the VxWorks target. The program `gdb` is installed and executed on the Unix host. (It may be installed with the name `vxgdb`, to distinguish it from a GDB for debugging programs on the host itself.)

`VxWorks-timeout args`

All VxWorks-based targets now support the option `vxworks-timeout`. This option is set by the user, and args represents the number of seconds GDB waits for responses to rpc's. You might use this if your VxWorks target is a slow software simulator or is on the far side of a thin network line.

The following information on connecting to VxWorks was current when this manual was produced; newer releases of VxWorks may use revised procedures.

To use GDB with VxWorks, you must rebuild your VxWorks kernel to include the remote debugging interface routines in the VxWorks library `` `rdb.a' ``. To do this, define `INCLUDE_RDB` in the VxWorks configuration file `` `configAll.h' `` and rebuild your VxWorks kernel. The resulting kernel contains `` `rdb.a' ``, and spawns the source debugging task `tRdbTask` when VxWorks is booted. For more information on configuring and remaking VxWorks, see the manufacturer's manual.

Once you have included `` `rdb.a' `` in your VxWorks system image and set your Unix execution search path to find GDB, you are ready to run GDB. From your Unix host, run `gdb` (or `vxgdb`, depending on your installation).

GDB comes up showing the prompt:

```
(vxgdb)
```

Connecting to VxWorks

The GDB command `target` lets you connect to a VxWorks target on the network. To connect to a target whose host name is "`tt`", type:

```
(vxgdb) target vxworks tt
```

GDB displays messages like these:

```
Attaching remote machine across net...
Connected to tt.
```

GDB then attempts to read the symbol tables of any object modules loaded into the VxWorks target since it was last booted. GDB locates these files by searching the directories listed in the command search path (see section Your program's environment); if it fails to find an object file, it displays a message such as:

```
prog.o: No such file or directory.
```

When this happens, add the appropriate directory to the search path with the GDB command `path`, and execute the `target` command again.

VxWorks download

If you have connected to the VxWorks target and you want to debug an object that has not yet been loaded, you can use the GDB `load` command to download a file from Unix to VxWorks incrementally. The object file given as an argument to the `load` command is actually opened twice: first by the VxWorks target in order to download the code, then by GDB in order to read the symbol table. This can lead to problems if the current working directories on the two systems differ. If both systems have NFS mounted the same filesystems, you can avoid these problems by using absolute paths. Otherwise, it is simplest to set the working directory on both systems to the directory in which the object file resides, and then to reference the file by its name, without any path. For instance, a program `` `prog.o' `` may reside in `` `vxpath/vw/demo/rdb' `` in VxWorks and in `` `hostpath/vw/demo/rdb' `` on the host. To load this program, type this on VxWorks:

```
-> cd "vxpath/vw/demo/rdb"
```

v Then, in GDB, type:

```
(vxgdb) cd hostpath/vw/demo/rdb
(vxgdb) load prog.o
```

GDB displays a response similar to this:

```
Reading symbol data from wherever/vw/demo/rdb/prog.o... done.
```

You can also use the `load` command to reload an object module after editing and recompiling the corresponding source file. Note that this makes GDB delete all currently-defined breakpoints, auto-displays, and convenience variables, and to clear the value history. (This is necessary in order to

preserve the integrity of debugger data structures that reference the target system's symbol table.)

Running tasks

You can also attach to an existing task using the `attach` command as follows:

```
(vxgdb) attach task
```

where task is the VxWorks hexadecimal task ID. The task can be running or suspended when you attach to it. Running tasks are suspended at the time of attachment.

GDB and Sparclet

GDB enables developers to debug tasks running on Sparclet targets from a Unix host. GDB uses code that runs on both the Unix host and on the Sparclet target. The program `gdb` is installed and executed on the Unix host.

`timeout args`

> GDB now supports the option `remotetimeout`. This option is set by the user, and args represents the number of seconds GDB waits for responses.

When compiling for debugging, include the options "-g" to get debug information and "-Ttext" to relocate the program to where you wish to load it on the target. You may also want to add the options "-n" or "-N" in order to reduce the size of the sections.

```
sparclet-aout-gcc prog.c -Ttext 0x12010000 -g -o prog -N
```

You can use objdump to verify that the addresses are what you intended.

```
sparclet-aout-objdump --headers --syms prog
```

Once you have set your Unix execution search path to find GDB, you are ready to run GDB. From your Unix host, run `gdb` (or `sparclet-aout-gdb`, depending on your installation).

GDB comes up showing the prompt:

```
(gdbslet)
```

Setting file to debug

The GDB command `file` lets you choose with program to debug.

```
(gdbslet) file prog
```

GDB then attempts to read the symbol table of `` `prog' ``. GDB locates the file by searching the directories listed in the command search path. If the file was compiled with debug information (option "-g"), source files will be searched as well. GDB locates the source files by searching the directories

listed in the directory search path (see section Your program's environment). If it fails to find a file, i displays a message such as:

```
prog: No such file or directory.
```

When this happens, add the appropriate directories to the search paths with the GDB commands `path` and `dir`, and execute the `target` command again.

Connecting to Sparclet

The GDB command `target` lets you connect to a Sparclet target. To connect to a target on serial port "`ttya`", type:

```
(gdbslet) target sparclet /dev/ttya
Remote target sparclet connected to /dev/ttya
main () at ../prog.c:3
```

GDB displays messages like these:

```
Connected to ttya.
```

Sparclet download

Once connected to the Sparclet target, you can use the GDB `load` command to download the file from the host to the target. The file name and load offset should be given as arguments to the `load` command. Since the file format is aout, the program must be loaded to the starting address. You can use objdump to find out what this value is. The load offset is an offset which is added to the VMA (virtual memory address) of each of the file's sections. For instance, if the program `` `prog' `` was linked to text address 0x1201000, with data at 0x12010160 and bss at 0x12010170, in GDB, type:

```
(gdbslet) load prog 0x12010000
Loading section .text, size 0xdb0 vma 0x12010000
```

If the code is loaded at a different address then what the program was linked to, you may need to use the `section` and `add-symbol-file` commands to tell GDB where to map the symbol table.

Running and debugging

You can now begin debugging the task using GDB's execution control commands, `b`, `step`, `run`, etc. See the GDB manual for the list of commands.

```
(gdbslet) b main
Breakpoint 1 at 0x12010000: file prog.c, line 3.
(gdbslet) run
Starting program: prog
Breakpoint 1, main (argc=1, argv=0xeffff21c) at prog.c:3
```

```
3         char *symarg = 0;
(gdbslet) step
4         char *execarg = "hello!";
(gdbslet)
```

GDB and Hitachi microprocessors

GDB needs to know these things to talk to your Hitachi SH, H8/300, or H8/500:

1. that you want to use `target hms', the remote debugging interface for Hitachi microprocessors, or `target e7000', the in-circuit emulator for the Hitachi SH and the Hitachi 300H. (`target hms' is the default when GDB is configured specifically for the Hitachi SH, H8/300, or H8/500.)
2. what serial device connects your host to your Hitachi board (the first serial device available on your host is the default).
3. what speed to use over the serial device.

Connecting to Hitachi boards

Use the special `gdb` command `device port' if you need to explicitly set the serial device. The default port is the first available port on your host. This is only necessary on Unix hosts, where it is typically something like `` `/dev/ttya' ``.

`gdb` has another special command to set the communications speed: `speed bps'. This command also is only used from Unix hosts; on DOS hosts, set the line speed as usual from outside GDB with the DOS mode command (for instance, `mode com2:9600,n,8,1,p' for a 9600 bps connection).

The `device' and `speed' commands are available only when you use a Unix host to debug your Hitachi microprocessor programs. If you use a DOS host, GDB depends on an auxiliary terminate-and-stay-resident program called `asynctsr` to communicate with the development board through a PC serial port. You must also use the DOS `mode` command to set up the serial port on the DOS side.

Using the E7000 in-circuit emulator

You can use the E7000 in-circuit emulator to develop code for either the Hitachi SH or the H8/300H. Use one of these forms of the `target e7000' command to connect GDB to your E7000:

`target e7000 port speed`

Use this form if your E7000 is connected to a serial port. The port argument identifies what serial port to use (for example, `com2'). The third argument is the line speed in bits per second (for example, `9600').

`target e7000 hostname`

If your E7000 is installed as a host on a TCP/IP network, you can just specify its hostname; GDB uses `telnet` to connect.

Special GDB commands for Hitachi micros

Some GDB commands are available only on the H8/300 or the H8/500 configurations:

`set machine h8300`

`set machine h8300h`

Condition GDB for one of the two variants of the H8/300 architecture with `set machine'. You can use `show machine' to check which variant is currently in effect.

`set memory mod`

`show memory`

Specify which H8/500 memory model (mod) you are using with `set memory'; check which memory model is in effect with `show memory'. The accepted values for mod are `small`, `big`, `medium`, and `compact`.

GDB and remote MIPS boards

GDB can use the MIPS remote debugging protocol to talk to a MIPS board attached to a serial line. This is available when you configure GDB with `--target=mips-idt-ecoff'.

Use these GDB commands to specify the connection to your target board:

`target mips port`

To run a program on the board, start up `gdb` with the name of your program as the argument. To connect to the board, use the command `target mips port', where port is the name of the serial port connected to the board. If the program has not already been downloaded to the board, you may use the `load` command to download it. You can then use all the usual GDB commands. For example, this sequence connects to the target board through a serial port, and loads and runs a program called prog through the debugger:

```
host$ gdb prog
GDB is free software and ...
(gdb) target mips /dev/ttyb
(gdb) load prog
(gdb) run
```

`target mips hostname:portnumber`

On some GDB host configurations, you can specify a TCP connection (for instance, to a serial line managed by a terminal concentrator) instead of a serial port, using the syntax `hostname:portnumber'.

`target pmon port`

`target ddb port`

`target lsi port`

GDB also supports these special commands for MIPS targets:

`set processor args`

`show processor`

Use the `set processor` command to set the type of MIPS processor when you want to access

processor-type-specific registers. For example, `set processor r3041` tells GDB to use t CPO registers appropriate for the 3041 chip. Use the `show processor` command to see wh MIPS processor GDB is using. Use the `info reg` command to see what registers GDB is using.

`set mipsfpu double`

`set mipsfpu single`

`set mipsfpu none`

`show mipsfpu`

If your target board does not support the MIPS floating point coprocessor, you should use the command `set mipsfpu none' (if you need this, you may wish to put the command in your file). This tells GDB how to find the return value of functions which return floating point values. It also allows GDB to avoid saving the floating point registers when calling functions on the board. If you are using a floating point coprocessor with only single precision floating point support, as on the R4650 processor, use the command `set mipsfpu single'. The default double precision floating point coprocessor may be selected using `set mipsfpu double'. In previous versions the only choices were double precision or no floating point, so `set mipsfpu on' will select double precision and `set mipsfpu off' will select no floating point. As usual, you can inquire about the `mipsfpu` variable with `show mipsfpu'.

`set remotedebug n`

`show remotedebug`

You can see some debugging information about communications with the board by setting the `remotedebug` variable. If you set it to `1` using `set remotedebug 1', every packet is displayed. If you set it to `2`, every character is displayed. You can check the current value at any time with the command `show remotedebug'.

`set timeout seconds`

`set retransmit-timeout seconds`

`show timeout`

`show retransmit-timeout`

You can control the timeout used while waiting for a packet, in the MIPS remote protocol, with the `set timeout seconds` command. The default is 5 seconds. Similarly, you can control the timeout used while waiting for an acknowledgement of a packet with the `set retransmit-timeout seconds` command. The default is 3 seconds. You can inspect both values with `show timeout` and `show retransmit-timeout`. (These commands are *only* available when GDB is configured for `--target=mips-idt-ecoff'.) The timeout set by `set timeout` does not apply when GDB is waiting for your program to stop. In that case, GDB waits forever because it has no way of knowing how long the program is going to run before stopping.

Simulated CPU target

For some configurations, GDB includes a CPU simulator that you can use instead of a hardware CPU to debug your programs. Currently, simulators are available for ARM, D10V, D30V, FR30, H8/300, H8/500, i960, M32R, MIPS, MN10200, MN10300, PowerPC, SH, Sparc, V850, W65, and Z8000.

For the Z8000 family, `target sim' simulates either the Z8002 (the unsegmented variant of the Z8000 architecture) or the Z8001 (the segmented variant). The simulator recognizes which architecture is appropriate by inspecting the object code.

`target sim args`

Debug programs on a simulated CPU. If the simulator supports setup options, specify them via args.

After specifying this target, you can debug programs for the simulated CPU in the same style as programs for your host computer; use the `file` command to load a new program image, the `run` command to run your program, and so on.

As well as making available all the usual machine registers (see `info reg`), the Z8000 simulator provides three additional items of information as specially named registers:

`cycles`

Counts clock-ticks in the simulator.

`insts`

Counts instructions run in the simulator.

`time`

Execution time in 60ths of a second.

You can refer to these values in GDB expressions with the usual conventions; for example, `b fputc if $cycles>5000' sets a conditional breakpoint that suspends only after at least 5000 simulated clock ticks.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Controlling GDB

You can alter the way GDB interacts with you by using the `set` command. For commands controlling how GDB displays data, see section Print settings; other settings are described here.

Prompt

GDB indicates its readiness to read a command by printing a string called the **prompt**. This string is normally `(gdb)'. You can change the prompt string with the `set prompt` command. For instance, when debugging GDB with GDB, it is useful to change the prompt in one of the GDB sessions so that you can always tell which one you are talking to.

Note: `set prompt` no longer adds a space for you after the prompt you set. This allows you to set a prompt which ends in a space or a prompt that does not.

`set prompt newprompt`

Directs GDB to use newprompt as its prompt string henceforth.

`show prompt`

Prints a line of the form: `Gdb's prompt is: your-prompt'

Command editing

GDB reads its input commands via the **readline** interface. This GNU library provides consistent behavior for programs which provide a command line interface to the user. Advantages are GNU Emacs-style or **vi**-style inline editing of commands, `csh`-like history substitution, and a storage and recall of command history across debugging sessions.

You may control the behavior of command line editing in GDB with the command `set`.

`set editing`

`set editing on`

Enable command line editing (enabled by default).

`set editing off`

Disable command line editing.

`show editing`

Show whether command line editing is enabled.

TOC

Command history

GDB can keep track of the commands you type during your debugging sessions, so that you can be certain of precisely what happened. Use these commands to manage the GDB command history facility.

`set history filename fname`

Set the name of the GDB command history file to fname. This is the file where GDB reads an initial command history list, and where it writes the command history from this session when it exits. You can access this list through history expansion or through the history command editing characters listed below. This file defaults to the value of the environment variable `GDBHISTFILE`, or to `` `./.gdb_history' `` if this variable is not set.

`set history save`

`set history save on`

Record command history in a file, whose name may be specified with the `set history filename` command. By default, this option is disabled.

`set history save off`

Stop recording command history in a file.

`set history size size`

Set the number of commands which GDB keeps in its history list. This defaults to the value of the environment variable `HISTSIZE`, or to 256 if this variable is not set.

History expansion assigns special meaning to the character !.

Since ! is also the logical not operator in C, history expansion is off by default. If you decide to enable history expansion with the `set history expansion on` command, you may sometimes need to follow ! (when it is used as logical not, in an expression) with a space or a tab to prevent it from being expanded. The readline history facilities do not attempt substitution on the strings != and !(, even when history expansion is enabled.

The commands to control history expansion are:

`set history expansion on`

`set history expansion`

Enable history expansion. History expansion is off by default.

`set history expansion off`

Disable history expansion. The readline code comes with more complete documentation of editing and history expansion features. Users unfamiliar with GNU Emacs or `vi` may wish to read it.

`show history`

`show history filename`

`show history save`

`show history size`

`show history expansion`

These commands display the state of the GDB history parameters. `show history` by itself

displays all four states.

`show commands`

Display the last ten commands in the command history.

`show commands n`

Print ten commands centered on command number n.

`show commands +`

Print ten commands just after the commands last printed.

Screen size

Certain commands to GDB may produce large amounts of information output to the screen. To help you read all of it, GDB pauses and asks you for input at the end of each page of output. Type RET when you want to continue the output, or q to discard the remaining output. Also, the screen width setting determines when to wrap lines of output. Depending on what is being printed, GDB tries to break the line at a readable place, rather than simply letting it overflow onto the following line.

Normally GDB knows the size of the screen from the termcap data base together with the value of the `TERM` environment variable and the `stty rows` and `stty cols` settings. If this is not correct, you can override it with the `set height` and `set width` commands:

`set height lpp`

`show height`

`set width cpl`

`show width`

These `set` commands specify a screen height of lpp lines and a screen width of cpl characters. The associated `show` commands display the current settings. If you specify a height of zero lines, GDB does not pause during output no matter how long the output is. This is useful if output is to a file or to an editor buffer. Likewise, you can specify `set width 0' to prevent GDB from wrapping its output.

Numbers

You can always enter numbers in octal, decimal, or hexadecimal in GDB by the usual conventions: octal numbers begin with `0', decimal numbers end with `.', and hexadecimal numbers begin with `0x'. Numbers that begin with none of these are, by default, entered in base 10; likewise, the default display for numbers--when no particular format is specified--is base 10. You can change the default base for both input and output with the `set radix` command.

`set input-radix base`

Set the default base for numeric input. Supported choices for base are decimal 8, 10, or 16. base must itself be specified either unambiguously or using the current default radix; for example, any of

```
set radix 012
set radix 10.
set radix 0xa
```

sets the base to decimal. On the other hand, `set radix 10' leaves the radix unchanged no matter what it was.

`set output-radix base`

Set the default base for numeric display. Supported choices for base are decimal 8, 10, or 16. base must itself be specified either unambiguously or using the current default radix.

`show input-radix`

Display the current default base for numeric input.

`show output-radix`

Display the current default base for numeric display.

Optional warnings and messages

By default, GDB is silent about its inner workings. If you are running on a slow machine, you may want to use the `set verbose` command. This makes GDB tell you when it does a lengthy internal operation, so you will not think it has crashed.

Currently, the messages controlled by `set verbose` are those which announce that the symbol table for a source file is being read; see `symbol-file` in section Commands to specify files.

`set verbose on`

Enables GDB output of certain informational messages.

`set verbose off`

Disables GDB output of certain informational messages.

`show verbose`

Displays whether `set verbose` is on or off.

By default, if GDB encounters bugs in the symbol table of an object file, it is silent; but if you are debugging a compiler, you may find this information useful (see section Errors reading symbol files).

`set complaints limit`

Permits GDB to output limit complaints about each type of unusual symbols before becoming silent about the problem. Set limit to zero to suppress all complaints; set it to a large number to prevent complaints from being suppressed.

`show complaints`

Displays how many symbol complaints GDB is permitted to produce.

By default, GDB is cautious, and asks what sometimes seems to be a lot of stupid questions to confirm certain commands. For example, if you try to run a program which is already running:

```
(gdb) run
```

```
The program being debugged has been started already.
Start it from the beginning? (y or n)
```

If you are willing to unflinchingly face the consequences of your own commands, you can disable this "feature":

`set confirm off`

Disables confirmation requests.

`set confirm on`

Enables confirmation requests (the default).

`show confirm`

Displays state of confirmation requests.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Canned Sequences of Commands

Aside from breakpoint commands (see section Breakpoint command lists), GDB provides two ways to store sequences of commands for execution as a unit: user-defined commands and command files.

User-defined commands

A **user-defined command** is a sequence of GDB commands to which you assign a new name as a command. This is done with the `define` command. User commands may accept up to 10 arguments separated by whitespace. Arguments are accessed within the user command via $arg0...$arg9. A trivial example:

```
define adder
  print $arg0 + $arg1 + $arg2
```

To execute the command use:

```
adder 1 2 3
```

This defines the command `adder`, which prints the sum of its three arguments. Note the arguments are text substitutions, so they may reference variables, use complex expressions, or even perform inferior functions calls.

`define commandname`

Define a command named commandname. If there is already a command by that name, you are asked to confirm that you want to redefine it. The definition of the command is made up of other GDB command lines, which are given following the `define` command. The end of these commands is marked by a line containing `end`.

`if`

Takes a single argument, which is an expression to evaluate. It is followed by a series of commands that are executed only if the expression is true (nonzero). There can then optionally be a line `else`, followed by a series of commands that are only executed if the expression was false. The end of the list is marked by a line containing `end`.

`while`

The syntax is similar to `if`: the command takes a single argument, which is an expression to evaluate, and must be followed by the commands to execute, one per line, terminated by an `end`. The commands are executed repeatedly as long as the expression evaluates to true.

`document commandname`

Document the user-defined command commandname, so that it can be accessed by `help`. The

command commandname must already be defined. This command reads lines of documentatic just as `define` reads the lines of the command definition, ending with `end`. After the `docur` command is finished, `help` on command commandname displays the documentation you have written. You may use the `document` command again to change the documentation of a command. Redefining the command with `define` does not change the documentation.

`help user-defined`

List all user-defined commands, with the first line of the documentation (if any) for each.

`show user`

`show user commandname`

Display the GDB commands used to define commandname (but not its documentation). If no commandname is given, display the definitions for all user-defined commands.

When user-defined commands are executed, the commands of the definition are not printed. An error in any command stops execution of the user-defined command.

If used interactively, commands that would ask for confirmation proceed without asking when used inside a user-defined command. Many GDB commands that normally print messages to say what they are doing omit the messages when used in a user-defined command.

User-defined command hooks

You may define *hooks*, which are a special kind of user-defined command. Whenever you run the command `foo', if the user-defined command `hook-foo' exists, it is executed (with no arguments) before that command.

In addition, a pseudo-command, `stop' exists. Defining (`hook-stop') makes the associated commands execute every time execution stops in your program: before breakpoint commands are run, displays are printed, or the stack frame is printed.

For example, to ignore `SIGALRM` signals while single-stepping, but treat them normally during normal execution, you could define:

```
define hook-stop
handle SIGALRM nopass
end

define hook-run
handle SIGALRM pass
end

define hook-continue
handle SIGLARM pass
end
```

You can define a hook for any single-word command in GDB, but not for command aliases; you should

define a hook for the basic command name, e.g. `backtrace` rather than `bt`. If an error occurs dur the execution of your hook, execution of GDB commands stops and GDB issues a prompt (before th command that you actually typed had a chance to run).

If you try to define a hook which does not match any known command, you get a warning from the `define` command.

Command files

A command file for GDB is a file of lines that are GDB commands. Comments (lines starting with #) may also be included. An empty line in a command file does nothing; it does not mean to repeat the last command, as it would from the terminal.

When you start GDB, it automatically executes commands from its **init files**. These are files named `` `.gdbinit' `` on Unix, or `` `gdb.ini' `` on DOS/Windows. GDB reads the init file (if any) in your home directory, then processes command line options and operands, and then reads the init file (if any) in the current working directory. This is so the init file in your home directory can set options (such as `set complaints`) which affect the processing of the command line options and operands. The init files are not executed if you use the `-nx' option; see section Choosing modes.

On some configurations of GDB, the init file is known by a different name (these are typically environments where a specialized form of GDB may need to coexist with other forms, hence a different name for the specialized version's init file). These are the environments with special init file names:

- VxWorks (Wind River Systems real-time OS): `.vxgdbinit'
- OS68K (Enea Data Systems real-time OS): `.os68gdbinit'
- ES-1800 (Ericsson Telecom AB M68000 emulator): `.esgdbinit'

You can also request the execution of a command file with the `source` command:

`source filename`

Execute the command file filename.

The lines in a command file are executed sequentially. They are not printed as they are executed. An error in any command terminates execution of the command file.

Commands that would ask for confirmation if used interactively proceed without asking when used in a command file. Many GDB commands that normally print messages to say what they are doing omit the messages when called from command files.

Commands for controlled output

During the execution of a command file or a user-defined command, normal GDB output is suppressed; the only output that appears is what is explicitly printed by the commands in the definition. This section describes three commands useful for generating exactly the output you want.

`echo text`

Print text. Nonprinting characters can be included in text using C escape sequences, such as `\n' to print a newline. **No newline is printed unless you specify one.** In addition to the standard C escape sequences, a backslash followed by a space stands for a space. This is useful for displaying a string with spaces at the beginning or the end, since leading and trailing spaces are otherwise trimmed from all arguments. To print ` and foo = ', use the command `echo \ and foo = \ '. A backslash at the end of text can be used, as in C, to continue the command onto subsequent lines. For example,

```
echo This is some text\n\
which is continued\n\
onto several lines.\n
```

produces the same output as

```
echo This is some text\n
echo which is continued\n
echo onto several lines.\n
```

`output expression`

Print the value of expression and nothing but that value: no newlines, no `$nn = '. The value is not entered in the value history either. See section Expressions, for more information on expressions.

`output/fmt expression`

Print the value of expression in format fmt. You can use the same formats as for `print`. See section Output formats, for more information.

`printf string, expressions...`

Print the values of the expressions under the control of string. The expressions are separated by commas and may be either numbers or pointers. Their values are printed as specified by string, exactly as if your program were to execute the C subroutine

```
printf (string, expressions...);
```

For example, you can print two values in hex like this:

```
printf "foo, bar-foo = 0x%x, 0x%x\n", foo, bar-foo
```

The only backslash-escape sequences that you can use in the format string are the simple ones that consist of backslash followed by a letter.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Using GDB under GNU Emacs

A special interface allows you to use GNU Emacs to view (and edit) the source files for the program you are debugging with GDB.

To use this interface, use the command M-x gdb in Emacs. Give the executable file you want to debug as an argument. This command starts GDB as a subprocess of Emacs, with input and output through a newly created Emacs buffer.

Using GDB under Emacs is just like using GDB normally except for two things:

- All "terminal" input and output goes through the Emacs buffer.

This applies both to GDB commands and their output, and to the input and output done by the program you are debugging.

This is useful because it means that you can copy the text of previous commands and input them again; you can even use parts of the output in this way.

All the facilities of Emacs' Shell mode are available for interacting with your program. In particular, you can send signals the usual way--for example, C-c C-c for an interrupt, C-c C-z for a stop.

- GDB displays source code through Emacs.

Each time GDB displays a stack frame, Emacs automatically finds the source file for that frame and puts an arrow (`=>') at the left margin of the current line. Emacs uses a separate buffer for source display, and splits the screen to show both your GDB session and the source.

Explicit GDB `list` or search commands still produce output as usual, but you probably have no reason to use them from Emacs.

> *Warning:* If the directory where your program resides is not your current directory, it can be easy to confuse Emacs about the location of the source files, in which case the auxiliary display buffer does not appear to show your source. GDB can find programs by searching your environment's `PATH` variable, so the GDB input and output session proceeds normally; but Emacs does not get enough information back from GDB to locate the source files in this situation. To avoid this problem, either start GDB mode from the directory where your program resides, or specify an absolute file name when prompted for the M-x gdb argument.
>
> A similar confusion can result if you use the GDB `file` command to switch to debugging a program in some other location, from an existing GDB buffer in Emacs.

By default, M-x gdb calls the program called `gdb'. If you need to call GDB by a different name (for example, if you keep several configurations around, with different names) you can set the Emacs variable `gdb-command-name`; for example,

```
(setq gdb-command-name "mygdb")
```

(preceded by ESC ESC, or typed in the `*scratch*` buffer, or in your `.emacs' file) makes Emacs call the program named "`mygdb`" instead.

In the GDB I/O buffer, you can use these special Emacs commands in addition to the standard Shell mode commands:

C-h m

Describe the features of Emacs' GDB Mode.

M-s

Execute to another source line, like the GDB `step` command; also update the display window to show the current file and location.

M-n

Execute to next source line in this function, skipping all function calls, like the GDB `next` command. Then update the display window to show the current file and location.

M-i

Execute one instruction, like the GDB `stepi` command; update display window accordingly.

M-x gdb-nexti

Execute to next instruction, using the GDB `nexti` command; update display window accordingly.

C-c C-f

Execute until exit from the selected stack frame, like the GDB `finish` command.

M-c

Continue execution of your program, like the GDB `continue` command. *Warning:* In Emacs v19, this command is C-c C-p.

M-u

Go up the number of frames indicated by the numeric argument (see section `Numeric Arguments' in The GNU Emacs Manual), like the GDB `up` command. *Warning:* In Emacs v19, this command is C-c C-u.

M-d

Go down the number of frames indicated by the numeric argument, like the GDB `down` command. *Warning:* In Emacs v19, this command is C-c C-d.

C-x &

Read the number where the cursor is positioned, and insert it at the end of the GDB I/O buffer. For example, if you wish to disassemble code around an address that was displayed earlier, type disassemble; then move the cursor to the address display, and pick up the argument for `disassemble` by typing C-x &. You can customize this further by defining elements of the list `gdb-print-command`; once it is defined, you can format or otherwise process numbers picked up by C-x & before they are inserted. A numeric argument to C-x & indicates that you wish special formatting, and also acts as an index to pick an element of the list. If the list element is a string, the number to be inserted is formatted using the Emacs function `format`; otherwise the

number is passed as an argument to the corresponding list element.

In any source file, the Emacs command C-x SPC (`gdb-break`) tells GDB to set a breakpoint on the source line point is on.

If you accidentally delete the source-display buffer, an easy way to get it back is to type the command `f` in the GDB buffer, to request a frame display; when you run under Emacs, this recreates the source buffer if necessary to show you the context of the current frame.

The source files displayed in Emacs are in ordinary Emacs buffers which are visiting the source files in the usual way. You can edit the files with these buffers if you wish; but keep in mind that GDB communicates with Emacs in terms of line numbers. If you add or delete lines from the text, the line numbers that GDB knows cease to correspond properly with the code.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Reporting Bugs in GDB

Your bug reports play an essential role in making GDB reliable.

Reporting a bug may help you by bringing a solution to your problem, or it may not. But in any case the principal function of a bug report is to help the entire community by making the next version of GDB work better. Bug reports are your contribution to the maintenance of GDB.

In order for a bug report to serve its purpose, you must include the information that enables us to fix the bug.

Have you found a bug?

If you are not sure whether you have found a bug, here are some guidelines:

- If the debugger gets a fatal signal, for any input whatever, that is a GDB bug. Reliable debuggers never crash.
- If GDB produces an error message for valid input, that is a bug. (Note that if you're cross debugging, the problem may also be somewhere in the connection to the target.)
- If GDB does not produce an error message for invalid input, that is a bug. However, you should note that your idea of "invalid input" might be our idea of "an extension" or "support for traditional practice".
- If you are an experienced user of debugging tools, your suggestions for improvement of GDB are welcome in any case.

How to report bugs

A number of companies and individuals offer support for GNU products. If you obtained GDB from a support organization, we recommend you contact that organization first.

You can find contact information for many support companies and individuals in the file `etc/SERVICE' in the GNU Emacs distribution.

In any event, we also recommend that you send bug reports for GDB to this addresses:

bug-gdb@prep.ai.mit.edu

Do not send bug reports to `info-gdb', or to `help-gdb', or to any newsgroups. Most users of GDB do not want to receive bug reports. Those that do have arranged to receive `bug-gdb'.

The mailing list `bug-gdb' has a newsgroup `gnu.gdb.bug' which serves as a repeater. The mailing list

and the newsgroup carry exactly the same messages. Often people think of posting bug reports to the newsgroup instead of mailing them. This appears to work, but it has one problem which can be crucial: newsgroup posting often lacks a mail path back to the sender. Thus, if we need to ask for more information, we may be unable to reach you. For this reason, it is better to send bug reports to the mailing list.

As a last resort, send bug reports on paper to:

```
GNU Debugger Bugs
Free Software Foundation Inc.
59 Temple Place - Suite 330
Boston, MA 02111-1307
USA
```

The fundamental principle of reporting bugs usefully is this: **report all the facts**. If you are not sure whether to state a fact or leave it out, state it!

Often people omit facts because they think they know what causes the problem and assume that some details do not matter. Thus, you might assume that the name of the variable you use in an example does not matter. Well, probably it does not, but one cannot be sure. Perhaps the bug is a stray memory reference which happens to fetch from the location where that name is stored in memory; perhaps, if the name were different, the contents of that location would fool the debugger into doing the right thing despite the bug. Play it safe and give a specific, complete example. That is the easiest thing for you to do, and the most helpful.

Keep in mind that the purpose of a bug report is to enable us to fix the bug. It may be that the bug has been reported previously, but neither you nor we can know that unless your bug report is complete and self-contained.

Sometimes people give a few sketchy facts and ask, "Does this ring a bell?" Those bug reports are useless, and we urge everyone to *refuse to respond to them* except to chide the sender to report bugs properly.

To enable us to fix the bug, you should include all these things:

- The version of GDB. GDB announces it if you start with no arguments; you can also print it at any time using `show version`. Without this, we will not know whether there is any point in looking for the bug in the current version of GDB.
- The type of machine you are using, and the operating system name and version number.
- What compiler (and its version) was used to compile GDB---e.g. "gcc--2.8.1".
- What compiler (and its version) was used to compile the program you are debugging--e.g. "gcc--2.8.1", or "HP92453-01 A.10.32.03 HP C Compiler". For GCC, you can say `gcc --version` to get this information; for other compilers, see the documentation for those compilers.
- The command arguments you gave the compiler to compile your example and observe the bug. For example, did you use `-O'? To guarantee you will not omit something important, list them all. A copy of the Makefile (or the output from make) is sufficient. If we were to try to guess the

arguments, we would probably guess wrong and then we might not encounter the bug.

- A complete input script, and all necessary source files, that will reproduce the bug.
- A description of what behavior you observe that you believe is incorrect. For example, "It gets a fatal signal." Of course, if the bug is that GDB gets a fatal signal, then we will certainly notice it. But if the bug is incorrect output, we might not notice unless it is glaringly wrong. You might as well not give us a chance to make a mistake. Even if the problem you experience is a fatal signal, you should still say so explicitly. Suppose something strange is going on, such as, your copy of GDB is out of synch, or you have encountered a bug in the C library on your system. (This has happened!) Your copy might crash and ours would not. If you told us to expect a crash, then when ours fails to crash, we would know that the bug was not happening for us. If you had not told us to expect a crash, then we would not be able to draw any conclusion from our observations.
- If you wish to suggest changes to the GDB source, send us context diffs. If you even discuss something in the GDB source, refer to it by context, not by line number. The line numbers in our development sources will not match those in your sources. Your line numbers would convey no useful information to us.

Here are some things that are not necessary:

- A description of the envelope of the bug. Often people who encounter a bug spend a lot of time investigating which changes to the input file will make the bug go away and which changes will not affect it. This is often time consuming and not very useful, because the way we will find the bug is by running a single example under the debugger with breakpoints, not by pure deduction from a series of examples. We recommend that you save your time for something else. Of course, if you can find a simpler example to report *instead* of the original one, that is a convenience for us. Errors in the output will be easier to spot, running under the debugger will take less time, and so on. However, simplification is not vital; if you do not want to do this, report the bug anyway and send us the entire test case you used.
- A patch for the bug. A patch for the bug does help us if it is a good one. But do not omit the necessary information, such as the test case, on the assumption that a patch is all we need. We might see problems with your patch and decide to fix the problem another way, or we might not understand it at all. Sometimes with a program as complicated as GDB it is very hard to construct an example that will make the program follow a certain path through the code. If you do not send us the example, we will not be able to construct one, so we will not be able to verify that the bug is fixed. And if we cannot understand what bug you are trying to fix, or why your patch should be an improvement, we will not install it. A test case will help us to understand.
- A guess about what the bug is or what it depends on. Such guesses are usually wrong. Even we cannot guess right about such things without first using the debugger to find the facts.

Go to the first, previous, next, last section, table of contents.

Command Line Editing

This chapter describes the basic features of the GNU command line editing interface.

Introduction to Line Editing

The following paragraphs describe the notation used to represent keystrokes.

The text C-k is read as `Control-K' and describes the character produced when the k key is pressed while the Control key is depressed.

The text M-k is read as `Meta-K' and describes the character produced when the meta key (if you have one) is depressed, and the k key is pressed. If you do not have a meta key, the identical keystroke can be generated by typing ESC *first*, and then typing k. Either process is known as **metafying** the k key.

The text M-C-k is read as `Meta-Control-k' and describes the character produced by **metafying** C-k.

In addition, several keys have their own names. Specifically, DEL, ESC, LFD, SPC, RET, and TAB all stand for themselves when seen in this text, or in an init file (@xref{Readline Init File}).

Readline Interaction

Often during an interactive session you type in a long line of text, only to notice that the first word on the line is misspelled. The Readline library gives you a set of commands for manipulating the text as you type it in, allowing you to just fix your typo, and not forcing you to retype the majority of the line. Using these editing commands, you move the cursor to the place that needs correction, and delete or insert the text of the corrections. Then, when you are satisfied with the line, you simply press RETURN. You do not have to be at the end of the line to press RETURN; the entire line is accepted regardless of the location of the cursor within the line.

Readline Init File Syntax

There are only a few basic constructs allowed in the Readline init file. Blank lines are ignored. Lines beginning with a `#' are comments. Lines beginning with a `$' indicate conditional constructs (see section Conditional Init Constructs). Other lines denote variable settings and key bindings.

Variable Settings

You can modify the run-time behavior of Readline by altering the values of variables in Readline using the `set` command within the init file. Here is how to change from the default Emacs-like key binding to use `vi` line editing commands:

```
set editing-mode vi
```

A great deal of run-time behavior is changeable with the following variables.

`bell-style`

Controls what happens when Readline wants to ring the terminal bell. If set to `none', Readline never rings the bell. If set to `visible', Readline uses a visible bell if one is available. If set to `audible' (the default), Readline attempts to ring the terminal's bell.

`comment-begin`

The string to insert at the beginning of the line when the `insert-comment` command is executed. The default value is `"#"`.

`completion-ignore-case`

If set to `on', Readline performs filename matching and completion in a case-insensitive fashion. The default value is `off'.

`completion-query-items`

The number of possible completions that determines when the user is asked whether he wants to see the list of possibilities. If the number of possible completions is greater than this value, Readline will ask the user whether or not he wishes to view them; otherwise, they are simply listed. The default limit is `100`.

`convert-meta`

If set to `on', Readline will convert characters with the eighth bit set to an ASCII key sequence by stripping the eighth bit and prepending an ESC character, converting them to a meta-prefixed key sequence. The default value is `on'.

`disable-completion`

If set to `On', Readline will inhibit word completion. Completion characters will be inserted into the line as if they had been mapped to `self-insert`. The default is `off'.

`editing-mode`

The `editing-mode` variable controls which default set of key bindings is used. By default, Readline starts up in Emacs editing mode, where the keystrokes are most similar to Emacs. This variable can be set to either `emacs' or `vi'.

`enable-keypad`

When set to `on', Readline will try to enable the application keypad when it is called. Some systems need this to enable the arrow keys. The default is `off'.

`expand-tilde`

If set to `on', tilde expansion is performed when Readline attempts word completion. The default is `off'.

`horizontal-scroll-mode`

This variable can be set to either `on' or `off'. Setting it to `on' means that the text of the lines being edited will scroll horizontally on a single screen line when they are longer than the width of the screen, instead of wrapping onto a new screen line. By default, this variable is set to `off'.

`keymap`

Sets Readline's idea of the current keymap for key binding commands. Acceptable `keymap` names are `emacs`, `emacs-standard`, `emacs-meta`, `emacs-ctlx`, `vi`, `vi-command`, and `vi-insert`. `vi` is equivalent to `vi-command`; `emacs` is equivalent to `emacs-standard`. The default value is `emacs`. The value of the `editing-mode` variable also affects the default keymap.

`mark-directories`

If set to `on', completed directory names have a slash appended. The default is `on'.

`mark-modified-lines`

This variable, when set to `on', causes Readline to display an asterisk (`*') at the start of history lines which have been modified. This variable is `off' by default.

`input-meta`

If set to `on', Readline will enable eight-bit input (it will not strip the eighth bit from the characters it reads), regardless of what the terminal claims it can support. The default value is `off'. The name `meta-flag` is a synonym for this variable.

`output-meta`

If set to `on', Readline will display characters with the eighth bit set directly rather than as a meta-prefixed escape sequence. The default is `off'.

`print-completions-horizontally`

If set to `on', Readline will display completions with matches sorted horizontally in alphabetical order, rather than down the screen. The default is `off'.

`show-all-if-ambiguous`

This alters the default behavior of the completion functions. If set to `on', words which have more than one possible completion cause the matches to be listed immediately instead of ringing the bell. The default value is `off'.

`visible-stats`

If set to `on', a character denoting a file's type is appended to the filename when listing possible completions. The default is `off'.

Key Bindings

The syntax for controlling key bindings in the init file is simple. First you have to know the name of the command that you want to change. The following sections contain tables of the command name, the default keybinding, if any, and a short description of what the command does. Once you know the name of the command, simply place the name of the key you wish to bind the command to, a colon, and then the name of the command on a line in the init file. The name of the key can be expressed in different ways, depending on which is most comfortable for you.

keyname: function-name or macro

keyname is the name of a key spelled out in English. For example:

```
Control-u: universal-argument
Meta-Rubout: backward-kill-word
Control-o: "> output"
```

In the above example, C-u is bound to the function `universal-argument`, and C-o is bound to run the macro expressed on the right hand side (that is, to insert the text `> output' into the line).

"keyseq": function-name or macro

keyseq differs from keyname above in that strings denoting an entire key sequence can be specified, by placing the key sequence in double quotes. Some GNU Emacs style key escapes can be used, as in the following example, but the special character names are not recognized.

```
"\C-u": universal-argument
"\C-x\C-r": re-read-init-file
"\e[11~": "Function Key 1"
```

In the above example, C-u is bound to the function `universal-argument` (just as it was in the first example), `C-x C-r' is bound to the function `re-read-init-file`, and `ESC [1 1 ~' is bound to insert the text `Function Key 1'.

The following GNU Emacs style escape sequences are available when specifying key sequences:

`\C-`

control prefix

`\M-`

meta prefix

`\e`

an escape character

`\\`
backslash

`\"`
"

`\'`
'

In addition to the GNU Emacs style escape sequences, a second set of backslash escapes is available:

`\a`
alert (bell)

`\b`
backspace

`\d`
delete

`\f`
form feed

`\n`
newline

`\r`
carriage return

`\t`
horizontal tab

`\v`
vertical tab

`\nnn`
the character whose ASCII code is the octal value nnn (one to three digits)

`\xnnn`
the character whose ASCII code is the hexadecimal value nnn (one to three digits)

When entering the text of a macro, single or double quotes must be used to indicate a macro definition. Unquoted text is assumed to be a function name. In the macro body, the backslash escapes described above are expanded. Backslash will quote any other character in the macro text, including `'" and `'". For example, the following binding will make `C-x \' insert a single `\' into the line:

```
"\C-x\\": "\\"
```

Conditional Init Constructs

Readline implements a facility similar in spirit to the conditional compilation features of the C preprocessor which allows key bindings and variable settings to be performed as the result of tests. There are four parser directives used.

`$if`

The `$if` construct allows bindings to be made based on the editing mode, the terminal being used, or the application using Readline. The text of the test extends to the end of the line; no characters are required to isolate it.

`mode`

The `mode=` form of the `$if` directive is used to test whether Readline is in `emacs` or `vi` mode. This may be used in conjunction with the `set keymap' command, for instance, to set bindings in the `emacs-standard` and `emacs-ctlx` keymaps only if Readline is starting out in `emacs` mode.

`term`

The `term=` form may be used to include terminal-specific key bindings, perhaps to bind the key sequences output by the terminal's function keys. The word on the right side of the `=' is tested against both the full name of the terminal and the portion of the terminal name before the first `-'. This allows `sun` to match both `sun` and `sun-cmd`, for instance.

`application`

The application construct is used to include application-specific settings. Each program using the Readline library sets the application name, and you can test for it. This could be used to bind key sequences to functions useful for a specific program. For instance, the following command adds a key sequence that quotes the current or previous word in Bash:

```
$if Bash
# Quote the current or previous word
"\C-xq": "\eb\"\ef\""
$endif
```

`$endif`

This command, as seen in the previous example, terminates an `$if` command.

`$else`

Commands in this branch of the `$if` directive are executed if the test fails.

`$include`

This directive takes a single filename as an argument and reads commands and bindings from that file.

```
$include /etc/inputrc
```

Sample Init File

Here is an example of an inputrc file. This illustrates key binding, variable assignment, and conditional syntax.

```
# This file controls the behaviour of line input editing for
# programs that use the Gnu Readline library.  Existing programs
# include FTP, Bash, and Gdb.
#
# You can re-read the inputrc file with C-x C-r.
# Lines beginning with '#' are comments.
#
# First, include any systemwide bindings and variable assignments from
# /etc/Inputrc
$include /etc/Inputrc

#
# Set various bindings for emacs mode.

set editing-mode emacs
```

```
$if mode=emacs

Meta-Control-h: backward-kill-word      Text after the function name is ignored

#
# Arrow keys in keypad mode
#
#"\M-OD":        backward-char
#"\M-OC":        forward-char
#"\M-OA":        previous-history
#"\M-OB":        next-history
#
# Arrow keys in ANSI mode
#
"\M-[D":        backward-char
"\M-[C":        forward-char
"\M-[A":        previous-history
"\M-[B":        next-history
#
# Arrow keys in 8 bit keypad mode
#
#"\M-\C-OD":       backward-char
#"\M-\C-OC":       forward-char
#"\M-\C-OA":       previous-history
#"\M-\C-OB":       next-history
#
# Arrow keys in 8 bit ANSI mode
#
#"\M-\C-[D":       backward-char
#"\M-\C-[C":       forward-char
#"\M-\C-[A":       previous-history
#"\M-\C-[B":       next-history

C-q: quoted-insert

$endif

# An old-style binding.  This happens to be the default.
TAB: complete

# Macros that are convenient for shell interaction
$if Bash
# edit the path
"\C-xp": "PATH=${PATH}\e\C-e\C-a\ef\C-f"
# prepare to type a quoted word -- insert open and close double quotes
# and move to just after the open quote
"\C-x\"": "\"\"\C-b"
# insert a backslash (testing backslash escapes in sequences and macros)
"\C-x\\": "\\"
# Quote the current or previous word
```

```
"\C-xq": "\eb\"\ef\""
# Add a binding to refresh the line, which is unbound
"\C-xr": redraw-current-line
# Edit variable on current line.
"\M-\C-v": "\C-a\C-k$\C-y\M-\C-e\C-a\C-y="
$endif

# use a visible bell if one is available
set bell-style visible

# don't strip characters to 7 bits when reading
set input-meta on

# allow iso-latin1 characters to be inserted rather than converted to
# prefix-meta sequences
set convert-meta off

# display characters with the eighth bit set directly rather than
# as meta-prefixed characters
set output-meta on

# if there are more than 150 possible completions for a word, ask the
# user if he wants to see all of them
set completion-query-items 150

# For FTP
$if Ftp
"\C-xg": "get \M-?"
"\C-xt": "put \M-?"
"\M-.": yank-last-arg
$endif
```

Bindable Readline Commands

This section describes Readline commands that may be bound to key sequences.

Commands For Moving

`beginning-of-line (C-a)`
: Move to the start of the current line.

`end-of-line (C-e)`
: Move to the end of the line.

`forward-char (C-f)`
: Move forward a character.

`backward-char (C-b)`
: Move back a character.

`forward-word (M-f)`
: Move forward to the end of the next word. Words are composed of letters and digits.

`backward-word (M-b)`

Move back to the start of this, or the previous, word. Words are composed of letters and digits.

`clear-screen (C-l)`

Clear the screen and redraw the current line, leaving the current line at the top of the screen.

`redraw-current-line ()`

Refresh the current line. By default, this is unbound.

Commands For Manipulating The History

`accept-line (Newline, Return)`

Accept the line regardless of where the cursor is. If this line is non-empty, add it to the history list. If this line was a history line, then restore the history line to its original state.

`previous-history (C-p)`

Move `up' through the history list.

`next-history (C-n)`

Move `down' through the history list.

`beginning-of-history (M-<)`

Move to the first line in the history.

`end-of-history (M->)`

Move to the end of the input history, i.e., the line currently being entered.

`reverse-search-history (C-r)`

Search backward starting at the current line and moving `up' through the history as necessary. This is an incremental search.

`forward-search-history (C-s)`

Search forward starting at the current line and moving `down' through the the history as necessary. This is an incremental search.

`non-incremental-reverse-search-history (M-p)`

Search backward starting at the current line and moving `up' through the history as necessary using a non-incremental search for a string supplied by the user.

`non-incremental-forward-search-history (M-n)`

Search forward starting at the current line and moving `down' through the the history as necessary using a non-incremental search for a string supplied by the user.

`history-search-forward ()`

Search forward through the history for the string of characters between the start of the current line and the current cursor position (the point). This is a non-incremental search. By default, this command is unbound.

`history-search-backward ()`

Search backward through the history for the string of characters between the start of the current line and the point. This is a non-incremental search. By default, this command is unbound.

`yank-nth-arg (M-C-y)`

Insert the first argument to the previous command (usually the second word on the previous line). With an argument n, insert the nth word from the previous command (the words in the previous command begin with word 0). A negative argument inserts the nth word from the end of the previous command.

`yank-last-arg (M-., M-_)`

TOC

Insert last argument to the previous command (the last word of the previous history entry). With an argum behave exactly like `yank-nth-arg`. Successive calls to `yank-last-arg` move back through the his list, inserting the last argument of each line in turn.

Commands For Changing Text

`delete-char (C-d)`

Delete the character under the cursor. If the cursor is at the beginning of the line, there are no characters in the line, and the last character typed was not bound to `delete-char`, then return `EOF`.

`backward-delete-char (Rubout)`

Delete the character behind the cursor. A numeric argument means to kill the characters instead of deleting them.

`quoted-insert (C-q, C-v)`

Add the next character typed to the line verbatim. This is how to insert key sequences like C-q, for example.

`tab-insert (M-TAB)`

Insert a tab character.

`self-insert (a, b, A, 1, !, ...)`

Insert yourself.

`transpose-chars (C-t)`

Drag the character before the cursor forward over the character at the cursor, moving the cursor forward as well. If the insertion point is at the end of the line, then this transposes the last two characters of the line. Negative arguments don't work.

`transpose-words (M-t)`

Drag the word behind the cursor past the word in front of the cursor moving the cursor over that word as well.

`upcase-word (M-u)`

Uppercase the current (or following) word. With a negative argument, uppercase the previous word, but do not move the cursor.

`downcase-word (M-l)`

Lowercase the current (or following) word. With a negative argument, lowercase the previous word, but do not move the cursor.

`capitalize-word (M-c)`

Capitalize the current (or following) word. With a negative argument, capitalize the previous word, but do not move the cursor.

Killing And Yanking

`kill-line (C-k)`

Kill the text from the current cursor position to the end of the line.

`backward-kill-line (C-x Rubout)`

Kill backward to the beginning of the line.

`unix-line-discard (C-u)`

Kill backward from the cursor to the beginning of the current line. The killed text is saved on the kill-ring.

`kill-whole-line ()`

Kill all characters on the current line, no matter where the cursor is. By default, this is unbound.

`kill-word (M-d)`

Kill from the cursor to the end of the current word, or if between words, to the end of the next word. Word boundaries are the same as `forward-word`.

`backward-kill-word (M-DEL)`

Kill the word behind the cursor. Word boundaries are the same as `backward-word`.

`unix-word-rubout (C-w)`

Kill the word behind the cursor, using white space as a word boundary. The killed text is saved on the kill-ring.

`delete-horizontal-space ()`

Delete all spaces and tabs around point. By default, this is unbound.

`kill-region ()`

Kill the text between the point and the *mark* (saved cursor position). This text is referred to as the region. By default, this command is unbound.

`copy-region-as-kill ()`

Copy the text in the region to the kill buffer, so it can be yanked right away. By default, this command is unbound.

`copy-backward-word ()`

Copy the word before point to the kill buffer. The word boundaries are the same as `backward-word`. By default, this command is unbound.

`copy-forward-word ()`

Copy the word following point to the kill buffer. The word boundaries are the same as `forward-word`. By default, this command is unbound.

`yank (C-y)`

Yank the top of the kill ring into the buffer at the current cursor position.

`yank-pop (M-y)`

Rotate the kill-ring, and yank the new top. You can only do this if the prior command is yank or yank-pop.

Specifying Numeric Arguments

`digit-argument (M-0, M-1, ... M--)`

Add this digit to the argument already accumulating, or start a new argument. M-- starts a negative argument.

`universal-argument ()`

This is another way to specify an argument. If this command is followed by one or more digits, optionally with a leading minus sign, those digits define the argument. If the command is followed by digits, executing `universal-argument` again ends the numeric argument, but is otherwise ignored. As a special case, if this command is immediately followed by a character that is neither a digit or minus sign, the argument count for the next command is multiplied by four. The argument count is initially one, so executing this function the first time makes the argument count four, a second time makes the argument count sixteen, and so on. By default, this is not bound to a key.

Letting Readline Type For You

`complete (TAB)`

Attempt to do completion on the text before the cursor. This is application-specific. Generally, if you are typing a filename argument, you can do filename completion; if you are typing a command, you can do command completion; if you are typing in a symbol to GDB, you can do symbol name completion; if you are typing in a

variable to Bash, you can do variable name completion, and so on.

`possible-completions (M-?)`

List the possible completions of the text before the cursor.

`insert-completions (M-*)`

Insert all completions of the text before point that would have been generated by `possible-completions`.

`menu-complete ()`

Similar to `complete`, but replaces the word to be completed with a single match from the list of possible completions. Repeated execution of `menu-complete` steps through the list of possible completions, inserting each match in turn. At the end of the list of completions, the bell is rung and the original text is restored. An argument of n moves n positions forward in the list of matches; a negative argument may be used to move backward through the list. This command is intended to be bound to `TAB`, but is unbound by default.

Keyboard Macros

`start-kbd-macro (C-x ()`

Begin saving the characters typed into the current keyboard macro.

`end-kbd-macro (C-x ))`

Stop saving the characters typed into the current keyboard macro and save the definition.

`call-last-kbd-macro (C-x e)`

Re-execute the last keyboard macro defined, by making the characters in the macro appear as if typed at the keyboard.

Some Miscellaneous Commands

`re-read-init-file (C-x C-r)`

Read in the contents of the inputrc file, and incorporate any bindings or variable assignments found there.

`abort (C-g)`

Abort the current editing command and ring the terminal's bell (subject to the setting of `bell-style`).

`do-uppercase-version (M-a, M-b, M-x, ...)`

If the metafied character x is lowercase, run the command that is bound to the corresponding uppercase character.

`prefix-meta (ESC)`

Make the next character typed be metafied. This is for keyboards without a meta key. Typing `ESC f' is equivalent to typing `M-f'.

`undo (C-_, C-x C-u)`

Incremental undo, separately remembered for each line.

`revert-line (M-r)`

Undo all changes made to this line. This is like executing the `undo` command enough times to get back to the beginning.

`tilde-expand (M-~)`

Perform tilde expansion on the current word.

`set-mark (C-@)`

Set the mark to the current point. If a numeric argument is supplied, the mark is set to that position.

`exchange-point-and-mark (C-x C-x)`

Swap the point with the mark. The current cursor position is set to the saved position, and the old cursor position is saved as the mark.

`character-search (C-])`

A character is read and point is moved to the next occurrence of that character. A negative count searches for previous occurrences.

`character-search-backward (M-C-])`

A character is read and point is moved to the previous occurrence of that character. A negative count searches for subsequent occurrences.

`insert-comment (M-#)`

The value of the `comment-begin` variable is inserted at the beginning of the current line, and the line is accepted as if a newline had been typed.

`dump-functions ()`

Print all of the functions and their key bindings to the Readline output stream. If a numeric argument is supplied, the output is formatted in such a way that it can be made part of an inputrc file. This command is unbound by default.

`dump-variables ()`

Print all of the settable variables and their values to the Readline output stream. If a numeric argument is supplied, the output is formatted in such a way that it can be made part of an inputrc file. This command is unbound by default.

`dump-macros ()`

Print all of the Readline key sequences bound to macros and the strings they ouput. If a numeric argument is supplied, the output is formatted in such a way that it can be made part of an inputrc file. This command is unbound by default.

Readline vi Mode

While the Readline library does not have a full set of `vi` editing functions, it does contain enough to allow simple editing of the line. The Readline `vi` mode behaves as specified in the POSIX 1003.2 standard.

In order to switch interactively between `emacs` and `vi` editing modes, use the command M-C-j (toggle-editing-mode). The Readline default is `emacs` mode.

When you enter a line in `vi` mode, you are already placed in `insertion' mode, as if you had typed an `i'. Pressing ESC switches you into `command' mode, where you can edit the text of the line with the standard `vi` movement keys, move to previous history lines with `k' and subsequent lines with `j', and so forth.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Using History Interactively

This chapter describes how to use the GNU History Library interactively, from a user's standpoint.

History Interaction

The History library provides a history expansion feature similar to the history expansion in `csh`. The following text describes the syntax you use to manipulate history information.

History expansion takes two parts. In the first part, determine which line from the previous history will be used for substitution. This line is called the **event**. In the second part, select portions of that line for inclusion into the current line. These portions are called **words**. GDB breaks the line into words in the same way that the Bash shell does, so that several English (or Unix) words surrounded by quotes are considered one word.

Event Designators

An **event designator** is a reference to a command line entry in the history list.

`!`
: Start a history subsititution, except when followed by a space, tab, or the end of the line... = or (.

`!!`
: Refer to the previous command. This is a synonym for `!-1`.

`!n`
: Refer to command line n.

`!-n`
: Refer to the command line n lines back.

`!string`
: Refer to the most recent command starting with string.

`!?string[?]`
: Refer to the most recent command containing string.

Word Designators

A : separates the event designator from the **word designator**. It can be omitted if the word designator begins with a ^, $, * or %. Words are numbered from the beginning of the line, with the first word being denoted by a 0 (zero).

`0 (zero)`

The zero'th word. For many applications, this is the command word.

`n`

The n'th word.

`^`

The first argument. that is, word 1.

`$`

The last argument.

`%`

The word matched by the most recent `?string?` search.

`x-y`

A range of words; `-y` Abbreviates `0-y`.

`*`

All of the words, excepting the zero'th. This is a synonym for `1-$`. It is not an error to use * if there is just one word in the event. The empty string is returned in that case.

Modifiers

After the optional word designator, you can add a sequence of one or more of the following **modifiers**, each preceded by a :.

`#`

The entire command line typed so far. This means the current command, not the previous command.

`h`

Remove a trailing pathname component, leaving only the head.

`r`

Remove a trailing suffix of the form `.'suffix, leaving the basename.

`e`

Remove all but the suffix.

`t`

Remove all leading pathname components, leaving the tail.

`p`

Print the new command but do not execute it.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Formatting Documentation

The GDB 4 release includes an already-formatted reference card, ready for printing with PostScript or Ghostscript, in the `gdb' subdirectory of the main source directory(4). If you can use PostScript or Ghostscript with your printer, you can print the reference card immediately with `refcard.ps'.

The release also includes the source for the reference card. You can format it, using TeX, by typing:

```
make refcard.dvi
```

The GDB reference card is designed to print in **landscape** mode on US "letter" size paper; that is, on a sheet 11 inches wide by 8.5 inches high. You will need to specify this form of printing as an option to your DVI output program.

All the documentation for GDB comes as part of the machine-readable distribution. The documentation is written in Texinfo format, which is a documentation system that uses a single source file to produce both on-line information and a printed manual. You can use one of the Info formatting commands to create the on-line version of the documentation and TeX (or `texi2roff`) to typeset the printed version.

GDB includes an already formatted copy of the on-line Info version of this manual in the `gdb' subdirectory. The main Info file is `gdb-4.18/gdb/gdb.info', and it refers to subordinate files matching `gdb.info*' in the same directory. If necessary, you can print out these files, or read them with any editor; but they are easier to read using the `info` subsystem in GNU Emacs or the standalone `info` program, available as part of the GNU Texinfo distribution.

If you want to format these Info files yourself, you need one of the Info formatting programs, such as `texinfo-format-buffer` or `makeinfo`.

If you have `makeinfo` installed, and are in the top level GDB source directory (`gdb-4.18', in the case of version 4.18), you can make the Info file by typing:

```
cd gdb
make gdb.info
```

If you want to typeset and print copies of this manual, you need TeX, a program to print its DVI output files, and `texinfo.tex', the Texinfo definitions file.

TeX is a typesetting program; it does not print files directly, but produces output files called DVI files. To print a typeset document, you need a program to print DVI files. If your system has TeX installed, chances are it has such a program. The precise command to use depends on your system; lpr -d is common; another (for PostScript devices) is dvips. The DVI print command may require a file name without any extension or a `.dvi' extension.

TeX also requires a macro definitions file called `texinfo.tex'. This file tells TeX how to typeset a document written in Texinfo format. On its own, TeX cannot either read or typeset a Texinfo file. `texinfo.tex' is distributed with GDB and is located in the `gdb-version-number/texinfo' directory.

If you have TeX and a DVI printer program installed, you can typeset and print this manual. First switch to the the `gdb' subdirectory of the main source directory (for example, to `gdb-4.18/gdb') and type:

```
make gdb.dvi
```

Then give `gdb.dvi' to your DVI printing program.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Installing GDB

GDB comes with a `configure` script that automates the process of preparing GDB for installation; you can then use `make` to build the `gdb` program. (5)

The GDB distribution includes all the source code you need for GDB in a single directory, whose name is usually composed by appending the version number to `gdb'.

For example, the GDB version 4.18 distribution is in the `` `gdb-4.18' `` directory. That directory contains:

`gdb-4.18/configure (and supporting files)`
: script for configuring GDB and all its supporting libraries

`gdb-4.18/gdb`
: the source specific to GDB itself

`gdb-4.18/bfd`
: source for the Binary File Descriptor library

`gdb-4.18/include`
: GNU include files

`gdb-4.18/libiberty`
: source for the `-liberty' free software library

`gdb-4.18/opcodes`
: source for the library of opcode tables and disassemblers

`gdb-4.18/readline`
: source for the GNU command-line interface

`gdb-4.18/glob`
: source for the GNU filename pattern-matching subroutine

`gdb-4.18/mmalloc`
: source for the GNU memory-mapped malloc package

The simplest way to configure and build GDB is to run `configure` from the `` `gdb-version-number' `` source directory, which in this example is the `` `gdb-4.18' `` directory.

First switch to the `` `gdb-version-number' `` source directory if you are not already in it; then run `configure`. Pass the identifier for the platform on which GDB will run as an argument.

For example:

```
cd gdb-4.18
```

```
./configure host
make
```

where host is an identifier such as `sun4' or `decstation', that identifies the platform where GDB will run. (You can often leave off host; `configure` tries to guess the correct value by examining your system.)

Running `configure host' and then running `make` builds the `bfd', `readline', `mmalloc', and `libiberty' libraries, then `gdb` itself. The configured source files, and the binaries, are left in the corresponding source directories.

`configure` is a Bourne-shell (`/bin/sh`) script; if your system does not recognize this automatically when you run a different shell, you may need to run `sh` on it explicitly:

```
sh configure host
```

If you run `configure` from a directory that contains source directories for multiple libraries or programs, such as the `gdb-4.18' source directory for version 4.18, `configure` creates configuration files for every directory level underneath (unless you tell it not to, with the `--norecursion' option).

You can run the `configure` script from any of the subordinate directories in the GDB distribution if you only want to configure that subdirectory, but be sure to specify a path to it.

For example, with version 4.18, type the following to configure only the `bfd` subdirectory:

```
cd gdb-4.18/bfd
../configure host
```

You can install `gdb` anywhere; it has no hardwired paths. However, you should make sure that the shell on your path (named by the `SHELL' environment variable) is publicly readable. Remember that GDB uses the shell to start your program--some systems refuse to let GDB debug child processes whose programs are not readable.

Compiling GDB in another directory

If you want to run GDB versions for several host or target machines, you need a different `gdb` compiled for each combination of host and target. `configure` is designed to make this easy by allowing you to generate each configuration in a separate subdirectory, rather than in the source directory. If your `make` program handles the `VPATH' feature (GNU `make` does), running `make` in each of these directories builds the `gdb` program specified there.

To build `gdb` in a separate directory, run `configure` with the `--srcdir' option to specify where to find the source. (You also need to specify a path to find `configure` itself from your working directory. If the path to `configure` would be the same as the argument to `--srcdir', you can leave out the `--srcdir' option; it is assumed.)

For example, with version 4.18, you can build GDB in a separate directory for a Sun 4 like this:

```
cd gdb-4.18
mkdir ../gdb-sun4
cd ../gdb-sun4
../gdb-4.18/configure sun4
make
```

When `configure` builds a configuration using a remote source directory, it creates a tree for the binaries with the same structure (and using the same names) as the tree under the source directory. In the example, you'd find the Sun 4 library `` `libiberty.a' `` in the directory `` `gdb-sun4/libiberty' ``, and GDB itself in `` `gdb-sun4/gdb' ``.

One popular reason to build several GDB configurations in separate directories is to configure GDB for cross-compiling (where GDB runs on one machine--the **host**---while debugging programs that run on another machine--the **target**). You specify a cross-debugging target by giving the `--target=target' option to `configure`.

When you run `make` to build a program or library, you must run it in a configured directory--whatever directory you were in when you called `configure` (or one of its subdirectories).

The `Makefile` that `configure` generates in each source directory also runs recursively. If you type `make` in a source directory such as `` `gdb-4.18' `` (or in a separate configured directory configured with `--srcdir=dirname/gdb-4.18'), you will build all the required libraries, and then build GDB.

When you have multiple hosts or targets configured in separate directories, you can run `make` on them in parallel (for example, if they are NFS-mounted on each of the hosts); they will not interfere with each other.

Specifying names for hosts and targets

The specifications used for hosts and targets in the `configure` script are based on a three-part naming scheme, but some short predefined aliases are also supported. The full naming scheme encodes three pieces of information in the following pattern:

```
architecture-vendor-os
```

For example, you can use the alias `sun4` as a host argument, or as the value for target in a `--target=target` option. The equivalent full name is `sparc-sun-sunos4'.

The `configure` script accompanying GDB does not provide any query facility to list all supported host and target names or aliases. `configure` calls the Bourne shell script `config.sub` to map abbreviations to full names; you can read the script, if you wish, or you can use it to test your guesses on abbreviations--for example:

```
% sh config.sub i386-linux
i386-pc-linux-gnu
% sh config.sub alpha-linux
```

```
alpha-unknown-linux-gnu
% sh config.sub hp9k700
hppa1.1-hp-hpux
% sh config.sub sun4
sparc-sun-sunos4.1.1
% sh config.sub sun3
m68k-sun-sunos4.1.1
% sh config.sub i986v
Invalid configuration `i986v': machine `i986v' not recognized
```

`config.sub` is also distributed in the GDB source directory (`gdb-4.18', for version 4.18).

`configure` options

Here is a summary of the `configure` options and arguments that are most often useful for building GDB. `configure` also has several other options not listed here. See Info file `configure.info', node `What Configure Does', for a full explanation of `configure`.

```
configure [--help]
          [--prefix=dir]
          [--exec-prefix=dir]
          [--srcdir=dirname]
          [--norecursion] [--rm]
          [--target=target]
          host
```

You may introduce options with a single `-' rather than `--' if you prefer; but you may abbreviate option names if you use `--'.

`--help`
: Display a quick summary of how to invoke `configure`.

`--prefix=dir`
: Configure the source to install programs and files under directory `dir'.

`--exec-prefix=dir`
: Configure the source to install programs under directory `dir'.

`--srcdir=dirname`
: **Warning: using this option requires GNU `make`, or another `make` that implements the `VPATH` feature.**
Use this option to make configurations in directories separate from the GDB source directories. Among other things, you can use this to build (or maintain) several configurations simultaneously, in separate directories. `configure` writes configuration specific files in the current directory, but arranges for them to use the source in the directory dirname. `configure` creates directories under the working directory in parallel to the source directories below dirname.

`--norecursion`

Configure only the directory level where `configure` is executed; do not propagate configura to subdirectories.

`--target=target`

Configure GDB for cross-debugging programs running on the specified target. Without this option, GDB is configured to debug programs that run on the same machine (host) as GDB itself. There is no convenient way to generate a list of all available targets.

`host ...`

Configure GDB to run on the specified host. There is no convenient way to generate a list of all available hosts.

There are many other options available as well, but they are generally needed for special purposes only.

Debugging with GDB

The GNU Source-Level Debugger

Seventh Edition, for GDB version 4.18

February 1999

Richard M. Stallman and Roland H. Pesch

---

(1)

`b' cannot be used because these format letters are also used with the `x` command, where `b' stands for "byte"; see section Examining memory.

(2)

This is a way of removing one word from the stack, on machines where stacks grow downward in memory (most machines, nowadays). This assumes that the innermost stack frame is selected; setting `$sp` is not allowed when other stack frames are selected. To pop entire frames off the stack, regardless of machine architecture, use `return`; see section Returning from a function.

(3)

If you choose a port number that conflicts with another service, `gdbserver` prints an error message and exits.

(4)

In `` `gdb-4.18/gdb/refcard.ps' `` of the version 4.18 release.

(5)

If you have a more recent version of GDB than 4.18, look at the `` `README' `` file in the sources; we may have improved the installation procedures since publishing this manual.

This document was generated on 20 May 1999 using the texi2html translator version 1.51a.

gdbm

Go to the next section.

Copying Conditions.

This library is free; this means that everyone is free to use it and free to redistribute it on a free basis. GNU `dbm` (`gdbm`) is not in the public domain; it is copyrighted and there are restrictions on its distribution, but these restrictions are designed to permit everything that a good cooperating citizen would want to do. What is not allowed is to try to prevent others from further sharing any version of `gdbm` that they might get from you.

Specifically, we want to make sure that you have the right to give away copies `gdbm`, that you receive source code or else can get it if you want it, that you can change these functions or use pieces of them in new free programs, and that you know you can do these things.

To make sure that everyone has such rights, we have to forbid you to deprive anyone else of these rights. For example, if you distribute copies `gdbm`, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must tell them their rights.

Also, for our own protection, we must make certain that everyone finds out that there is no warranty for anything in the `gdbm` distribution. If these functions are modified by someone else and passed on, we want their recipients to know that what they have is not what we distributed, so that any problems introduced by others will not reflect on our reputation.

`gdbm` is currently distributed under the terms of the GNU General Public License, Version 2. (*NOT* under the GNU General Library Public License.) A copy the GNU General Public License is included with the distribution of `gdbm`.

Go to the next section.

Go to the previous, next section.

Introduction to GNU dbm.

GNU `dbm` (`gdbm`)is a library of database functions that use extendible hashing and works similar to the standard UNIX `dbm` functions. These routines are provided to a programmer needing to create and manipulate a hashed database. (`gdbm` is *NOT* a complete database package for an end user.)

The basic use of `gdbm` is to store key/data pairs in a data file. Each key must be unique and each key is paired with only one data item. The keys can not be directly accessed in sorted order. The basic unit of data in `gdbm` is the structure:

```
typedef struct {
           char *dptr;
           int  dsize;
         } datum;
```

This structure allows for arbitrary sized keys and data items.

The key/data pairs are stored in a `gdbm` disk file, called a `gdbm` database. An application must open a `gdbm` database to be able manipulate the keys and data contained in the database. `gdbm` allows an application to have multiple databases open at the same time. When an application opens a `gdbm` database, it is designated as a `reader` or a `writer`. A `gdbm` database opened by at most one writer at a time. However, many readers may open the database open simultaneously. Readers and writers can not open the `gdbm` database at the same time.

Go to the previous, next section.

Go to the previous, next section.

List of functions.

The following is a quick list of the functions contained in the `gdbm` library. The include file `gdbm.h`, that can be included by the user, contains a definition of these functions.

```
#include <gdbm.h>

GDBM_FILE gdbm_open(name, block_size, flags, mode, fatal_func);
void gdbm_close(dbf);
int gdbm_store(dbf, key, content, flag);
datum gdbm_fetch(dbf, key);
int gdbm_delete(dbf, key);
datum gdbm_firstkey(dbf);
datum gdbm_nextkey(dbf, key);
int gdbm_reorganize(dbf);
void gdbm_sync(dbf);
int gdbm_exists(dbf, key);
char *gdbm_strerror(errno);
int gdbm_setopt(dbf, option, value, size)
```

The `gdbm.h` include file is often in the `` `/usr/local/gnu/include' `` directory. (The actual location of `gdbm.h` depends on your local installation of `gdbm`.)

Go to the previous, next section.

Go to the previous, next section.

Opening the database.

Initialize gdbm system. If the file has a size of zero bytes, a file initialization procedure is performed, setting up the initial structure in the file.

The procedure for opening a gdbm file is:

```
GDBM_FILE dbf;

dbf = gdbm_open(name, block_size, flags, mode, fatal_func);
```

The parameters are:

char *name

The name of the file (the complete name, gdbm does not append any characters to this name).

int block_size

It is used during initialization to determine the size of various constructs. It is the size of a single transfer from disk to memory. This parameter is ignored if the file has been previously initialized. The minimum size is 512. If the value is less than 512, the file system blocksize is used, otherwise the value of block_size is used.

int flags

If flags is set to GDBM_READER, the user wants to just read the database and any call to gdbm_store or gdbm_delete will fail. Many readers can access the database at the same time. If flags is set to GDBM_WRITER, the user wants both read and write access to the database and requires exclusive access. If flags is set to GDBM_WRCREAT, the user wants both read and write access to the database and if the database does not exist, create a new one. If flags is set to GDBM_NEWDB, the user want a new database created, regardless of whether one existed, and wants read and write access to the new database. For all writers (GDBM_WRITER, GDBM_WRCREAT and GDBM_NEWDB) the value GDBM_FAST can be added to the flags field using logical or. This option causes gdbm to write the database without any disk file synchronization. This allows faster writes, but may produce an inconsistent database in the event of abnormal termination of the writer. Any error detected will cause a return value of NULL and an appropriate value will be in gdbm_errno (see Variables). If no errors occur, a pointer to the gdbm file descriptor will be returned.

int mode

File mode (see chmod(2) and open(2) if the file is created).

void (*fatal_func) ()

A function for gdbm to call if it detects a fatal error. The only parameter of this function is a string. If the value of NULL is provided, gdbm will use a default function.

The return value, dbf, is the pointer needed by all other functions to access that gdbm file. If the return

is the NULL pointer, `gdbm_open` was not successful. The errors can be found in `gdbm_errno` for `gdbm` errors and in `errno` for file system errors (for error codes, see `gdbm.h`).

In all of the following calls, the parameter `dbf` refers to the pointer returned from `gdbm_open`.

Go to the previous, next section.

Go to the previous, next section.

Closing the database.

It is important that every file opened is also closed. This is needed to update the reader/writer count on the file. This is done by:

```
gdbm_close(dbf);
```

The parameter is:

GDBM_FILE dbf

The pointer returned by `gdbm_open`.

Closes the `gdbm` file and frees all memory associated with the file `dbf`.

Go to the previous, next section.

Go to the previous, next section.

Inserting and replacing records in the database.

The function `gdbm_store` inserts or replaces records in the database.

```
ret = gdbm_store(dbf, key, content, flag);
```

The parameters are:

GDBM_FILE dbf

The pointer returned by `gdbm_open`.

datum key

The `key` data.

datum content

The data to be associated with the key.

int flag

Defines the action to take when the key is already in the database. The value GDBM_REPLACE (defined in `gdbm.h`) asks that the old data be replaced by the new `content`. The value GDBM_INSERT asks that an error be returned and no action taken if the `key` already exists.

The values returned in `ret` are:

-1

The item was not stored in the database because the caller was not an official writer or either `key` or `content` have a NULL dptr field. Both `key` and `content` must have the dptr field be a non-NULL value. Since a NULL dptr field is used by other functions to indicate an error, a NULL field cannot be valid data.

+1

The item was not stored because the argument `flag` was GDBM_INSERT and the `key` was already in the database.

0

No error. `content` is keyed by `key`. The file on disk is updated to reflect the structure of the new database before returning from this function.

If you store data for a `key` that is already in the data base, `gdbm` replaces the old data with the new data if called with GDBM_REPLACE. You do not get two data items for the same `key` and you do not get an error from `gdbm_store`.

The size in `gdbm` is not restricted like `dbm` or `ndbm`. Your data can be as large as you want.

Go to the previous, next section.

Go to the previous, next section.

Searching for records in the database.

Looks up a given `key` and returns the information associated with that key. The pointer in the structure that is returned is a pointer to dynamically allocated memory block. To search for some data:

```
content = gdbm_fetch(dbf, key);
```

The parameters are:

GDBM_FILE dbf

The pointer returned by `gdbm_open`.

datum key

The `key` data.

The datum returned in `content` is a pointer to the data found. If the dptr is NULL, no data was found. If dptr is not NULL, then it points to data allocated by malloc. `gdbm` does not automatically free this data. The user must free this storage when done using it. This eliminates the need to copy the result to save it for later use (you just save the pointer).

You may also search for a particular key without retrieving it, using:

```
ret = gdbm_exists(dbf, key);
```

The parameters are:

GDBM_FILE dbf

The pointer returned by `gdbm_open`.

datum key

The `key` data.

Unlike `gdbm_fetch`, this routine does not allocate any memory, and simply returns true or false, depending on whether the `key` exists, or not.

Go to the previous, next section.

Go to the previous, next section.

Removing records from the database.

To remove some data from the database:

```
ret = gdbm_delete(dbf, key);
```

The parameters are:

GDBM_FILE dbf

The pointer returned by `gdbm_open`.

datum key

The `key` data.

The ret value is -1 if the item is not present or the requester is a reader. The ret value is 0 if there was a successful delete.

`gdbm_delete` removes the keyed item and the `key` from the database `dbf`. The file on disk is updated to reflect the structure of the new database before returning from this function.

Go to the previous, next section.

Go to the previous, next section.

TOC

Sequential access to records.

The next two functions allow for accessing all items in the database. This access is not `key` sequential, but it is guaranteed to visit every `key` in the database once. The order has to do with the hash values. `gdbm_firstkey` starts the visit of all keys in the database. `gdbm_nextkey` finds and reads the next entry in the hash structure for `dbf`.

```
key = gdbm_firstkey(dbf);

nextkey = gdbm_nextkey(dbf, key);
```

The parameters are:

GDBM_FILE dbf

The pointer returned by `gdbm_open`.

datum `key`

datum nextkey

The `key` data.

The return values are both datum. If `key`.dptr or nextkey.dptr is NULL, there is no first `key` or next `key`. Again notice that dptr points to data allocated by malloc and `gdbm` will not free it for you.

These functions were intended to visit the database in read-only algorithms, for instance, to validate the database or similar operations.

File `visiting` is based on a `hash table`. `gdbm_delete` re-arranges the hash table to make sure that any collisions in the table do not leave some item `un-findable`. The original key order is NOT guaranteed to remain unchanged in ALL instances. It is possible that some key will not be visited if a loop like the following is executed:

```
key = gdbm_firstkey ( dbf );
while ( key.dptr ) {
   nextkey = gdbm_nextkey ( dbf, key );
   if ( some condition ) {
      gdbm_delete ( dbf, key );
      free ( key.dptr );
   }
   key = nextkey;
}
```

Go to the previous, next section.

Go to the previous, next section.

Database reorganization.

The following function should be used very seldom.

```
ret = gdbm_reorganize(dbf);
```

The parameter is:

GDBM_FILE dbf

The pointer returned by `gdbm_open`.

If you have had a lot of deletions and would like to shrink the space used by the `gdbm` file, this function will reorganize the database. `gdbm` will not shorten the length of a `gdbm` file (deleted file space will be reused) except by using this reorganization.

This reorganization requires creating a new file and inserting all the elements in the old file `dbf` into the new file. The new file is then renamed to the same name as the old file and `dbf` is updated to contain all the correct information about the new file. If an error is detected, the return value is negative. The value zero is returned after a successful reorganization.

Go to the previous, next section.

TOC

Go to the previous, next section.

Database Synchronization

If your database was opened with the GDBM_FAST flag, `gdbm` does not wait for writes to the disk to complete before continuing. This allows faster writing of databases at the risk of having a corrupted database if the application terminates in an abnormal fashion. The following function allows the programmer to make sure the disk version of the database has been completely updated with all changes to the current time.

```
gdbm_sync(dbf);
```

The parameter is:

GDBM_FILE dbf

> The pointer returned by `gdbm_open`.

This would usually be called after a complete set of changes have been made to the database and before some long waiting time. `gdbm_close` automatically calls the equivalent of `gdbm_sync` so no call is needed if the database is to be closed immediately after the set of changes have been made.

Go to the previous, next section.

Go to the previous, next section.

Error strings.

To convert a `gdbm` error code into English text, use this routine:

```
ret = gdbm_strerror(errno)
```

The parameter is:

gdbm_error errno

The `gdbm` error code, usually `gdbm_errno`.

The appropiate phrase for reading by humans is returned.

Go to the previous, next section.

Go to the previous, next section.

Seting options.

`Gdbm` now supports the ability to set certain options on an already open database.

```
ret = gdbm_setopt(dbf, option, value, size)
```

The parameters are:

GDBM_FILE dbf

The pointer returned by `gdbm_open`.

int option

The option to be set.

int *value

A pointer to the value to which `option` will be set.

int size

The length of the data pointed to by `value`.

The only legal option currently is GDBM_CACHESIZE, which sets the size of the internal bucket cache. This option may only be set once on each GDBM_FILE descriptor, and is set automatically to 100 upon the first access to the database.

The return value will be -1 upon failure, or 0 upon success. The global variable `gdbm_errno` will be set upon failure.

For instance, to set a database to use a cache of 10, after opening it with `gdbm_open`, but prior to accessing it in any way, the following code could be used:

```
int value = 10;
ret = gdbm_setopt(dbf, GDBM_CACHESIZE, &value, sizeof(int));
```

Go to the previous, next section.

Go to the previous, next section.

Two useful variables.

The following two variables are variables that may need to be used:

gdbm_error gdbm_errno

: The variable that contains more information about `gdbm` errors (`gdbm.h` has the definitions of the error values).

char * gdbm_version

: The string containing the version information.

Go to the previous, next section.

Go to the previous, next section.

Compatibility with standard dbm and ndbm.

GNU `dbm` files are not `sparse`. You can copy them with the UNIX `cp` command and they will not expand in the copying process.

There is a compatibility mode for use with programs that already use UNIX `dbm` and UNIX `ndbm`.

GNU `dbm` has compatibility functions for `dbm`. For `dbm` compatibility functions, you need the include file `dbm.h`.

In this compatibility mode, no `gdbm` file pointer is required by the user, and Only one file may be opened at a time. All users in compatibility mode are assumed to be writers. If the `gdbm` file is a read only, it will fail as a writer, but will also try to open it as a reader. All returned pointers in datum structures point to data that `gdbm` WILL free. They should be treated as static pointers (as standard UNIX `dbm` does). The compatibility function names are the same as the UNIX `dbm` function names. Their definitions follow:

```
int dbminit(name);
int store(key, content);
datum fetch(key);
int delete(key);
datum firstkey();
datum nextkey(key);
int dbmclose();
```

Standard UNIX `dbm` and GNU `dbm` do not have the same data format in the file. You cannot access a standard UNIX `dbm` file with GNU `dbm`! If you want to use an old database with GNU `dbm`, you must use the `conv2gdbm` program.

Also, GNU `dbm` has compatibility functions for `ndbm`. For `ndbm` compatibility functions, you need the include file `ndbm.h`.

Again, just like `ndbm`, any returned datum can be assumed to be static storage. You do not have to free that memory, the `ndbm` compatibility functions will do it for you.

The functions are:

```
DBM *dbm_open(name, flags, mode);
void dbm_close(file);
datum dbm_fetch(file, key);
int dbm_store(file, key, content, flags);
int dbm_delete(file, key);
```

```
datum dbm_firstkey(file);
datum dbm_nextkey(file);
int dbm_error(file);
int dbm_clearerr(file);
int dbm_dirfno(file);
int dbm_pagfno(file);
int dbm_rdonly(file);
```

If you want to compile an old C program that used UNIX `dbm` or `ndbm` and want to use `gdbm` files, execute the following `cc` command:

```
cc ... -L /usr/local/lib -lgdbm
```

Go to the previous, next section.

Go to the previous, next section.

Converting dbm files to gdbm format.

The program `conv2gdbm` has been provided to help you convert from `dbm` databases to `gdbm`. The usage is:

```
conv2gdbm [-q] [-b block_size] dbm_file [gdbm_file]
```

The options are:

-q
: Causes `conv2gdbm` to work quietly.

block_size
: Is the same as in `gdbm_open`.

dbm_file
: Is the name of the `dbm` file without the `.pag` or `.dir` extensions.

gdbm_file
: Is the complete file name. If not included, the `gdbm` file name is the same as the `dbm` file name without any extensions. That is `conv2gdbm dbmfile` converts the files `dbmfile.pag` and `dbmfile.dir` into a `gdbm` file called `dbmfile`.

Go to the previous, next section.

Go to the previous section.

Problems and bugs.

If you have problems with GNU `dbm` or think you've found a bug, please report it. Before reporting a bug, make sure you've actually found a real bug. Carefully reread the documentation and see if it really says you can do what you're trying to do. If it's not clear whether you should be able to do something or not, report that too; it's a bug in the documentation!

Before reporting a bug or trying to fix it yourself, try to isolate it to the smallest possible input file that reproduces the problem. Then send us the input file and the exact results `gdbm` gave you. Also say what you expected to occur; this will help us decide whether the problem was really in the documentation.

Once you've got a precise problem, send e-mail to:

```
Internet: `bug-gnu-utils@prep.ai.mit.edu'.
UUCP: `mit-eddie!prep.ai.mit.edu!bug-gnu-utils'.
```

Please include the version number of GNU `dbm` you are using. You can get this information by printing the variable `gdbm_version` (see Variables).

Non-bug suggestions are always welcome as well. If you have questions about things that are unclear in the documentation or are just obscure features, please report them too.

You may contact the author by:

```
   e-mail:  phil@cs.wwu.edu
 us-mail:  Philip A. Nelson
           Computer Science Department
           Western Washington University
           Bellingham, WA 98226
```

Comparing and Merging Files

`diff`, `diff3`, `sdiff`, `cmp`, and `patch`

Edition 1.1, for `diff` 2.1 and `patch` 2.0.12g8

January 1993

by David MacKenzie, Paul Eggert, and Richard Stallman

Comparing and Merging Files

Overview

Computer users often find occasion to ask how two files differ. Perhaps one file is a newer version of the other file. Or maybe the two files started out as identical copies but were changed by different people.

You can use the `diff` command to show differences between two files, or each corresponding file in two directories. `diff` outputs differences between files line by line in any of several formats, selectable by command line options. This set of differences is often called a diff or patch. For files that are identical, `diff` normally produces no output; for binary (non-text) files, `diff` normally reports only that they are different.

You can use the `cmp` command to show the offsets and line numbers where two files differ. `cmp` can also show all the characters that differ between the two files, side by side. Another way to compare two files character by character is the Emacs command M-x compare-windows. See section 'Other Window' in The GNU Emacs Manual, for more information on that command.

You can use the `diff3` command to show differences among three files. When two people have made independent changes to a common original, `diff3` can report the differences between the original and the two changed versions, and can produce a merged file that contains both persons' changes together with warnings about conflicts.

You can use the `sdiff` command to merge two files interactively.

You can use the set of differences produced by `diff` to distribute updates to text files (such as program source code) to other people. This method is especially useful when the differences are small compared to the complete files. Given `diff` output, you can use the `patch` program to update, or patch, a copy of the file. If you think of `diff` as subtracting one file from another to produce their difference, you can think of `patch` as adding the difference to one file to reproduce the other.

This manual first concentrates on making diffs, and later shows how to use diffs to update files.

GNU `diff` was written by Mike Haertel, David Hayes, Richard Stallman, Len Tower, and Paul Eggert. Wayne Davison designed and implemented the unified output format. The basic algorithm is described in "An O(ND) Difference Algorithm and its Variations", Eugene Myers, Algorithmica Vol. 1 No. 2, 1986, p. 251; and in "A File Comparison Program", W. Miller and E. Myers, Software Practice and Experience Vol. 15 No. 11, 1985, p. 1025. GNU `diff3` was written by Randy Smith. GNU `sdiff` was written by Thomas Lord. GNU `cmp` was written by Torbjorn Granlund and David MacKenzie.

`patch` was written mainly by Larry Wall; the GNU enhancements were written mainly by Wayne Davison and David MacKenzie. Parts of this manual are adapted from a manual page written by Larry Wall, with his permission.

What Comparison Means

There are several ways to think about the differences between two files. One way to think of the differences is as a series of lines that were deleted from, inserted in, or changed in one file to produce the other file. `diff` compares two files line by line, finds groups of lines that differ, and reports each group of differing lines. It can report the differing lines in several formats, which have different purposes.

GNU `diff` can show whether files are different without detailing the differences. It also provides ways to suppress certain kinds of differences that are not important to you. Most commonly, such differences are changes in the amount of whitespace between words or lines. `diff` also provides ways to suppress differences in alphabetic case or in lines that match a regular expression that you provide. These options can accumulate; for example, you can ignore changes in both whitespace and alphabetic case.

Another way to think of the differences between two files is as a sequence of pairs of characters that can be either identical or different. `cmp` reports the differences between two files character by character, instead of line by line. As a result, it is more useful than `diff` for comparing binary files. For text files, `cmp` is useful mainly when you want to know only whether two files are identical. For this purpose, it is better than `diff` because it is much faster.

To illustrate the effect that considering changes character by character can have compared with considering them line by line, think of what happens if a single newline character is added to the beginning of a file. If that file is then compared with an otherwise identical file that lacks the newline at the beginning, `diff` will report that a blank line has been added to the file, while `cmp` will report that almost every character of the two files differs.

`diff3` normally compares three input files line by line, finds groups of lines that differ, and reports each group of differing lines. Its output is designed to make it easy to inspect two different sets of changes to the same file.

Hunks

When comparing two files, `diff` finds sequences of lines common to both files, interspersed with groups of differing lines called hunks. Comparing two identical files yields one sequence of common lines and no hunks, because no lines differ. Comparing two entirely different files yields no common lines and one large hunk that contains all lines of both files. In general, there are many ways to match up lines between two given files. `diff` tries to minimize the total hunk size by finding large sequences of common lines interspersed with small hunks of differing lines.

For example, suppose the file `` `F' `` contains the three lines `a', `b', `c', and the file `` `G' `` contains the same three lines in reverse order `c', `b', `a'. If `diff` finds the line `c' as common, then the command `diff F G' produces this output:

```
1,2d0
< a
< b
3a2,3
```

```
> b
> a
```

But if `diff` notices the common line `b' instead, it produces this output:

```
1c1
< a
---
> c
3c3
< c
---
> a
```

It is also possible to find `a' as the common line. `diff` does not always find an optimal matching between the files; it takes shortcuts to run faster. But its output is usually close to the shortest possible. You can adjust this tradeoff with the `--minimal' option (see section `diff` Performance Tradeoffs).

Suppressing Differences in Blank and Tab Spacing

The `-b' and `--ignore-space-change' options ignore blanks and tabs at line end, and to consider all other sequences of one or more blank and tab characters to be equivalent. With these options, `diff` considers the following two lines to be equivalent, where `$' denotes the line end:

```
Here lyeth  muche rychnesse  in lytell space.   -- John Heywood$
Here lyeth muche rychnesse in lytell space. -- John Heywood   $
```

The `-w' and `--ignore-all-space' options are stronger than `-b'. They ignore difference even if one file has whitespace where the other file has none, and they ignore all whitespace characters, not just blanks and tabs. (The whitespace characters include backspace, tab, vertical tab, formfeed, carriage return, space, and no-break space.) With these options, `diff` considers the following two lines to be equivalent, where `$' denotes the line end and `^M' denotes a carriage return:

```
Here lyeth  muche  rychnesse in lytell space.--  John Heywood$
  He relyeth much erychnes  seinly tells pace.  --John Heywood   ^M$
```

Suppressing Differences in Blank Lines

The `-B' and `--ignore-blank-lines' options ignore insertions or deletions of blank lines. These options normally affect only lines that are completely empty; they do not affect lines that look empty but contain space or tab characters. With these options, for example, a file containing

```
1.  A point is that which has no part.

2.  A line is breadthless length.
```

```
-- Euclid, The Elements, I
```

is considered identical to a file containing

```
1.  A point is that which has no part.
2.  A line is breadthless length.

-- Euclid, The Elements, I
```

Suppressing Case Differences

GNU `diff` can treat lowercase letters as equivalent to their uppercase counterparts, so that, for example, it considers `Funky Stuff', `funky STUFF', and `fUNKy stuFf' to all be the same. To request this, use the `-i' or `--ignore-case' option.

Suppressing Lines Matching a Regular Expression

To ignore insertions and deletions of lines that match a regular expression, use the `-I regexp' or `--ignore-matching-lines=regexp' option. You should escape regular expressions that contain shell metacharacters to prevent the shell from expanding them. For example, `diff -I '^[0-9]" ignores all changes to lines beginning with a digit.

However, `-I' only ignores the insertion or deletion of lines that contain the regular expression if every changed line in the hunk--every insertion and every deletion--matches the regular expression. In other words, for each nonignorable change, `diff` prints the complete set of changes in its vicinity, including the ignorable ones.

You can specify more than one regular expression for lines to ignore by using more than one `-I' option. `diff` tries to match each line against each regular expression, starting with the last one given.

Summarizing Which Files Differ

When you only want to find out whether files are different, and you don't care what the differences are, you can use the summary output format. In this format, instead of showing the differences between the files, `diff` simply reports whether files differ. The `-q' and `--brief' options select this output format.

This format is especially useful when comparing the contents of two directories. It is also much faster than doing the normal line by line comparisons, because `diff` can stop analyzing the files as soon as it knows that there are any differences.

You can also get a brief indication of whether two files differ by using `cmp`. For files that are identical, `cmp` produces no output. When the files differ, by default, `cmp` outputs the byte offset and line number where the first difference occurs. You can use the `-s' option to suppress that information, so that `cmp` produces no output and reports whether the files differ using only its exit status (see section Invoking `cmp`).

Unlike `diff`, `cmp` cannot compare directories; it can only compare two files.

Binary Files and Forcing Text Comparisons

If `diff` thinks that either of the two files it is comparing is binary (a non-text file), it normally treats that pair of files much as if the summary output format had been selected (see section Summarizing Which Files Differ), and reports only that the binary files are different. This is because line by line comparisons are usually not meaningful for binary files.

`diff` determines whether a file is text or binary by checking the first few bytes in the file; the exact number of bytes is system dependent, but it is typically several thousand. If every character in that part of the file is non-null, `diff` considers the file to be text; otherwise it considers the file to be binary.

Sometimes you might want to force `diff` to consider files to be text. For example, you might be comparing text files that contain null characters; `diff` would erroneously decide that those are non-text files. Or you might be comparing documents that are in a format used by a word processing system that uses null characters to indicate special formatting. You can force `diff` to consider all files to be text files, and compare them line by line, by using the `-a' or `--text' option. If the files you compare using this option do not in fact contain text, they will probably contain few newline characters, and the `diff` output will consist of hunks showing differences between long lines of whatever characters the files contain.

You can also force `diff` to consider all files to be binary files, and report only whether they differ (but not how). Use the `--brief' option for this.

If you want to compare two files byte by byte, you can use the `cmp` program with the `-l' option to show the values of each differing byte in the two files. With GNU `cmp`, you can also use the `-c' option to show the ASCII representation of those bytes. See section Invoking `cmp`, for more information.

If `diff3` thinks that any of the files it is comparing is binary (a non-text file), it normally reports an error, because such comparisons are usually not useful. `diff3` uses the same test as `diff` to decide whether a file is binary. As with `diff`, if the input files contain a few non-text characters but otherwise are like text files, you can force `diff3` to consider all files to be text files and compare them line by line by using the `-a' or `--text' options.

`diff` Output Formats

`diff` has several mutually exclusive options for output format. The following sections describe each format, illustrating how `diff` reports the differences between two sample input files.

Two Sample Input Files

Here are two sample files that we will use in numerous examples to illustrate the output of `diff` and how various options can change it.

This is the file `lao':

```
The Way that can be told of is not the eternal Way;
The name that can be named is not the eternal name.
The Nameless is the origin of Heaven and Earth;
The Named is the mother of all things.
Therefore let there always be non-being,
  so we may see their subtlety,
And let there always be being,
  so we may see their outcome.
The two are the same,
But after they are produced,
  they have different names.
```

This is the file `tzu':

```
The Nameless is the origin of Heaven and Earth;
The named is the mother of all things.

Therefore let there always be non-being,
  so we may see their subtlety,
And let there always be being,
  so we may see their outcome.
The two are the same,
But after they are produced,
  they have different names.
They both may be called deep and profound.
Deeper and more profound,
The door of all subtleties!
```

In this example, the first hunk contains just the first two lines of `lao', the second hunk contains the fourth line of `lao' opposing the second and third lines of `tzu', and the last hunk contains just the last three lines of `tzu'.

Showing Differences Without Context

The "normal" `diff` output format shows each hunk of differences without any surrounding context. Sometimes such output is the clearest way to see how lines have changed, without the clutter of nearby unchanged lines (although you can get similar results with the context or unified formats by using 0 lines of context). However, this format is no longer widely used for sending out patches; for that purpose, the context format (see section Context Format) and the unified format (see section Unified Format) are superior. Normal format is the default for compatibility with older versions of `diff` and the POSIX standard.

Detailed Description of Normal Format

The normal output format consists of one or more hunks of differences; each hunk shows one area where the files differ. Normal format hunks look like this:

```
change-command
< from-file-line
< from-file-line...
---
> to-file-line
> to-file-line...
```

There are three types of change commands. Each consists of a line number or comma-separated range of lines in the first file, a single character indicating the kind of change to make, and a line number or comma-separated range of lines in the second file. All line numbers are the original line numbers in each file. The types of change commands are:

`lar'

Add the lines in range r of the second file after line l of the first file. For example, `8a12,15' means append lines 12--15 of file 2 after line 8 of file 1; or, if changing file 2 into file 1, delete lines 12--15 of file 2.

`fct'

Replace the lines in range f of the first file with lines in range t of the second file. This is like a combined add and delete, but more compact. For example, `5,7c8,10' means change lines 5--7 of file 1 to read as lines 8--10 of file 2; or, if changing file 2 into file 1, change lines 8--10 of file 2 to read as lines 5--7 of file 1.

`rdl'

Delete the lines in range r from the first file; line l is where they would have appeared in the second file had they not been deleted. For example, `5,7d3' means delete lines 5--7 of file 1; or, if changing file 2 into file 1, append lines 5--7 of file 1 after line 3 of file 2.

An Example of Normal Format

Here is the output of the command `diff lao tzu' (see section Two Sample Input Files, for the complete contents of the two files). Notice that it shows only the lines that are different between the two files.

```
1,2d0
< The Way that can be told of is not the eternal Way;
< The name that can be named is not the eternal name.
4c2,3
< The Named is the mother of all things.
---
> The named is the mother of all things.
>
11a11,13
```

```
> They both may be called deep and profound.
> Deeper and more profound,
> The door of all subtleties!
```

Showing Differences in Their Context

Usually, when you are looking at the differences between files, you will also want to see the parts of the files near the lines that differ, to help you understand exactly what has changed. These nearby parts of the files are called the context.

GNU `diff` provides two output formats that show context around the differing lines: context format and unified format. It can optionally show in which function or section of the file the differing lines are found.

If you are distributing new versions of files to other people in the form of `diff` output, you should use one of the output formats that show context so that they can apply the diffs even if they have made small changes of their own to the files. `patch` can apply the diffs in this case by searching in the files for the lines of context around the differing lines; if those lines are actually a few lines away from where the diff says they are, `patch` can adjust the line numbers accordingly and still apply the diff correctly. See section Applying Imperfect Patches, for more information on using `patch` to apply imperfect diffs.

Context Format

The context output format shows several lines of context around the lines that differ. It is the standard format for distributing updates to source code.

To select this output format, use the `-C lines', `--context[=lines]', or `-c' option. The argument lines that some of these options take is the number of lines of context to show. If you do not specify lines, it defaults to three.

Detailed Description of Context Format

The context output format starts with a two-line header, which looks like this:

```
*** from-file from-file-modification-time
--- to-file to-file-modification time
```

You can change the header's content with the `-L label' or `--label=label' option; see section Showing Alternate File Names.

Next come one or more hunks of differences; each hunk shows one area where the files differ. Context format hunks look like this:

```
***************
*** from-file-line-range ****
  from-file-line
  from-file-line...
--- to-file-line-range ----
```

```
  to-file-line
  to-file-line...
```

The lines of context around the lines that differ start with two space characters. The lines that differ between the two files start with one of the following indicator characters, followed by a space character:

`!'

A line that is part of a group of one or more lines that changed between the two files. There is a corresponding group of lines marked with `!' in the part of this hunk for the other file.

`+'

An "inserted" line in the second file that corresponds to nothing in the first file.

`-'

A "deleted" line in the first file that corresponds to nothing in the second file.

If all of the changes in a hunk are insertions, the lines of from-file are omitted. If all of the changes are deletions, the lines of to-file are omitted.

An Example of Context Format

Here is the output of `diff -c lao tzu' (see section Two Sample Input Files, for the complete contents of the two files). Notice that up to three lines that are not different are shown around each line that is different; they are the context lines. Also notice that the first two hunks have run together, because their contents overlap.

```

Unified Format

The unified output format is a variation on the context format that is more compact because it omits redundant context lines. To select this output format, use the `-U lines', `--unified[=lines]', or `-u' option. The argument lines is the number of lines of context to show. When it is not given, it defaults to three.

At present, only GNU `diff` can produce this format and only GNU `patch` can automatically apply diffs in this format.

Detailed Description of Unified Format

The unified output format starts with a two-line header, which looks like this:

```
--- from-file from-file-modification-time
+++ to-file to-file-modification-time
```

You can change the header's content with the `-L label' or `--label=label' option; see See section Showing Alternate File Names.

Next come one or more hunks of differences; each hunk shows one area where the files differ. Unified format hunks look like this:

```
@@ from-file-range to-file-range @@
 line-from-either-file
 line-from-either-file...
```

The lines common to both files begin with a space character. The lines that actually differ between the two files have one of the following indicator characters in the left column:

`+'
: A line was added here to the first file.

`-'
: A line was removed here from the first file.

An Example of Unified Format

Here is the output of the command `diff -u lao tzu' (see section Two Sample Input Files, for the complete contents of the two files):

```

Showing Which Sections Differences Are in

Sometimes you might want to know which part of the files each change falls in. If the files are source code, this could mean which function was changed. If the files are documents, it could mean which chapter or appendix was changed. GNU `diff` can show this by displaying the nearest section heading line that precedes the differing lines. Which lines are "section headings" is determined by a regular expression.

Showing Lines That Match Regular Expressions

To show in which sections differences occur for files that are not source code for C or similar languages, use the `-F regexp' or `--show-function-line=regexp' option. `diff` considers lines that match the argument regexp to be the beginning of a section of the file. Here are suggested regular expressions for some common languages:

`^[A-Za-z_]'
: C, C++, Prolog

`^('
: Lisp

`^@\(chapter\|appendix\|unnumbered\|chapheading\)'
: Texinfo

This option does not automatically select an output format; in order to use it, you must select the context format (see section Context Format) or unified format (see section Unified Format). In other output formats it has no effect.

The `-F' and `--show-function-line' options find the nearest unchanged line that precedes each hunk of differences and matches the given regular expression. Then they add that line to the end of the line of asterisks in the context format, or to the `@@' line in unified format. If no matching line exists, they leave the output for that hunk unchanged. If that line is more than 40 characters long, they output only the first 40 characters. You can specify more than one regular expression for such lines; `diff` tries to match each line against each regular expression, starting with the last one given. This means that you can use `-p' and `-F' together, if you wish.

Showing C Function Headings

To show in which functions differences occur for C and similar languages, you can use the `-p' or `--show-c-function' option. This option automatically selects the context output format (see section Context Format), with the default number of lines of context. You can override that number with `-C lines' later in the command line. You can override both the format and the number with `-U lines' later in the command line.

The `-p' and `--show-c-function' options are equivalent to `-c -F'^[_a-zA-Z$]'' (see section Showing Lines That Match Regular Expressions). GNU `diff` provides them for the sake of convenience.

Showing Alternate File Names

If you are comparing two files that have meaningless or uninformative names, you might want `diff` to show alternate names in the header of the context and unified output formats. To do this, use the `-L label' or `--label=label' option. The first time you give this option, its argument replaces the name and date of the first file in the header; the second time, its argument replaces the name and date of the second file. If you give this option more than twice, `diff` reports an error. The `-L' option does not affect the file names in the `pr` header when the `-l' or `--paginate' option is used (see section Paginating `diff` Output).

Here are the first two lines of the output from `diff -C2 -Loriginal -Lmodified lao tzu':

```
*** original
--- modified
```

Showing Differences Side by Side

`diff` can produce a side by side difference listing of two files. The files are listed in two columns with a gutter between them. The gutter contains one of the following markers:

white space
: The corresponding lines are in common. That is, either the lines are identical, or the difference is ignored because of one of the `--ignore' options (see section Suppressing Differences in Blank and Tab Spacing).

`|'
: The corresponding lines differ, and they are either both complete or both incomplete.

`<'
: The files differ and only the first file contains the line.

`>'
: The files differ and only the second file contains the line.

`('
: Only the first file contains the line, but the difference is ignored.

`)'
: Only the second file contains the line, but the difference is ignored.

`\'
: The corresponding lines differ, and only the first line is incomplete.

`/'
: The corresponding lines differ, and only the second line is incomplete.

Normally, an output line is incomplete if and only if the lines that it contains are incomplete; See section Incomplete Lines. However, when an output line represents two differing lines, one might be incomplete while the other is not. In this case, the output line is complete, but its the gutter is marked `\' if the first line is incomplete, `/' if the second line is.

Side by side format is sometimes easiest to read, but it has limitations. It generates much wider output than usual, and truncates lines that are too long to fit. Also, it relies on lining up output more heavily than usual, so its output looks particularly bad if you use varying width fonts, nonstandard tab stops, or nonprinting characters.

You can use the `sdiff` command to interactively merge side by side differences. See section Interactive Merging with `sdiff`, for more information on merging files.

Controlling Side by Side Format

The `-y' or `--side-by-side' option selects side by side format. Because side by side output lines contain two input lines, they are wider than usual. They are normally 130 columns, which can fit onto a traditional printer line. You can set the length of output lines with the `-W columns' or `--width=columns' option. The output line is split into two halves of equal length, separated by a small gutter to mark differences; the right half is aligned to a tab stop so that tabs line up. Input lines that are too long to fit in half of an output line are truncated for output.

The `--left-column' option prints only the left column of two common lines. The `--suppress-common-lines' option suppresses common lines entirely.

An Example of Side by Side Format

Here is the output of the command `diff -y -W 72 lao tzu' (see section Two Sample Input Files, for the complete contents of the two files).

```

```

Making Edit Scripts

Several output modes produce command scripts for editing from-file to produce to-file.

ed Scripts

`diff` can produce commands that direct the `ed` text editor to change the first file into the second file. Long ago, this was the only output mode that was suitable for editing one file into another automatically; today, with `patch`, it is almost obsolete. Use the `-e' or `--ed' option to select this output format.

Like the normal format (see section Showing Differences Without Context), this output format does not show any context; unlike the normal format, it does not include the information necessary to apply the diff in reverse (to produce the first file if all you have is the second file and the diff).

If the file `d' contains the output of `diff -e old new', then the command `(cat d && echo w) | ed - old' edits `old' to make it a copy of `new'. More generally, if `d1', `d2', ..., `dN' contain the outputs of `diff -e old new1', `diff -e new1 new2', ..., `diff -e newN-1 newN', respectively, then the command `(cat d1 d2 ... dN && echo w) | ed - old' edits `old' to make it a copy of `newN'.

Detailed Description of ed Format

The `ed` output format consists of one or more hunks of differences. The changes closest to the ends of the files come first so that commands that change the number of lines do not affect how `ed` interprets line numbers in succeeding commands. `ed` format hunks look like this:

```
change-command
to-file-line
to-file-line...
.
```

Because `ed` uses a single period on a line to indicate the end of input, GNU `diff` protects lines of changes that contain a single period on a line by writing two periods instead, then writing a subsequent `ed` command to change the two periods into one. The `ed` format cannot represent an incomplete line, so if the second file ends in a changed incomplete line, `diff` reports an error and then pretends that a newline was appended.

There are three types of change commands. Each consists of a line number or comma-separated range of lines in the first file and a single character indicating the kind of change to make. All line numbers are the original line numbers in the file. The types of change commands are:

`la'

Add text from the second file after line l in the first file. For example, `8a' means to add the following lines after line 8 of file 1.

`rc'

Replace the lines in range r in the first file with the following lines. Like a combined add and delete, but more compact. For example, `5,7c' means change lines 5--7 of file 1 to read as the text file 2.

`rd'

Delete the lines in range r from the first file. For example, `5,7d' means delete lines 5--7 of file 1.

Example ed Script

Here is the output of `diff -e lao tzu' (see section Two Sample Input Files, for the complete contents of the two files):

```
11a
They both may be called deep and profound.
Deeper and more profound,
The door of all subtleties!
.
4c
The named is the mother of all things.

.
1,2d
```

Forward ed Scripts

`diff` can produce output that is like an `ed` script, but with hunks in forward (front to back) order. The format of the commands is also changed slightly: command characters precede the lines they modify, spaces separate line numbers in ranges, and no attempt is made to disambiguate hunk lines consisting of a single period. Like `ed` format, forward `ed` format cannot represent incomplete lines.

Forward `ed` format is not very useful, because neither `ed` nor `patch` can apply diffs in this format. It exists mainly for compatibility with older versions of `diff`. Use the `-f' or `--forward-ed' option to select it.

RCS Scripts

The RCS output format is designed specifically for use by the Revision Control System, which is a set of free programs used for organizing different versions and systems of files. Use the `-n' or `--rcs' option to select this output format. It is like the forward `ed` format (see section Forward `ed` Scripts), but it can represent arbitrary changes to the contents of a file because it avoids the forward `ed` format's problems with lines consisting of a single period and with incomplete lines. Instead of ending text sections with a line consisting of a single period, each command specifies the number of lines it affects; a combination of the `a' and `d' commands are used instead of `c'. Also, if the second file ends in a changed incomplete line, then the output also ends in an incomplete line.

Here is the output of `diff -n lao tzu' (see section Two Sample Input Files, for the complete contents of the two files):

```
d1 2
d4 1
a4 2
```

```
The named is the mother of all things.

a11 3
They both may be called deep and profound.
Deeper and more profound,
The door of all subtleties!
```

Merging Files with If-then-else

You can use `diff` to merge two files of C source code. The output of `diff` in this format contains all the lines of both files. Lines common to both files are output just once; the differing parts are separated by the C preprocessor directives `#ifdef name` or `#ifndef name`, `#else`, and `#endif`. When compiling the output, you select which version to use by either defining or leaving undefined the macro name.

To merge two files, use `diff` with the `-D name' or `--ifdef=name' option. The argument name is the C preprocessor identifier to use in the `#ifdef` and `#ifndef` directives.

For example, if you change an instance of `wait (&s)` to `waitpid (-1, &s, 0)` and then merge the old and new files with the `--ifdef=HAVE_WAITPID' option, then the affected part of your code might look like this:

```
    do {
#ifndef HAVE_WAITPID
        if ((w = wait (&s)) < 0  &&  errno != EINTR)
#else /* HAVE_WAITPID */
        if ((w = waitpid (-1, &s, 0)) < 0  &&  errno != EINTR)
#endif /* HAVE_WAITPID */
            return w;
    } while (w != child);
```

You can specify formats for languages other than C by using line group formats and line formats, as described in the next sections.

Line Group Formats

Line group formats let you specify formats suitable for many applications that allow if-then-else input, including programming languages and text formatting languages. A line group format specifies the output format for a contiguous group of similar lines.

For example, the following command compares the TeX files `old' and `new', and outputs a merged file in which old regions are surrounded by `\begin{em}'-`\end{em}' lines, and new regions are surrounded by `\begin{bf}'-`\end{bf}' lines.

```
diff \
   --old-group-format='\begin{em}
%<\end{em}
' \
```

```
   --new-group-format='\begin{bf}
%>\end{bf}
' \
   old new
```

The following command is equivalent to the above example, but it is a little more verbose, because it spells out the default line group formats.

```
diff \
   --old-group-format='\begin{em}
%<\end{em}
' \
   --new-group-format='\begin{bf}
%>\end{bf}
' \
   --unchanged-group-format='%=' \
   --changed-group-format='\begin{em}
%<\end{em}
\begin{bf}
%>\end{bf}
' \
   old new
```

To specify a line group format, use `diff` with one of the options listed below. You can specify up to four line group formats, one for each kind of line group. You should quote format, because it typically contains shell metacharacters.

`--old-group-format=format'

These line groups are hunks containing only lines from the first file. The default old group format is the same as the changed group format if it is specified; otherwise it a format that outputs the line group as-is.

`--new-group-format=format'

These line groups are hunks containing only lines from the second file. The default new group format is same as the the changed group format if it is specified; otherwise it is a format that outputs the line group as-is.

`--changed-group-format=format'

These line groups are hunks containing lines from both files. The default changed group format is the concatenation of the old and new group formats.

`--unchanged-group-format=format'

These line groups contain lines common to both files. The default unchanged group format is a format that outputs the line group as-is.

In a line group format, ordinary characters represent themselves; conversion specifications start with `%' and have one of the following forms.

`%<'

stands for the lines from the first file, including the trailing newline. Each line is formatted according

to the old line format (see section Line Formats).

`%>'

stands for the lines from the second file, including the trailing newline. Each line is formatted according to the new line format.

`%='

stands for the lines common to both files, including the trailing newline. Each line is formatted according to the unchanged line format.

`%0'

stands for a null character.

`%%'

stands for `%'.

Line Formats

Line formats control how each line taken from an input file is output as part of a line group in if-then-else format.

For example, the following command outputs text with a one-column change indicator to the left of the text. The first column of output is `-' for deleted lines, `|' for added lines, and a space for unchanged lines. The formats contain newline characters where newlines are desired on output.

```
diff \
   --old-line-format='-%l
' \
   --new-line-format='|%l
' \
   --unchanged-line-format=' %l
' \
   old new
```

To specify a line format, use one of the following options. You should quote format, since it often contains shell metacharacters.

`--old-line-format=format'

formats lines just from the first file.

`--new-line-format=format'

formats lines just from the second file.

`--unchanged-line-format=format'

formats lines common to both files.

In a line format, ordinary characters represent themselves; conversion specifications start with `%' and have one of the following forms.

`%l'

stands for the the contents of the line, not counting its trailing newline (if any). This format ignores

whether the line is incomplete; See section Incomplete Lines.

`%L'

stands for the the contents of the line, including its trailing newline (if any). If a line is incomplete, this format preserves its incompleteness.

`%0'

stands for a null character.

`%%'

stands for `%'.

The default line format is `%l' followed by a newline character.

If the input contains tab characters and it is important that they line up on output, you should ensure that `%l' or `%L' in a line format is just after a tab stop (e.g. by preceding `%l' or `%L' with a tab character), or you should use the `-t' or `--expand-tabs' option.

Detailed Description of If-then-else Format

For lines common to both files, `diff` uses the unchanged line group format. For each hunk of differences in the merged output format, if the hunk contains only lines from the first file, `diff` uses the old line group format; if the hunk contains only lines from the second file, `diff` uses the new group format; otherwise, `diff` uses the changed group format.

The old, new, and unchanged line formats specify the output format of lines from the first file, lines from the second file, and lines common to both files, respectively.

The option `--ifdef=name' is equivalent to the following sequence of options using shell syntax:

```
--old-group-format='#ifndef name
%<#endif /* not name */
' \
--new-group-format='#ifdef name
%>#endif /* name */
' \
--unchanged-group-format='%=' \
--changed-group-format='#ifndef name
%<#else /* name */
%>#endif /* name */
'
```

You should carefully check the `diff` output for proper nesting. For example, when using the the `-D name' or `--ifdef=name' option, you should check that if the differing lines contain any of the C preprocessor directives `#ifdef', `#ifndef', `#else', `#elif', or `#endif', they are nested properly and match. If they don't, you must make corrections manually. It is a good idea to carefully check the resulting code anyway to make sure that it really does what you want it to; depending on how the input files were produced, the output might contain duplicate or otherwise incorrect code.

The `patch` `-D name' option behaves just like the `diff` `-D name' option, except it operates on a file and

a diff to produce a merged file; See section Options to `patch`.

An Example of If-then-else Format

Here is the output of `diff -DTWO lao tzu' (see section Two Sample Input Files, for the complete contents of the two files):

```
#ifndef TWO
The Way that can be told of is not the eternal Way;
The name that can be named is not the eternal name.
#endif /* not TWO */
The Nameless is the origin of Heaven and Earth;
#ifndef TWO
The Named is the mother of all things.
#else /* TWO */
The named is the mother of all things.

#endif /* TWO */
Therefore let there always be non-being,
  so we may see their subtlety,
And let there always be being,
  so we may see their outcome.
The two are the same,
But after they are produced,
  they have different names.
#ifdef TWO
They both may be called deep and profound.
Deeper and more profound,
The door of all subtleties!
#endif /* TWO */
```

Comparing Directories

You can use `diff` to compare some or all of the files in two directory trees. When both file name arguments to `diff` are directories, it compares each file that is contained in both directories, examining file names in alphabetical order. Normally `diff` is silent about pairs of files that contain no differences, but if you use the `-s' or `--report-identical-files' option, it reports pairs of identical files. Normally `diff` reports subdirectories common to both directories without comparing subdirectories' files, but if you use the `-r' or `--recursive' option, it compares every corresponding pair of files in the directory trees, as many levels deep as they go.

For file names that are in only one of the directories, `diff` normally does not show the contents of the file that exists; it reports only that the file exists in that directory and not in the other. You can make `diff` act as though the file existed but was empty in the other directory, so that it outputs the entire contents of the file that actually exists. (It is output as either an insertion or a deletion, depending on whether it is in the

first or the second directory given.) To do this, use the `-N' or `--new-file' option.

If the older directory contains one or more large files that are not in the newer directory, you can make the patch smaller by using the `-P' or `--unidirectional-new-file' option instead of `-N'. This option is like `-N' except that it only inserts the contents of files that appear in the second directory but not the first (that is, files that were added). At the top of the patch, write instructions for the user applying the patch to remove the files that were deleted before applying the patch. See section Tips for Making Patch Distributions, for more discussion of making patches for distribution.

To ignore some files while comparing directories, use the `-x pattern' or `--exclude=pattern' option. This option ignores any files or subdirectories whose base names match the shell pattern pattern. Unlike in the shell, a period at the start of the base of a file name matches a wildcard at the start of a pattern. You should enclose pattern in quotes so that the shell does not expand it. For example, the option `-x '*.[ao]" ignores any file whose name ends with `.a' or `.o'.

This option accumulates if you specify it more than once. For example, using the options `-x 'RCS' -x '*,v" ignores any file or subdirectory whose base name is `RCS' or ends with `,v'.

If you need to give this option many times, you can instead put the patterns in a file, one pattern per line, and use the `-X file' or `--exclude-from=file' option.

If you have been comparing two directories and stopped partway through, later you might want to continue where you left off. You can do this by using the `-S file' or `--starting-file=file' option. This compares only the file file and all alphabetically later files in the topmost directory level.

Making `diff` Output Prettier

`diff` provides several ways to adjust the appearance of its output. These adjustments can be applied to any output format.

Preserving Tabstop Alignment

The lines of text in some of the `diff` output formats are preceded by one or two characters that indicate whether the text is inserted, deleted, or changed. The addition of those characters can cause tabs to move to the next tabstop, throwing off the alignment of columns in the line. GNU `diff` provides two ways to make tab-aligned columns line up correctly.

The first way is to have `diff` convert all tabs into the correct number of spaces before outputting them; select this method with the `-t' or `--expand-tabs' option. `diff` assumes that tabstops are set every 8 columns. To use this form of output with `patch`, you must give `patch` the `-l' or `--ignore-whitespace' option (see section Applying Patches with Changed Whitespace, for more information).

The other method for making tabs line up correctly is to add a tab character instead of a space after the indicator character at the beginning of the line. This ensures that all following tab characters are in the same position relative to tabstops that they were in the original files, so that the output is aligned correctly. Its disadvantage is that it can make long lines too long to fit on one line of the screen or the paper. It also does not work with the unified output format, which does not have a space character after the change type

indicator character. Select this method with the `-T' or `--initial-tab' option.

Paginating `diff` Output

It can be convenient to have long output page-numbered and time-stamped. The `-l' and `--paginate' options do this by sending the `diff` output through the `pr` program. Here is what the page header might look like for `diff -lc lao tzu':

```
Mar 11 13:37 1991  diff -lc lao tzu Page 1
```

`diff` Performance Tradeoffs

GNU `diff` runs quite efficiently; however, in some circumstances you can cause it to run faster or produce a more compact set of changes. There are two ways that you can affect the performance of GNU `diff` by changing the way it compares files.

Performance has more than one dimension. These options improve one aspect of performance at the cost of another, or they improve performance in some cases while hurting it in others.

The way that GNU `diff` determines which lines have changed always comes up with a near-minimal set of differences. Usually it is good enough for practical purposes. If the `diff` output is large, you might want `diff` to use a modified algorithm that sometimes produces a smaller set of differences. The `-d' or `--minimal' option does this; however, it can also cause `diff` to run more slowly than usual, so it is not the default behavior.

When the files you are comparing are large and have small groups of changes scattered throughout them, you can use the `-H' or `--speed-large-files' option to make a different modification to the algorithm that `diff` uses. If the input files have a constant small density of changes, this option speeds up the comparisons without changing the output. If not, `diff` might produce a larger set of differences; however, the output will still be correct.

Comparing Three Files

Use the program `diff3` to compare three files and show any differences among them. (`diff3` can also merge files; see section Merging From a Common Ancestor).

The "normal" `diff3` output format shows each hunk of differences without surrounding context. Hunks are labeled depending on whether they are two-way or three-way, and lines are annotated by their location in the input files.

See section Invoking `diff3`, for more information on how to run `diff3`.

A Third Sample Input File

Here is a third sample file that will be used in examples to illustrate the output of `diff3` and how various options can change it. The first two files are the same that we used for `diff` (see section Two Sample Input Files). This is the third sample file, called `` `tao' ``:

```
The Way that can be told of is not the eternal Way;
The name that can be named is not the eternal name.
The Nameless is the origin of Heaven and Earth;
The named is the mother of all things.

Therefore let there always be non-being,
  so we may see their subtlety,
And let there always be being,
  so we may see their result.
The two are the same,
But after they are produced,
  they have different names.

  -- The Way of Lao-Tzu, tr. Wing-tsit Chan
```

Detailed Description of `diff3` Normal Format

Each hunk begins with a line marked `` `====' ``. Three-way hunks have plain `` `====' `` lines, and two-way hunks have `1', `2', or `3' appended to specify which of the three input files differ in that hunk. The hunks contain copies of two or three sets of input lines each preceded by one or two commands identifying where the lines came from. Two spaces precede each copy of an input line to distinguish it from the commands. Commands take the following forms:

`file:la'

> This hunk appears after line l of file file, and contains no lines in that file. To edit this file to yield the other files, one must append hunk lines taken from the other files. For example, `1:11a' means that the hunk follows line 11 in the first file and contains no lines from that file.

`file:rc'

> This hunk contains the lines in the range r of file file. The range r is a comma-separated pair of line numbers, or just one number if the range is a singleton. To edit this file to yield the other files, one must change the specified lines to be the lines taken from the other files. For example, `2:11,13c' means that the hunk contains lines 11 through 13 from the second file.

If the last line in a set of input lines is incomplete (see section Incomplete Lines), it is distinguished on output from a full line by a following line that starts with `\'.

`diff3` Hunks

Groups of lines that differ in two or three of the input files are called diff3 hunks, by analogy with `diff` hunks (see section Hunks). If all three input files differ in a `diff3` hunk, the hunk is called a three-way hunk; if just two input files differ, it is a two-way hunk.

As with `diff`, several solutions are possible. When comparing the files `A', `B', and `C', `diff3` normally finds `diff3` hunks by merging the two-way hunks output by the two commands `diff A B' and `diff A C'. This does not necessarily minimize the size of the output, but exceptions should be rare.

For example, suppose `F' contains the three lines `a', `b', `f', `G' contains the lines `g', `b', `g', and `H' contains the lines `a', `b', `h'. `diff3 F G H' might output the following:

```
====2
1:1c
3:1c
  a
2:1c
  g
====
1:3c
  f
2:3c
  g
3:3c
  h
```

because it found a two-way hunk containing `a' in the first and third files and `g' in the second file, then the single line `b' common to all three files, then a three-way hunk containing the last line of each file.

An Example of `diff3` Normal Format

Here is the output of the command `diff3 lao tzu tao' (see section A Third Sample Input File, for the complete contents of the files). Notice that it shows only the lines that are different among the three files.

```
====2
1:1,2c
3:1,2c
  The Way that can be told of is not the eternal Way;
  The name that can be named is not the eternal name.
2:0a
====1
1:4c
  The Named is the mother of all things.
2:2,3c
```

```
3:4,5c
  The named is the mother of all things.

====3
1:8c
2:7c
    so we may see their outcome.
3:9c
    so we may see their result.
====
1:11a
2:11,13c
  They both may be called deep and profound.
  Deeper and more profound,
  The door of all subtleties!
3:13,14c

    -- The Way of Lao-Tzu, tr. Wing-tsit Chan
```

Merging From a Common Ancestor

When two people have made changes to copies of the same file, `diff3` can produce a merged output that contains both sets of changes together with warnings about conflicts.

One might imagine programs with names like `diff4` and `diff5` to compare more than three files simultaneously, but in practice the need rarely arises. You can use `diff3` to merge three or more sets of changes to a file by merging two change sets at a time.

`diff3` can incorporate changes from two modified versions into a common preceding version. This lets you merge the sets of changes represented by the two newer files. Specify the common ancestor version as the second argument and the two newer versions as the first and third arguments, like this:

```
diff3 mine older yours
```

You can remember the order of the arguments by noting that they are in alphabetical order.

You can think of this as subtracting older from yours and adding the result to mine, or as merging into mine the changes that would turn older into yours. This merging is well-defined as long as mine and older match in the neighborhood of each such change. This fails to be true when all three input files differ or when only older differs; we call this a conflict. When all three input files differ, we call the conflict an overlap.

`diff3` gives you several ways to handle overlaps and conflicts. You can omit overlaps or conflicts, or select only overlaps, or mark conflicts with special `<<<<<<<' and `>>>>>>>' lines.

`diff3` can output the merge results as an `ed` script that that can be applied to the first file to yield the merged output. However, it is usually better to have `diff3` generate the merged output directly; this bypasses some problems with `ed`.

Selecting Which Changes to Incorporate

You can select all unmerged changes from older to yours for merging into mine with the `-e' or `--ed' option. You can select only the nonoverlapping unmerged changes with `-3' or `--easy-only', and you can select only the overlapping changes with `-x' or `--overlap-only'.

The `-e', `-3' and `-x' options select only unmerged changes, i.e. changes where mine and yours differ; they ignore changes from older to yours where mine and yours are identical, because they assume that such changes have already been merged. If this assumption is not a safe one, you can use the `-A' or `--show-all' option (see section Marking Conflicts).

Here is the output of the command `diff3` with each of these three options (see section A Third Sample Input File, for the complete contents of the files). Notice that `-e' outputs the union of the disjoint sets of changes output by `-3' and `-x'.

Output of `diff3 -e lao tzu tao':

```
11a

  -- The Way of Lao-Tzu, tr. Wing-tsit Chan
.
8c
  so we may see their result.
.
```

Output of `diff3 -3 lao tzu tao':

```
8c
  so we may see their result.
.
```

Output of `diff3 -x lao tzu tao':

```
11a

  -- The Way of Lao-Tzu, tr. Wing-tsit Chan
.
```

Marking Conflicts

`diff3` can mark conflicts in the merged output by bracketing them with special marker lines. A conflict that comes from two files A and B is marked as follows:

```
<<<<<<< A
lines from A
```

```
=======
lines from B
>>>>>>> B
```

A conflict that comes from three files A, B and C is marked as follows:

```
<<<<<<< A
lines from A
||||||| B
lines from B
=======
lines from C
>>>>>>> C
```

The `-A' or `--show-all' option acts like the `-e' option, except that it brackets conflicts, and it outputs all changes from older to yours, not just the unmerged changes. Thus, given the sample input files (see section A Third Sample Input File), `diff3 -A lao tzu tao' puts brackets around the conflict where only `tzu' differs:

```
<<<<<<< tzu
=======
The Way that can be told of is not the eternal Way;
The name that can be named is not the eternal name.
>>>>>>> tao
```

And it outputs the three-way conflict as follows:

```
<<<<<<< lao
||||||| tzu
They both may be called deep and profound.
Deeper and more profound,
The door of all subtleties!
=======

  -- The Way of Lao-Tzu, tr. Wing-tsit Chan
>>>>>>> tao
```

The `-E' or `--show-overlap' option outputs less information than the `-A' or `--show-all' option, because it outputs only unmerged changes, and it never outputs the contents of the second file. Thus the `-E' option acts like the `-e' option, except that it brackets the first and third files from three-way overlapping changes. Similarly, `-X' acts like `-x', except it brackets all its (necessarily overlapping) changes. For example, for the three-way overlapping change above, the `-E' and `-X' options output the following:

```
<<<<<<< lao
=======

  -- The Way of Lao-Tzu, tr. Wing-tsit Chan
```

```
>>>>>>> tao
```

If you are comparing files that have meaningless or uninformative names, you can use the `-L label' or `--label=label' option to show alternate names in the `<<<<<<<', `|||||||' and `>>>>>>>' brackets. This option can be given up to three times, once for each input file. Thus `diff3 -A -L X -L Y -L Z A B C' acts like `diff3 -A A B C', except that the output looks like it came from files named `X', `Y' and `Z' rather than from files named `A', `B' and `C'.

Generating the Merged Output Directly

With the `-m' or `--merge' option, `diff3` outputs the merged file directly. This is more efficient than using `ed` to generate it, and works even with non-text files that `ed` would reject. If you specify `-m' without an `ed` script option, `-A' (`--show-all') is assumed.

For example, the command `diff3 -m lao tzu tao' (see section A Third Sample Input File for a copy of the input files) would output the following:

```
<<<<<<< tzu
=======
The Way that can be told of is not the eternal Way;
The name that can be named is not the eternal name.
>>>>>>> tao
The Nameless is the origin of Heaven and Earth;
The Named is the mother of all things.
Therefore let there always be non-being,
  so we may see their subtlety,
And let there always be being,
  so we may see their result.
The two are the same,
But after they are produced,
  they have different names.
<<<<<<< lao
||||||| tzu
They both may be called deep and profound.
Deeper and more profound,
The door of all subtleties!
=======

  -- The Way of Lao-Tzu, tr. Wing-tsit Chan
>>>>>>> tao
```

How `diff3` Merges Incomplete Lines

With `-m', incomplete lines (see section Incomplete Lines) are simply copied to the output as they are found; if the merged output ends in an conflict and one of the input files ends in an incomplete line,

succeeding `|||||||', `=======' or `>>>>>>>' brackets appear somewhere other than the start of a line because they are appended to the incomplete line.

Without `-m', if an `ed` script option is specified and an incomplete line is found, `diff3` generates a warning and acts as if a newline had been present.

Saving the Changed File

Traditional Unix `diff3` generates an `ed` script without the trailing `w' and and `q' commands that save the changes. System V `diff3` generates these extra commands. GNU `diff3` normally behaves like traditional Unix `diff3`, but with the `-i' option it behaves like System V `diff3` and appends the `w' and `q' commands.

The `-i' option requires one of the `ed` script options `-AeExX3', and is incompatible with the merged output option `-m'.

Interactive Merging with `sdiff`

With `sdiff`, you can merge two files interactively based on a side-by-side `-y' format comparison (see section Showing Differences Side by Side). Use `-o file' or `--output=file' to specify where to put the merged text. See section Invoking `sdiff`, for more details on the options to `sdiff`.

Another way to merge files interactively is to use the Emacs Lisp package `emerge`. See section 'emerge' in The GNU Emacs Manual, for more information.

Specifying `diff` Options to `sdiff`

The following `sdiff` options have the same meaning as for `diff`. See section Options to `diff`, for the use of these options.

```
-a -b -d -i -t -v
-B -H -I regexp

--ignore-blank-lines  --ignore-case
--ignore-matching-lines=regexp  --ignore-space-change
--left-column  --minimal  --speed-large-files
--suppress-common-lines  --expand-tabs
--text  --version  --width=columns
```

For historical reasons, `sdiff` has alternate names for some options. The `-l' option is equivalent to the `--left-column' option, and similarly `-s' is equivalent to `--suppress-common-lines'. The meaning of the `sdiff` `-w' and `-W' options is interchanged from that of `diff`: with `sdiff`, `-w columns' is equivalent to `--width=columns', and `-W' is equivalent to `--ignore-all-space'. `sdiff` without the `-o' option is equivalent to `diff` with the `-y' or `--side-by-side' option (see section Showing Differences Side by Side).

Merge Commands

Groups of common lines, with a blank gutter, are copied from the first file to the output. After each group of differing lines, `sdiff` prompts with `%' and pauses, waiting for one of the following commands. Follow each command with RET.

`e'

Discard both versions. Invoke a text editor on an empty temporary file, then copy the resulting file to the output.

`eb'

Concatenate the two versions, edit the result in a temporary file, then copy the edited result to the output.

`el'

Edit a copy of the left version, then copy the result to the output.

`er'

Edit a copy of the right version, then copy the result to the output.

`l'

Copy the left version to the output.

`q'

Quit.

`r'

Copy the right version to the output.

`s'

Silently copy common lines.

`v'

Verbosely copy common lines. This is the default.

The text editor invoked is specified by the `EDITOR` environment variable if it is set. The default is system-dependent.

Merging with `patch`

`patch` takes comparison output produced by `diff` and applies the differences to a copy of the original file, producing a patched version. With `patch`, you can distribute just the changes to a set of files instead of distributing the entire file set; your correspondents can apply `patch` to update their copy of the files with your changes. `patch` automatically determines the diff format, skips any leading or trailing headers, and uses the headers to determine which file to patch. This lets your correspondents feed an article or message containing a difference listing directly to `patch`.

`patch` detects and warns about common problems like forward patches. It saves the original version of the files it patches, and saves any patches that it could not apply. It can also maintain a `patchlevel.h` file

to ensures that your correspondents apply diffs in the proper order.

`patch` accepts a series of diffs in its standard input, usually separated by headers that specify which file to patch. It applies `diff` hunks (see section Hunks) one by one. If a hunk does not exactly match the original file, `patch` uses heuristics to try to patch the file as well as it can. If no approximate match can be found, `patch` rejects the hunk and skips to the next hunk. `patch` normally replaces each file f with its new version, saving the original file in `f.orig', and putting reject hunks (if any) into `f.rej'.

See section Invoking `patch`, for detailed information on the options to `patch`. See section Backup File Names, for more information on how `patch` names backup files. See section Reject File Names, for more information on where `patch` puts reject hunks.

Selecting the `patch` Input Format

`patch` normally determines which `diff` format the patch file uses by examining its contents. For patch files that contain particularly confusing leading text, you might need to use one of the following options to force `patch` to interpret the patch file as a certain format of diff. The output formats listed here are the only ones that `patch` can understand.

`-c'

`--context'

context diff.

`-e'

`--ed'

`ed` script.

`-n'

`--normal'

normal diff.

`-u'

`--unified'

unified diff.

Applying Imperfect Patches

`patch` tries to skip any leading text in the patch file, apply the diff, and then skip any trailing text. Thus you can feed a news article or mail message directly to `patch`, and it should work. If the entire diff is indented by a constant amount of whitespace, `patch` automatically ignores the indentation.

However, certain other types of imperfect input require user intervention.

Applying Patches with Changed Whitespace

Sometimes mailers, editors, or other programs change spaces into tabs, or vice versa. If this happens to a patch file or an input file, the files might look the same, but `patch` will not be able to match them properly. If this problem occurs, use the `-l' or `--ignore-whitespace' option, which makes `patch` compare whitespace loosely so that any sequence of whitespace in the patch file matches any sequence of whitespace in the input files. Non-whitespace characters must still match exactly. Each line of the context must still match a line in the input file.

Applying Reversed Patches

Sometimes people run `diff` with the new file first instead of second. This creates a diff that is "reversed". To apply such patches, give `patch` the `-R' or `--reverse' option. `patch` then attempts to swap each hunk around before applying it. Rejects come out in the swapped format. The `-R' option does not work with `ed` scripts because there is too little information in them to reconstruct the reverse operation.

Often `patch` can guess that the patch is reversed. If the first hunk of a patch fails, `patch` reverses the hunk to see if it can apply it that way. If it can, `patch` asks you if you want to have the `-R' option set; if it can't, `patch` continues to apply the patch normally. This method cannot detect a reversed patch if it is a normal diff and the first command is an append (which should have been a delete) since appends always succeed, because a null context matches anywhere. But most patches add or change lines rather than delete them, so most reversed normal diffs begin with a delete, which fails, and `patch` notices.

If you apply a patch that you have already applied, `patch` thinks it is a reversed patch and offers to un-apply the patch. This could be construed as a feature. If you did this inadvertently and you don't want to un-apply the patch, just answer `n' to this offer and to the subsequent "apply anyway" question--or type C-c to kill the `patch` process.

Helping `patch` Find Inexact Matches

For context diffs, and to a lesser extent normal diffs, `patch` can detect when the line numbers mentioned in the patch are incorrect, and it attempts to find the correct place to apply each hunk of the patch. As a first guess, it takes the line number mentioned in the hunk, plus or minus any offset used in applying the previous hunk. If that is not the correct place, `patch` scans both forward and backward for a set of lines matching the context given in the hunk.

First `patch` looks for a place where all lines of the context match. If it cannot find such a place, and it is reading a context or unified diff, and the maximum fuzz factor is set to 1 or more, then `patch` makes another scan, ignoring the first and last line of context. If that fails, and the maximum fuzz factor is set to 2 or more, it makes another scan, ignoring the first two and last two lines of context are ignored. It continues similarly if the maximum fuzz factor is larger.

The `-F lines' or `--fuzz=lines' option sets the maximum fuzz factor to lines. This option only applies to context and unified diffs; it ignores up to lines lines while looking for the place to install a hunk. Note that a larger fuzz factor increases the odds of making a faulty patch. The default fuzz factor is 2; it may not be set to more than the number of lines of context in the diff, ordinarily 3.

If `patch` cannot find a place to install a hunk of the patch, it writes the hunk out to a reject file (see section

Reject File Names, for information on how reject files are named). It writes out rejected hunks in context format no matter what form the input patch is in. If the input is a normal or `ed` diff, many of the contexts are simply null. The line numbers on the hunks in the reject file may be different from those in the patch file: they show the approximate location where `patch` thinks the failed hunks belong in the new file rather than in the old one.

As it completes each hunk, `patch` tells you whether the hunk succeeded or failed, and if it failed, on which line (in the new file) `patch` thinks the hunk should go. If this is different from the line number specified in the diff, it tells you the offset. A single large offset *may* indicate that `patch` installed a hunk in the wrong place. `patch` also tells you if it used a fuzz factor to make the match, in which case you should also be slightly suspicious.

`patch` cannot tell if the line numbers are off in an `ed` script, and can only detect wrong line numbers in a normal diff when it finds a change or delete command. It may have the same problem with a context diff using a fuzz factor equal to or greater than the number of lines of context shown in the diff (typically 3). In these cases, you should probably look at a context diff between your original and patched input files to see if the changes make sense. Compiling without errors is a pretty good indication that the patch worked, but not a guarantee.

`patch` usually produces the correct results, even when it must make many guesses. However, the results are guaranteed only when the patch is applied to an exact copy of the file that the patch was generated from.

Removing Empty Files

Sometimes when comparing two directories, the first directory contains a file that the second directory does not. If you give `diff` the `-N' or `--new-file' option, it outputs a diff that deletes the contents of this file. By default, `patch` leaves an empty file after applying such a diff. The `-E' or `--remove-empty-files' option to `patch` deletes output files that are empty after applying the diff.

Multiple Patches in a File

If the patch file contains more than one patch, `patch` tries to apply each of them as if they came from separate patch files. This means that it determines the name of the file to patch for each patch, and that it examines the leading text before each patch for file names and prerequisite revision level (see section Tips for Making Patch Distributions, for more on that topic).

For the second and subsequent patches in the patch file, you can give options and another original file name by separating their argument lists with a `+'. However, the argument list for a second or subsequent patch may not specify a new patch file, since that does not make sense.

For example, to tell `patch` to strip the first three slashes from the name of the first patch in the patch file and none from subsequent patches, and to use `` `code.c' `` as the first input file, you can use:

```
patch -p3 code.c + -p0 < patchfile
```

The `-S' or `--skip' option ignores the current patch from the patch file, but continue looking for the next

patch in the file. Thus, to ignore the first and third patches in the patch file, you can use:

```
patch -S + + -S + < patch file
```

Messages and Questions from `patch`

`patch` can produce a variety of messages, especially if it has trouble decoding its input. In a few situations where it's not sure how to proceed, `patch` normally prompts you for more information from the keyboard. There are options to suppress printing non-fatal messages and stopping for keyboard input.

The message `Hmm...' indicates that `patch` is reading text in the patch file, attempting to determine whether there is a patch in that text, and if so, what kind of patch it is.

You can inhibit all terminal output from `patch`, unless an error occurs, by using the `-s', `--quiet', or `--silent' option.

There are two ways you can prevent `patch` from asking you any questions. The `-f' or `--force' option assumes that you know what you are doing. It assumes the following:

- skip patches for which it can't find a file to patch;
- patch files even though they have the wrong version for the `Prereq:' line in the patch;
- assume that patches are not reversed even if they look like they are.

The `-t' or `--batch' option is similar to `-f', in that it suppresses questions, but it makes somewhat different assumptions:

- skip patches for which it can't find a file to patch (the same as `-f');
- skip patches for which the file has the wrong version for the `Prereq:' line in the patch;
- assume that patches are reversed if they look like they are.

`patch` exits with a non-zero status if it creates any reject files. When applying a set of patches in a loop, you should check the exit status, so you don't apply a later patch to a partially patched file.

Tips for Making Patch Distributions

Here are some things you should keep in mind if you are going to distribute patches for updating a software package.

Make sure you have specified the file names correctly, either in a context diff header or with an `Index:' line. If you are patching files in a subdirectory, be sure to tell the patch user to specify a `-p' or `--strip' option as needed. Take care to not send out reversed patches, since these make people wonder whether they have already applied the patch.

To save people from partially applying a patch before other patches that should have gone before it, you can make the first patch in the patch file update a file with a name like `patchlevel.h' or `version.c', which contains a patch level or version number. If the input file contains the wrong version number, `patch` will complain immediately.

An even clearer way to prevent this problem is to put a `Prereq:' line before the patch. If the leading text of the patch file contains a line that starts with `Prereq:', `patch` takes the next word from that line (normally a version number) and checks whether the next input file contains that word, preceded and followed by either whitespace or a newline. If not, `patch` prompts you for confirmation before proceeding. This makes it difficult to accidentally apply patches in the wrong order.

Since `patch` does not handle incomplete lines properly, make sure that all the source files in your program end with a newline whenever you release a version.

To create a patch that changes an older version of a package into a newer version, first make a copy of the older version in a scratch directory. Typically you do that by unpacking a `tar` or `shar` archive of the older version.

You might be able to reduce the size of the patch by renaming or removing some files before making the patch. If the older version of the package contains any files that the newer version does not, or if any files have been renamed between the two versions, make a list of `rm` and `mv` commands for the user to execute in the old version directory before applying the patch. Then run those commands yourself in the scratch directory.

If there are any files that you don't need to include in the patch because they can easily be rebuilt from other files (for example, `` `TAGS' `` and output from `yacc` and `makeinfo`), replace the versions in the scratch directory with the newer versions, using `rm` and `ln` or `cp`.

Now you can create the patch. The de-facto standard `diff` format for patch distributions is context format with two lines of context, produced by giving `diff` the `-C 2' option. Give `diff` the `-N' option in case the newer version of the package contains any files that the older one does not. Make sure to specify the scratch directory first and the newer directory second.

Add to the top of the patch a note telling the user any `rm` and `mv` commands to run before applying the patch. Then you can remove the scratch directory.

Invoking cmp

The `cmp` command compares two files, and if they differ, tells the first byte and line number where they differ. Its arguments are as follows:

```
cmp options... from-file [to-file]
```

The file name `-' is always the standard input. `cmp` also uses the standard input if one file name is omitted.

An exit status of 0 means no differences were found, 1 means some differences were found, and 2 means trouble.

Options to `cmp`

Below is a summary of all of the options that GNU `cmp` accepts. Most options have two equivalent names, one of which is a single letter preceded by `-', and the other of which is a long name preceded by `--'. Multiple single letter options (unless they take an argument) can be combined into a single command line word: `-cl' is equivalent to `-c -l'.

`-c'

Print the differing characters. Display control characters as a `^' followed by a letter of the alphabet and precede characters that have the high bit set with `M-' (which stands for "meta").

`-l'

Print the (decimal) offsets and (octal) values of all differing bytes.

`--print-chars'

Print the differing characters. Display control characters as a `^' followed by a letter of the alphabet and precede characters that have the high bit set with `M-' (which stands for "meta").

`--quiet'

`-s'

`--silent'

Do not print anything; only return an exit status indicating whether the files differ.

`--verbose'

Print the (decimal) offsets and (octal) values of all differing bytes.

Invoking `diff`

The format for running the `diff` command is:

```
diff options... from-file to-file
```

In the simplest case, `diff` compares the contents of the two files from-file and to-file. A file name of `-' stands for text read from the standard input. As a special case, `diff - -' compares a copy of standard input to itself.

If from-file is a directory and to-file is not, `diff` compares the file in from-file whose file name is that of to-file, and vice versa. The non-directory file must not be `-'.

If both from-file and to-file are directories, `diff` compares corresponding files in both directories, in alphabetical order; this comparison is not recursive unless the `-r' or `--recursive' option is given. `diff` never compares the actual contents of a directory as if it were a file. The file that is fully specified may not be standard input, because standard input is nameless and the notion of "file with the same name" does not apply.

`diff` options begin with `-', so normally from-file and to-file may not begin with `-'. However, `--' as an argument by itself treats the remaining arguments as file names even if they begin with `-'.

An exit status of 0 means no differences were found, 1 means some differences were found, and 2 mea trouble.

Options to `diff`

Below is a summary of all of the options that GNU `diff` accepts. Most options have two equivalent names, one of which is a single letter preceded by `-', and the other of which is a long name preceded by `--'. Multiple single letter options (unless they take an argument) can be combined into a single command line word: `-ac' is equivalent to `-a -c'. Long named options can be abbreviated to any unique prefix of their name. Brackets ([and]) indicate that an option takes an optional argument.

`-lines'

Show lines (an integer) lines of context. This option does not specify an output format by itself; it has no effect unless it is combined with `-c' (see section Context Format) or `-u' (see section Unified Format). This option is obsolete.

`-a'

Treat all files as text and compare them line-by-line, even if they do not seem to be text. See section Binary Files and Forcing Text Comparisons.

`-b'

Ignore changes in amount of blank and tab whitespace. See section Suppressing Differences in Blank and Tab Spacing.

`-B'

Ignore changes that just insert or delete blank lines. See section Suppressing Differences in Blank Lines.

`--brief'

Report only whether the files differ, not the details of the differences. See section Summarizing Which Files Differ.

`-c'

Use the context output format. See section Context Format.

`-C lines'

`--context[=lines]'

Use the context output format, showing lines (an integer) lines of context, or three if lines is not given. See section Context Format.

`--changed-group-format=format'

Use format to output a line group containing differing lines from both files in if-then-else format. See section Line Group Formats.

`-d'

Change the algorithm perhaps find a smaller set of changes. This makes `diff` slower (sometimes much slower). See section `diff` Performance Tradeoffs.

`-D name'

Make merged `#ifdef' format output, conditional on the preprocessor macro name. See section Merging Files with If-then-else.

`-e'

`--ed'

Make output that is a valid `ed` script. See section `ed` Scripts.

`--exclude=pattern'

When comparing directories, ignore files and subdirectories whose basenames match pattern. See section Comparing Directories.

`--exclude-from=file'

When comparing directories, ignore files and subdirectories whose basenames match any pattern contained in file. See section Comparing Directories.

`--expand-tabs'

Expand tabs to spaces in the output, to preserve the alignment of tabs in the input files. See section Preserving Tabstop Alignment.

`-f'

Make output that looks vaguely like an `ed` script but has changes in the order they appear in the file. See section Forward `ed` Scripts.

`-F regexp'

In context and unified format, for each hunk of differences, show some of the last preceding line that matches regexp. See section Showing Lines That Match Regular Expressions.

`--forward-ed'

Make output that looks vaguely like an `ed` script but has changes in the order they appear in the file. See section Forward `ed` Scripts.

`-h'

This option currently has no effect; it is present for Unix compatibility.

`-H'

Use heuristics to speed handling of large files that have numerous scattered small changes. See section `diff` Performance Tradeoffs.

`-i'

Ignore changes in case; consider upper- and lower-case letters equivalent. See section Suppressing Case Differences.

`-I regexp'

Ignore changes that just insert or delete lines that match regexp. See section Suppressing Lines Matching a Regular Expression.

`--ifdef=name'

Make merged if-then-else output using format. See section Merging Files with If-then-else.

`--ignore-all-space'

Ignore whitespace when comparing lines. See section Suppressing Differences in Blank and Tab

Spacing.

`--ignore-blank-lines'

Ignore changes that just insert or delete blank lines. See section Suppressing Differences in Blank Lines.

`--ignore-case'

Ignore changes in case; consider upper- and lower-case to be the same. See section Suppressing Case Differences.

`--ignore-matching-lines=regexp'

Ignore changes that just insert or delete lines that match regexp. See section Suppressing Lines Matching a Regular Expression.

`--ignore-space-change'

Ignore changes in amount of blank and tab whitespace. See section Suppressing Differences in Blank and Tab Spacing.

`--initial-tab'

Output a tab rather than a space before the text of a line in normal or context format. This causes the alignment of tabs in the line to look normal. See section Preserving Tabstop Alignment.

`-l'

Pass the output through `pr` to paginate it. See section Paginating `diff` Output.

`-L label'

Use label instead of the file name in the context format (see section Context Format) and unified format (see section Unified Format) headers. See section RCS Scripts.

`--label=label'

Use label instead of the file name in the context format (see section Context Format) and unified format (see section Unified Format) headers.

`--left-column'

Print only the left column of two common lines in side by side format. See section Controlling Side by Side Format.

`--minimal'

Change the algorithm to perhaps find a smaller set of changes. This makes `diff` slower (sometimes much slower). See section `diff` Performance Tradeoffs.

`-n'

Output RCS-format diffs; like `-f' except that each command specifies the number of lines affected. See section RCS Scripts.

`-N'

`--new-file'

In directory comparison, if a file is found in only one directory, treat it as present but empty in the other directory. See section Comparing Directories.

`--new-group-format=format'

Use format to output a group of lines taken from just the second file in if-then-else format. See section Line Group Formats.

`--new-line-format=format'

Use format to output a line taken from just the second file in if-then-else format. See section Line Formats.

`--old-group-format=format'

Use format to output a group of lines taken from just the first file in if-then-else format. See section Line Group Formats.

`--old-line-format=format'

Use format to output a line taken from just the first file in if-then-else format. See section Line Formats.

`-p'

Show which C function each change is in. See section Showing C Function Headings.

`-P'

When comparing directories, if a file appears only in the second directory of the two, treat it as present but empty in the other.

`--paginate'

Pass the output through `pr` to paginate it. See section Paginating `diff` Output.

`-q'

Report only whether the files differ, not the details of the differences. See section Summarizing Which Files Differ.

`-r'

When comparing directories, recursively compare any subdirectories found. See section Comparing Directories.

`--rcs'

Output RCS-format diffs; like `-f' except that each command specifies the number of lines affected. See section RCS Scripts.

`--recursive'

When comparing directories, recursively compare any subdirectories found. See section Comparing Directories.

`--report-identical-files'

Report when two files are the same. See section Comparing Directories.

`-s'

Report when two files are the same. See section Comparing Directories.

`-S file'

When comparing directories, start with the file file. This is used for resuming an aborted comparison.

See section Comparing Directories.

`--sdiff-merge-assist'

Print extra information to help `sdiff`. `sdiff` uses this option when it runs `diff`. This option is not intended for users to use directly.

`--show-c-function'

Show which C function each change is in. See section Showing C Function Headings.

`--show-function-line=regexp'

In context and unified format, for each hunk of differences, show some of the last preceding line that matches regexp. See section Showing Lines That Match Regular Expressions.

`--side-by-side'

Use the side by side output format. See section Controlling Side by Side Format.

`--speed-large-files'

Use heuristics to speed handling of large files that have numerous scattered small changes. See section `diff` Performance Tradeoffs.

`--starting-file=file'

When comparing directories, start with the file file. This is used for resuming an aborted comparison. See section Comparing Directories.

`--suppress-common-lines'

Do not print common lines in side by side format. See section Controlling Side by Side Format.

`-t'

Expand tabs to spaces in the output, to preserve the alignment of tabs in the input files. See section Preserving Tabstop Alignment.

`-T'

Output a tab rather than a space before the text of a line in normal or context format. This causes the alignment of tabs in the line to look normal. See section Preserving Tabstop Alignment.

`--text'

Treat all files as text and compare them line-by-line, even if they do not appear to be text. See section Binary Files and Forcing Text Comparisons.

`-u'

Use the unified output format. See section Unified Format.

`--unchanged-group-format=format'

Use format to output a group of common lines taken from both files in if-then-else format. See section Line Group Formats.

`--unchanged-line-format=format'

Use format to output a line common to both files in if-then-else format. See section Line Formats.

`--unidirectional-new-file'

When comparing directories, if a file appears only in the second directory of the two, treat it as present but empty in the other. See section Comparing Directories.

`-U lines'

`--unified[=lines]'

Use the unified output format, showing lines (an integer) lines of context, or three if lines is not given. See section Unified Format.

`-v'

`--version'

Output the version number of `diff`.

`-w'

Ignore horizontal whitespace when comparing lines. See section Suppressing Differences in Blank and Tab Spacing.

`-W columns'

`--width=columns'

Use an output width of columns in side by side format. See section Controlling Side by Side Format.

`-x pattern'

When comparing directories, ignore files and subdirectories whose basenames match pattern. See section Comparing Directories.

`-X file'

When comparing directories, ignore files and subdirectories whose basenames match any pattern contained in file. See section Comparing Directories.

`-y'

Use the side by side output format. See section Controlling Side by Side Format.

Invoking `diff3`

The `diff3` command compares three files and outputs descriptions of their differences. Its arguments are as follows:

```
diff3 options... mine older yours
```

The files to compare are mine, older, and yours. At most one of these three file names may be `-', which tells `diff3` to read the standard input for that file.

An exit status of 0 means `diff3` was successful, 1 means some conflicts were found, and 2 means trouble.

Options to `diff3`

Below is a summary of all of the options that GNU `diff3` accepts. Multiple single letter options (unless they take an argument) can be combined into a single command line argument.

`-a'

Treat all files as text and compare them line-by-line, even if they do not appear to be text. See section Binary Files and Forcing Text Comparisons.

`-A'

Incorporate all changes from older to yours into mine, surrounding all conflicts with bracket lines. See section Marking Conflicts.

`-e'

Generate an `ed` script that incorporates all the changes from older to yours into mine. See section Selecting Which Changes to Incorporate.

`-E'

Like `-e', except bracket lines from overlapping changes' first and third files. See section Marking Conflicts. With `-e', an overlapping change looks like this:

```
<<<<<<< mine
lines from mine
=======
lines from yours
>>>>>>> yours
```

`--ed'

Generate an `ed` script that incorporates all the changes from older to yours into mine. See section Selecting Which Changes to Incorporate.

`--easy-only'

Like `-e', except output only the nonoverlapping changes. See section Selecting Which Changes to Incorporate.

`-i'

Generate `w' and `q' commands at the end of the `ed` script for System V compatibility. This option must be combined with one of the `-AeExX3' options, and may not be combined with `-m'. See section Saving the Changed File.

`-L label'

`--label=label'

Use the label label for the brackets output by the `-A', `-E' and `-X' options. This option may be given up to three times, one for each input file. The default labels are the names of the input files. Thus `diff3 -L X -L Y -L Z -m A B C' acts like `diff3 -m A B C', except that the output looks like it came from files named `X', `Y' and `Z' rather than from files named `A', `B' and `C'. See section Marking Conflicts.

`-m'

`--merge'

Apply the edit script to the first file and send the result to standard output. Unlike piping the output from `diff3` to `ed`, this works even for binary files and incomplete lines. `-A' is assumed if no edit script option is specified. See section Generating the Merged Output Directly.

`--overlap-only'

Like `-e', except output only the overlapping changes. See section Selecting Which Changes to Incorporate.

`--show-all'

Incorporate all unmerged changes from older to yours into mine, surrounding all overlapping changes with bracket lines. See section Marking Conflicts.

`--show-overlap'

Like `-e', except bracket lines from overlapping changes' first and third files. See section Marking Conflicts.

`--text'

Treat all files as text and compare them line-by-line, even if they do not appear to be text. See section Binary Files and Forcing Text Comparisons.

`-v'

`--version'

Output the version number of `diff3`.

`-x'

Like `-e', except output only the overlapping changes. See section Selecting Which Changes to Incorporate.

`-X'

Like `-E', except output only the overlapping changes. In other words, like `-x', except bracket changes as in `-E'. See section Marking Conflicts.

`-3'

Like `-e', except output only the nonoverlapping changes. See section Selecting Which Changes to Incorporate.

Invoking `patch`

Normally `patch` is invoked like this:

```
patch <patchfile
```

The full format for invoking `patch` is:

```
patch options... [origfile [patchfile]] [+ options... [origfile]]...
```

If you do not specify patchfile, or if patchfile is `-', `patch` reads the patch (that is, the `diff` output) from the standard input.

You can specify one or more of the original files as orig arguments; each one and options for interpreting it is separated from the others with a `+'. See section Multiple Patches in a File, for more information.

If you do not specify an input file on the command line, `patch` tries to figure out from the leading text

(any text in the patch that comes before the `diff` output) which file to edit. In the header of a context or unified diff, `patch` looks in lines beginning with `***', `---', or `+++'; among those, it chooses the shortest name of an existing file. Otherwise, if there is an `Index:' line in the leading text, `patch` tries to use the file name from that line. If `patch` cannot figure out the name of an existing file from the leading text, it prompts you for the name of the file to patch.

If the input file does not exist or is read-only, and a suitable RCS or SCCS file exists, `patch` attempts to check out or get the file before proceeding.

By default, `patch` replaces the original input file with the patched version, after renaming the original file into a backup file (see section Backup File Names, for a description of how `patch` names backup files). You can also specify where to put the output with the `-o output-file' or `--output=output-file' option.

Applying Patches in Other Directories

The `-d directory' or `--directory=directory' option to `patch` makes directory directory the current directory for interpreting both file names in the patch file, and file names given as arguments to other options (such as `-B' and `-o'). For example, while in a news reading program, you can patch a file in the `/usr/src/emacs' directory directly from the article containing the patch like this:

```
| patch -d /usr/src/emacs
```

Sometimes the file names given in a patch contain leading directories, but you keep your files in a directory different from the one given in the patch. In those cases, you can use the `-p[number]' or `--strip[=number]' option to set the file name strip count to number. The strip count tells `patch` how many slashes, along with the directory names between them, to strip from the front of file names. `-p' with no number given is equivalent to `-p0'. By default, `patch` strips off all leading paths, leaving just the base file names, except that when a file name given in the patch is a relative path and all of its leading directories already exist, `patch` does not strip off the leading path. (A relative path is one that does not start with a slash.)

`patch` looks for each file (after any slashes have been stripped) in the current directory, or if you used the `-d directory' option, in that directory.

For example, suppose the file name in the patch file is `/gnu/src/emacs/etc/NEWS'. Using `-p' or `-p0' gives the entire file name unmodified, `-p1' gives `gnu/src/emacs/etc/NEWS' (no leading slash), `-p4' gives `etc/NEWS', and not specifying `-p' at all gives `NEWS'.

Backup File Names

Normally, `patch` renames an original input file into a backup file by appending to its name the extension `.orig', or `~' on systems that do not support long file names. The `-b backup-suffix' or `--suffix=backup-suffix' option uses backup-suffix as the backup extension instead.

Alternately, you can specify the extension for backup files with the `SIMPLE_BACKUP_SUFFIX` environment variable, which the options override.

`patch` can also create numbered backup files the way GNU Emacs does. With this method, instead of

having a single backup of each file, `patch` makes a new backup file name each time it patches a file. I example, the backups of a file named `` `sink' `` would be called, successively, `` `sink.~1~' ``, `` `sink.~2~' ``, `` `sink.~3~' ``, etc.

The `-V backup-style' or `--version-control=backup-style' option takes as an argument a method for creating backup file names. You can alternately control the type of backups that `patch` makes with the `VERSION_CONTROL` environment variable, which the `-V' option overrides. The value of the `VERSION_CONTROL` environment variable and the argument to the `-V' option are like the GNU Emacs `version-control` variable (see section Backup File Names, for more information on backup versions in Emacs). They also recognize synonyms that are more descriptive. The valid values are listed below; unique abbreviations are acceptable.

`t'

`numbered'

Always make numbered backups.

`nil'

`existing'

Make numbered backups of files that already have them, simple backups of the others. This is the default.

`never'

`simple'

Always make simple backups.

Alternately, you can tell `patch` to prepend a prefix, such as a directory name, to produce backup file names. The `-B backup-prefix' or `--prefix=backup-prefix' option makes backup files by prepending backup-prefix to them. If you use this option, `patch` ignores any `-b' option that you give.

If the backup file already exists, `patch` creates a new backup file name by changing the first lowercase letter in the last component of the file name into uppercase. If there are no more lowercase letters in the name, it removes the first character from the name. It repeats this process until it comes up with a backup file name that does not already exist.

If you specify the output file with the `-o' option, that file is the one that is backed up, not the input file.

Reject File Names

The names for reject files (files containing patches that `patch` could not find a place to apply) are normally the name of the output file with `.rej' appended (or `#' on systems that do not support long file names).

Alternatively, you can tell `patch` to place all of the rejected patches in a single file. The `-r reject-file' or `--reject-file=reject-file' option uses reject-file as the reject file name.

Options to `patch`

Here is a summary of all of the options that `patch` accepts. Older versions of `patch` do not accept long-named options or the `-t', `-E', or `-V' options.

Multiple single-letter options that do not take an argument can be combined into a single command line argument (with only one dash). Brackets ([and]) indicate that an option takes an optional argument.

`-b backup-suffix'

Use backup-suffix as the backup extension instead of `.orig' or `~'. See section Backup File Names.

`-B backup-prefix'

Use backup-prefix as a prefix to the backup file name. If this option is specified, any `-b' option is ignored. See section Backup File Names.

`--batch'

Do not ask any questions. See section Messages and Questions from `patch`.

`-c'

`--context'

Interpret the patch file as a context diff. See section Selecting the `patch` Input Format.

`-d directory'

`--directory=directory'

Makes directory directory the current directory for interpreting both file names in the patch file, and file names given as arguments to other options. See section Applying Patches in Other Directories.

`-D name'

Make merged if-then-else output using format. See section Merging Files with If-then-else.

`--debug=number'

Set internal debugging flags. Of interest only to `patch` patchers.

`-e'

`--ed'

Interpret the patch file as an `ed` script. See section Selecting the `patch` Input Format.

`-E'

Remove output files that are empty after the patches have been applied. See section Removing Empty Files.

`-f'

Assume that the user knows exactly what he or she is doing, and do not ask any questions. See section Messages and Questions from `patch`.

`-F lines'

Set the maximum fuzz factor to lines. See section Helping `patch` Find Inexact Matches.

`--force'

Assume that the user knows exactly what he or she is doing, and do not ask any questions. See

section Messages and Questions from `patch`.

`--forward'

Ignore patches that `patch` thinks are reversed or already applied. See also `-R'. See section Applying Reversed Patches.

`--fuzz=lines'

Set the maximum fuzz factor to lines. See section Helping `patch` Find Inexact Matches.

`--ifdef=name'

Make merged if-then-else output using format. See section Merging Files with If-then-else.

`--ignore-whitespace'

`-l'

Let any sequence of whitespace in the patch file match any sequence of whitespace in the input file. See section Applying Patches with Changed Whitespace.

`-n'

`--normal'

Interpret the patch file as a normal diff. See section Selecting the `patch` Input Format.

`-N'

Ignore patches that `patch` thinks are reversed or already applied. See also `-R'. See section Applying Reversed Patches.

`-o output-file'

`--output=output-file'

Use output-file as the output file name. See section Options to `patch`.

`-p[number]'

Set the file name strip count to number. See section Applying Patches in Other Directories.

`--prefix=backup-prefix'

Use backup-prefix as a prefix to the backup file name. If this option is specified, any `-b' option is ignored. See section Backup File Names.

`--quiet'

Work silently unless an error occurs. See section Messages and Questions from `patch`.

`-r reject-file'

Use reject-file as the reject file name. See section Reject File Names.

`-R'

Assume that this patch was created with the old and new files swapped. See section Applying Reversed Patches.

`--reject-file=reject-file'

Use reject-file as the reject file name. See section Reject File Names.

`--remove-empty-files'

Remove output files that are empty after the patches have been applied. See section Removing

Empty Files.

`--reverse'

Assume that this patch was created with the old and new files swapped. See section Applying Reversed Patches.

`-s'

Work silently unless an error occurs. See section Messages and Questions from `patch`.

`-S'

Ignore this patch from the patch file, but continue looking for the next patch in the file. See section Multiple Patches in a File.

`--silent'

Work silently unless an error occurs. See section Messages and Questions from `patch`.

`--skip'

Ignore this patch from the patch file, but continue looking for the next patch in the file. See section Multiple Patches in a File.

`--strip[=number]'

Set the file name strip count to number. See section Applying Patches in Other Directories.

`--suffix=backup-suffix'

Use backup-suffix as the backup extension instead of `.orig' or `~'. See section Backup File Names.

`-t'

Do not ask any questions. See section Messages and Questions from `patch`.

`-u'

`--unified'

Interpret the patch file as a unified diff. See section Selecting the `patch` Input Format.

`-v'

Output the revision header and patch level of `patch`.

`-V backup-style'

Select the kind of backups to make. See section Backup File Names.

`--version'

Output the revision header and patch level of `patch`.

`--version=control=backup-style'

Select the kind of backups to make. See section Backup File Names.

`-x number'

Set internal debugging flags. Of interest only to `patch` patchers.

Invoking `sdiff`

The `sdiff` command merges two files and interactively outputs the results. Its arguments are as follows:

```
sdiff -o outfile options... from-file to-file
```

This merges from-file with to-file, with output to outfile. If from-file is a directory and to-file is not, `sdiff` compares the file in from-file whose file name is that of to-file, and vice versa. from-file and to-file may not both be directories.

`sdiff` options begin with `-', so normally from-file and to-file may not begin with `-'. However, `--' as an argument by itself treats the remaining arguments as file names even if they begin with `-'. You may not use `-' as an input file.

An exit status of 0 means no differences were found, 1 means some differences were found, and 2 means trouble.

`sdiff` without `-o' (or `--output') produces a side-by-side difference. This usage is obsolete; use `diff --side-by-side' instead.

Options to `sdiff`

Below is a summary of all of the options that GNU `sdiff` accepts. Each option has two equivalent names, one of which is a single letter preceded by `-', and the other of which is a long name preceded by `--'. Multiple single letter options (unless they take an argument) can be combined into a single command line argument. Long named options can be abbreviated to any unique prefix of their name.

`-a'

Treat all files as text and compare them line-by-line, even if they do not appear to be text. See section Binary Files and Forcing Text Comparisons.

`-b'

Ignore changes in amount of blank and tab whitespace. See section Suppressing Differences in Blank and Tab Spacing.

`-B'

Ignore changes that just insert or delete blank lines. See section Suppressing Differences in Blank Lines.

`-d'

Change the algorithm to perhaps find a smaller set of changes. This makes `sdiff` slower (sometimes much slower). See section `diff` Performance Tradeoffs.

`-H'

Use heuristics to speed handling of large files that have numerous scattered small changes. See section `diff` Performance Tradeoffs.

`--expand-tabs'

Expand tabs to spaces in the output, to preserve the alignment of tabs in the input files. See section Preserving Tabstop Alignment.

`-i'

Ignore changes in case; consider upper- and lower-case to be the same. See section Suppressing Case Differences.

`-I regexp'

Ignore changes that just insert or delete lines that match regexp. See section Suppressing Lines Matching a Regular Expression.

`--ignore-all-space'

Ignore whitespace when comparing lines. See section Suppressing Differences in Blank and Tab Spacing.

`--ignore-blank-lines'

Ignore changes that just insert or delete blank lines. See section Suppressing Differences in Blank Lines.

`--ignore-case'

Ignore changes in case; consider upper- and lower-case to be the same. See section Suppressing Case Differences.

`--ignore-matching-lines=regexp'

Ignore changes that just insert or delete lines that match regexp. See section Suppressing Lines Matching a Regular Expression.

`--ignore-space-change'

Ignore changes in amount of blank and tab whitespace. See section Suppressing Differences in Blank and Tab Spacing.

`-l'

`--left-column'

Print only the left column of two common lines. See section Controlling Side by Side Format.

`--minimal'

Change the algorithm to perhaps find a smaller set of changes. This makes `sdiff` slower (sometimes much slower). See section `diff` Performance Tradeoffs.

`-o file'

`--output=file'

Put merged output into file. This option is required for merging.

`-s'

`--suppress-common-lines'

Do not print common lines. See section Controlling Side by Side Format.

`--speed-large-files'

Use heuristics to speed handling of large files that have numerous scattered small changes. See

section `diff` Performance Tradeoffs.

`-t'

Expand tabs to spaces in the output, to preserve the alignment of tabs in the input files. See section Preserving Tabstop Alignment.

`--text'

Treat all files as text and compare them line-by-line, even if they do not appear to be text. See section Binary Files and Forcing Text Comparisons.

`-v'

`--version'

Output the version number of `sdiff`.

`-w columns'

`--width=columns'

Use an output width of columns. See section Controlling Side by Side Format. Note that for historical reasons, this option is `-W' in `diff`, `-w' in `sdiff`.

`-W'

Ignore horizontal whitespace when comparing lines. See section Suppressing Differences in Blank and Tab Spacing. Note that for historical reasons, this option is `-w' in `diff`, `-W' in `sdiff`.

Incomplete Lines

When an input file ends in a non-newline character, its last line is called an incomplete line because its last character is not a newline. All other lines are called full lines and end in a newline character. Incomplete lines do not match full lines unless differences in blank lines are ignored (see section Suppressing Differences in Blank Lines).

An incomplete line is normally distinguished on output from a full line by a following line that starts with `\'. However, the RCS format (see section RCS Scripts) outputs the incomplete line as-is, without any trailing newline or following line. The side by side format normally represents incomplete lines as-is, but in some cases uses a `\' or `/' gutter marker; See section Showing Differences Side by Side. The if-then-else line format preserves a line's incompleteness with `%L', and discards the newline with `%l'; See section Line Formats. Finally, with the `ed` and forward `ed` output formats (see section `diff` Output Formats) `diff` cannot represent an incomplete line, so it pretends there was a newline and reports an error.

For example, suppose `F' and `G' are one-byte files that contain just `f' and `g', respectively. Then `diff F G' outputs

```
1c1
< f
\ No newline at end of file
---
> g
```

```
\ No newline at end of file
```

(The exact message may differ in non-English locales.) `diff -n F G' outputs the following without a trailing newline:

```
d1 1
a1 1
g
```

`diff -e F G' reports two errors and outputs the following:

```
1c
g
.
```

Future Projects

Here are some ideas for improving GNU `diff` and `patch`. The GNU project has identified some improvements as potential programming projects for volunteers. You can also help by reporting any bugs that you find.

If you are a programmer and would like to contribute something to the GNU project, please consider volunteering for one of these projects. If you are seriously contemplating work, please write to `gnu@prep.ai.mit.edu' to coordinate with other volunteers.

Suggested Projects for Improving GNU `diff` and `patch`

One should be able to use GNU `diff` to generate a patch from any pair of directory trees, and given the patch and a copy of one such tree, use `patch` to generate a faithful copy of the other. Unfortunately, some changes to directory trees cannot be expressed using current patch formats; also, `patch` does not handle some of the existing formats. These shortcomings motivate the following suggested projects.

Handling Changes to the Directory Structure

`diff` and `patch` do not handle some changes to directory structure. For example, suppose one directory tree contains a directory named `D' with some subsidiary files, and another contains a file with the same name `D'. `diff -r' does not output enough information for `patch` to transform the the directory subtree into the file.

There should be a way to specify that a file has been deleted without having to include its entire contents in the patch file. There should also be a way to tell `patch` that a file was renamed, even if there is no way for `diff` to generate such information.

These problems can be fixed by extending the `diff` output format to represent changes in directory

structure, and extending `patch` to understand these extensions.

Files that are Neither Directories Nor Regular Files

Some files are neither directories nor regular files: they are unusual files like symbolic links, device special files, named pipes, and sockets. Currently, `diff` treats all these files like regular files. However, this means that `patch` cannot represent changes to such files. For example, if you change which file a symbolic link points to, `diff` outputs the difference between the two files, instead of the change to the symbolic link.

`diff` should optionally report changes to special files specially, and `patch` should be extended to understand these extensions.

File Names that Contain Unusual Characters

When a file name contains an unusual character like a newline or whitespace, `diff -r' generates a patch that `patch` cannot parse. The problem is with format of `diff` output, not just with `patch`, because with odd enough file names one can cause `diff` to generate a patch that is syntactically correct but patches the wrong files. The format of `diff` output should be extended to handle all possible file names.

Arbitrary Limits

GNU `diff` can analyze files with arbitrarily long lines and files that end in incomplete lines. However, `patch` cannot patch such files. The `patch` internal limits on line lengths should be removed, and `patch` should be extended to parse `diff` reports of incomplete lines.

Handling Files that Do Not Fit in Memory

`diff` operates by reading both files into memory. This method fails if the files are too large, and `diff` should have a fallback.

One way to do this is to scan the files sequentially to compute hash codes of the lines and put the lines in equivalence classes based only on hash code. Then compare the files normally. This does produce some false matches.

Then scan the two files sequentially again, checking each match to see whether it is real. When a match is not real, mark both the "matching" lines as changed. Then build an edit script as usual.

The output routines would have to be changed to scan the files sequentially looking for the text to print.

Ignoring Certain Changes

It would be nice to have a feature for specifying two strings, one in from-file and one in to-file, which should be considered to match. Thus, if the two strings are `foo' and `bar', then if two lines differ only in that `foo' in file 1 corresponds to `bar' in file 2, the lines are treated as identical.

It is not clear how general this feature can or should be, or what syntax should be used for it.

Reporting Bugs

If you think you have found a bug in GNU `cmp`, `diff`, `diff3`, `sdiff`, or `patch`, please report it by electronic mail to `bug-gnu-utils@prep.ai.mit.edu'. Send as precise a description of the problem as you can, including sample input files that produce the bug, if applicable.

Because Larry Wall has not released a new version of `patch` since mid 1988 and the GNU version of `patch` has been changed since then, please send bug reports for `patch` by electronic mail to both `bug-gnu-utils@prep.ai.mit.edu' and `lwall@netlabs.com'.

GNU MP Copying Conditions

This library is free; this means that everyone is free to use it and free to redistribute it on a free basis. The library is not in the public domain; it is copyrighted and there are restrictions on its distribution, but these restrictions are designed to permit everything that a good cooperating citizen would want to do. What is not allowed is to try to prevent others from further sharing any version of this library that they might get from you.

Specifically, we want to make sure that you have the right to give away copies of the library, that you receive source code or else can get it if you want it, that you can change this library or use pieces of it in new free programs, and that you know you can do these things.

To make sure that everyone has such rights, we have to forbid you to deprive anyone else of these rights. For example, if you distribute copies of the GMP library, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must tell them their rights.

Also, for our own protection, we must make certain that everyone finds out that there is no warranty for the GMP library. If it is modified by someone else and passed on, we want their recipients to know that what they have is not what we distributed, so that any problems introduced by others will not reflect on our reputation.

The precise conditions of the license for the GMP library are found in the General Public License that accompany the source code.

Introduction to MP

GNU MP is a portable library for arbitrary precision integer and rational number arithmetic.(1) It aims to provide the fastest possible arithmetic for all applications that need more than two words of integer precision.

Most often, applications tend to use just a few words of precision; but some applications may need thousands of words. GNU MP is designed to give good performance for both kinds of applications, by choosing algorithms based on the sizes of the operands.

There are five groups of functions in the MP library:

1. Functions for signed integer arithmetic, with names beginning with `mpz_`.
2. Functions for rational number arithmetic, with names beginning with `mpq_`.
3. Functions compatible with Berkeley MP, such as `itom`, `madd`, and `mult`.
4. Fast low-level functions that operate on natural numbers. These are used by the functions in the preceding groups, and you can also call them directly from very time-critical user programs. These functions' names begin with `mpn_`.
5. Miscellaneous functions.

As a general rule, all MP functions expect output arguments before input arguments. This notation is based on an analogy with the assignment operator. (The BSD MP compatibility functions disobey this rule, having the output argument(s) last.) Multi-precision numbers, whether output or input, are always passed as addresses to the declared type.

Nomenclature and Data Types

In this manual, integer means a multiple precision integer, as used in the MP package. The C data type for such integers is `MP_INT`. For example:

```
MP_INT sum;

struct foo { MP_INT x, y; };

MP_INT vec[20];
```

Rational number means a multiple precision fraction. The C data type for these fractions is `MP_RAT`. For example:

```
MP_RAT quotient;
```

A limb means the part of a multi-precision number that fits in a single word. (We chose this word because a limb of the human body is analogous to a digit, only larger, and containing several digits.) Normally a limb contains 32 bits.

Thanks

I would like to thank Gunnar Sjoedin and Hans Riesel for their help with mathematical problems, Richard Stallman for his help with design issues and for revising this manual, Brian Beuning and Doug Lea for their testing of various versions of the library, and Joachim Hollman for his many valuable suggestions.

Special thanks to Brian Beuning, he has shaked out many bugs from early versions of the code!

John Amanatides of York University in Canada contributed the function `mpz_probab_prime_p`.

Initialization

Before you can use a variable or object of type `MP_INT` or `MP_RAT`, you must initialize it. This fills in the components that point to dynamically allocated space for the limbs of the number.

When you are finished using the object, you should clear out the object. This frees the dynamic space that it points to, so the space can be used again.

Once you have initialized the object, you need not be concerned about allocating additional space. The functions in the MP package automatically allocate additional space when the object does not already have enough space. They do not, however, reduce the space in use when a smaller number is stored in the object. Most of the time, this policy is best, since it avoids frequent re-allocation. If you want to reduce the space in an object to the minimum needed, you can do `_mpz_realloc (&object, mpz_size (&object))`.

The functions to initialize numbers are `mpz_init` (for `MP_INT`) and `mpq_init` (for `MP_RAT`).

`mpz_init` allocates space for the limbs, and stores a pointer to that space in the `MP_INT` object. It also stores the value 0 in the object.

In the same manner, `mpq_init` allocates space for the numerator and denominator limbs, and stores pointers to these spaces in the `MP_RAT` object.

To clear out a number object, use `mpz_clear` and `mpq_clear`, respectively.

Here is an example of use:

```
{
  MP_INT temp;
  mpz_init (&temp);

  ... store and read values in temp zero or more times ...

  mpz_clear (&temp):
}
```

You might be tempted to copy an integer from one object to another like this:

```
MP_INT x, y;

x = y;
```

Although valid C, **this is an error.** Rather than copying the integer value from `y` to `x` it will make the two variables share storage. Subsequent assignments to one variable would change the other mysteriously. And if you were to clear out both variables subsequently, you would confuse `malloc` and cause your program to crash.

To copy the value properly, you must use the function `mpz_set`. (see section Integer Assignment Functions)

Integer Functions

This chapter describes the MP functions for performing integer arithmetic.

The integer functions use arguments and values of type pointer-to-`MP_INT` (see section Nomenclature and Data Types). The type `MP_INT` is a structure, but applications should not refer directly to its components. Include the header `` `gmp.h' `` to get the definition of `MP_INT`.

Initializing Integer Objects

Most of the functions for integer arithmetic assume that the output is stored in an object already initialized. For example, `mpz_add` stores the result of addition (see section Integer Arithmetic Functions). Thus, you must initialize the object before storing the first value in it. You can do this separately by calling the function `mpz_init`.

Function: void **mpz_init** *(MP_INT *integer)*

Initialize integer with limb space and set the initial numeric value to 0. Each variable should normally only be initialized once, or at least cleared out (using `mpz_clear`) between each initialization.

Here is an example of using `mpz_init`:

```
{
  MP_INT integ;
  mpz_init (&integ);
  ...
  mpz_add (&integ, ...);
  ...
  mpz_sub (&integ, ...);

  /* Unless you are now exiting the program, do ... */
  mpz_clear (&integ);
}
```

As you can see, you can store new values any number of times, once an object is initialized.

Function: void **mpz_clear** *(MP_INT *integer)*

Free the limb space occupied by integer. Make sure to call this function for all `MP_INT` variables when you are done with them.

Function: void * **_mpz_realloc** *(MP_INT *integer, mp_size new_alloc)*

Change the limb space allocation to new_alloc limbs. This function is not normally called from user code, but it can be used to give memory back to the heap, or to increase the space of a variable to avoid repeated automatic re-allocation.

Function: void **mpz_array_init** *(MP_INT integer_array[], size_t array_size, mp_size fixed_num_limbs)*

Allocate **fixed** limb space for all array_size integers in integer_array. The fixed allocation for each integer in the array is fixed_num_limbs. This function is useful for decreasing the working set for some algorithms that use large integer arrays. If the fixed space will be insufficient for storing the result of a subsequent calculation, the result is unpredictable.

There is no way to de-allocate the storage allocated by this function. Don't call `mpz_clear`!

Integer Assignment Functions

These functions assign new values to already initialized integers (see section Initializing Integer Objects).

Function: void **mpz_set** *(MP_INT *dest_integer, MP_INT *src_integer)*

Assign dest_integer from src_integer.

Function: void **mpz_set_ui** *(MP_INT *integer, unsigned long int initial_value)*

Set the value of integer from initial_value.

Function: void **mpz_set_si** *(MP_INT *integer, signed long int initial_value)*

Set the value of integer from initial_value.

Function: int **mpz_set_str** *(MP_INT *integer, char *initial_value, int base)*

Set the value of integer from initial_value, a '\0'-terminated C string in base base. White space is allowed in the string, and is simply ignored. The base may vary from 2 to 36. If base is 0, the actual base is determined from the leading characters: if the first two characters are `0x' or `0X', hexadecimal is assumed, otherwise if the first character is `0', octal is assumed, otherwise decimal is assumed.

This function returns 0 if the entire string up to the '\0' is a valid number in base base. Otherwise it returns -1.

Combined Initialization and Assignment Functions

For your convenience, MP provides a parallel series of initialize-and-set arithmetic functions which initialize the output and then store the value there. These functions' names have the form `mpz_init_set...`

Here is an example of using one:

```
{
  MP_INT integ;
  mpz_init_set_str (&integ, "3141592653589793238462643383279502884", 10);
  ...
  mpz_sub (&integ, ...);

  mpz_clear (&integ);
}
```

Once the integer has been initialized by any of the `mpz_init_set...` functions, it can be used as the source or destination operand for the ordinary integer functions. Don't use an initialize-and-set function on a variable already initialized!

Function: void **mpz_init_set** *(MP_INT *dest_integer, MP_INT *src_integer)*

Initialize dest_integer with limb space and set the initial numeric value from src_integer.

Function: void **mpz_init_set_ui** *(MP_INT *dest_integer, unsigned long int src_ulong)*

Initialize dest_integer with limb space and set the initial numeric value from src_ulong.

Function: void **mpz_init_set_si** *(MP_INT *dest_integer, signed long int src_slong)*

Initialize dest_integer with limb space and set the initial numeric value from src_slong.

Function: int **mpz_init_set_str** *(MP_INT *dest_integer, char *src_cstring, int base)*

Initialize dest_integer with limb space and set the initial numeric value from src_cstring, a '\0'-terminated C string in base base. The base may vary from 2 to 36. There may be white space in the string.

If the string is a correct base base number, the function returns 0; if an error occurs it returns -1. dest_integer is initialized even if an error occurs. (I.e., you have to call mpz_clear for it.)

Conversion Functions

Function: unsigned long int **mpz_get_ui** *(MP_INT *src_integer)*

Return the least significant limb from src_integer. This function together with `mpz_div_2exp(..., src_integer, CHAR_BIT*sizeof(unsigned long int))` can be used to extract the limbs of an integer efficiently.

Function: signed long int **mpz_get_si** *(MP_INT *src_integer)*

If src_integer fits into a `signed long int` return the value of src_integer. Otherwise return the least significant bits of src_integer, with the same sign as src_integer.

Function: char * **mpz_get_str** *(char *string, int base, MP_INT *integer)*

Convert integer to a '\0'-terminated C string in string, using base base. The base may vary from 2 to 36. If string is NULL, space for the string is allocated using the default allocation function.

If string is not NULL, it should point to a block of storage enough large for the result. To find out the right

amount of space to provide for string, use `mpz_sizeinbase (integer, base) + 2`. The "+ 2" for a possible minus sign, and for the terminating null character. (see section Miscellaneous Functions).

This function returns a pointer to the result string.

Integer Arithmetic Functions

Function: void **mpz_add** *(MP_INT *sum, MP_INT *addend1, MP_INT *addend2)*

Function: void **mpz_add_ui** *(MP_INT *sum, MP_INT *addend1, unsigned long int addend2)*

Set sum to addend1 + addend2.

Function: void **mpz_sub** *(MP_INT *difference, MP_INT *minuend, MP_INT *subtrahend)*

Function: void **mpz_sub_ui** *(MP_INT *difference, MP_INT *minuend, unsigned long int subtrahend)*

Set difference to minuend - subtrahend.

Function: void **mpz_mul** *(MP_INT *product, MP_INT *multiplicator, MP_INT *multiplicand)*

Function: void **mpz_mul_ui** *(MP_INT *product, MP_INT *multiplicator, unsigned long int multiplicand)*

Set product to multiplicator times multiplicand.

Division is undefined if the divisor is zero, and passing a zero divisor to the divide or modulo functions, as well passing a zero mod argument to the powm functions, will make these functions intentionally divide by zero. This gives the user the possibility to handle arithmetic exceptions in these functions in the same manner as other arithmetic exceptions.

Function: void **mpz_div** *(MP_INT *quotient, MP_INT *dividend, MP_INT *divisor)*

Function: void **mpz_div_ui** *(MP_INT *quotient, MP_INT *dividend, unsigned long int divisor)*

Set quotient to dividend / divisor. The quotient is rounded towards 0.

Function: void **mpz_mod** *(MP_INT *remainder, MP_INT *divdend, MP_INT *divisor)*

Function: void **mpz_mod_ui** *(MP_INT *remainder, MP_INT *divdend, unsigned long int divisor)*

Divide dividend and divisor and put the remainder in remainder. The remainder has the same sign as the dividend, and its absolute value is less than the absolute value of the divisor.

Function: void **mpz_divmod** *(MP_INT *quotient, MP_INT *remainder, MP_INT *dividend, MP_INT *divisor)*

Function: void **mpz_divmod_ui** *(MP_INT *quotient, MP_INT *remainder, MP_INT *dividend, unsigned long int divisor)*

Divide dividend and divisor and put the quotient in quotient and the remainder in remainder. The quotient is rounded towards 0. The remainder has the same sign as the dividend, and its absolute value is less than the absolute value of the divisor.

If quotient and remainder are the same variable, the results are not defined.

TOC

Function: void **mpz_mdiv** *(MP_INT *quotient, MP_INT *dividend, MP_INT *divisor)*

Function: void **mpz_mdiv_ui** *(MP_INT *quotient, MP_INT *dividend, unsigned long int divisor)*

Set quotient to dividend / divisor. The quotient is rounded towards -infinity.

Function: void **mpz_mmod** *(MP_INT *remainder, MP_INT *divdend, MP_INT *divisor)*

Function: unsigned long int **mpz_mmod_ui** *(MP_INT *remainder, MP_INT *divdend, unsigned long int divisor)*

Divide dividend and divisor and put the remainder in remainder. The remainder is always positive, and its value is less than the value of the divisor.

For `mpz_mmod_ui` the remainder is returned, and if remainder is not NULL, also stored there.

Function: void **mpz_mdivmod** *(MP_INT *quotient, MP_INT *remainder, MP_INT *dividend, MP_INT *divisor)*

Function: unsigned long int **mpz_mdivmod_ui** *(MP_INT *quotient, MP_INT *remainder, MP_INT *dividend, unsigned long int divisor)*

Divide dividend and divisor and put the quotient in quotient and the remainder in remainder. The quotient is rounded towards -infinity. The remainder is always positive, and its value is less than the value of the divisor.

For `mpz_mdivmod_ui` the remainder is small enough to fit in an `unsigned long int`, and is therefore returned. If remainder is not NULL, the remainder is also stored there.

If quotient and remainder are the same variable, the results are not defined.

Function: void **mpz_sqrt** *(MP_INT *root, MP_INT *operand)*

Set root to the square root of operand. The result is rounded towards zero.

Function: void **mpz_sqrtrem** *(MP_INT *root, MP_INT *remainder, MP_INT *operand)*

Set root to the square root of operand, as with `mpz_sqrt`. Set remainder to (i.e. zero if operand is a perfect square).

If root and remainder are the same variable, the results are not defined.

Function: int **mpz_perfect_square_p** *(MP_INT *square)*

Return non-zero if square is perfect, i.e. if the square root of square is integral. Return zero otherwise.

Function: int **mpz_probab_prime_p** *(MP_INT *n, int reps)*

An implementation of the probabilistic primality test found in Knuth's Seminumerical Algorithms book. If the function `mpz_probab_prime_p(n, reps)` returns 0 then n is not prime. If it returns 1, then n is `probably' prime. The probability of a false positive is (1/4)**reps, where reps is the number of internal passes of the probabilistic algorithm. Knuth indicates that 25 passes are reasonable.

Function: void **mpz_powm** *(MP_INT *res, MP_INT *base, MP_INT *exp, MP_INT *mod)*

Function: void **mpz_powm_ui** *(MP_INT *res, MP_INT *base, unsigned long int exp, MP_INT *mod)*

Set res to (base raised to exp) modulo mod. If exp is negative, the result is undefined.

Function: void **mpz_pow_ui** *(MP_INT *res, MP_INT *base, unsigned long int exp)*

Set res to base raised to exp.

Function: void **mpz_fac_ui** *(MP_INT *res, unsigned long int n)*

Set res n!, the factorial of n.

Function: void **mpz_gcd** *(MP_INT *res, MP_INT *operand1, MP_INT *operand2)*

Set res to the greatest common divisor of operand1 and operand2.

Function: void **mpz_gcdext** *(MP_INT *g, MP_INT *s, MP_INT *t, MP_INT *a, MP_INT *b)*

Compute g, s, and t, such that as + bt = g = `gcd` (a, b). If t is NULL, that argument is not computed.

Function: void **mpz_neg** *(MP_INT *negated_operand, MP_INT *operand)*

Set negated_operand to -operand.

Function: void **mpz_abs** *(MP_INT *positive_operand, MP_INT *signed_operand)*

Set positive_operand to the absolute value of signed_operand.

Function: int **mpz_cmp** *(MP_INT *operand1, MP_INT *operand2)*

Function: int **mpz_cmp_ui** *(MP_INT *operand1, unsigned long int operand2)*

Function: int **mpz_cmp_si** *(MP_INT *operand1, signed long int operand2)*

Compare operand1 and operand2. Return a positive value if operand1 > operand2, zero if operand1 = operand2, and a negative value if operand1 < operand2.

Function: void **mpz_mul_2exp** *(MP_INT *product, MP_INT *multiplicator, unsigned long int exponent_of_2)*

Set product to multiplicator times 2 raised to exponent_of_2. This operation can also be defined as a left shift, exponent_of_2 steps.

Function: void **mpz_div_2exp** *(MP_INT *quotient, MP_INT *dividend, unsigned long int exponent_of_2)*

Set quotient to dividend divided by 2 raised to exponent_of_2. This operation can also be defined as a right shift, exponent_of_2 steps, but unlike the >> operator in C, the result is rounded towards 0.

Function: void **mpz_mod_2exp** *(MP_INT *remainder, MP_INT *dividend, unsigned long int exponent_of_2)*

Set remainder to dividend mod (2 raised to exponent_of_2). The sign of remainder will have the same sign as dividend.

This operation can also be defined as a masking of the exponent_of_2 least significant bits.

TOC

Logical Functions

Function: void **mpz_and** *(MP_INT *conjunction, MP_INT *operand1, MP_INT *operand2)*

Set conjunction to operand1 logical-and operand2.

Function: void **mpz_ior** *(MP_INT *disjunction, MP_INT *operand1, MP_INT *operand2)*

Set disjunction to operand1 inclusive-or operand2.

Function: void **mpz_xor** *(MP_INT *disjunction, MP_INT *operand1, MP_INT *operand2)*

Set disjunction to operand1 exclusive-or operand2.

This function is missing in the current release.

Function: void **mpz_com** *(MP_INT *complemented_operand, MP_INT *operand)*

Set complemented_operand to the one's complement of operand.

Input and Output Functions

Functions that perform input from a standard I/O stream, and functions for output conversion.

Function: void **mpz_inp_raw** *(MP_INT *integer, FILE *stream)*

Input from standard I/O stream stream in the format written by `mpz_out_raw`, and put the result in integer.

Function: void **mpz_inp_str** *(MP_INT *integer, FILE *stream, int base)*

Input a string in base base from standard I/O stream stream, and put the read integer in integer. The base may vary from 2 to 36. If base is 0, the actual base is determined from the leading characters: if the first two characters are `0x' or `0X', hexadecimal is assumed, otherwise if the first character is `0', octal is assumed, otherwise decimal is assumed.

Function: void **mpz_out_raw** *(FILE *stream, MP_INT *integer)*

Output integer on standard I/O stream stream, in raw binary format. The integer is written in a portable format, with 4 bytes of size information, and that many bytes of limbs. Both the size and the limbs are written in decreasing significance order.

Function: void **mpz_out_str** *(FILE *stream, int base, MP_INT *integer)*

Output integer on standard I/O stream stream, as a string of digits in base base. The base may vary from 2 to 36.

Rational Number Functions

All rational arithmetic functions canonicalize the result, so that the denominator and the numerator have no common factors. Zero has the unique representation 0/1.

The set of functions is quite small. Maybe it will be extended in a future release.

Function: void **mpq_init** *(MP_RAT *dest_rational)*

Initialize dest_rational with limb space and set the initial numeric value to 0/1. Each variable should normally only be initialized once, or at least cleared out (using the function `mpq_clear`) between each initialization.

Function: void **mpq_clear** *(MP_RAT *rational_number)*

Free the limb space occupied by rational_number. Make sure to call this function for all `MP_RAT` variables when you are done with them.

Function: void **mpq_set** *(MP_RAT *dest_rational, MP_RAT *src_rational)*

Assign dest_rational from src_rational.

Function: void **mpq_set_ui** *(MP_RAT *rational_number, unsigned long int numerator, unsigned long int denominator)*

Set the value of rational_number to numerator/denominator. If numerator and denominator have common factors, they are divided out before rational_number is assigned.

Function: void **mpq_set_si** *(MP_RAT *rational_number, signed long int numerator, unsigned long int denominator)*

Like `mpq_set_ui`, but numerator is signed.

Function: void **mpq_add** *(MP_RAT *sum, MP_RAT *addend1, MP_RAT *addend2)*

Set sum to addend1 + addend2.

Function: void **mpq_sub** *(MP_RAT *difference, MP_RAT *minuend, MP_RAT *subtrahend)*

Set difference to minuend - subtrahend.

Function: void **mpq_mul** *(MP_RAT *product, MP_RAT *multiplicator, MP_RAT *multiplicand)*

Set product to multiplicator * multiplicand

Function: void **mpq_div** *(MP_RAT *quotient, MP_RAT *dividend, MP_RAT *divisor)*

Set quotient to dividend / divisor.

Function: void **mpq_neg** *(MP_RAT *negated_operand, MP_RAT *operand)*

Set negated_operand to -operand.

Function: int **mpq_cmp** *(MP_RAT *operand1, MP_RAT *operand2)*

Compare operand1 and operand2. Return a positive value if operand1 > operand2, zero if operand1 = operand2, and a negative value if operand1 < operand2.

Function: void **mpq_inv** *(MP_RAT *inverted_number, MP_RAT *number)*

Invert number by swapping the numerator and denominator. If the new denominator becomes zero, this routine will divide by zero.

Function: void **mpq_set_num** *(MP_RAT *rational_number, MP_INT *numerator)*

Make numerator become the numerator of rational_number by copying.

Function: void **mpq_set_den** *(MP_RAT *rational_number, MP_INT *denominator)*

Make denominator become the denominator of rational_number by copying. If denominator < 0 the denominator of rational_number is set to the absolute value of denominator, and the sign of the numerator of rational_number is changed.

Function: void **mpq_get_num** *(MP_INT *numerator, MP_RAT *rational_number)*

Copy the numerator of rational_number to the integer numerator, to prepare for integer operations on the numerator.

Function: void **mpq_get_den** *(MP_INT *denominator, MP_RAT *rational_number)*

Copy the denominator of rational_number to the integer denominator, to prepare for integer operations on the denominator.

Low-level Functions

The next release of the GNU MP library (2.0) will include changes to some mpn functions. Programs that use these functions according to the descriptions below will therefore not work with the next release.

The low-level function layer is designed to be as fast as possible, **not** to provide a coherent calling interface. The different functions have similar interfaces, but there are variations that might be confusing. These functions do as little as possible apart from the real multiple precision computation, so that no time is spent on things that not all callers need.

A source operand is specified by a pointer to the least significant limb and a limb count. A destination operand is specified by just a pointer. It is the responsability of the caller to ensure that the destination has enough space for storing the result.

With this way of specifying source operands, it is possible to perform computations on subranges of an argument, and store the result into a subrange of a destination.

All these functions require that the operands are normalized in the sense that the most significant limb must be non-zero. (A future release of might drop this requirement.)

The low-level layer is the base for the implementation of the `mpz_` and `mpq_` layers.

The code below adds the number beginning at src1_ptr and the number beginning at src2_ptr and writes the

sum at dest_ptr. A constraint for `mpn_add` is that src1_size must not be smaller that src2_size.

`mpn_add (dest_ptr, src1_ptr, src1_size, src2_ptr, src2_size)`

In the description below, a source operand is identified by the pointer to the least significant limb, and the limb count in braces.

Function: mp_size **mpn_add** *(mp_ptr dest_ptr, mp_srcptr src1_ptr, mp_size src1_size, mp_srcptr src2_ptr, mp_size src2_size)*

Add {src1_ptr, src1_size} and {src2_ptr, src2_size}, and write the src1_size least significant limbs of the result to dest_ptr. Carry-out, either 0 or 1, is returned.

This function requires that src1_size is greater than or equal to src2_size.

Function: mp_size **mpn_sub** *(mp_ptr dest_ptr, mp_srcptr src1_ptr, mp_size src1_size, mp_srcptr src2_ptr, mp_size src2_size)*

Subtarct {src2_ptr, src2_size} from {src1_ptr, src1_size}, and write the result to dest_ptr.

Return 1 if the minuend < the subtrahend. Otherwise, return the negative difference between the number of words in the result and the minuend. I.e. return 0 if the result has src1_size words, -1 if it has src1_size - 1 words, etc.

This function requires that src1_size is greater than or equal to src2_size.

Function: mp_size **mpn_mul** *(mp_ptr dest_ptr, mp_srcptr src1_ptr, mp_size src1_size, mp_srcptr src2_ptr, mp_size src2_size)*

Multiply {src1_ptr, src1_size} and {src2_ptr, src2_size}, and write the result to dest_ptr. The exact size of the result is returned.

The destination has to have space for src1_size + src1_size limbs, even if the result might be one limb smaller.

This function requires that src1_size is greater than or equal to src2_size. The destination must be distinct from either input operands.

Function: mp_size **mpn_div** *(mp_ptr dest_ptr, mp_ptr src1_ptr, mp_size src1_size, mp_srcptr src2_ptr, mp_size src2_size)*

Divide {src1_ptr, src1_size} by {src2_ptr, src2_size}, and write the quotient to dest_ptr, and the remainder to src1_ptr.

Return 0 if the quotient size is at most (src1_size - src2_size), and 1 if the quotient size is at most (src1_size - src2_size + 1). The caller has to check the most significant limb to find out the exact size.

The most significant bit of the most significant limb of the divisor has to be set.

This function requires that src1_size is greater than or equal to src2_size. The quotient, pointed to by dest_ptr, must be distinct from either input operands.

Function: mp_limb **mpn_lshift** *(mp_ptr dest_ptr, mp_srcptr src_ptr, mp_size src_size, unsigned long int count)*

Shift {src_ptr, src_size} count bits to the left, and write the src_size least significant limbs of the result t dest_ptr. count might be in the range 1 to n - 1, on an n-bit machine. The limb shifted out is returned.

Overlapping of the destination space and the source space is allowed in this function, provdied dest_ptr >= src_ptr.

Function: mp_size **mpn_rshift** *(mp_ptr dest_ptr, mp_srcptr src_ptr, mp_size src_size, unsigned long int count)*

Shift {src_ptr, src_size} count bits to the right, and write the src_size least significant limbs of the result to dest_ptr. count might be in the range 1 to n - 1, on an n-bit machine. The size of the result is returned.

Overlaping of the destination space and the source space is allowed in this function, provdied dest_ptr <= src_ptr.

Function: mp_size **mpn_rshiftci** *(mp_ptr dest_ptr, mp_srcptr src_ptr, mp_size src_size, unsigned long int count, mp_limb inlimb)*

Like mpn_rshift, but use inlimb to feed the least significant end of the destination.

Function: int **mpn_cmp** *(mp_srcptr src1_ptr, mp_srcptr src2_ptr, mp_size size)*

Compare {src1_ptr, size} and {src2_ptr, size} and return a positive value if src1 > src2, 0 of they are equal, and a negative value if src1 < src2.

Berkeley MP Compatible Functions

These functions are intended to be fully compatible with the Berkeley MP library which is available on many BSD derived U*ix systems.

The original Berkeley MP library has a usage restriction: you cannot use the same variable as both source and destination in a single function call. The compatible functions in GNU MP do not share this restriction--inputs and outputs may overlap.

It is not recommended that new programs are written using these functions. Apart from the incomplete set of functions, the interface for initializing `MINT` objects is more error prone, and the `pow` function collides with `pow` in `` `libm.a' ``.

Include the header `` `mp.h' `` to get the definition of the necessary types and functions. If you are on a BSD derived system, make sure to include GNU `` `mp.h' `` if you are going to link the GNU `` `libmp.a' `` to you program. This means that you probably need to give the -I<dir> option to the compiler, where <dir> is the directory where you have GNU `` `mp.h' ``.

Function: MINT * **itom** *(signed short int initial_value)*

Allocate an integer consisting of a `MINT` object and dynamic limb space. Initialize the integer to initial_value. Return a pointer to the `MINT` object.

Function: MINT * **xtom** *(char *initial_value)*

Allocate an integer consisting of a `MINT` object and dynamic limb space. Initialize the integer from

initial_value, a hexadecimal, '\0'-terminate C string. Return a pointer to the `MINT` object.

Function: void **move** *(MINT *src, MINT *dest)*

Set dest to src by copying. Both variables must be previously initialized.

Function: void **madd** *(MINT *src_1, MINT *src_2, MINT *destination)*

Add src_1 and src_2 and put the sum in destination.

Function: void **msub** *(MINT *src_1, MINT *src_2, MINT *destination)*

Subtract src_2 from src_1 and put the difference in destination.

Function: void **mult** *(MINT *src_1, MINT *src_2, MINT *destination)*

Multiply src_1 and src_2 and put the product in destination.

Function: void **mdiv** *(MINT *dividend, MINT *divisor, MINT *quotient, MINT *remainder)*

Function: void **sdiv** *(MINT *dividend, signed short int divisor, MINT *quotient, signed short int *remainder)*

Set quotient to dividend / divisor, and remainder to dividend mod divisor. The quotient is rounded towards zero; the remainder has the same sign as the dividend.

Some implementations of this function return a remainder whose sign is inverted if the divisor is negative. Such a definition makes little sense from a mathematical point of view. GNU MP might be considered incompatible with the traditional MP in this respect.

Function: void **msqrt** *(MINT *operand, MINT *root, MINT *remainder)*

Set root to the square root of operand, as with `mpz_sqrt`. Set remainder to (i.e. zero if operand is a perfect square).

Function: void **pow** *(MINT *base, MINT *exp, MINT *mod, MINT *dest)*

Set dest to (base raised to exp) modulo mod.

Function: void **rpow** *(MINT *base, signed short int exp, MINT *dest)*

Set dest to base raised to exp.

Function: void **gcd** *(MINT *operand1, MINT *operand2, MINT *res)*

Set res to the greatest common divisor of operand1 and operand2.

Function: int **mcmp** *(MINT *operand1, MINT *operand2)*

Compare operand1 and operand2. Return a positive value if operand1 > operand2, zero if operand1 = operand2, and a negative value if operand1 < operand2.

Function: void **min** *(MINT *dest)*

Input a decimal string from stdin, and put the read integer in dest. SPC and TAB are allowed in the number string, and are ignored.

Function: void **mout** *(MINT *src)*

Output src to stdout, as a decimal string. Also output a newline.

Function: char * **mtox** *(MINT *operand)*

Convert operand to a hexadecimal string, and return a pointer to the string. The returned string is allocated using the default memory allocation function, `malloc` by default. (See section Initialization, for an explanation of the memory allocation in MP).

Function: void **mfree** *(MINT *operand)*

De-allocate, the space used by operand. **This function should only be passed a value returned by `itom` or `xtom`.**

Miscellaneous Functions

Function: void **mpz_random** *(MP_INT *random_integer, mp_size max_size)*

Generate a random integer of at most max_size limbs. The generated random number doesn't satisfy any particular requirements of randomness.

Function: void **mpz_random2** *(MP_INT *random_integer, mp_size max_size)*

Generate a random integer of at most max_size limbs, with long strings of zeros and ones in the binary representation. Useful for testing functions and algorithms, since this kind of random numbers have proven to be more likely to trigger bugs.

Function: size_t **mpz_size** *(MP_INT *integer)*

Return the size of integer measured in number of limbs. If integer is zero, the returned value will be zero, if integer has one limb, the returned value will be one, etc. (See section Nomenclature and Data Types, for an explanation of the concept limb.)

Function: size_t **mpz_sizeinbase** *(MP_INT *integer, int base)*

Return the size of integer measured in number of digits in base base. The base may vary from 2 to 36. The returned value will be exact or 1 too big. If base is a power of 2, the returned value will always be exact.

This function is useful in order to allocate the right amount of space before converting integer to a string. The right amount of allocation is normally two more than the value returned by `mpz_sizeinbase` (one extra for a minus sign and one for the terminating '\0').

Custom Allocation

By default, the initialization functions use `malloc`, `realloc`, and `free` to do their work. If `malloc` or `realloc` fails, the MP package terminates execution after a printing fatal error message on standard error.

In some applications, you may wish to allocate memory in other ways, or you may not want to have a fatal error when there is no more memory available. To accomplish this, you can specify alternative functions for allocating and de-allocating memory. Use `mp_set_memory_functions` to do this.

`mp_set_memory_functions` has three arguments, allocate_function, reallocate_function, and deallocate_function, in that order. If an argument is NULL, the corresponding default function is retained.

The functions you supply should fit the following declarations:

`void * allocate_function (size_t alloc_size)`

This function should return a pointer to newly allocated space with at least alloc_size storage units.

`void * reallocate_function (void *ptr, size_t old_size, size_t new_size)`

This function should return a pointer to newly allocated space of at least new_size storage units, after copying the first old_size storage units from ptr. It should also de-allocate the space at ptr.

You can assume that the space at ptr was formely returned from allocate_function or reallocate_function, for a request for old_size storage units.

`void deallocate_function (void *ptr, size_t size)`

De-allocate the space pointed to by ptr.

You can assume that the space at ptr was formely returned from allocate_function or reallocate_function, for a request for size storage units.

(A storage unit is the unit in which the `sizeof` operator returns the size of an object, normally an 8 bit byte.)

NOTE: call `mp_set_memory_functions` only before calling any other MP functions. Otherwise, the user-defined allocation functions may be asked to re-allocate or de-allocate something previously allocated by the default allocation functions.

Reporting Bugs

If you think you have found a bug in the GNU MP library, please investigate it and report it. We have made this library available to you, and it is not to ask too much from you, to ask you to report the bugs that you find.

Please make sure that the bug is really in the GNU MP library.

You have to send us a test case that makes it possible for us to reproduce the bug.

You also have to explain what is wrong; if you get a crash, or if the results printed are not good and in that case, in what way.

Make sure that the bug report includes all information you would need to fix this kind of bug for someone else. Think twice.

If your bug report is good, we will do our best to help you to get a corrected version of the library; if the bug report is poor, we won't do anything about it (aside of chiding you to send better bug reports).

Send your bug report to: tege@gnu.ai.mit.edu.

If you think something in this manual is unclear, or downright incorrect, or if the language needs to be improved, please send a note to the same address.

GNU Make

A Program for Directing Recompilation

Edition 0.48, for `make` Version 3.73 Beta.

April 1995

Richard M. Stallman and Roland McGrath

Overview of `make`

The `make` utility automatically determines which pieces of a large program need to be recompiled, and issues commands to recompile them. This manual describes GNU `make`, which was implemented by Richard Stallman and Roland McGrath. GNU `make` conforms to section 6.2 of IEEE Standard 1003.2-1992 (POSIX.2).

Our examples show C programs, since they are most common, but you can use `make` with any programming language whose compiler can be run with a shell command. Indeed, `make` is not limited to programs. You can use it to describe any task where some files must be updated automatically from others whenever the others change.

To prepare to use `make`, you must write a file called the makefile that describes the relationships among files in your program and provides commands for updating each file. In a program, typically, the executable file is updated from object files, which are in turn made by compiling source files.

Once a suitable makefile exists, each time you change some source files, this simple shell command:

```
make
```

suffices to perform all necessary recompilations. The `make` program uses the makefile data base and the last-modification times of the files to decide which of the files need to be updated. For each of those files, it issues the commands recorded in the data base.

You can provide command line arguments to `make` to control which files should be recompiled, or h
See section How to Run `make`}.

How to Read This Manual

If you are new to `make`, or are looking for a general introduction, read the first few sections of each chapter, skipping the later sections. In each chapter, the first few sections contain introductory or general information and the later sections contain specialized or technical information. The exception is section An Introduction to Makefiles, all of which is introductory.

If you are familiar with other `make` programs, see section Features of GNU `make`}, which lists the enhancements GNU `make` has, and section Incompatibilities and Missing Features, which explains the few things GNU `make` lacks that others have.

For a quick summary, see section Summary of Options, section Quick Reference, and section Special Built-in Target Names.

Problems and Bugs

If you have problems with GNU `make` or think you've found a bug, please report it to the developers; we cannot promise to do anything but we might well want to fix it.

Before reporting a bug, make sure you've actually found a real bug. Carefully reread the documentation and see if it really says you can do what you're trying to do. If it's not clear whether you should be able to do something or not, report that too; it's a bug in the documentation!

Before reporting a bug or trying to fix it yourself, try to isolate it to the smallest possible makefile that reproduces the problem. Then send us the makefile and the exact results `make` gave you. Also say what you expected to occur; this will help us decide whether the problem was really in the documentation.

Once you've got a precise problem, please send electronic mail either through the Internet or via UUCP:

```
Internet address:
    bug-gnu-utils@prep.ai.mit.edu

UUCP path:
    mit-eddie!prep.ai.mit.edu!bug-gnu-utils
```

Please include the version number of `make` you are using. You can get this information with the command `make --version'. Be sure also to include the type of machine and operating system you are using. If possible, include the contents of the file `` `config.h' `` that is generated by the configuration process.

Non-bug suggestions are always welcome as well. If you have questions about things that are unclear in the documentation or are just obscure features, send a message to the bug reporting address. We cannot guarantee you'll get help with your problem, but many seasoned `make` users read the mailing list and

TOC

they will probably try to help you out. The maintainers sometimes answer such questions as well, wh
time permits.

Go to the next section.

Go to the previous, next section.

An Introduction to Makefiles

You need a file called a makefile to tell `make` what to do. Most often, the makefile tells `make` how to compile and link a program.

In this chapter, we will discuss a simple makefile that describes how to compile and link a text editor which consists of eight C source files and three header files. The makefile can also tell `make` how to run miscellaneous commands when explicitly asked (for example, to remove certain files as a clean-up operation). To see a more complex example of a makefile, see section Complex Makefile Example.

When `make` recompiles the editor, each changed C source file must be recompiled. If a header file has changed, each C source file that includes the header file must be recompiled to be safe. Each compilation produces an object file corresponding to the source file. Finally, if any source file has been recompiled, all the object files, whether newly made or saved from previous compilations, must be linked together to produce the new executable editor.

What a Rule Looks Like

A simple makefile consists of "rules" with the following shape:

```
target ... : dependencies ...
        command
        ...
        ...
```

A target is usually the name of a file that is generated by a program; examples of targets are executable or object files. A target can also be the name of an action to carry out, such as `clean' (see section Phony Targets).

A dependency is a file that is used as input to create the target. A target often depends on several files.

A command is an action that `make` carries out. A rule may have more than one command, each on its own line. **Please note:** you need to put a tab character at the beginning of every command line! This is an obscurity that catches the unwary.

Usually a command is in a rule with dependencies and serves to create a target file if any of the dependencies change. However, the rule that specifies commands for the target need not have dependencies. For example, the rule containing the delete command associated with the target `clean' does not have dependencies.

A rule, then, explains how and when to remake certain files which are the targets of the particular rule. `make` carries out the commands on the dependencies to create or update the target. A rule can also explain how and when to carry out an action. See section Writing Rules.

A makefile may contain other text besides rules, but a simple makefile need only contain rules. Rules may look somewhat more complicated than shown in this template, but all fit the pattern more or less.

A Simple Makefile

Here is a straightforward makefile that describes the way an executable file called `edit` depends on eight object files which, in turn, depend on eight C source and three header files.

In this example, all the C files include `` `defs.h' ``, but only those defining editing commands include `` `command.h' ``, and only low level files that change the editor buffer include `` `buffer.h' ``.

```
edit : main.o kbd.o command.o display.o \
       insert.o search.o files.o utils.o
        cc -o edit main.o kbd.o command.o display.o \
                   insert.o search.o files.o utils.o

main.o : main.c defs.h
        cc -c main.c
kbd.o : kbd.c defs.h command.h
        cc -c kbd.c
command.o : command.c defs.h command.h
        cc -c command.c
display.o : display.c defs.h buffer.h
        cc -c display.c
insert.o : insert.c defs.h buffer.h
        cc -c insert.c
search.o : search.c defs.h buffer.h
        cc -c search.c
files.o : files.c defs.h buffer.h command.h
        cc -c files.c
utils.o : utils.c defs.h
        cc -c utils.c
clean :
        rm edit main.o kbd.o command.o display.o \
           insert.o search.o files.o utils.o
```

We split each long line into two lines using backslash-newline; this is like using one long line, but is easier to read.

To use this makefile to create the executable file called `` `edit' ``, type:

```
make
```

To use this makefile to delete the executable file and all the object files from the directory, type:

```
make clean
```

In the example makefile, the targets include the executable file `edit', and the object files `main.o' and `kbd.o'. The dependencies are files such as `main.c' and `defs.h'. In fact, each `.o' file is both a target and a dependency. Commands include `cc -c main.c' and `cc -c kbd.c'.

When a target is a file, it needs to be recompiled or relinked if any of its dependencies change. In addition, any dependencies that are themselves automatically generated should be updated first. In this example, `edit' depends on each of the eight object files; the object file `main.o' depends on the source file `main.c' and on the header file `defs.h'.

A shell command follows each line that contains a target and dependencies. These shell commands say how to update the target file. A tab character must come at the beginning of every command line to distinguish commands lines from other lines in the makefile. (Bear in mind that `make` does not know anything about how the commands work. It is up to you to supply commands that will update the target file properly. All `make` does is execute the commands in the rule you have specified when the target file needs to be updated.)

The target `clean' is not a file, but merely the name of an action. Since you normally do not want to carry out the actions in this rule, `clean' is not a dependency of any other rule. Consequently, `make` never does anything with it unless you tell it specifically. Note that this rule not only is not a dependency, it also does not have any dependencies, so the only purpose of the rule is to run the specified commands. Targets that do not refer to files but are just actions are called phony targets. See section Phony Targets, for information about this kind of target. See section Errors in Commands, to see how to cause `make` to ignore errors from `rm` or any other command.

How `make` Processes a Makefile

By default, `make` starts with the first rule (not counting rules whose target names start with `.'). This is called the default goal. (Goals are the targets that `make` strives ultimately to update. See section Arguments to Specify the Goals.)

In the simple example of the previous section, the default goal is to update the executable program `edit'; therefore, we put that rule first.

Thus, when you give the command:

```
make
```

`make` reads the makefile in the current directory and begins by processing the first rule. In the example, this rule is for relinking `edit'; but before `make` can fully process this rule, it must process the rules for the files that `edit' depends on, which in this case are the object files. Each of these files is processed according to its own rule. These rules say to update each `.o' file by compiling its source file. The recompilation must be done if the source file, or any of the header files named as dependencies, is more recent than the object file, or if the object file does not exist.

The other rules are processed because their targets appear as dependencies of the goal. If some other rule

is not depended on by the goal (or anything it depends on, etc.), that rule is not processed, unless you tell `make` to do so (with a command such as `make clean`).

Before recompiling an object file, `make` considers updating its dependencies, the source file and header files. This makefile does not specify anything to be done for them--the `.c' and `.h' files are not the targets of any rules--so `make` does nothing for these files. But `make` would update automatically generated C programs, such as those made by Bison or Yacc, by their own rules at this time.

After recompiling whichever object files need it, `make` decides whether to relink `edit'. This must be done if the file `edit' does not exist, or if any of the object files are newer than it. If an object file was just recompiled, it is now newer than `edit', so `edit' is relinked.

Thus, if we change the file `insert.c' and run `make`, `make` will compile that file to update `insert.o', and then link `edit'. If we change the file `command.h' and run `make`, `make` will recompile the object files `kbd.o', `command.o' and `files.o' and then link the file `edit'.

Variables Make Makefiles Simpler

In our example, we had to list all the object files twice in the rule for `edit' (repeated here):

```
edit : main.o kbd.o command.o display.o \
               insert.o search.o files.o utils.o
        cc -o edit main.o kbd.o command.o display.o \
                    insert.o search.o files.o utils.o
```

Such duplication is error-prone; if a new object file is added to the system, we might add it to one list and forget the other. We can eliminate the risk and simplify the makefile by using a variable. Variables allow a text string to be defined once and substituted in multiple places later (see section How to Use Variables).

It is standard practice for every makefile to have a variable named `objects`, `OBJECTS`, `objs`, `OBJS`, `obj`, or `OBJ` which is a list of all object file names. We would define such a variable `objects` with a line like this in the makefile:

```
objects = main.o kbd.o command.o display.o \
          insert.o search.o files.o utils.o
```

Then, each place we want to put a list of the object file names, we can substitute the variable's value by writing `$(objects)' (see section How to Use Variables).

Here is how the complete simple makefile looks when you use a variable for the object files:

```
objects = main.o kbd.o command.o display.o \
          insert.o search.o files.o utils.o

edit : $(objects)
```

```
        cc -o edit $(objects)
main.o : main.c defs.h
        cc -c main.c
kbd.o : kbd.c defs.h command.h
        cc -c kbd.c
command.o : command.c defs.h command.h
        cc -c command.c
display.o : display.c defs.h buffer.h
        cc -c display.c
insert.o : insert.c defs.h buffer.h
        cc -c insert.c
search.o : search.c defs.h buffer.h
        cc -c search.c
files.o : files.c defs.h buffer.h command.h
        cc -c files.c
utils.o : utils.c defs.h
        cc -c utils.c
clean :
        rm edit $(objects)
```

Letting `make` Deduce the Commands

It is not necessary to spell out the commands for compiling the individual C source files, because `make` can figure them out: it has an implicit rule for updating a `.o' file from a correspondingly named `.c' file using a `cc -c' command. For example, it will use the command `cc -c main.c -o main.o' to compile `main.c' into `main.o'. We can therefore omit the commands from the rules for the object files. See section Using Implicit Rules.

When a `.c' file is used automatically in this way, it is also automatically added to the list of dependencies. We can therefore omit the `.c' files from the dependencies, provided we omit the commands.

Here is the entire example, with both of these changes, and a variable `objects` as suggested above:

```
objects = main.o kbd.o command.o display.o \
          insert.o search.o files.o utils.o

edit : $(objects)
        cc -o edit $(objects)

main.o : defs.h
kbd.o : defs.h command.h
command.o : defs.h command.h
display.o : defs.h buffer.h
insert.o : defs.h buffer.h
```

```
search.o : defs.h buffer.h
files.o : defs.h buffer.h command.h
utils.o : defs.h

.PHONY : clean
clean :
        -rm edit $(objects)
```

This is how we would write the makefile in actual practice. (The complications associated with `clean' are described elsewhere. See section Phony Targets, and section Errors in Commands.)

Because implicit rules are so convenient, they are important. You will see them used frequently.

Another Style of Makefile

When the objects of a makefile are created only by implicit rules, an alternative style of makefile is possible. In this style of makefile, you group entries by their dependencies instead of by their targets. Here is what one looks like:

```
objects = main.o kbd.o command.o display.o \
          insert.o search.o files.o utils.o

edit : $(objects)
        cc -o edit $(objects)

$(objects) : defs.h
kbd.o command.o files.o : command.h
display.o insert.o search.o files.o : buffer.h
```

Here `defs.h' is given as a dependency of all the object files; `command.h' and `buffer.h' are dependencies of the specific object files listed for them.

Whether this is better is a matter of taste: it is more compact, but some people dislike it because they find it clearer to put all the information about each target in one place.

Rules for Cleaning the Directory

Compiling a program is not the only thing you might want to write rules for. Makefiles commonly tell how to do a few other things besides compiling a program: for example, how to delete all the object files and executables so that the directory is `clean'.

Here is how we could write a `make` rule for cleaning our example editor:

```
clean:
        rm edit $(objects)
```

In practice, we might want to write the rule in a somewhat more complicated manner to handle unanticipated situations. We would do this:

```
.PHONY : clean
clean :
        -rm edit $(objects)
```

This prevents `make` from getting confused by an actual file called `` `clean' `` and causes it to continue in spite of errors from `rm`. (See section Phony Targets, and section Errors in Commands.)

A rule such as this should not be placed at the beginning of the makefile, because we do not want it to run by default! Thus, in the example makefile, we want the rule for `edit`, which recompiles the editor, to remain the default goal.

Since `clean` is not a dependency of `edit`, this rule will not run at all if we give the command `make' with no arguments. In order to make the rule run, we have to type `make clean'. See section How to Run `make`.

Go to the previous, next section.

Go to the previous, next section.

Writing Makefiles

The information that tells `make` how to recompile a system comes from reading a data base called the makefile.

What Makefiles Contain

Makefiles contain five kinds of things: explicit rules, implicit rules, variable definitions, directives, and comments. Rules, variables, and directives are described at length in later chapters.

- An explicit rule says when and how to remake one or more files, called the rule's targets. It lists the other files that the targets depend on, and may also give commands to use to create or update the targets. See section Writing Rules.
- An implicit rule says when and how to remake a class of files based on their names. It describes how a target may depend on a file with a name similar to the target and gives commands to create or update such a target. See section Using Implicit Rules.
- A variable definition is a line that specifies a text string value for a variable that can be substituted into the text later. The simple makefile example shows a variable definition for `objects` as a list of all object files (see section Variables Make Makefiles Simpler).
- A directive is a command for `make` to do something special while reading the makefile. These include:
  - Reading another makefile (see section Including Other Makefiles).
  - Deciding (based on the values of variables) whether to use or ignore a part of the makefile (see section Conditional Parts of Makefiles).
  - Defining a variable from a verbatim string containing multiple lines (see section Defining Variables Verbatim).
- `#' in a line of a makefile starts a comment. It and the rest of the line are ignored, except that a trailing backslash not escaped by another backslash will continue the comment across multiple lines. Comments may appear on any of the lines in the makefile, except within a `define` directive, and perhaps within commands (where the shell decides what is a comment). A line containing just a comment (with perhaps spaces before it) is effectively blank, and is ignored.

What Name to Give Your Makefile

By default, when `make` looks for the makefile, it tries the following names, in order: `GNUmakefile', `makefile' and `Makefile'.

Normally you should call your makefile either `makefile' or `Makefile'. (We recommend `Makefile' because it appears prominently near the beginning of a directory listing, right near other

important files such as `README'.) The first name checked, `GNUmakefile', is not recommend for most makefiles. You should use this name if you have a makefile that is specific to GNU make, a will not be understood by other versions of make. Other make programs look for `makefile' and `Makefile', but not `GNUmakefile'.

If make finds none of these names, it does not use any makefile. Then you must specify a goal with a command argument, and make will attempt to figure out how to remake it using only its built-in implicit rules. See section Using Implicit Rules.

If you want to use a nonstandard name for your makefile, you can specify the makefile name with the `-f' or `--file' option. The arguments `-f name' or `--file=name' tell make to read the file name as the makefile. If you use more than one `-f' or `--file' option, you can specify several makefiles. All the makefiles are effectively concatenated in the order specified. The default makefile names `GNUmakefile', `makefile' and `Makefile' are not checked automatically if you specify `-f' or `--file'.

Including Other Makefiles

The include directive tells make to suspend reading the current makefile and read one or more other makefiles before continuing. The directive is a line in the makefile that looks like this:

```
include filenames...
```

filenames can contain shell file name patterns.

Extra spaces are allowed and ignored at the beginning of the line, but a tab is not allowed. (If the line begins with a tab, it will be considered a command line.) Whitespace is required between include and the file names, and between file names; extra whitespace is ignored there and at the end of the directive. A comment starting with `#' is allowed at the end of the line. If the file names contain any variable or function references, they are expanded. See section How to Use Variables.

For example, if you have three `.mk' files, `a.mk', `b.mk', and `c.mk', and $(bar) expands to bish bash, then the following expression

```
include foo *.mk $(bar)
```

is equivalent to

```
include foo a.mk b.mk c.mk bish bash
```

When make processes an include directive, it suspends reading of the containing makefile and reads from each listed file in turn. When that is finished, make resumes reading the makefile in which the directive appears.

One occasion for using include directives is when several programs, handled by individual makefiles in various directories, need to use a common set of variable definitions (see section Setting Variables) or

pattern rules (see section Defining and Redefining Pattern Rules).

Another such occasion is when you want to generate dependencies from source files automatically; the dependencies can be put in a file that is included by the main makefile. This practice is generally cleaner than that of somehow appending the dependencies to the end of the main makefile as has been traditionally done with other versions of `make`. See section Generating Dependencies Automatically.

If the specified name does not start with a slash, and the file is not found in the current directory, several other directories are searched. First, any directories you have specified with the `-I' or `--include-dir' option are searched (see section Summary of Options). Then the following directories (if they exist) are searched, in this order: `prefix/include' (normally `/usr/local/include') `/usr/gnu/include', `/usr/local/include', `/usr/include'.

If an included makefile cannot be found in any of these directories, a warning message is generated, but it is not an immediately fatal error; processing of the makefile containing the `include` continues. Once it has finished reading makefiles, `make` will try to remake any that are out of date or don't exist. See section How Makefiles Are Remade. Only after it has tried to find a way to remake a makefile and failed, will `make` diagnose the missing makefile as a fatal error.

If you want `make` to simply ignore a makefile which does not exist and cannot be remade, with no error message, use the `-include` directive instead of `include`, like this:

```
-include filenames...
```

This is acts like `include` in every way except that there is no error (not even a warning) if any of the filenames do not exist.

The Variable `MAKEFILES`

If the environment variable `MAKEFILES` is defined, `make` considers its value as a list of names (separated by whitespace) of additional makefiles to be read before the others. This works much like the `include` directive: various directories are searched for those files (see section Including Other Makefiles). In addition, the default goal is never taken from one of these makefiles and it is not an error if the files listed in `MAKEFILES` are not found.

The main use of `MAKEFILES` is in communication between recursive invocations of `make` (see section Recursive Use of `make`}). It usually is not desirable to set the environment variable before a top-level invocation of `make`, because it is usually better not to mess with a makefile from outside. However, if you are running `make` without a specific makefile, a makefile in `MAKEFILES` can do useful things to help the built-in implicit rules work better, such as defining search paths (see section Searching Directories for Dependencies).

Some users are tempted to set `MAKEFILES` in the environment automatically on login, and program makefiles to expect this to be done. This is a very bad idea, because such makefiles will fail to work if run by anyone else. It is much better to write explicit `include` directives in the makefiles. See section Including Other Makefiles.

How Makefiles Are Remade

Sometimes makefiles can be remade from other files, such as RCS or SCCS files. If a makefile can be remade from other files, you probably want `make` to get an up-to-date version of the makefile to read in.

To this end, after reading in all makefiles, `make` will consider each as a goal target and attempt to update it. If a makefile has a rule which says how to update it (found either in that very makefile or in another one) or if an implicit rule applies to it (see section Using Implicit Rules), it will be updated if necessary. After all makefiles have been checked, if any have actually been changed, `make` starts with a clean slate and reads all the makefiles over again. (It will also attempt to update each of them over again, but normally this will not change them again, since they are already up to date.)

If the makefiles specify a double-colon rule to remake a file with commands but no dependencies, that file will always be remade (see section Double-Colon Rules). In the case of makefiles, a makefile that has a double-colon rule with commands but no dependencies will be remade every time `make` is run, and then again after `make` starts over and reads the makefiles in again. This would cause an infinite loop: `make` would constantly remake the makefile, and never do anything else. So, to avoid this, `make` will **not** attempt to remake makefiles which are specified as double-colon targets but have no dependencies.

If you do not specify any makefiles to be read with `-f' or `--file' options, `make` will try the default makefile names; see section What Name to Give Your Makefile. Unlike makefiles explicitly requested with `-f' or `--file' options, `make` is not certain that these makefiles should exist. However, if a default makefile does not exist but can be created by running `make` rules, you probably want the rules to be run so that the makefile can be used.

Therefore, if none of the default makefiles exists, `make` will try to make each of them in the same order in which they are searched for (see section What Name to Give Your Makefile) until it succeeds in making one, or it runs out of names to try. Note that it is not an error if `make` cannot find or make any makefile; a makefile is not always necessary.

When you use the `-t' or `--touch' option (see section Instead of Executing the Commands), you would not want to use an out-of-date makefile to decide which targets to touch. So the `-t' option has no effect on updating makefiles; they are really updated even if `-t' is specified. Likewise, `-q' (or `--question') and `-n' (or `--just-print') do not prevent updating of makefiles, because an out-of-date makefile would result in the wrong output for other targets. Thus, `make -f mfile -n foo' will update `mfile', read it in, and then print the commands to update `foo' and its dependencies without running them. The commands printed for `foo' will be those specified in the updated contents of `mfile'.

However, on occasion you might actually wish to prevent updating of even the makefiles. You can do this by specifying the makefiles as goals in the command line as well as specifying them as makefiles. When the makefile name is specified explicitly as a goal, the options `-t' and so on do apply to them.

Thus, `make -f mfile -n mfile foo' would read the makefile `mfile', print the commands needed to update it without actually running them, and then print the commands needed to update `foo' without running them. The commands for `foo' will be those specified by the existing contents of `mfile'.

Overriding Part of Another Makefile

Sometimes it is useful to have a makefile that is mostly just like another makefile. You can often use the `include' directive to include one in the other, and add more targets or variable definitions. However, if the two makefiles give different commands for the same target, `make` will not let you just do this. But there is another way.

In the containing makefile (the one that wants to include the other), you can use a match-anything pattern rule to say that to remake any target that cannot be made from the information in the containing makefile, `make` should look in another makefile. See section Defining and Redefining Pattern Rules, for more information on pattern rules.

For example, if you have a makefile called `Makefile' that says how to make the target `foo' (and other targets), you can write a makefile called `GNUmakefile' that contains:

```
foo:
        frobnicate > foo

%: force
        @$(MAKE) -f Makefile $@
force: ;
```

If you say `make foo', `make` will find `GNUmakefile', read it, and see that to make `foo', it needs to run the command `frobnicate > foo'. If you say `make bar', `make` will find no way to make `bar' in `GNUmakefile', so it will use the commands from the pattern rule: `make -f Makefile bar'. If `Makefile' provides a rule for updating `bar', `make` will apply the rule. And likewise for any other target that `GNUmakefile' does not say how to make.

The way this works is that the pattern rule has a pattern of just `%', so it matches any target whatever. The rule specifies a dependency `force', to guarantee that the commands will be run even if the target file already exists. We give `force' target empty commands to prevent `make` from searching for an implicit rule to build it--otherwise it would apply the same match-anything rule to `force' itself and create a dependency loop!

Go to the previous, next section.

Go to the previous, next section.

Writing Rules

A rule appears in the makefile and says when and how to remake certain files, called the rule's targets (most often only one per rule). It lists the other files that are the dependencies of the target, and commands to use to create or update the target.

The order of rules is not significant, except for determining the default goal: the target for `make` to consider, if you do not otherwise specify one. The default goal is the target of the first rule in the first makefile. If the first rule has multiple targets, only the first target is taken as the default. There are two exceptions: a target starting with a period is not a default unless it contains one or more slashes, `/', as well; and, a target that defines a pattern rule has no effect on the default goal. (See section Defining and Redefining Pattern Rules.)

Therefore, we usually write the makefile so that the first rule is the one for compiling the entire program or all the programs described by the makefile (often with a target called `all'). See section Arguments to Specify the Goals.

Rule Syntax

In general, a rule looks like this:

```
targets : dependencies
        command
        ...
```

or like this:

```
targets : dependencies ; command
        command
        ...
```

The targets are file names, separated by spaces. Wildcard characters may be used (see section Using Wildcard Characters in File Names) and a name of the form `a'(m) represents member m in archive file a (see section Archive Members as Targets). Usually there is only one target per rule, but occasionally there is a reason to have more (see section Multiple Targets in a Rule).

The command lines start with a tab character. The first command may appear on the line after the dependencies, with a tab character, or may appear on the same line, with a semicolon. Either way, the effect is the same. See section Writing the Commands in Rules.

Because dollar signs are used to start variable references, if you really want a dollar sign in a rule you must write two of them, `$$' (see section How to Use Variables). You may split a long line by inserting a

backslash followed by a newline, but this is not required, as `make` places no limit on the length of a line in a makefile.

A rule tells `make` two things: when the targets are out of date, and how to update them when necessary.

The criterion for being out of date is specified in terms of the dependencies, which consist of file names separated by spaces. (Wildcards and archive members (see section Using `make` to Update Archive Files) are allowed here too.) A target is out of date if it does not exist or if it is older than any of the dependencies (by comparison of last-modification times). The idea is that the contents of the target file are computed based on information in the dependencies, so if any of the dependencies changes, the contents of the existing target file are no longer necessarily valid.

How to update is specified by commands. These are lines to be executed by the shell (normally `sh'), but with some extra features (see section Writing the Commands in Rules).

Using Wildcard Characters in File Names

A single file name can specify many files using wildcard characters. The wildcard characters in `make` are `*', `?' and `[...]', the same as in the Bourne shell. For example, `` `*.c' `` specifies a list of all the files (in the working directory) whose names end in `.c'.

The character `~' at the beginning of a file name also has special significance. If alone, or followed by a slash, it represents your home directory. For example `` `~/bin' `` expands to `` `/home/you/bin' ``. If the `~' is followed by a word, the string represents the home directory of the user named by that word. For example `` `~john/bin' `` expands to `` `/home/john/bin' ``.

Wildcard expansion happens automatically in targets, in dependencies, and in commands (where the shell does the expansion). In other contexts, wildcard expansion happens only if you request it explicitly with the `wildcard` function.

The special significance of a wildcard character can be turned off by preceding it with a backslash. Thus, `` `foo\*bar' `` would refer to a specific file whose name consists of `foo', an asterisk, and `bar'.

Wildcard Examples

Wildcards can be used in the commands of a rule, where they are expanded by the shell. For example, here is a rule to delete all the object files:

```
clean:
        rm -f *.o
```

Wildcards are also useful in the dependencies of a rule. With the following rule in the makefile, `make print' will print all the `.c' files that have changed since the last time you printed them:

```
print: *.c
```

```
        lpr -p $?
        touch print
```

This rule uses `print' as an empty target file; see section Empty Target Files to Record Events. (The automatic variable `$?' is used to print only those files that have changed; see section Automatic Variables.)

Wildcard expansion does not happen when you define a variable. Thus, if you write this:

```
objects = *.o
```

then the value of the variable `objects` is the actual string `*.o'. However, if you use the value of `objects` in a target, dependency or command, wildcard expansion will take place at that time. To set `objects` to the expansion, instead use:

```
objects := $(wildcard *.o)
```

See section The Function `wildcard`.

Pitfalls of Using Wildcards

Now here is an example of a naive way of using wildcard expansion, that does not do what you would intend. Suppose you would like to say that the executable file `foo' is made from all the object files in the directory, and you write this:

```
objects = *.o

foo : $(objects)
        cc -o foo $(CFLAGS) $(objects)
```

The value of `objects` is the actual string `*.o'. Wildcard expansion happens in the rule for `foo', so that each *existing* `.o' file becomes a dependency of `foo' and will be recompiled if necessary.

But what if you delete all the `.o' files? When a wildcard matches no files, it is left as it is, so then `foo' will depend on the oddly-named file `*.o'. Since no such file is likely to exist, `make` will give you an error saying it cannot figure out how to make `*.o'. This is not what you want!

Actually it is possible to obtain the desired result with wildcard expansion, but you need more sophisticated techniques, including the `wildcard` function and string substitution. These are described in the following section.

The Function `wildcard`

Wildcard expansion happens automatically in rules. But wildcard expansion does not normally take place when a variable is set, or inside the arguments of a function. If you want to do wildcard expansion in such places, you need to use the `wildcard` function, like this:

```
$(wildcard pattern...)
```

This string, used anywhere in a makefile, is replaced by a space-separated list of names of existing files that match one of the given file name patterns. If no existing file name matches a pattern, then that pattern is omitted from the output of the `wildcard` function. Note that this is different from how unmatched wildcards behave in rules, where they are used verbatim rather than ignored (see section Pitfalls of Using Wildcards).

One use of the `wildcard` function is to get a list of all the C source files in a directory, like this:

```
$(wildcard *.c)
```

We can change the list of C source files into a list of object files by replacing the `.o' suffix with `.c' in the result, like this:

```
$(patsubst %.c,%.o,$(wildcard *.c))
```

(Here we have used another function, `patsubst`. See section Functions for String Substitution and Analysis.)

Thus, a makefile to compile all C source files in the directory and then link them together could be written as follows:

```
objects := $(patsubst %.c,%.o,$(wildcard *.c))

foo : $(objects)
        cc -o foo $(objects)
```

(This takes advantage of the implicit rule for compiling C programs, so there is no need to write explicit rules for compiling the files. See section The Two Flavors of Variables, for an explanation of `:=', which is a variant of `='.)

Searching Directories for Dependencies

For large systems, it is often desirable to put sources in a separate directory from the binaries. The directory search features of `make` facilitate this by searching several directories automatically to find a dependency. When you redistribute the files among directories, you do not need to change the individual rules, just the search paths.

VPATH: Search Path for All Dependencies

The value of the `make` variable `VPATH` specifies a list of directories that `make` should search. Most often, the directories are expected to contain dependency files that are not in the current directory; however, `VPATH` specifies a search list that `make` applies for all files, including files which are targets of rules.

Thus, if a file that is listed as a target or dependency does not exist in the current directory, `make` searches the directories listed in `VPATH` for a file with that name. If a file is found in one of them, that file becomes the dependency. Rules may then specify the names of source files in the dependencies as if they all existed in the current directory. See section Writing Shell Commands with Directory Search.

In the `VPATH` variable, directory names are separated by colons or blanks. The order in which directories are listed is the order followed by `make` in its search.

For example,

```
VPATH = src:../headers
```

specifies a path containing two directories, `` `src' `` and `` `../headers' ``, which `make` searches in that order.

With this value of `VPATH`, the following rule,

```
foo.o : foo.c
```

is interpreted as if it were written like this:

```
foo.o : src/foo.c
```

assuming the file `` `foo.c' `` does not exist in the current directory but is found in the directory `` `src' ``.

The `vpath` Directive

Similar to the `VPATH` variable but more selective is the `vpath` directive (note lower case), which allows you to specify a search path for a particular class of file names, those that match a particular pattern. Thus you can supply certain search directories for one class of file names and other directories (or none) for other file names.

There are three forms of the `vpath` directive:

`vpath pattern directories`

Specify the search path directories for file names that match pattern.

The search path, directories, is a list of directories to be searched, separated by colons or blanks, just like the search path used in the `VPATH` variable.

`vpath pattern`

Clear out the search path associated with pattern.

`vpath`

Clear all search paths previously specified with `vpath` directives.

A `vpath` pattern is a string containing a `%' character. The string must match the file name of a dependency that is being searched for, the `%' character matching any sequence of zero or more

characters (as in pattern rules; see section Defining and Redefining Pattern Rules). For example, `%.h` matches files that end in `.h`. (If there is no `%', the pattern must match the dependency exactly, which is not useful very often.)

`%' characters in a `vpath` directive's pattern can be quoted with preceding backslashes (`\'). Backslashes that would otherwise quote `%' characters can be quoted with more backslashes. Backslashes that quote `%' characters or other backslashes are removed from the pattern before it is compared to file names. Backslashes that are not in danger of quoting `%' characters go unmolested.

When a dependency fails to exist in the current directory, if the pattern in a `vpath` directive matches the name of the dependency file, then the directories in that directive are searched just like (and before) the directories in the `VPATH` variable.

For example,

```
vpath %.h ../headers
```

tells `make` to look for any dependency whose name ends in `.h' in the directory `../headers' if the file is not found in the current directory.

If several `vpath` patterns match the dependency file's name, then `make` processes each matching `vpath` directive one by one, searching all the directories mentioned in each directive. `make` handles multiple `vpath` directives in the order in which they appear in the makefile; multiple directives with the same pattern are independent of each other.

Thus,

```
vpath %.c foo
vpath %   blish
vpath %.c bar
```

will look for a file ending in `.c' in `foo', then `blish', then `bar', while

```
vpath %.c foo:bar
vpath %   blish
```

will look for a file ending in `.c' in `foo', then `bar', then `blish'.

Writing Shell Commands with Directory Search

When a dependency is found in another directory through directory search, this cannot change the commands of the rule; they will execute as written. Therefore, you must write the commands with care so that they will look for the dependency in the directory where `make` finds it.

This is done with the automatic variables such as `$^' (see section Automatic Variables). For instance, the value of `$^' is a list of all the dependencies of the rule, including the names of the directories in which they were found, and the value of `$@' is the target. Thus:

```
foo.o : foo.c
        cc -c $(CFLAGS) $^ -o $@
```

(The variable CFLAGS exists so you can specify flags for C compilation by implicit rules; we use it here for consistency so it will affect all C compilations uniformly; see section Variables Used by Implicit Rules.)

Often the dependencies include header files as well, which you do not want to mention in the commands. The automatic variable `$<' is just the first dependency:

```
VPATH = src:../headers
foo.o : foo.c defs.h hack.h
        cc -c $(CFLAGS) $< -o $@
```

Directory Search and Implicit Rules

The search through the directories specified in VPATH or with vpath also happens during consideration of implicit rules (see section Using Implicit Rules).

For example, when a file `foo.o' has no explicit rule, make considers implicit rules, such as the built-in rule to compile `foo.c' if that file exists. If such a file is lacking in the current directory, the appropriate directories are searched for it. If `foo.c' exists (or is mentioned in the makefile) in any of the directories, the implicit rule for C compilation is applied.

The commands of implicit rules normally use automatic variables as a matter of necessity; consequently they will use the file names found by directory search with no extra effort.

Directory Search for Link Libraries

Directory search applies in a special way to libraries used with the linker. This special feature comes into play when you write a dependency whose name is of the form `-lname'. (You can tell something strange is going on here because the dependency is normally the name of a file, and the *file name* of the library looks like `libname.a', not like `-lname'.)

When a dependency's name has the form `-lname', make handles it specially by searching for the file `libname.a' in the current directory, in directories specified by matching vpath search paths and the VPATH search path, and then in the directories `/lib', `/usr/lib', and `prefix/lib' (normally `/usr/local/lib').

For example,

```
foo : foo.c -lcurses
        cc $^ -o $@
```

would cause the command `cc foo.c /usr/lib/libcurses.a -o foo' to be executed when `foo' is older than `foo.c' or than `/usr/lib/libcurses.a'.

Phony Targets

A phony target is one that is not really the name of a file. It is just a name for some commands to be executed when you make an explicit request. There are two reasons to use a phony target: to avoid a conflict with a file of the same name, and to improve performance.

If you write a rule whose commands will not create the target file, the commands will be executed every time the target comes up for remaking. Here is an example:

```
clean:
        rm *.o temp
```

Because the `rm` command does not create a file named `` `clean' ``, probably no such file will ever exist. Therefore, the `rm` command will be executed every time you say `make clean'.

The phony target will cease to work if anything ever does create a file named `` `clean' `` in this directory. Since it has no dependencies, the file `` `clean' `` would inevitably be considered up to date, and its commands would not be executed. To avoid this problem, you can explicitly declare the target to be phony, using the special target `.PHONY` (see section Special Built-in Target Names) as follows:

```
.PHONY : clean
```

Once this is done, `make clean' will run the commands regardless of whether there is a file named `` `clean' ``.

Since it knows that phony targets do not name actual files that could be remade from other files, `make` skips the implicit rule search for phony targets (see section Using Implicit Rules). This is why declaring a target phony is good for performance, even if you are not worried about the actual file existing.

Thus, you first write the line that states that `clean` is a phony target, then you write the rule, like this:

```
.PHONY: clean
clean:
        rm *.o temp
```

A phony target should not be a dependency of a real target file; if it is, its commands are run every time `make` goes to update that file. As long as a phony target is never a dependency of a real target, the phony target commands will be executed only when the phony target is a specified goal (see section Arguments to Specify the Goals).

Phony targets can have dependencies. When one directory contains multiple programs, it is most convenient to describe all of the programs in one makefile `` `./Makefile' ``. Since the target remade by default will be the first one in the makefile, it is common to make this a phony target named `all' and give it, as dependencies, all the individual programs. For example:

```
all : prog1 prog2 prog3
```

```
.PHONY : all

prog1 : prog1.o utils.o
        cc -o prog1 prog1.o utils.o

prog2 : prog2.o
        cc -o prog2 prog2.o

prog3 : prog3.o sort.o utils.o
        cc -o prog3 prog3.o sort.o utils.o
```

Now you can say just `make' to remake all three programs, or specify as arguments the ones to remake (as in `make prog1 prog3').

When one phony target is a dependency of another, it serves as a subroutine of the other. For example, here `make cleanall' will delete the object files, the difference files, and the file `program':

```
.PHONY: cleanall cleanobj cleandiff

cleanall : cleanobj cleandiff
        rm program

cleanobj :
        rm *.o

cleandiff :
        rm *.diff
```

Rules without Commands or Dependencies

If a rule has no dependencies or commands, and the target of the rule is a nonexistent file, then `make` imagines this target to have been updated whenever its rule is run. This implies that all targets depending on this one will always have their commands run.

An example will illustrate this:

```
clean: FORCE
        rm $(objects)
FORCE:
```

Here the target `FORCE' satisfies the special conditions, so the target `clean' that depends on it is forced to run its commands. There is nothing special about the name `FORCE', but that is one name commonly used this way.

As you can see, using `FORCE' this way has the same results as using `.PHONY: clean'.

Using `.PHONY' is more explicit and more efficient. However, other versions of `make' do not suppo `.PHONY'; thus `FORCE' appears in many makefiles. See section Phony Targets.

Empty Target Files to Record Events

The empty target is a variant of the phony target; it is used to hold commands for an action that you request explicitly from time to time. Unlike a phony target, this target file can really exist; but the file's contents do not matter, and usually are empty.

The purpose of the empty target file is to record, with its last-modification time, when the rule's commands were last executed. It does so because one of the commands is a `touch' command to update the target file.

The empty target file must have some dependencies. When you ask to remake the empty target, the commands are executed if any dependency is more recent than the target; in other words, if a dependency has changed since the last time you remade the target. Here is an example:

```
print: foo.c bar.c
        lpr -p $?
        touch print
```

With this rule, `make print' will execute the `lpr' command if either source file has changed since the last `make print'. The automatic variable `$?' is used to print only those files that have changed (see section Automatic Variables).

Special Built-in Target Names

Certain names have special meanings if they appear as targets.

`.PHONY`

The dependencies of the special target `.PHONY` are considered to be phony targets. When it is time to consider such a target, `make` will run its commands unconditionally, regardless of whether a file with that name exists or what its last-modification time is. See section Phony Targets.

`.SUFFIXES`

The dependencies of the special target `.SUFFIXES` are the list of suffixes to be used in checking for suffix rules. See section Old-Fashioned Suffix Rules.

`.DEFAULT`

The commands specified for `.DEFAULT` are used for any target for which no rules are found (either explicit rules or implicit rules). See section Defining Last-Resort Default Rules. If `.DEFAULT` commands are specified, every file mentioned as a dependency, but not as a target in a

rule, will have these commands executed on its behalf. See section Implicit Rule Search Algorithm.

`.PRECIOUS`

The targets which `.PRECIOUS` depends on are given the following special treatment: if `make` is killed or interrupted during the execution of their commands, the target is not deleted. See section Interrupting or Killing `make`. Also, if the target is an intermediate file, it will not be deleted after it is no longer needed, as is normally done. See section Chains of Implicit Rules.

You can also list the target pattern of an implicit rule (such as `%.o') as a dependency file of the special target `.PRECIOUS` to preserve intermediate files created by rules whose target patterns match that file's name.

`.IGNORE`

If you specify dependencies for `.IGNORE`, then `make` will ignore errors in execution of the commands run for those particular files. The commands for `.IGNORE` are not meaningful.

If mentioned as a target with no dependencies, `.IGNORE` says to ignore errors in execution of commands for all files. This usage of `.IGNORE' is supported only for historical compatibility. Since this affects every command in the makefile, it is not very useful; we recommend you use the more selective ways to ignore errors in specific commands. See section Errors in Commands.

`.SILENT`

If you specify dependencies for `.SILENT`, then `make` will not the print commands to remake those particular files before executing them. The commands for `.SILENT` are not meaningful.

If mentioned as a target with no dependencies, `.SILENT` says not to print any commands before executing them. This usage of `.SILENT' is supported only for historical compatibility. We recommend you use the more selective ways to silence specific commands. See section Command Echoing. If you want to silence all commands for a particular run of `make`, use the `-s' or `--silent' option (see section Summary of Options).

`.EXPORT_ALL_VARIABLES`

Simply by being mentioned as a target, this tells `make` to export all variables to child processes by default. See section Communicating Variables to a Sub-`make`}.

Any defined implicit rule suffix also counts as a special target if it appears as a target, and so does the concatenation of two suffixes, such as `.c.o'. These targets are suffix rules, an obsolete way of defining implicit rules (but a way still widely used). In principle, any target name could be special in this way if you break it in two and add both pieces to the suffix list. In practice, suffixes normally begin with `.', so these special target names also begin with `.'. See section Old-Fashioned Suffix Rules.

Multiple Targets in a Rule

A rule with multiple targets is equivalent to writing many rules, each with one target, and all identical aside from that. The same commands apply to all the targets, but their effects may vary because you can substitute the actual target name into the command using `$@'. The rule contributes the same dependencies to all the targets also.

This is useful in two cases.

- You want just dependencies, no commands. For example:

  ```
  kbd.o command.o files.o: command.h
  ```

  gives an additional dependency to each of the three object files mentioned.
- Similar commands work for all the targets. The commands do not need to be absolutely identical, since the automatic variable `$@' can be used to substitute the particular target to be remade into the commands (see section Automatic Variables). For example:

  ```
  bigoutput littleoutput : text.g
          generate text.g -$(subst output,,$@) > $@
  ```

  is equivalent to

  ```
  bigoutput : text.g
          generate text.g -big > bigoutput
  littleoutput : text.g
          generate text.g -little > littleoutput
  ```

  Here we assume the hypothetical program `generate` makes two types of output, one if given `-big' and one if given `-little'. See section Functions for String Substitution and Analysis, for an explanation of the `subst` function.

Suppose you would like to vary the dependencies according to the target, much as the variable `$@' allows you to vary the commands. You cannot do this with multiple targets in an ordinary rule, but you can do it with a static pattern rule. See section Static Pattern Rules.

Multiple Rules for One Target

One file can be the target of several rules. All the dependencies mentioned in all the rules are merged into one list of dependencies for the target. If the target is older than any dependency from any rule, the commands are executed.

There can only be one set of commands to be executed for a file. If more than one rule gives commands for the same file, `make` uses the last set given and prints an error message. (As a special case, if the file's name begins with a dot, no error message is printed. This odd behavior is only for compatibility with

other implementations of `make`.) There is no reason to write your makefiles this way; that is why `ma` gives you an error message.

An extra rule with just dependencies can be used to give a few extra dependencies to many files at once. For example, one usually has a variable named `objects` containing a list of all the compiler output files in the system being made. An easy way to say that all of them must be recompiled if `` `config.h' `` changes is to write the following:

```
objects = foo.o bar.o
foo.o : defs.h
bar.o : defs.h test.h
$(objects) : config.h
```

This could be inserted or taken out without changing the rules that really specify how to make the object files, making it a convenient form to use if you wish to add the additional dependency intermittently.

Another wrinkle is that the additional dependencies could be specified with a variable that you set with a command argument to `make` (see section Overriding Variables). For example,

```
extradeps=
$(objects) : $(extradeps)
```

means that the command `make extradeps=foo.h' will consider `` `foo.h' `` as a dependency of each object file, but plain `make' will not.

If none of the explicit rules for a target has commands, then `make` searches for an applicable implicit rule to find some commands see section Using Implicit Rules).

Static Pattern Rules

Static pattern rules are rules which specify multiple targets and construct the dependency names for each target based on the target name. They are more general than ordinary rules with multiple targets because the targets do not have to have identical dependencies. Their dependencies must be *analogous*, but not necessarily *identical*.

Syntax of Static Pattern Rules

Here is the syntax of a static pattern rule:

```
targets ...: target-pattern: dep-patterns ...
        commands
        ...
```

The targets list specifies the targets that the rule applies to. The targets can contain wildcard characters, just like the targets of ordinary rules (see section Using Wildcard Characters in File Names).

The target-pattern and dep-patterns say how to compute the dependencies of each target. Each target is matched against the target-pattern to extract a part of the target name, called the stem. This stem is substituted into each of the dep-patterns to make the dependency names (one from each dep-pattern).

Each pattern normally contains the character `%' just once. When the target-pattern matches a target, the `%' can match any part of the target name; this part is called the stem. The rest of the pattern must match exactly. For example, the target `foo.o' matches the pattern `%.o', with `foo' as the stem. The targets `foo.c' and `foo.out' do not match that pattern.

The dependency names for each target are made by substituting the stem for the `%' in each dependency pattern. For example, if one dependency pattern is `%.c', then substitution of the stem `foo' gives the dependency name `foo.c'. It is legitimate to write a dependency pattern that does not contain `%'; then this dependency is the same for all targets.

`%' characters in pattern rules can be quoted with preceding backslashes (`\'). Backslashes that would otherwise quote `%' characters can be quoted with more backslashes. Backslashes that quote `%' characters or other backslashes are removed from the pattern before it is compared to file names or has a stem substituted into it. Backslashes that are not in danger of quoting `%' characters go unmolested. For example, the pattern `the\%weird\\%pattern\\' has `the%weird\' preceding the operative `%' character, and `pattern\\' following it. The final two backslashes are left alone because they cannot affect any `%' character.

Here is an example, which compiles each of `foo.o' and `bar.o' from the corresponding `.c' file:

```
objects = foo.o bar.o

$(objects): %.o: %.c
        $(CC) -c $(CFLAGS) $< -o $@
```

Here `$<' is the automatic variable that holds the name of the dependency and `$@' is the automatic variable that holds the name of the target; see section Automatic Variables.

Each target specified must match the target pattern; a warning is issued for each target that does not. If you have a list of files, only some of which will match the pattern, you can use the `filter` function to remove nonmatching file names (see section Functions for String Substitution and Analysis):

```
files = foo.elc bar.o lose.o

$(filter %.o,$(files)): %.o: %.c
        $(CC) -c $(CFLAGS) $< -o $@
$(filter %.elc,$(files)): %.elc: %.el
        emacs -f batch-byte-compile $<
```

In this example the result of `$(filter %.o,$(files))' is `bar.o lose.o', and the first static pattern rule causes each of these object files to be updated by compiling the corresponding C source file. The result of `$(filter %.elc,$(files))' is `foo.elc', so that file is made from `foo.el'.

Another example shows how to use `$*` in static pattern rules:

```
bigoutput littleoutput : %output : text.g
        generate text.g -$* > $@
```

When the `generate` command is run, `$*` will expand to the stem, either `big' or `little'.

Static Pattern Rules versus Implicit Rules

A static pattern rule has much in common with an implicit rule defined as a pattern rule (see section Defining and Redefining Pattern Rules). Both have a pattern for the target and patterns for constructing the names of dependencies. The difference is in how `make` decides *when* the rule applies.

An implicit rule *can* apply to any target that matches its pattern, but it *does* apply only when the target has no commands otherwise specified, and only when the dependencies can be found. If more than one implicit rule appears applicable, only one applies; the choice depends on the order of rules.

By contrast, a static pattern rule applies to the precise list of targets that you specify in the rule. It cannot apply to any other target and it invariably does apply to each of the targets specified. If two conflicting rules apply, and both have commands, that's an error.

The static pattern rule can be better than an implicit rule for these reasons:

- You may wish to override the usual implicit rule for a few files whose names cannot be categorized syntactically but can be given in an explicit list.
- If you cannot be sure of the precise contents of the directories you are using, you may not be sure which other irrelevant files might lead `make` to use the wrong implicit rule. The choice might depend on the order in which the implicit rule search is done. With static pattern rules, there is no uncertainty: each rule applies to precisely the targets specified.

Double-Colon Rules

Double-colon rules are rules written with `::' instead of `:' after the target names. They are handled differently from ordinary rules when the same target appears in more than one rule.

When a target appears in multiple rules, all the rules must be the same type: all ordinary, or all double-colon. If they are double-colon, each of them is independent of the others. Each double-colon rule's commands are executed if the target is older than any dependencies of that rule. This can result in executing none, any, or all of the double-colon rules.

Double-colon rules with the same target are in fact completely separate from one another. Each double-colon rule is processed individually, just as rules with different targets are processed.

The double-colon rules for a target are executed in the order they appear in the makefile. However, the cases where double-colon rules really make sense are those where the order of executing the commands would not matter.

Double-colon rules are somewhat obscure and not often very useful; they provide a mechanism for cases

in which the method used to update a target differs depending on which dependency files caused the update, and such cases are rare.

Each double-colon rule should specify commands; if it does not, an implicit rule will be used if one applies. See section Using Implicit Rules.

Generating Dependencies Automatically

In the makefile for a program, many of the rules you need to write often say only that some object file depends on some header file. For example, if `main.c' uses `defs.h' via an `#include`, you would write:

```
main.o: defs.h
```

You need this rule so that `make` knows that it must remake `main.o' whenever `defs.h' changes. You can see that for a large program you would have to write dozens of such rules in your makefile. And, you must always be very careful to update the makefile every time you add or remove an `#include`.

To avoid this hassle, most modern C compilers can write these rules for you, by looking at the `#include` lines in the source files. Usually this is done with the `-M' option to the compiler. For example, the command:

```
cc -M main.c
```

generates the output:

```
main.o : main.c defs.h
```

Thus you no longer have to write all those rules yourself. The compiler will do it for you.

Note that such a dependency constitutes mentioning `main.o' in a makefile, so it can never be considered an intermediate file by implicit rule search. This means that `make` won't ever remove the file after using it; see section Chains of Implicit Rules.

With old `make` programs, it was traditional practice to use this compiler feature to generate dependencies on demand with a command like `make depend'. That command would create a file `depend' containing all the automatically-generated dependencies; then the makefile could use `include` to read them in (see section Including Other Makefiles).

In GNU `make`, the feature of remaking makefiles makes this practice obsolete--you need never tell `make` explicitly to regenerate the dependencies, because it always regenerates any makefile that is out of date. See section How Makefiles Are Remade.

The practice we recommend for automatic dependency generation is to have one makefile corresponding to each source file. For each source file `name.c' there is a makefile `name.d' which lists what files the object file `name.o' depends on. That way only the source files that have changed need to be

rescanned to produce the new dependencies.

Here is the pattern rule to generate a file of dependencies (i.e., a makefile) called `name.d' from a C source file called `name.c':

```
%.d: %.c
        $(SHELL) -ec '$(CC) -M $(CPPFLAGS) $< \
                      | sed '\"s/$*\\.o[ :]*/& $@/g'\" > $@'
```

See section Defining and Redefining Pattern Rules, for information on defining pattern rules. The `-e' flag to the shell makes it exit immediately if the `$(CC)` command fails (exits with a nonzero status). Normally the shell exits with the status of the last command in the pipeline (`sed` in this case), so `make` would not notice a nonzero status from the compiler.

With the GNU C compiler, you may wish to use the `-MM' flag instead of `-M'. This omits dependencies on system header files. See section 'Options Controlling the Preprocessor' in Using GNU CC, for details.

The purpose of the `sed` command is to translate (for example):

```
main.o : main.c defs.h
```

into:

```
main.o main.d : main.c defs.h
```

This makes each `.d' file depend on all the source and header files that the corresponding `.o' file depends on. `make` then knows it must regenerate the dependencies whenever any of the source or header files changes.

Once you've defined the rule to remake the `.d' files, you then use the `include` directive to read them all in. See section Including Other Makefiles. For example:

```
sources = foo.c bar.c

include $(sources:.c=.d)
```

(This example uses a substitution variable reference to translate the list of source files `foo.c bar.c' into a list of dependency makefiles, `foo.d bar.d'. See section Substitution References, for full information on substitution references.) Since the `.d' files are makefiles like any others, `make` will remake them as necessary with no further work from you. See section How Makefiles Are Remade.

Go to the previous, next section.

Go to the previous, next section.

Writing the Commands in Rules

The commands of a rule consist of shell command lines to be executed one by one. Each command line must start with a tab, except that the first command line may be attached to the target-and-dependencies line with a semicolon in between. Blank lines and lines of just comments may appear among the command lines; they are ignored. (But beware, an apparently "blank" line that begins with a tab is *not* blank! It is an empty command; see section Using Empty Commands.)

Users use many different shell programs, but commands in makefiles are always interpreted by `/bin/sh' unless the makefile specifies otherwise. See section Command Execution.

The shell that is in use determines whether comments can be written on command lines, and what syntax they use. When the shell is `/bin/sh', a `#' starts a comment that extends to the end of the line. The `#' does not have to be at the beginning of a line. Text on a line before a `#' is not part of the comment.

Command Echoing

Normally `make` prints each command line before it is executed. We call this echoing because it gives the appearance that you are typing the commands yourself.

When a line starts with `@', the echoing of that line is suppressed. The `@' is discarded before the command is passed to the shell. Typically you would use this for a command whose only effect is to print something, such as an `echo` command to indicate progress through the makefile:

```
@echo About to make distribution files
```

When `make` is given the flag `-n' or `--just-print', echoing is all that happens, no execution. See section Summary of Options. In this case and only this case, even the commands starting with `@' are printed. This flag is useful for finding out which commands `make` thinks are necessary without actually doing them.

The `-s' or `--silent' flag to `make` prevents all echoing, as if all commands started with `@'. A rule in the makefile for the special target `.SILENT` without dependencies has the same effect (see section Special Built-in Target Names). `.SILENT` is essentially obsolete since `@' is more flexible.

Command Execution

When it is time to execute commands to update a target, they are executed by making a new subshell for each line. (In practice, `make` may take shortcuts that do not affect the results.)

Please note: this implies that shell commands such as `cd` that set variables local to each process will not affect the following command lines. If you want to use `cd` to affect the next command, put the two on a

single line with a semicolon between them. Then `make` will consider them a single command and pa them, together, to a shell which will execute them in sequence. For example:

```
foo : bar/lose
        cd bar; gobble lose > ../foo
```

If you would like to split a single shell command into multiple lines of text, you must use a backslash at the end of all but the last subline. Such a sequence of lines is combined into a single line, by deleting the backslash-newline sequences, before passing it to the shell. Thus, the following is equivalent to the preceding example:

```
foo : bar/lose
        cd bar;  \
        gobble lose > ../foo
```

The program used as the shell is taken from the variable `SHELL`. By default, the program `` `/bin/sh' `` is used.

Unlike most variables, the variable `SHELL` is never set from the environment. This is because the `SHELL` environment variable is used to specify your personal choice of shell program for interactive use. It would be very bad for personal choices like this to affect the functioning of makefiles. See section Variables from the Environment.

Parallel Execution

GNU `make` knows how to execute several commands at once. Normally, `make` will execute only one command at a time, waiting for it to finish before executing the next. However, the `-j' or `--jobs' option tells `make` to execute many commands simultaneously.

If the `-j' option is followed by an integer, this is the number of commands to execute at once; this is called the number of job slots. If there is nothing looking like an integer after the `-j' option, there is no limit on the number of job slots. The default number of job slots is one, which means serial execution (one thing at a time).

One unpleasant consequence of running several commands simultaneously is that output from all of the commands comes when the commands send it, so messages from different commands may be interspersed.

Another problem is that two processes cannot both take input from the same device; so to make sure that only one command tries to take input from the terminal at once, `make` will invalidate the standard input streams of all but one running command. This means that attempting to read from standard input will usually be a fatal error (a `Broken pipe' signal) for most child processes if there are several.

It is unpredictable which command will have a valid standard input stream (which will come from the terminal, or wherever you redirect the standard input of `make`). The first command run will always get it first, and the first command started after that one finishes will get it next, and so on.

We will change how this aspect of `make` works if we find a better alternative. In the mean time, you should not rely on any command using standard input at all if you are using the parallel execution feature; but if you are not using this feature, then standard input works normally in all commands.

If a command fails (is killed by a signal or exits with a nonzero status), and errors are not ignored for that command (see section Errors in Commands), the remaining command lines to remake the same target will not be run. If a command fails and the `-k' or `--keep-going' option was not given (see section Summary of Options), `make` aborts execution. If make terminates for any reason (including a signal) with child processes running, it waits for them to finish before actually exiting.

When the system is heavily loaded, you will probably want to run fewer jobs than when it is lightly loaded. You can use the `-l' option to tell `make` to limit the number of jobs to run at once, based on the load average. The `-l' or `--max-load' option is followed by a floating-point number. For example,

```
-l 2.5
```

will not let `make` start more than one job if the load average is above 2.5. The `-l' option with no following number removes the load limit, if one was given with a previous `-l' option.

More precisely, when `make` goes to start up a job, and it already has at least one job running, it checks the current load average; if it is not lower than the limit given with `-l', `make` waits until the load average goes below that limit, or until all the other jobs finish.

By default, there is no load limit.

Errors in Commands

After each shell command returns, `make` looks at its exit status. If the command completed successfully, the next command line is executed in a new shell; after the last command line is finished, the rule is finished.

If there is an error (the exit status is nonzero), `make` gives up on the current rule, and perhaps on all rules.

Sometimes the failure of a certain command does not indicate a problem. For example, you may use the `mkdir` command to ensure that a directory exists. If the directory already exists, `mkdir` will report an error, but you probably want `make` to continue regardless.

To ignore errors in a command line, write a `-' at the beginning of the line's text (after the initial tab). The `-' is discarded before the command is passed to the shell for execution.

For example,

```
clean:
        -rm -f *.o
```

This causes `rm` to continue even if it is unable to remove a file.

When you run `make` with the `-i' or `--ignore-errors' flag, errors are ignored in all commands of all rules. A rule in the makefile for the special target `.IGNORE` has the same effect, if there are no dependencies. These ways of ignoring errors are obsolete because `-' is more flexible.

When errors are to be ignored, because of either a `-' or the `-i' flag, `make` treats an error return just like success, except that it prints out a message that tells you the status code the command exited with, and says that the error has been ignored.

When an error happens that `make` has not been told to ignore, it implies that the current target cannot be correctly remade, and neither can any other that depends on it either directly or indirectly. No further commands will be executed for these targets, since their preconditions have not been achieved.

Normally `make` gives up immediately in this circumstance, returning a nonzero status. However, if the `-k' or `--keep-going' flag is specified, `make` continues to consider the other dependencies of the pending targets, remaking them if necessary, before it gives up and returns nonzero status. For example, after an error in compiling one object file, `make -k' will continue compiling other object files even though it already knows that linking them will be impossible. See section Summary of Options.

The usual behavior assumes that your purpose is to get the specified targets up to date; once `make` learns that this is impossible, it might as well report the failure immediately. The `-k' option says that the real purpose is to test as many of the changes made in the program as possible, perhaps to find several independent problems so that you can correct them all before the next attempt to compile. This is why Emacs' `compile` command passes the `-k' flag by default.

Usually when a command fails, if it has changed the target file at all, the file is corrupted and cannot be used--or at least it is not completely updated. Yet the file's timestamp says that it is now up to date, so the next time `make` runs, it will not try to update that file. The situation is just the same as when the command is killed by a signal; see section Interrupting or Killing `make`. So generally the right thing to do is to delete the target file if the command fails after beginning to change the file. `make` will do this if `.DELETE_ON_ERROR` appears as a target. This is almost always what you want `make` to do, but it is not historical practice; so for compatibility, you must explicitly request it.

Interrupting or Killing `make`

If `make` gets a fatal signal while a command is executing, it may delete the target file that the command was supposed to update. This is done if the target file's last-modification time has changed since `make` first checked it.

The purpose of deleting the target is to make sure that it is remade from scratch when `make` is next run. Why is this? Suppose you type Ctrl-c while a compiler is running, and it has begun to write an object file `foo.o'. The Ctrl-c kills the compiler, resulting in an incomplete file whose last-modification time is newer than the source file `foo.c'. But `make` also receives the Ctrl-c signal and deletes this incomplete file. If `make` did not do this, the next invocation of `make` would think that `foo.o' did not require updating--resulting in a strange error message from the linker when it tries to link an object file half of which is missing.

You can prevent the deletion of a target file in this way by making the special target `.PRECIOUS` depend on it. Before remaking a target, `make` checks to see whether it appears on the dependencies of `.PRECIOUS`, and thereby decides whether the target should be deleted if a signal happens. Some reasons why you might do this are that the target is updated in some atomic fashion, or exists only to record a modification-time (its contents do not matter), or must exist at all times to prevent other sorts of trouble.

Recursive Use of `make`

Recursive use of `make` means using `make` as a command in a makefile. This technique is useful when you want separate makefiles for various subsystems that compose a larger system. For example, suppose you have a subdirectory `` `subdir' `` which has its own makefile, and you would like the containing directory's makefile to run `make` on the subdirectory. You can do it by writing this:

```
subsystem:
        cd subdir; $(MAKE)
```

or, equivalently, this (see section Summary of Options):

```
subsystem:
        $(MAKE) -C subdir
```

You can write recursive `make` commands just by copying this example, but there are many things to know about how they work and why, and about how the sub-`make` relates to the top-level `make`.

How the `MAKE` Variable Works

Recursive `make` commands should always use the variable `MAKE`, not the explicit command name `make', as shown here:

```
subsystem:
        cd subdir; $(MAKE)
```

The value of this variable is the file name with which `make` was invoked. If this file name was `` `/bin/make' ``, then the command executed is `cd subdir; /bin/make'. If you use a special version of `make` to run the top-level makefile, the same special version will be executed for recursive invocations.

As a special feature, using the variable `MAKE` in the commands of a rule alters the effects of the `-t' (`--touch'), `-n' (`--just-print'), or `-q' (`--question') option. Using the `MAKE` variable has the same effect as using a `+' character at the beginning of the command line. See section Instead of Executing the Commands.

Consider the command `make -t' in the above example. (The `-t' option marks targets as up to date

without actually running any commands; see section Instead of Executing the Commands.) Following the usual definition of `-t', a `make -t' command in the example would create a file named `subsystem' and do nothing else. What you really want it to do is run `cd subdir; make -t'; but that would require executing the command, and `-t' says not to execute commands.

The special feature makes this do what you want: whenever a command line of a rule contains the variable MAKE, the flags `-t', `-n' and `-q' do not apply to that line. Command lines containing MAKE are executed normally despite the presence of a flag that causes most commands not to be run. The usual MAKEFLAGS mechanism passes the flags to the sub-make (see section Communicating Options to a Sub-make}), so your request to touch the files, or print the commands, is propagated to the subsystem.

Communicating Variables to a Sub-make

Variable values of the top-level make can be passed to the sub-make through the environment by explicit request. These variables are defined in the sub-make as defaults, but do not override what is specified in the makefile used by the sub-make makefile unless you use the `-e' switch (see section Summary of Options).

To pass down, or export, a variable, make adds the variable and its value to the environment for running each command. The sub-make, in turn, uses the environment to initialize its table of variable values. See section Variables from the Environment.

Except by explicit request, make exports a variable only if it is either defined in the environment initially or set on the command line, and if its name consists only of letters, numbers, and underscores. Some shells cannot cope with environment variable names consisting of characters other than letters, numbers, and underscores.

The special variables SHELL and MAKEFLAGS are always exported (unless you unexport them). MAKEFILES is exported if you set it to anything.

make automatically passes down variable values that were defined on the command line, by putting them in the MAKEFLAGS variable. See the next section.

Variables are *not* normally passed down if they were created by default by make (see section Variables Used by Implicit Rules). The sub-make will define these for itself.

If you want to export specific variables to a sub-make, use the export directive, like this:

```
export variable ...
```

If you want to *prevent* a variable from being exported, use the unexport directive, like this:

```
unexport variable ...
```

As a convenience, you can define a variable and export it at the same time by doing:

```
export variable = value
```

has the same result as:

```
variable = value
export variable
```

and

```
export variable := value
```

has the same result as:

```
variable := value
export variable
```

Likewise,

```
export variable += value
```

is just like:

```
variable += value
export variable
```

See section Appending More Text to Variables.

You may notice that the `export` and `unexport` directives work in `make` in the same way they work in the shell, `sh`.

If you want all variables to be exported by default, you can use `export` by itself:

```
export
```

This tells `make` that variables which are not explicitly mentioned in an `export` or `unexport` directive should be exported. Any variable given in an `unexport` directive will still *not* be exported. If you use `export` by itself to export variables by default, variables whose names contain characters other than alphanumerics and underscores will not be exported unless specifically mentioned in an `export` directive.

The behavior elicited by an `export` directive by itself was the default in older versions of GNU `make`. If your makefiles depend on this behavior and you want to be compatible with old versions of `make`, you can write a rule for the special target `.EXPORT_ALL_VARIABLES` instead of using the `export` directive. This will be ignored by old `make`s, while the `export` directive will cause a syntax error.

Likewise, you can use `unexport` by itself to tell `make` *not* to export variables by default. Since this is the default behavior, you would only need to do this if `export` had been used by itself earlier (in an included makefile, perhaps). You **cannot** use `export` and `unexport` by themselves to have variables exported for some commands and not for others. The last `export` or `unexport` directive that appears

by itself determines the behavior for the entire run of `make`.

As a special feature, the variable `MAKELEVEL` is changed when it is passed down from level to level. This variable's value is a string which is the depth of the level as a decimal number. The value is `0' for the top-level `make`; `1' for a sub-`make`, `2' for a sub-sub-`make`, and so on. The incrementation happens when `make` sets up the environment for a command.

The main use of `MAKELEVEL` is to test it in a conditional directive (see section Conditional Parts of Makefiles); this way you can write a makefile that behaves one way if run recursively and another way if run directly by you.

You can use the variable `MAKEFILES` to cause all sub-`make` commands to use additional makefiles. The value of `MAKEFILES` is a whitespace-separated list of file names. This variable, if defined in the outer-level makefile, is passed down through the environment; then it serves as a list of extra makefiles for the sub-`make` to read before the usual or specified ones. See section The Variable `MAKEFILES`}.

Communicating Options to a Sub-`make`

Flags such as `-s' and `-k' are passed automatically to the sub-`make` through the variable `MAKEFLAGS`. This variable is set up automatically by `make` to contain the flag letters that `make` received. Thus, if you do `make -ks' then `MAKEFLAGS` gets the value `ks'.

As a consequence, every sub-`make` gets a value for `MAKEFLAGS` in its environment. In response, it takes the flags from that value and processes them as if they had been given as arguments. See section Summary of Options.

Likewise variables defined on the command line are passed to the sub-`make` through `MAKEFLAGS`. Words in the value of `MAKEFLAGS` that contain `=', `make` treats as variable definitions just as if they appeared on the command line. See section Overriding Variables.

The options `-C', `-f', `-o', and `-W' are not put into `MAKEFLAGS`; these options are not passed down.

The `-j' option is a special case (see section Parallel Execution). If you set it to some numeric value, `-j 1' is always put into `MAKEFLAGS` instead of the value you specified. This is because if the `-j' option were passed down to sub-`make`s, you would get many more jobs running in parallel than you asked for. If you give `-j' with no numeric argument, meaning to run as many jobs as possible in parallel, this is passed down, since multiple infinities are no more than one.

If you do not want to pass the other flags down, you must change the value of `MAKEFLAGS`, like this:

```
MAKEFLAGS=
subsystem:
        cd subdir; $(MAKE)
```

or like this:

```
subsystem:
```

```
        cd subdir; $(MAKE) MAKEFLAGS=
```

The command line variable definitions really appear in the variable `MAKEOVERRIDES`, and `MAKEFLAGS` contains a reference to this variable. If you do want to pass flags down normally, but don't want to pass down the command line variable definitions, you can reset `MAKEOVERRIDES` to empty, like this:

```
MAKEOVERRIDES =
```

This is not usually useful to do. However, some systems have a small fixed limit on the size of the environment, and putting so much information in into the value of `MAKEFLAGS` can exceed it. If you see the error message `Arg list too long', this may be the problem. (For strict compliance with POSIX.2, changing `MAKEOVERRIDES` does not affect `MAKEFLAGS` if the special target `.POSIX' appears in the makefile. You probably do not care about this.)

A similar variable `MFLAGS` exists also, for historical compatibility. It has the same value as `MAKEFLAGS` except that it does not contain the command line variable definitions, and it always begins with a hyphen unless it is empty (`MAKEFLAGS` begins with a hyphen only when it begins with an option that has no single-letter version, such as `--warn-undefined-variables'). `MFLAGS` was traditionally used explicitly in the recursive `make` command, like this:

```
subsystem:
        cd subdir; $(MAKE) $(MFLAGS)
```

but now `MAKEFLAGS` makes this usage redundant. If you want your makefiles to be compatible with old `make` programs, use this technique; it will work fine with more modern `make` versions too.

The `MAKEFLAGS` variable can also be useful if you want to have certain options, such as `-k' (see section Summary of Options), set each time you run `make`. You simply put a value for `MAKEFLAGS` in your environment. You can also set `MAKEFLAGS` in a makefile, to specify additional flags that should also be in effect for that makefile. (Note that you cannot use `MFLAGS` this way. That variable is set only for compatibility; `make` does not interpret a value you set for it in any way.)

When `make` interprets the value of `MAKEFLAGS` (either from the environment or from a makefile), it first prepends a hyphen if the value does not already begin with one. Then it chops the value into words separated by blanks, and parses these words as if they were options given on the command line (except that `-C', `-f', `-h', `-o', `-W', and their long-named versions are ignored; and there is no error for an invalid option).

If you do put `MAKEFLAGS` in your environment, you should be sure not to include any options that will drastically affect the actions of `make` and undermine the purpose of makefiles and of `make` itself. For instance, the `-t', `-n', and `-q' options, if put in one of these variables, could have disastrous consequences and would certainly have at least surprising and probably annoying effects.

The `--print-directory' Option

If you use several levels of recursive `make` invocations, the `-w' or `--print-directory' option can make the output a lot easier to understand by showing each directory as `make` starts processing it and as `make` finishes processing it. For example, if `make -w' is run in the directory `/u/gnu/make', `make` will print a line of the form:

```
make: Entering directory `/u/gnu/make'.
```

before doing anything else, and a line of the form:

```
make: Leaving directory `/u/gnu/make'.
```

when processing is completed.

Normally, you do not need to specify this option because `make' does it for you: `-w' is turned on automatically when you use the `-C' option, and in sub-`make`s. `make` will not automatically turn on `-w' if you also use `-s', which says to be silent, or if you use `--no-print-directory' to explicitly disable it.

Defining Canned Command Sequences

When the same sequence of commands is useful in making various targets, you can define it as a canned sequence with the `define` directive, and refer to the canned sequence from the rules for those targets. The canned sequence is actually a variable, so the name must not conflict with other variable names.

Here is an example of defining a canned sequence of commands:

```
define run-yacc
yacc $(firstword $^)
mv y.tab.c $@
endef
```

Here `run-yacc` is the name of the variable being defined; `endef` marks the end of the definition; the lines in between are the commands. The `define` directive does not expand variable references and function calls in the canned sequence; the `$' characters, parentheses, variable names, and so on, all become part of the value of the variable you are defining. See section Defining Variables Verbatim, for a complete explanation of `define`.

The first command in this example runs Yacc on the first dependency of whichever rule uses the canned sequence. The output file from Yacc is always named `y.tab.c'. The second command moves the output to the rule's target file name.

To use the canned sequence, substitute the variable into the commands of a rule. You can substitute it like any other variable (see section Basics of Variable References). Because variables defined by `define` are recursively expanded variables, all the variable references you wrote inside the `define` are

expanded now. For example:

```
foo.c : foo.y
        $(run-yacc)
```

`foo.y' will be substituted for the variable `$^' when it occurs in `run-yacc`'s value, and `foo.c' for `$@'.

This is a realistic example, but this particular one is not needed in practice because `make` has an implicit rule to figure out these commands based on the file names involved (see section Using Implicit Rules).

In command execution, each line of a canned sequence is treated just as if the line appeared on its own in the rule, preceded by a tab. In particular, `make` invokes a separate subshell for each line. You can use the special prefix characters that affect command lines (`@', `-', and `+') on each line of a canned sequence. See section Writing the Commands in Rules. For example, using this canned sequence:

```
define frobnicate
@echo "frobnicating target $@"
frob-step-1 $< -o $@-step-1
frob-step-2 $@-step-1 -o $@
endef
```

`make` will not echo the first line, the `echo` command. But it *will* echo the following two command lines.

On the other hand, prefix characters on the command line that refers to a canned sequence apply to every line in the sequence. So the rule:

```
frob.out: frob.in
        @$(frobnicate)
```

does not echo *any* commands. (See section Command Echoing, for a full explanation of `@'.)

Using Empty Commands

It is sometimes useful to define commands which do nothing. This is done simply by giving a command that consists of nothing but whitespace. For example:

```
target: ;
```

defines an empty command string for `target'. You could also use a line beginning with a tab character to define an empty command string, but this would be confusing because such a line looks empty.

You may be wondering why you would want to define a command string that does nothing. The only reason this is useful is to prevent a target from getting implicit commands (from implicit rules or the `.DEFAULT` special target; see section Using Implicit Rules and see section Defining Last-Resort Default Rules).

You may be inclined to define empty command strings for targets that are not actual files, but only e so that their dependencies can be remade. However, this is not the best way to do that, because the dependencies may not be remade properly if the target file actually does exist. See section Phony Targets, for a better way to do this.

Go to the previous, next section.

Go to the previous, next section.

How to Use Variables

A variable is a name defined in a makefile to represent a string of text, called the variable's value. These values are substituted by explicit request into targets, dependencies, commands, and other parts of the makefile. (In some other versions of `make`, variables are called macros.)

Variables and functions in all parts of a makefile are expanded when read, except for the shell commands in rules, the right-hand sides of variable definitions using `=', and the bodies of variable definitions using the `define` directive.

Variables can represent lists of file names, options to pass to compilers, programs to run, directories to look in for source files, directories to write output in, or anything else you can imagine.

A variable name may be any sequence of characters not containing `:', `#', `=', or leading or trailing whitespace. However, variable names containing characters other than letters, numbers, and underscores should be avoided, as they may be given special meanings in the future, and with some shells they cannot be passed through the environment to a sub-`make` (see section Communicating Variables to a Sub-`make`).

Variable names are case-sensitive. The names `foo', `FOO', and `Foo' all refer to different variables.

It is traditional to use upper case letters in variable names, but we recommend using lower case letters for variable names that serve internal purposes in the makefile, and reserving upper case for parameters that control implicit rules or for parameters that the user should override with command options (see section Overriding Variables).

A few variables have names that are a single punctuation character or just a few characters. These are the automatic variables, and they have particular specialized uses. See section Automatic Variables.

Basics of Variable References

To substitute a variable's value, write a dollar sign followed by the name of the variable in parentheses or braces: either `$(foo)' or `${foo}' is a valid reference to the variable `foo`. This special significance of `$' is why you must write `$$' to have the effect of a single dollar sign in a file name or command.

Variable references can be used in any context: targets, dependencies, commands, most directives, and new variable values. Here is an example of a common case, where a variable holds the names of all the object files in a program:

```
objects = program.o foo.o utils.o
program : $(objects)
        cc -o program $(objects)
```

```
$(objects) : defs.h
```

Variable references work by strict textual substitution. Thus, the rule

```
foo = c
prog.o : prog.$(foo)
        $(foo)$(foo) -$(foo) prog.$(foo)
```

could be used to compile a C program `prog.c'. Since spaces before the variable value are ignored in variable assignments, the value of `foo` is precisely `c'. (Don't actually write your makefiles this way!)

A dollar sign followed by a character other than a dollar sign, open-parenthesis or open-brace treats that single character as the variable name. Thus, you could reference the variable `x` with `$x'. However, this practice is strongly discouraged, except in the case of the automatic variables (see section Automatic Variables).

The Two Flavors of Variables

There are two ways that a variable in GNU `make` can have a value; we call them the two flavors of variables. The two flavors are distinguished in how they are defined and in what they do when expanded.

The first flavor of variable is a recursively expanded variable. Variables of this sort are defined by lines using `=' (see section Setting Variables) or by the `define` directive (see section Defining Variables Verbatim). The value you specify is installed verbatim; if it contains references to other variables, these references are expanded whenever this variable is substituted (in the course of expanding some other string). When this happens, it is called recursive expansion.

For example,

```
foo = $(bar)
bar = $(ugh)
ugh = Huh?

all:;echo $(foo)
```

will echo `Huh?': `$(foo)' expands to `$(bar)' which expands to `$(ugh)' which finally expands to `Huh?'.

This flavor of variable is the only sort supported by other versions of `make`. It has its advantages and its disadvantages. An advantage (most would say) is that:

```
CFLAGS = $(include_dirs) -O
include_dirs = -Ifoo -Ibar
```

will do what was intended: when `CFLAGS' is expanded in a command, it will expand to `-Ifoo -Ibar -O'. A major disadvantage is that you cannot append something on the end of a variable, as in

```
CFLAGS = $(CFLAGS) -O
```

because it will cause an infinite loop in the variable expansion. (Actually `make` detects the infinite loop and reports an error.)

Another disadvantage is that any functions (see section Functions for Transforming Text) referenced in the definition will be executed every time the variable is expanded. This makes `make` run slower; worse, it causes the `wildcard` and `shell` functions to give unpredictable results because you cannot easily control when they are called, or even how many times.

To avoid all the problems and inconveniences of recursively expanded variables, there is another flavor: simply expanded variables.

Simply expanded variables are defined by lines using `:=' (see section Setting Variables). The value of a simply expanded variable is scanned once and for all, expanding any references to other variables and functions, when the variable is defined. The actual value of the simply expanded variable is the result of expanding the text that you write. It does not contain any references to other variables; it contains their values *as of the time this variable was defined*. Therefore,

```
x := foo
y := $(x) bar
x := later
```

is equivalent to

```
y := foo bar
x := later
```

When a simply expanded variable is referenced, its value is substituted verbatim.

Here is a somewhat more complicated example, illustrating the use of `:=' in conjunction with the `shell` function. (See section The `shell` Function.) This example also shows use of the variable `MAKELEVEL`, which is changed when it is passed down from level to level. (See section Communicating Variables to a Sub-`make`}, for information about `MAKELEVEL`.)

```
ifeq (0,${MAKELEVEL})
cur-dir   := $(shell pwd)
whoami    := $(shell whoami)
host-type := $(shell arch)
MAKE := ${MAKE} host-type=${host-type} whoami=${whoami}
endif
```

An advantage of this use of `:=' is that a typical `descend into a directory' command then looks like this:

```
${subdirs}:
      ${MAKE} cur-dir=${cur-dir}/$@ -C $@ all
```

Simply expanded variables generally make complicated makefile programming more predictable bec they work like variables in most programming languages. They allow you to redefine a variable usin own value (or its value processed in some way by one of the expansion functions) and to use the expansion functions much more efficiently (see section Functions for Transforming Text).

You can also use them to introduce controlled leading whitespace into variable values. Leading whitespace characters are discarded from your input before substitution of variable references and function calls; this means you can include leading spaces in a variable value by protecting them with variable references, like this:

```
nullstring :=
space := $(nullstring) # end of the line
```

Here the value of the variable `space` is precisely one space. The comment `# end of the line' is included here just for clarity. Since trailing space characters are *not* stripped from variable values, just a space at the end of the line would have the same effect (but be rather hard to read). If you put whitespace at the end of a variable value, it is a good idea to put a comment like that at the end of the line to make your intent clear. Conversely, if you do *not* want any whitespace characters at the end of your variable value, you must remember not to put a random comment on the end of the line after some whitespace, such as this:

```
dir := /foo/bar    # directory to put the frobs in
```

Here the value of the variable `dir` is `/foo/bar ' (with four trailing spaces), which was probably not the intention. (Imagine something like `$(dir)/file' with this definition!)

Advanced Features for Reference to Variables

This section describes some advanced features you can use to reference variables in more flexible ways.

Substitution References

A substitution reference substitutes the value of a variable with alterations that you specify. It has the form `$(var:a=b)' (or `${var:a=b}') and its meaning is to take the value of the variable var, replace every a at the end of a word with b in that value, and substitute the resulting string.

When we say "at the end of a word", we mean that a must appear either followed by whitespace or at the end of the value in order to be replaced; other occurrences of a in the value are unaltered. For example:

```
foo := a.o b.o c.o
bar := $(foo:.o=.c)
```

sets `bar' to `a.c b.c c.c'. See section Setting Variables.

A substitution reference is actually an abbreviation for use of the `patsubst` expansion function (see section Functions for String Substitution and Analysis). We provide substitution references as well as

`patsubst` for compatibility with other implementations of `make`.

Another type of substitution reference lets you use the full power of the `patsubst` function. It has the same form `$(var:a=b)' described above, except that now a must contain a single `%' character. This case is equivalent to `$(patsubst a,b,$(var))'. See section Functions for String Substitution and Analysis, for a description of the `patsubst` function.

For example:

```
foo := a.o b.o c.o
bar := $(foo:%.o=%.c)
```

sets `bar' to `a.c b.c c.c'.

Computed Variable Names

Computed variable names are a complicated concept needed only for sophisticated makefile programming. For most purposes you need not consider them, except to know that making a variable with a dollar sign in its name might have strange results. However, if you are the type that wants to understand everything, or you are actually interested in what they do, read on.

Variables may be referenced inside the name of a variable. This is called a computed variable name or a nested variable reference. For example,

```
x = y
y = z
a := $($(x))
```

defines `a` as `z': the `$(x)' inside `$($(x))' expands to `y', so `$($(x))' expands to `$(y)' which in turn expands to `z'. Here the name of the variable to reference is not stated explicitly; it is computed by expansion of `$(x)'. The reference `$(x)' here is nested within the outer variable reference.

The previous example shows two levels of nesting, but any number of levels is possible. For example, here are three levels:

```
x = y
y = z
z = u
a := $($($(x)))
```

Here the innermost `$(x)' expands to `y', so `$($(x))' expands to `$(y)' which in turn expands to `z'; now we have `$(z)', which becomes `u'.

References to recursively-expanded variables within a variable name are reexpanded in the usual fashion. For example:

```
x = $(y)
```

```
y = z
z = Hello
a := $($(x))
```

defines `a` as `Hello': `$($(x))' becomes `$($(y))' which becomes `$(z)' which becomes `Hello'.

Nested variable references can also contain modified references and function invocations (see section Functions for Transforming Text), just like any other reference. For example, using the `subst` function (see section Functions for String Substitution and Analysis):

```
x = variable1
variable2 := Hello
y = $(subst 1,2,$(x))
z = y
a := $($($(z)))
```

eventually defines `a` as `Hello'. It is doubtful that anyone would ever want to write a nested reference as convoluted as this one, but it works: `$($($(z)))' expands to `$($(y))' which becomes `$($(subst 1,2,$(x)))'. This gets the value `variable1' from `x` and changes it by substitution to `variable2', so that the entire string becomes `$(variable2)', a simple variable reference whose value is `Hello'.

A computed variable name need not consist entirely of a single variable reference. It can contain several variable references, as well as some invariant text. For example,

```
a_dirs := dira dirb
1_dirs := dir1 dir2

a_files := filea fileb
1_files := file1 file2

ifeq "$(use_a)" "yes"
a1 := a
else
a1 := 1
endif

ifeq "$(use_dirs)" "yes"
df := dirs
else
df := files
endif

dirs := $($(a1)_$(df))
```

will give `dirs` the same value as `a_dirs`, `1_dirs`, `a_files` or `1_files` depending on the settings of `use_a` and `use_dirs`.

Computed variable names can also be used in substitution references:

```
a_objects := a.o b.o c.o
1_objects := 1.o 2.o 3.o

sources := $($(a1)_objects:.o=.c)
```

defines `sources` as either `a.c b.c c.c' or `1.c 2.c 3.c', depending on the value of `a1`.

The only restriction on this sort of use of nested variable references is that they cannot specify part of the name of a function to be called. This is because the test for a recognized function name is done before the expansion of nested references. For example,

```
ifdef do_sort
func := sort
else
func := strip
endif

bar := a d b g q c

foo := $($(func) $(bar))
```

attempts to give `foo' the value of the variable `sort a d b g q c' or `strip a d b g q c', rather than giving `a d b g q c' as the argument to either the `sort` or the `strip` function. This restriction could be removed in the future if that change is shown to be a good idea.

You can also use computed variable names in the left-hand side of a variable assignment, or in a `define` directive, as in:

```
dir = foo
$(dir)_sources := $(wildcard $(dir)/*.c)
define $(dir)_print
lpr $($(dir)_sources)
endef
```

This example defines the variables `dir', `foo_sources', and `foo_print'.

Note that nested variable references are quite different from recursively expanded variables (see section The Two Flavors of Variables), though both are used together in complex ways when doing makefile programming.

How Variables Get Their Values

Variables can get values in several different ways:

- You can specify an overriding value when you run `make`. See section Overriding Variables.
- You can specify a value in the makefile, either with an assignment (see section Setting Variables) or with a verbatim definition (see section Defining Variables Verbatim).
- Variables in the environment become `make` variables. See section Variables from the Environment.
- Several automatic variables are given new values for each rule. Each of these has a single conventional use. See section Automatic Variables.
- Several variables have constant initial values. See section Variables Used by Implicit Rules.

Setting Variables

To set a variable from the makefile, write a line starting with the variable name followed by `=' or `:='. Whatever follows the `=' or `:=' on the line becomes the value. For example,

```
objects = main.o foo.o bar.o utils.o
```

defines a variable named `objects`. Whitespace around the variable name and immediately after the `=' is ignored.

Variables defined with `=' are recursively expanded variables. Variables defined with `:=' are simply expanded variables; these definitions can contain variable references which will be expanded before the definition is made. See section The Two Flavors of Variables.

The variable name may contain function and variable references, which are expanded when the line is read to find the actual variable name to use.

There is no limit on the length of the value of a variable except the amount of swapping space on the computer. When a variable definition is long, it is a good idea to break it into several lines by inserting backslash-newline at convenient places in the definition. This will not affect the functioning of `make`, but it will make the makefile easier to read.

Most variable names are considered to have the empty string as a value if you have never set them. Several variables have built-in initial values that are not empty, but you can set them in the usual ways (see section Variables Used by Implicit Rules). Several special variables are set automatically to a new value for each rule; these are called the automatic variables (see section Automatic Variables).

Appending More Text to Variables

Often it is useful to add more text to the value of a variable already defined. You do this with a line containing `+=', like this:

```
objects += another.o
```

This takes the value of the variable `objects`, and adds the text `another.o' to it (preceded by a single space). Thus:

```
objects = main.o foo.o bar.o utils.o
objects += another.o
```

sets `objects` to `main.o foo.o bar.o utils.o another.o'.

Using `+=' is similar to:

```
objects = main.o foo.o bar.o utils.o
objects := $(objects) another.o
```

but differs in ways that become important when you use more complex values.

When the variable in question has not been defined before, `+=' acts just like normal `=': it defines a recursively-expanded variable. However, when there *is* a previous definition, exactly what `+=' does depends on what flavor of variable you defined originally. See section The Two Flavors of Variables, for an explanation of the two flavors of variables.

When you add to a variable's value with `+=', `make` acts essentially as if you had included the extra text in the initial definition of the variable. If you defined it first with `:=', making it a simply-expanded variable, `+=' adds to that simply-expanded definition, and expands the new text before appending it to the old value just as `:=' does (see section Setting Variables, for a full explanation of `:='). In fact,

```
variable := value
variable += more
```

is exactly equivalent to:

```
variable := value
variable := $(variable) more
```

On the other hand, when you use `+=' with a variable that you defined first to be recursively-expanded using plain `=', `make` does something a bit different. Recall that when you define a recursively-expanded variable, `make` does not expand the value you set for variable and function references immediately. Instead it stores the text verbatim, and saves these variable and function references to be expanded later, when you refer to the new variable (see section The Two Flavors of Variables). When you use `+=' on a recursively-expanded variable, it is this unexpanded text to which `make` appends the new text you

specify.

```
variable = value
variable += more
```

is roughly equivalent to:

```
temp = value
variable = $(temp) more
```

except that of course it never defines a variable called `temp`. The importance of this comes when the variable's old value contains variable references. Take this common example:

```
CFLAGS = $(includes) -O
...
CFLAGS += -pg # enable profiling
```

The first line defines the `CFLAGS` variable with a reference to another variable, `includes`. (`CFLAGS` is used by the rules for C compilation; see section Catalogue of Implicit Rules.) Using `=' for the definition makes `CFLAGS` a recursively-expanded variable, meaning `$(includes) -O' is *not* expanded when `make` processes the definition of `CFLAGS`. Thus, `includes` need not be defined yet for its value to take effect. It only has to be defined before any reference to `CFLAGS`. If we tried to append to the value of `CFLAGS` without using `+=', we might do it like this:

```
CFLAGS := $(CFLAGS) -pg # enable profiling
```

This is pretty close, but not quite what we want. Using `:=' redefines `CFLAGS` as a simply-expanded variable; this means `make` expands the text `$(CFLAGS) -pg' before setting the variable. If `includes` is not yet defined, we get ` -O -pg', and a later definition of `includes` will have no effect. Conversely, by using `+=' we set `CFLAGS` to the *unexpanded* value `$(includes) -O -pg'. Thus we preserve the reference to `includes`, so if that variable gets defined at any later point, a reference like `$(CFLAGS)' still uses its value.

The `override` Directive

If a variable has been set with a command argument (see section Overriding Variables), then ordinary assignments in the makefile are ignored. If you want to set the variable in the makefile even though it was set with a command argument, you can use an `override` directive, which is a line that looks like this:

```
override variable = value
```

or

```
override variable := value
```

To append more text to a variable defined on the command line, use:

```
override variable += more text
```

See section Appending More Text to Variables.

The `override` directive was not invented for escalation in the war between makefiles and command arguments. It was invented so you can alter and add to values that the user specifies with command arguments.

For example, suppose you always want the `-g' switch when you run the C compiler, but you would like to allow the user to specify the other switches with a command argument just as usual. You could use this `override` directive:

```
override CFLAGS += -g
```

You can also use `override` directives with `define` directives. This is done as you might expect:

```
override define foo
bar
endef
```

See the next section for information about `define`.

Defining Variables Verbatim

Another way to set the value of a variable is to use the `define` directive. This directive has an unusual syntax which allows newline characters to be included in the value, which is convenient for defining canned sequences of commands (see section Defining Canned Command Sequences).

The `define` directive is followed on the same line by the name of the variable and nothing more. The value to give the variable appears on the following lines. The end of the value is marked by a line containing just the word `endef`. Aside from this difference in syntax, `define` works just like `=': it creates a recursively-expanded variable (see section The Two Flavors of Variables). The variable name may contain function and variable references, which are expanded when the directive is read to find the actual variable name to use.

```
define two-lines
echo foo
echo $(bar)
endef
```

The value in an ordinary assignment cannot contain a newline; but the newlines that separate the lines of the value in a `define` become part of the variable's value (except for the final newline which precedes the `endef` and is not considered part of the value).

The previous example is functionally equivalent to this:

```
two-lines = echo foo; echo $(bar)
```

since two commands separated by semicolon behave much like two separate shell commands. However, note that using two separate lines means `make` will invoke the shell twice, running an independent subshell for each line. See section Command Execution.

If you want variable definitions made with `define` to take precedence over command-line variable definitions, you can use the `override` directive together with `define`:

```
override define two-lines
foo
$(bar)
endef
```

See section The `override` Directive.

Variables from the Environment

Variables in `make` can come from the environment in which `make` is run. Every environment variable that `make` sees when it starts up is transformed into a `make` variable with the same name and value. But an explicit assignment in the makefile, or with a command argument, overrides the environment. (If the `-e' flag is specified, then values from the environment override assignments in the makefile. See section Summary of Options. But this is not recommended practice.)

Thus, by setting the variable `CFLAGS` in your environment, you can cause all C compilations in most makefiles to use the compiler switches you prefer. This is safe for variables with standard or conventional meanings because you know that no makefile will use them for other things. (But this is not totally reliable; some makefiles set `CFLAGS` explicitly and therefore are not affected by the value in the environment.)

When `make` is invoked recursively, variables defined in the outer invocation can be passed to inner invocations through the environment (see section Recursive Use of `make`). By default, only variables that came from the environment or the command line are passed to recursive invocations. You can use the `export` directive to pass other variables. See section Communicating Variables to a Sub-`make`}, for full details.

Other use of variables from the environment is not recommended. It is not wise for makefiles to depend for their functioning on environment variables set up outside their control, since this would cause different users to get different results from the same makefile. This is against the whole purpose of most makefiles.

Such problems would be especially likely with the variable `SHELL`, which is normally present in the environment to specify the user's choice of interactive shell. It would be very undesirable for this choice to affect `make`. So `make` ignores the environment value of `SHELL`.

Conditional Parts of Makefiles

A conditional causes part of a makefile to be obeyed or ignored depending on the values of variables. Conditionals can compare the value of one variable to another, or the value of a variable to a constant string. Conditionals control what `make` actually "sees" in the makefile, so they *cannot* be used to control shell commands at the time of execution.

Example of a Conditional

The following example of a conditional tells `make` to use one set of libraries if the `CC` variable is `gcc', and a different set of libraries otherwise. It works by controlling which of two command lines will be used as the command for a rule. The result is that `CC=gcc' as an argument to `make` changes not only which compiler is used but also which libraries are linked.

```
libs_for_gcc = -lgnu
normal_libs =

foo: $(objects)
ifeq ($(CC),gcc)
        $(CC) -o foo $(objects) $(libs_for_gcc)
else
        $(CC) -o foo $(objects) $(normal_libs)
endif
```

This conditional uses three directives: one `ifeq`, one `else` and one `endif`.

The `ifeq` directive begins the conditional, and specifies the condition. It contains two arguments, separated by a comma and surrounded by parentheses. Variable substitution is performed on both arguments and then they are compared. The lines of the makefile following the `ifeq` are obeyed if the two arguments match; otherwise they are ignored.

The `else` directive causes the following lines to be obeyed if the previous conditional failed. In the example above, this means that the second alternative linking command is used whenever the first alternative is not used. It is optional to have an `else` in a conditional.

The `endif` directive ends the conditional. Every conditional must end with an `endif`. Unconditional makefile text follows.

As this example illustrates, conditionals work at the textual level: the lines of the conditional are treated as part of the makefile, or ignored, according to the condition. This is why the larger syntactic units of the makefile, such as rules, may cross the beginning or the end of the conditional.

When the variable `CC` has the value `gcc', the above example has this effect:

```
foo: $(objects)
        $(CC) -o foo $(objects) $(libs_for_gcc)
```

When the variable `CC` has any other value, the effect is this:

```
foo: $(objects)
        $(CC) -o foo $(objects) $(normal_libs)
```

Equivalent results can be obtained in another way by conditionalizing a variable assignment and then using the variable unconditionally:

```
libs_for_gcc = -lgnu
normal_libs =

ifeq ($(CC),gcc)
  libs=$(libs_for_gcc)
else
  libs=$(normal_libs)
endif

foo: $(objects)
        $(CC) -o foo $(objects) $(libs)
```

Syntax of Conditionals

The syntax of a simple conditional with no `else` is as follows:

```
conditional-directive
text-if-true
endif
```

The text-if-true may be any lines of text, to be considered as part of the makefile if the condition is true. If the condition is false, no text is used instead.

The syntax of a complex conditional is as follows:

```
conditional-directive
text-if-true
else
text-if-false
endif
```

If the condition is true, text-if-true is used; otherwise, text-if-false is used instead. The text-if-false can be any number of lines of text.

The syntax of the conditional-directive is the same whether the conditional is simple or complex. Th
are four different directives that test different conditions. Here is a table of them:

`ifeq (arg1, arg2)`
`ifeq 'arg1' 'arg2'`
`ifeq "arg1" "arg2"`
`ifeq "arg1" 'arg2'`
`ifeq 'arg1' "arg2"`

Expand all variable references in arg1 and arg2 and compare them. If they are identical, the text-if-true is effective; otherwise, the text-if-false, if any, is effective.

Often you want to test if a variable has a non-empty value. When the value results from complex expansions of variables and functions, expansions you would consider empty may actually contain whitespace characters and thus are not seen as empty. However, you can use the `strip` function (see section Functions for String Substitution and Analysis) to avoid interpreting whitespace as a non-empty value. For example:

```
ifeq ($(strip $(foo)),)
text-if-empty
endif
```

will evaluate text-if-empty even if the expansion of `$(foo)` contains whitespace characters.

`ifneq (arg1, arg2)`
`ifneq 'arg1' 'arg2'`
`ifneq "arg1" "arg2"`
`ifneq "arg1" 'arg2'`
`ifneq 'arg1' "arg2"`

Expand all variable references in arg1 and arg2 and compare them. If they are different, the text-if-true is effective; otherwise, the text-if-false, if any, is effective.

`ifdef variable-name`

If the variable variable-name has a non-empty value, the text-if-true is effective; otherwise, the text-if-false, if any, is effective. Variables that have never been defined have an empty value.

Note that `ifdef` only tests whether a variable has a value. It does not expand the variable to see if that value is nonempty. Consequently, tests using `ifdef` return true for all definitions except those like `foo =`. To test for an empty value, use `ifeq ($(foo),)`. For example,

```
bar =
foo = $(bar)
ifdef foo
frobozz = yes
else
frobozz = no
```

```
endif
```

sets `frobozz' to `yes', while:

```
foo =
ifdef foo
frobozz = yes
else
frobozz = no
endif
```

sets `frobozz' to `no'.

`ifndef variable-name`

If the variable variable-name has an empty value, the text-if-true is effective; otherwise, the text-if-false, if any, is effective.

Extra spaces are allowed and ignored at the beginning of the conditional directive line, but a tab is not allowed. (If the line begins with a tab, it will be considered a command for a rule.) Aside from this, extra spaces or tabs may be inserted with no effect anywhere except within the directive name or within an argument. A comment starting with `#' may appear at the end of the line.

The other two directives that play a part in a conditional are `else` and `endif`. Each of these directives is written as one word, with no arguments. Extra spaces are allowed and ignored at the beginning of the line, and spaces or tabs at the end. A comment starting with `#' may appear at the end of the line.

Conditionals affect which lines of the makefile `make` uses. If the condition is true, `make` reads the lines of the text-if-true as part of the makefile; if the condition is false, `make` ignores those lines completely. It follows that syntactic units of the makefile, such as rules, may safely be split across the beginning or the end of the conditional.

`make` evaluates conditionals when it reads a makefile. Consequently, you cannot use automatic variables in the tests of conditionals because they are not defined until commands are run (see section Automatic Variables).

To prevent intolerable confusion, it is not permitted to start a conditional in one makefile and end it in another. However, you may write an `include` directive within a conditional, provided you do not attempt to terminate the conditional inside the included file.

Conditionals that Test Flags

You can write a conditional that tests `make` command flags such as `-t' by using the variable `MAKEFLAGS` together with the `findstring` function (see section Functions for String Substitution and Analysis). This is useful when `touch` is not enough to make a file appear up to date.

The `findstring` function determines whether one string appears as a substring of another. If you want to test for the `-t' flag, use `t' as the first string and the value of `MAKEFLAGS` as the other.

For example, here is how to arrange to use `ranlib -t' to finish marking an archive file up to date:

```
archive.a: ...
ifneq (,$(findstring t,$(MAKEFLAGS)))
        +touch archive.a
        +ranlib -t archive.a
else
        ranlib archive.a
endif
```

The `+' prefix marks those command lines as "recursive" so that they will be executed despite use of the `-t' flag. See section Recursive Use of `make`.

Go to the previous, next section.

Go to the previous, next section.

Functions for Transforming Text

Functions allow you to do text processing in the makefile to compute the files to operate on or the commands to use. You use a function in a function call, where you give the name of the function and some text (the arguments) for the function to operate on. The result of the function's processing is substituted into the makefile at the point of the call, just as a variable might be substituted.

Function Call Syntax

A function call resembles a variable reference. It looks like this:

```
$(function arguments)
```

or like this:

```
${function arguments}
```

Here function is a function name; one of a short list of names that are part of `make`. There is no provision for defining new functions.

The arguments are the arguments of the function. They are separated from the function name by one or more spaces or tabs, and if there is more than one argument, then they are separated by commas. Such whitespace and commas are not part of an argument's value. The delimiters which you use to surround the function call, whether parentheses or braces, can appear in an argument only in matching pairs; the other kind of delimiters may appear singly. If the arguments themselves contain other function calls or variable references, it is wisest to use the same kind of delimiters for all the references; write `$(subst a,b,$(x))', not `$(subst a,b,${x})'. This is because it is clearer, and because only one type of delimiter is matched to find the end of the reference.

The text written for each argument is processed by substitution of variables and function calls to produce the argument value, which is the text on which the function acts. The substitution is done in the order in which the arguments appear.

Commas and unmatched parentheses or braces cannot appear in the text of an argument as written; leading spaces cannot appear in the text of the first argument as written. These characters can be put into the argument value by variable substitution. First define variables `comma` and `space` whose values are isolated comma and space characters, then substitute these variables where such characters are wanted, like this:

```
comma:= ,
empty:=
space:= $(empty) $(empty)
```

```
foo:= a b c
bar:= $(subst $(space),$(comma),$(foo))
# bar is now `a,b,c'.
```

Here the `subst` function replaces each space with a comma, through the value of `foo`, and substitutes the result.

Functions for String Substitution and Analysis

Here are some functions that operate on strings:

`$(subst from,to,text)`

Performs a textual replacement on the text text: each occurrence of from is replaced by to. The result is substituted for the function call. For example,

```
$(subst ee,EE,feet on the street)
```

substitutes the string `fEEt on the strEEt'.

`$(patsubst pattern,replacement,text)`

Finds whitespace-separated words in text that match pattern and replaces them with replacement. Here pattern may contain a `%' which acts as a wildcard, matching any number of any characters within a word. If replacement also contains a `%', the `%' is replaced by the text that matched the `%' in pattern.

`%' characters in `patsubst` function invocations can be quoted with preceding backslashes (`\'). Backslashes that would otherwise quote `%' characters can be quoted with more backslashes. Backslashes that quote `%' characters or other backslashes are removed from the pattern before it is compared file names or has a stem substituted into it. Backslashes that are not in danger of quoting `%' characters go unmolested. For example, the pattern `` `the\%weird\\%pattern\\' `` has `the%weird\' preceding the operative `%' character, and `pattern\\' following it. The final two backslashes are left alone because they cannot affect any `%' character.

Whitespace between words is folded into single space characters; leading and trailing whitespace is discarded.

For example,

```
$(patsubst %.c,%.o,x.c.c bar.c)
```

produces the value `x.c.o bar.o'.

Substitution references (see section Substitution References) are a simpler way to get the effect of the `patsubst` function:

```
$(var:pattern=replacement)
```

is equivalent to

```
$(patsubst pattern,replacement,$(var))
```

The second shorthand simplifies one of the most common uses of `patsubst`: replacing the suffix at the end of file names.

```
$(var:suffix=replacement)
```

is equivalent to

```
$(patsubst %suffix,%replacement,$(var))
```

For example, you might have a list of object files:

```
objects = foo.o bar.o baz.o
```

To get the list of corresponding source files, you could simply write:

```
$(objects:.o=.c)
```

instead of using the general form:

```
$(patsubst %.o,%.c,$(objects))
```

`$(strip string)`

Removes leading and trailing whitespace from string and replaces each internal sequence of one or more whitespace characters with a single space. Thus, `$(strip a b c )' results in `a b c'.

The function `strip` can be very useful when used in conjunction with conditionals. When comparing something with the empty string `' using `ifeq` or `ifneq`, you usually want a string of just whitespace to match the empty string (see section Conditional Parts of Makefiles).

Thus, the following may fail to have the desired results:

```
.PHONY: all
ifneq   "$(needs_made)" ""
all: $(needs_made)
else
all:;@echo 'Nothing to make!'
endif
```

Replacing the variable reference `$(needs_made)' with the function call `$(strip $(needs_made))' in the `ifneq` directive would make it more robust.

`$(findstring find,in)`

Searches in for an occurrence of find. If it occurs, the value is find; otherwise, the value is empty. You can use this function in a conditional to test for the presence of a specific substring in a given

string. Thus, the two examples,

```
$(findstring a,a b c)
$(findstring a,b c)
```

produce the values `a' and `' (the empty string), respectively. See section Conditionals that Test Flags, for a practical application of `findstring`.

`$(filter pattern...,text)`

Removes all whitespace-separated words in text that do *not* match any of the pattern words, returning only matching words. The patterns are written using `%', just like the patterns used in the `patsubst` function above.

The `filter` function can be used to separate out different types of strings (such as file names) in a variable. For example:

```
sources := foo.c bar.c baz.s ugh.h
foo: $(sources)
        cc $(filter %.c %.s,$(sources)) -o foo
```

says that `foo' depends of `foo.c', `bar.c', `baz.s' and `ugh.h' but only `foo.c', `bar.c' and `baz.s' should be specified in the command to the compiler.

`$(filter-out pattern...,text)`

Removes all whitespace-separated words in text that *do* match the pattern words, returning only the words that *do not* match. This is the exact opposite of the `filter` function.

For example, given:

```
objects=main1.o foo.o main2.o bar.o
mains=main1.o main2.o
```

the following generates a list which contains all the object files not in `mains':

```
$(filter-out $(mains),$(objects))
```

`$(sort list)`

Sorts the words of list in lexical order, removing duplicate words. The output is a list of words separated by single spaces. Thus,

```
$(sort foo bar lose)
```

returns the value `bar foo lose'.

Incidentally, since `sort` removes duplicate words, you can use it for this purpose even if you don't care about the sort order.

Here is a realistic example of the use of `subst` and `patsubst`. Suppose that a makefile uses the

VPATH variable to specify a list of directories that make should search for dependency files (see sec VPATH: Search Path for All Dependencies). This example shows how to tell the C compiler to searc header files in the same list of directories.

The value of VPATH is a list of directories separated by colons, such as `src:../headers'. First, the subst function is used to change the colons to spaces:

```
$(subst :, ,$(VPATH))
```

This produces `src ../headers'. Then patsubst is used to turn each directory name into a `-I' flag. These can be added to the value of the variable CFLAGS, which is passed automatically to the C compiler, like this:

```
override CFLAGS += $(patsubst %,-I%,$(subst :, ,$(VPATH)))
```

The effect is to append the text `-Isrc -I../headers' to the previously given value of CFLAGS. The override directive is used so that the new value is assigned even if the previous value of CFLAGS was specified with a command argument (see section The override Directive Directive}).

Functions for File Names

Several of the built-in expansion functions relate specifically to taking apart file names or lists of file names.

Each of the following functions performs a specific transformation on a file name. The argument of the function is regarded as a series of file names, separated by whitespace. (Leading and trailing whitespace is ignored.) Each file name in the series is transformed in the same way and the results are concatenated with single spaces between them.

`$(dir names...)`

Extracts the directory-part of each file name in names. The directory-part of the file name is everything up through (and including) the last slash in it. If the file name contains no slash, the directory part is the string `./'. For example,

```
$(dir src/foo.c hacks)
```

produces the result `src/ ./'.

`$(notdir names...)`

Extracts all but the directory-part of each file name in names. If the file name contains no slash, it is left unchanged. Otherwise, everything through the last slash is removed from it.

A file name that ends with a slash becomes an empty string. This is unfortunate, because it means that the result does not always have the same number of whitespace-separated file names as the argument had; but we do not see any other valid alternative.

For example,

```
$(notdir src/foo.c hacks)
```

produces the result `foo.c hacks'.

`$(suffix names...)`

Extracts the suffix of each file name in names. If the file name contains a period, the suffix is everything starting with the last period. Otherwise, the suffix is the empty string. This frequently means that the result will be empty when names is not, and if names contains multiple file names, the result may contain fewer file names.

For example,

```
$(suffix src/foo.c hacks)
```

produces the result `.c'.

`$(basename names...)`

Extracts all but the suffix of each file name in names. If the file name contains a period, the basename is everything starting up to (and not including) the last period. Otherwise, the basename is the entire file name. For example,

```
$(basename src/foo.c hacks)
```

produces the result `src/foo hacks'.

`$(addsuffix suffix,names...)`

The argument names is regarded as a series of names, separated by whitespace; suffix is used as a unit. The value of suffix is appended to the end of each individual name and the resulting larger names are concatenated with single spaces between them. For example,

```
$(addsuffix .c,foo bar)
```

produces the result `foo.c bar.c'.

`$(addprefix prefix,names...)`

The argument names is regarded as a series of names, separated by whitespace; prefix is used as a unit. The value of prefix is prepended to the front of each individual name and the resulting larger names are concatenated with single spaces between them. For example,

```
$(addprefix src/,foo bar)
```

produces the result `src/foo src/bar'.

`$(join list1,list2)`

Concatenates the two arguments word by word: the two first words (one from each argument) concatenated form the first word of the result, the two second words form the second word of the result, and so on. So the nth word of the result comes from the nth word of each argument. If one argument has more words that the other, the extra words are copied unchanged into the result.

For example, `$(join a b,.c .o)' produces `a.c b.o'.

Whitespace between the words in the lists is not preserved; it is replaced with a single space.

This function can merge the results of the `dir` and `notdir` functions, to produce the original list of files which was given to those two functions.

`$(word n,text)`

Returns the nth word of text. The legitimate values of n start from 1. If n is bigger than the number of words in text, the value is empty. For example,

```
$(word 2, foo bar baz)
```

returns `bar'.

`$(words text)`

Returns the number of words in text. Thus, the last word of text is `$(word $(words text),text)`.

`$(firstword names...)`

The argument names is regarded as a series of names, separated by whitespace. The value is the first name in the series. The rest of the names are ignored.

For example,

```
$(firstword foo bar)
```

produces the result `foo'. Although `$(firstword text)` is the same as `$(word 1,text)`, the `firstword` function is retained for its simplicity.

`$(wildcard pattern)`

The argument pattern is a file name pattern, typically containing wildcard characters (as in shell file name patterns). The result of `wildcard` is a space-separated list of the names of existing files that match the pattern. See section Using Wildcard Characters in File Names.

The `foreach` Function

The `foreach` function is very different from other functions. It causes one piece of text to be used repeatedly, each time with a different substitution performed on it. It resembles the `for` command in the shell `sh` and the `foreach` command in the C-shell `csh`.

The syntax of the `foreach` function is:

```
$(foreach var,list,text)
```

The first two arguments, var and list, are expanded before anything else is done; note that the last argument, text, is **not** expanded at the same time. Then for each word of the expanded value of list, the variable named by the expanded value of var is set to that word, and text is expanded. Presumably text

contains references to that variable, so its expansion will be different each time.

The result is that text is expanded as many times as there are whitespace-separated words in list. The multiple expansions of text are concatenated, with spaces between them, to make the result of `foreach`.

This simple example sets the variable `files' to the list of all files in the directories in the list `dirs':

```
dirs := a b c d
files := $(foreach dir,$(dirs),$(wildcard $(dir)/*))
```

Here text is `$(wildcard $(dir)/*)'. The first repetition finds the value `a' for `dir`, so it produces the same result as `$(wildcard a/*)'; the second repetition produces the result of `$(wildcard b/*)'; and the third, that of `$(wildcard c/*)'.

This example has the same result (except for setting `dirs') as the following example:

```
files := $(wildcard a/* b/* c/* d/*)
```

When text is complicated, you can improve readability by giving it a name, with an additional variable:

```
find_files = $(wildcard $(dir)/*)
dirs := a b c d
files := $(foreach dir,$(dirs),$(find_files))
```

Here we use the variable `find_files` this way. We use plain `=' to define a recursively-expanding variable, so that its value contains an actual function call to be reexpanded under the control of `foreach`; a simply-expanded variable would not do, since `wildcard` would be called only once at the time of defining `find_files`.

The `foreach` function has no permanent effect on the variable var; its value and flavor after the `foreach` function call are the same as they were beforehand. The other values which are taken from list are in effect only temporarily, during the execution of `foreach`. The variable var is a simply-expanded variable during the execution of `foreach`. If var was undefined before the `foreach` function call, it is undefined after the call. See section The Two Flavors of Variables.

You must take care when using complex variable expressions that result in variable names because many strange things are valid variable names, but are probably not what you intended. For example,

```
files := $(foreach Esta escrito en espanol!,b c ch,$(find_files))
```

might be useful if the value of `find_files` references the variable whose name is `Esta escrito en espanol!' (es un nombre bastante largo, no?), but it is more likely to be a mistake.

The `origin` Function

The `origin` function is unlike most other functions in that it does not operate on the values of variables; it tells you something *about* a variable. Specifically, it tells you where it came from.

The syntax of the `origin` function is:

```
$(origin variable)
```

Note that variable is the *name* of a variable to inquire about; not a *reference* to that variable. Therefore you would not normally use a `$' or parentheses when writing it. (You can, however, use a variable reference in the name if you want the name not to be a constant.)

The result of this function is a string telling you how the variable variable was defined:

`undefined'

if variable was never defined.

`default'

if variable has a default definition, as is usual with `CC` and so on. See section Variables Used by Implicit Rules. Note that if you have redefined a default variable, the `origin` function will return the origin of the later definition.

`environment'

if variable was defined as an environment variable and the `-e' option is *not* turned on (see section Summary of Options).

`environment override'

if variable was defined as an environment variable and the `-e' option *is* turned on (see section Summary of Options).

`file'

if variable was defined in a makefile.

`command line'

if variable was defined on the command line.

`override'

if variable was defined with an `override` directive in a makefile (see section The `override` Directive).

`automatic'

if variable is an automatic variable defined for the execution of the commands for each rule (see section Automatic Variables).

This information is primarily useful (other than for your curiosity) to determine if you want to believe the

value of a variable. For example, suppose you have a makefile `foo' that includes another makefile `bar'. You want a variable `bletch' to be defined in `bar' if you run the command `make -f bar', even if the environment contains a definition of `bletch'. However, if `foo' defined `bletch' before including `bar', you do not want to override that definition. This could be done by using an `override' directive in `foo', giving that definition precedence over the later definition in `bar'; unfortunately, the `override' directive would also override any command line definitions. So, `bar' could include:

```
ifdef bletch
ifeq "$(origin bletch)" "environment"
bletch = barf, gag, etc.
endif
endif
```

If `bletch' has been defined from the environment, this will redefine it.

If you want to override a previous definition of `bletch' if it came from the environment, even under `-e', you could instead write:

```
ifneq "$(findstring environment,$(origin bletch))" ""
bletch = barf, gag, etc.
endif
```

Here the redefinition takes place if `$(origin bletch)' returns either `environment' or `environment override'. See section Functions for String Substitution and Analysis.

The `shell' Function

The `shell' function is unlike any other function except the `wildcard' function (see section The Function `wildcard') in that it communicates with the world outside of `make'.

The `shell' function performs the same function that backquotes (``') perform in most shells: it does command expansion. This means that it takes an argument that is a shell command and returns the output of the command. The only processing `make' does on the result, before substituting it into the surrounding text, is to convert newlines to spaces.

The commands run by calls to the `shell' function are run when the function calls are expanded. In most cases, this is when the makefile is read in. The exception is that function calls in the commands of the rules are expanded when the commands are run, and this applies to `shell' function calls like all others.

Here are some examples of the use of the `shell' function:

```
contents := $(shell cat foo)
```

sets `contents' to the contents of the file `foo', with a space (rather than a newline) separating each line.

```
files := $(shell echo *.c)
```

sets `files` to the expansion of `*.c'. Unless `make` is using a very strange shell, this has the same result as `$(wildcard *.c)'.

Go to the previous, next section.

Go to the previous, next section.

How to Run `make`

A makefile that says how to recompile a program can be used in more than one way. The simplest use is to recompile every file that is out of date. Usually, makefiles are written so that if you run `make` with no arguments, it does just that.

But you might want to update only some of the files; you might want to use a different compiler or different compiler options; you might want just to find out which files are out of date without changing them.

By giving arguments when you run `make`, you can do any of these things and many others.

The exit status of `make` is always one of three values:

`0`

The exit status is zero if `make` is successful.

`2`

The exit status is two if `make` encounters any errors. It will print messages describing the particular errors.

`1`

The exit status is one if you use the `-q' flag and `make` determines that some target is not already up to date. See section Instead of Executing the Commands.

Arguments to Specify the Makefile

The way to specify the name of the makefile is with the `-f' or `--file' option (`--makefile' also works). For example, `-f altmake' says to use the file `` `altmake' `` as the makefile.

If you use the `-f' flag several times and follow each `-f' with an argument, all the specified files are used jointly as makefiles.

If you do not use the `-f' or `--file' flag, the default is to try `` `GNUmakefile' ``, `` `makefile' ``, and `` `Makefile' ``, in that order, and use the first of these three which exists or can be made (see section Writing Makefiles).

Arguments to Specify the Goals

The goals are the targets that `make` should strive ultimately to update. Other targets are updated as well if they appear as dependencies of goals, or dependencies of dependencies of goals, etc.

By default, the goal is the first target in the makefile (not counting targets that start with a period). Therefore, makefiles are usually written so that the first target is for compiling the entire program or

programs they describe. If the first rule in the makefile has several targets, only the first target in the becomes the default goal, not the whole list.

You can specify a different goal or goals with arguments to `make`. Use the name of the goal as an argument. If you specify several goals, `make` processes each of them in turn, in the order you name them.

Any target in the makefile may be specified as a goal (unless it starts with `-' or contains an `=', in which case it will be parsed as a switch or variable definition, respectively). Even targets not in the makefile may be specified, if `make` can find implicit rules that say how to make them.

One use of specifying a goal is if you want to compile only a part of the program, or only one of several programs. Specify as a goal each file that you wish to remake. For example, consider a directory containing several programs, with a makefile that starts like this:

```
.PHONY: all
all: size nm ld ar as
```

If you are working on the program `size`, you might want to say `make size' so that only the files of that program are recompiled.

Another use of specifying a goal is to make files that are not normally made. For example, there may be a file of debugging output, or a version of the program that is compiled specially for testing, which has a rule in the makefile but is not a dependency of the default goal.

Another use of specifying a goal is to run the commands associated with a phony target (see section Phony Targets) or empty target (see section Empty Target Files to Record Events). Many makefiles contain a phony target named `` `clean' `` which deletes everything except source files. Naturally, this is done only if you request it explicitly with `make clean'. Following is a list of typical phony and empty target names. See section Standard Targets for Users, for a detailed list of all the standard target names which GNU software packages use.

`` `all' ``

Make all the top-level targets the makefile knows about.

`` `clean' ``

Delete all files that are normally created by running `make`.

`` `mostlyclean' ``

Like `clean', but may refrain from deleting a few files that people normally don't want to recompile. For example, the `mostlyclean' target for GCC does not delete `` `libgcc.a' ``, because recompiling it is rarely necessary and takes a lot of time.

`` `distclean' ``

`` `realclean' ``

`` `clobber' ``

Any of these targets might be defined to delete *more* files than `clean' does. For example, this would delete configuration files or links that you would normally create as preparation for compilation, even if the makefile itself cannot create these files.

`install'
: Copy the executable file into a directory that users typically search for commands; copy any auxiliary files that the executable uses into the directories where it will look for them.

`print'
: Print listings of the source files that have changed.

`tar'
: Create a tar file of the source files.

`shar'
: Create a shell archive (shar file) of the source files.

`dist'
: Create a distribution file of the source files. This might be a tar file, or a shar file, or a compressed version of one of the above, or even more than one of the above.

`TAGS'
: Update a tags table for this program.

`check'

`test'
: Perform self tests on the program this makefile builds.

Instead of Executing the Commands

The makefile tells `make` how to tell whether a target is up to date, and how to update each target. But updating the targets is not always what you want. Certain options specify other activities for `make`.

`-n'

`--just-print'

`--dry-run'

`--recon'
: "No-op". The activity is to print what commands would be used to make the targets up to date, but not actually execute them.

`-t'

`--touch'
: "Touch". The activity is to mark the targets as up to date without actually changing them. In other words, `make` pretends to compile the targets but does not really change their contents.

`-q'

`--question'
: "Question". The activity is to find out silently whether the targets are up to date already; but execute no commands in either case. In other words, neither compilation nor output will occur.

`-W file'

`--what-if=file'

`--assume-new=file'

`--new-file=file'

> "What if". Each `-W' flag is followed by a file name. The given files' modification times are recorded by `make` as being the present time, although the actual modification times remain the same. You can use the `-W' flag in conjunction with the `-n' flag to see what would happen if you were to modify specific files.

With the `-n' flag, `make` prints the commands that it would normally execute but does not execute them.

With the `-t' flag, `make` ignores the commands in the rules and uses (in effect) the command `touch` for each target that needs to be remade. The `touch` command is also printed, unless `-s' or `.SILENT` is used. For speed, `make` does not actually invoke the program `touch`. It does the work directly.

With the `-q' flag, `make` prints nothing and executes no commands, but the exit status code it returns is zero if and only if the targets to be considered are already up to date. If the exit status is one, then some updating needs to be done. If `make` encounters an error, the exit status is two, so you can distinguish an error from a target that is not up to date.

It is an error to use more than one of these three flags in the same invocation of `make`.

The `-n', `-t', and `-q' options do not affect command lines that begin with `+' characters or contain the strings `$(MAKE)' or `${MAKE}'. Note that only the line containing the `+' character or the strings `$(MAKE)' or `${MAKE}' is run regardless of these options. Other lines in the same rule are not run unless they too begin with `+' or contain `$(MAKE)' or `${MAKE}' (See section How the `MAKE` Variable Works.)

The `-W' flag provides two features:

- If you also use the `-n' or `-q' flag, you can see what `make` would do if you were to modify some files.
- Without the `-n' or `-q' flag, when `make` is actually executing commands, the `-W' flag can direct `make` to act as if some files had been modified, without actually modifying the files.

Note that the options `-p' and `-v' allow you to obtain other information about `make` or about the makefiles in use (see section Summary of Options).

Avoiding Recompilation of Some Files

Sometimes you may have changed a source file but you do not want to recompile all the files that depend on it. For example, suppose you add a macro or a declaration to a header file that many other files depend on. Being conservative, `make` assumes that any change in the header file requires recompilation of all dependent files, but you know that they do not need to be recompiled and you would rather not waste the time waiting for them to compile.

If you anticipate the problem before changing the header file, you can use the `-t' flag. This flag tells `make` not to run the commands in the rules, but rather to mark the target up to date by changing its

last-modification date. You would follow this procedure:

1. Use the command `make' to recompile the source files that really need recompilation.
2. Make the changes in the header files.
3. Use the command `make -t' to mark all the object files as up to date. The next time you run `make`, the changes in the header files will not cause any recompilation.

If you have already changed the header file at a time when some files do need recompilation, it is too late to do this. Instead, you can use the `-o file' flag, which marks a specified file as "old" (see section Summary of Options). This means that the file itself will not be remade, and nothing else will be remade on its account. Follow this procedure:

1. Recompile the source files that need compilation for reasons independent of the particular header file, with `make -o headerfile'. If several header files are involved, use a separate `-o' option for each header file.
2. Touch all the object files with `make -t'.

Overriding Variables

An argument that contains `=' specifies the value of a variable: `v=x' sets the value of the variable v to x. If you specify a value in this way, all ordinary assignments of the same variable in the makefile are ignored; we say they have been overridden by the command line argument.

The most common way to use this facility is to pass extra flags to compilers. For example, in a properly written makefile, the variable `CFLAGS` is included in each command that runs the C compiler, so a file `` `foo.c' `` would be compiled something like this:

```
cc -c $(CFLAGS) foo.c
```

Thus, whatever value you set for `CFLAGS` affects each compilation that occurs. The makefile probably specifies the usual value for `CFLAGS`, like this:

```
CFLAGS=-g
```

Each time you run `make`, you can override this value if you wish. For example, if you say `make CFLAGS='-g -O'', each C compilation will be done with `cc -c -g -O'. (This illustrates how you can use quoting in the shell to enclose spaces and other special characters in the value of a variable when you override it.)

The variable `CFLAGS` is only one of many standard variables that exist just so that you can change them this way. See section Variables Used by Implicit Rules, for a complete list.

You can also program the makefile to look at additional variables of your own, giving the user the ability to control other aspects of how the makefile works by changing the variables.

When you override a variable with a command argument, you can define either a recursively-expanded variable or a simply-expanded variable. The examples shown above make a recursively-expanded

variable; to make a simply-expanded variable, write `:=' instead of `='. But, unless you want to include a variable reference or function call in the *value* that you specify, it makes no difference which kind of variable you create.

There is one way that the makefile can change a variable that you have overridden. This is to use the `override` directive, which is a line that looks like this: `override variable = value' (see section The `override` Directive).

Testing the Compilation of a Program

Normally, when an error happens in executing a shell command, `make` gives up immediately, returning a nonzero status. No further commands are executed for any target. The error implies that the goal cannot be correctly remade, and `make` reports this as soon as it knows.

When you are compiling a program that you have just changed, this is not what you want. Instead, you would rather that `make` try compiling every file that can be tried, to show you as many compilation errors as possible.

On these occasions, you should use the `-k' or `--keep-going' flag. This tells `make` to continue to consider the other dependencies of the pending targets, remaking them if necessary, before it gives up and returns nonzero status. For example, after an error in compiling one object file, `make -k' will continue compiling other object files even though it already knows that linking them will be impossible. In addition to continuing after failed shell commands, `make -k' will continue as much as possible after discovering that it does not know how to make a target or dependency file. This will always cause an error message, but without `-k', it is a fatal error (see section Summary of Options).

The usual behavior of `make` assumes that your purpose is to get the goals up to date; once `make` learns that this is impossible, it might as well report the failure immediately. The `-k' flag says that the real purpose is to test as much as possible of the changes made in the program, perhaps to find several independent problems so that you can correct them all before the next attempt to compile. This is why Emacs' M-x compile command passes the `-k' flag by default.

Summary of Options

Here is a table of all the options `make` understands:

`-b'

`-m'

These options are ignored for compatibility with other versions of `make`.

`-C dir'

`--directory=dir'

Change to directory dir before reading the makefiles. If multiple `-C' options are specified, each is interpreted relative to the previous one: `-C / -C etc' is equivalent to `-C /etc'. This is typically used with recursive invocations of `make` (see section Recursive Use of `make`).

`-d'

`--debug'

Print debugging information in addition to normal processing. The debugging information says which files are being considered for remaking, which file-times are being compared and with what results, which files actually need to be remade, which implicit rules are considered and which are applied--everything interesting about how `make` decides what to do.

`-e'

`--environment-overrides'

Give variables taken from the environment precedence over variables from makefiles. See section Variables from the Environment.

`-f file'

`--file=file'

`--makefile=file'

Read the file named file as a makefile. See section Writing Makefiles.

`-h'

`--help'

Remind you of the options that `make` understands and then exit.

`-i'

`--ignore-errors'

Ignore all errors in commands executed to remake files. See section Errors in Commands.

`-I dir'

`--include-dir=dir'

Specifies a directory dir to search for included makefiles. See section Including Other Makefiles. If several `-I' options are used to specify several directories, the directories are searched in the order specified.

`-j [jobs]'

`--jobs=[jobs]'

Specifies the number of jobs (commands) to run simultaneously. With no argument, `make` runs as many jobs simultaneously as possible. If there is more than one `-j' option, the last one is effective. See section Parallel Execution, for more information on how commands are run.

`-k'

`--keep-going'

Continue as much as possible after an error. While the target that failed, and those that depend on it, cannot be remade, the other dependencies of these targets can be processed all the same. See section Testing the Compilation of a Program.

`-l [load]'

`--load-average[=load]'

`--max-load[=load]'

Specifies that no new jobs (commands) should be started if there are other jobs running and the load average is at least load (a floating-point number). With no argument, removes a previous load limit. See section Parallel Execution.

`-n'

`--just-print'

`--dry-run'

`--recon'

Print the commands that would be executed, but do not execute them. See section Instead of Executing the Commands.

`-o file'

`--old-file=file'

`--assume-old=file'

Do not remake the file file even if it is older than its dependencies, and do not remake anything on account of changes in file. Essentially the file is treated as very old and its rules are ignored. See section Avoiding Recompilation of Some Files.

`-p'

`--print-data-base'

Print the data base (rules and variable values) that results from reading the makefiles; then execute as usual or as otherwise specified. This also prints the version information given by the `-v' switch (see below). To print the data base without trying to remake any files, use `make -p -f /dev/null'.

`-q'

`--question'

"Question mode". Do not run any commands, or print anything; just return an exit status that is zero if the specified targets are already up to date, one if any remaking is required, or two if an error is encountered. See section Instead of Executing the Commands.

`-r'

`--no-builtin-rules'

Eliminate use of the built-in implicit rules (see section Using Implicit Rules). You can still define your own by writing pattern rules (see section Defining and Redefining Pattern Rules). The `-r' option also clears out the default list of suffixes for suffix rules (see section Old-Fashioned Suffix Rules). But you can still define your own suffixes with a rule for `.SUFFIXES`, and then define your own suffix rules.

`-s'

`--silent'

`--quiet'

Silent operation; do not print the commands as they are executed. See section Command Echoing.

`-S'

`--no-keep-going'

`--stop'

Cancel the effect of the `-k' option. This is never necessary except in a recursive `make` where `-k' might be inherited from the top-level `make` via `MAKEFLAGS` (see section Recursive Use of `make`) or if you set `-k' in `MAKEFLAGS` in your environment.

`-t'

`--touch'

Touch files (mark them up to date without really changing them) instead of running their commands. This is used to pretend that the commands were done, in order to fool future invocations of `make`. See section Instead of Executing the Commands.

`-v'

`--version'

Print the version of the `make` program plus a copyright, a list of authors, and a notice that there is no warranty; then exit.

`-w'

`--print-directory'

Print a message containing the working directory both before and after executing the makefile. This may be useful for tracking down errors from complicated nests of recursive `make` commands. See section Recursive Use of `make`. (In practice, you rarely need to specify this option since `make' does it for you; see section The `--print-directory' Option.)

`--no-print-directory'

Disable printing of the working directory under `-w`. This option is useful when `-w` is turned on automatically, but you do not want to see the extra messages. See section The `--print-directory' Option.

`-W file'

`--what-if=file'

`--new-file=file'

`--assume-new=file'

Pretend that the target file has just been modified. When used with the `-n' flag, this shows you what would happen if you were to modify that file. Without `-n', it is almost the same as running a `touch` command on the given file before running `make`, except that the modification time is changed only in the imagination of `make`. See section Instead of Executing the Commands.

`--warn-undefined-variables'

Issue a warning message whenever `make` sees a reference to an undefined variable. This can be helpful when you are trying to debug makefiles which use variables in complex ways.

Go to the previous, next section.

Go to the previous, next section.

Using Implicit Rules

Certain standard ways of remaking target files are used very often. For example, one customary way to make an object file is from a C source file using the C compiler, `cc`.

Implicit rules tell `make` how to use customary techniques so that you do not have to specify them in detail when you want to use them. For example, there is an implicit rule for C compilation. File names determine which implicit rules are run. For example, C compilation typically takes a `.c' file and makes a `.o' file. So `make` applies the implicit rule for C compilation when it sees this combination of file name endings.

A chain of implicit rules can apply in sequence; for example, `make` will remake a `.o' file from a `.y' file by way of a `.c' file. See section Chains of Implicit Rules.

The built-in implicit rules use several variables in their commands so that, by changing the values of the variables, you can change the way the implicit rule works. For example, the variable `CFLAGS` controls the flags given to the C compiler by the implicit rule for C compilation. See section Variables Used by Implicit Rules.

You can define your own implicit rules by writing pattern rules. See section Defining and Redefining Pattern Rules.

Suffix rules are a more limited way to define implicit rules. Pattern rules are more general and clearer, but suffix rules are retained for compatibility. See section Old-Fashioned Suffix Rules.

Using Implicit Rules

To allow `make` to find a customary method for updating a target file, all you have to do is refrain from specifying commands yourself. Either write a rule with no command lines, or don't write a rule at all. Then `make` will figure out which implicit rule to use based on which kind of source file exists or can be made.

For example, suppose the makefile looks like this:

```
foo : foo.o bar.o
        cc -o foo foo.o bar.o $(CFLAGS) $(LDFLAGS)
```

Because you mention `foo.o' but do not give a rule for it, `make` will automatically look for an implicit rule that tells how to update it. This happens whether or not the file `foo.o' currently exists.

If an implicit rule is found, it can supply both commands and one or more dependencies (the source files). You would want to write a rule for `foo.o' with no command lines if you need to specify additional dependencies, such as header files, that the implicit rule cannot supply.

Each implicit rule has a target pattern and dependency patterns. There may be many implicit rules wi the same target pattern. For example, numerous rules make `.o' files: one, from a `.c' file with the C compiler; another, from a `.p' file with the Pascal compiler; and so on. The rule that actually applies is the one whose dependencies exist or can be made. So, if you have a file `foo.c', make will run the C compiler; otherwise, if you have a file `foo.p', make will run the Pascal compiler; and so on.

Of course, when you write the makefile, you know which implicit rule you want make to use, and you know it will choose that one because you know which possible dependency files are supposed to exist. See section Catalogue of Implicit Rules, for a catalogue of all the predefined implicit rules.

Above, we said an implicit rule applies if the required dependencies "exist or can be made". A file "can be made" if it is mentioned explicitly in the makefile as a target or a dependency, or if an implicit rule can be recursively found for how to make it. When an implicit dependency is the result of another implicit rule, we say that chaining is occurring. See section Chains of Implicit Rules.

In general, make searches for an implicit rule for each target, and for each double-colon rule, that has no commands. A file that is mentioned only as a dependency is considered a target whose rule specifies nothing, so implicit rule search happens for it. See section Implicit Rule Search Algorithm, for the details of how the search is done.

Note that explicit dependencies do not influence implicit rule search. For example, consider this explicit rule:

```
foo.o: foo.p
```

The dependency on `foo.p' does not necessarily mean that make will remake `foo.o' according to the implicit rule to make an object file, a `.o' file, from a Pascal source file, a `.p' file. For example, if `foo.c' also exists, the implicit rule to make an object file from a C source file is used instead, because it appears before the Pascal rule in the list of predefined implicit rules (see section Catalogue of Implicit Rules).

If you do not want an implicit rule to be used for a target that has no commands, you can give that target empty commands by writing a semicolon (see section Using Empty Commands).

Catalogue of Implicit Rules

Here is a catalogue of predefined implicit rules which are always available unless the makefile explicitly overrides or cancels them. See section Canceling Implicit Rules, for information on canceling or overriding an implicit rule. The `-r' or `--no-builtin-rules' option cancels all predefined rules.

Not all of these rules will always be defined, even when the `-r' option is not given. Many of the predefined implicit rules are implemented in make as suffix rules, so which ones will be defined depends on the suffix list (the list of dependencies of the special target .SUFFIXES). The default suffix list is: .out, .a, .ln, .o, .c, .cc, .C, .p, .f, .F, .r, .y, .l, .s, .S, .mod, .sym, .def, .h, .info, .dvi, .tex, .texinfo, .texi, .txinfo, .w, .ch .web, .sh, .elc, .el. All of the implicit rules described below whose dependencies have one of these suffixes are actually suffix rules. If you

modify the suffix list, the only predefined suffix rules in effect will be those named by one or two of the suffixes that are on the list you specify; rules whose suffixes fail to be on the list are disabled. See section Old-Fashioned Suffix Rules, for full details on suffix rules.

Compiling C programs

`n.o' is made automatically from `n.c' with a command of the form `$(CC) -c $(CPPFLAGS) $(CFLAGS)'.

Compiling C++ programs

`n.o' is made automatically from `n.cc' or `n.C' with a command of the form `$(CXX) -c $(CPPFLAGS) $(CXXFLAGS)'. We encourage you to use the suffix `.cc' for C++ source files instead of `.C'.

Compiling Pascal programs

`n.o' is made automatically from `n.p' with the command `$(PC) -c $(PFLAGS)'.

Compiling Fortran and Ratfor programs

`n.o' is made automatically from `n.r', `n.F' or `n.f' by running the Fortran compiler. The precise command used is as follows:

`.f'

`$(FC) -c $(FFLAGS)'.

`.F'

`$(FC) -c $(FFLAGS) $(CPPFLAGS)'.

`.r'

`$(FC) -c $(FFLAGS) $(RFLAGS)'.

- Preprocessing Fortran and Ratfor programs `n.f' is made automatically from `n.r' or `n.F'. This rule runs just the preprocessor to convert a Ratfor or preprocessable Fortran program into a strict Fortran program. The precise command used is as follows:

`.F'

`$(FC) -F $(CPPFLAGS) $(FFLAGS)'.

`.r'

`$(FC) -F $(FFLAGS) $(RFLAGS)'.

- Compiling Modula-2 programs `n.sym' is made from `n.def' with a command of the form `$(M2C) $(M2FLAGS) $(DEFFLAGS)'. `n.o' is made from `n.mod'; the form is: `$(M2C) $(M2FLAGS) $(MODFLAGS)'.

- Assembling and preprocessing assembler programs `n.o' is made automatically from `n.s' by running the assembler, as. The precise command is `$(AS) $(ASFLAGS)'.

`n.s' is made automatically from `n.S' by running the C preprocessor, cpp. The precise command is `$(CPP) $(CPPFLAGS)'.

- Linking a single object file `n' is made automatically from `n.o' by running the linker (usually called ld) via the C compiler. The precise command used is `$(CC) $(LDFLAGS) n.o $(LOADLIBES)'.

This rule does the right thing for a simple program with only one source file. It will also do the right thing if there are multiple object files (presumably coming from various other source files), one of which

has a name matching that of the executable file. Thus,

```
x: y.o z.o
```

when `x.c', `y.c' and `z.c' all exist will execute:

```
cc -c x.c -o x.o
cc -c y.c -o y.o
cc -c z.c -o z.o
cc x.o y.o z.o -o x
rm -f x.o
rm -f y.o
rm -f z.o
```

In more complicated cases, such as when there is no object file whose name derives from the executable file name, you must write an explicit command for linking.

Each kind of file automatically made into `.o' object files will be automatically linked by using the compiler (`$(CC)', `$(FC)' or `$(PC)'; the C compiler `$(CC)' is used to assemble `.s' files) without the `-c' option. This could be done by using the `.o' object files as intermediates, but it is faster to do the compiling and linking in one step, so that's how it's done.

- Yacc for C programs `n.c' is made automatically from `n.y' by running Yacc with the command `$(YACC) $(YFLAGS)'.
- Lex for C programs `n.c' is made automatically from `n.l' by by running Lex. The actual command is `$(LEX) $(LFLAGS)'.
- Lex for Ratfor programs `n.r' is made automatically from `n.l' by by running Lex. The actual command is `$(LEX) $(LFLAGS)'.

The convention of using the same suffix `.l' for all Lex files regardless of whether they produce C code or Ratfor code makes it impossible for `make` to determine automatically which of the two languages you are using in any particular case. If `make` is called upon to remake an object file from a `.l' file, it must guess which compiler to use. It will guess the C compiler, because that is more common. If you are using Ratfor, make sure `make` knows this by mentioning `n.r' in the makefile. Or, if you are using Ratfor exclusively, with no C files, remove `.c' from the list of implicit rule suffixes with:

```
.SUFFIXES:
.SUFFIXES: .o .r .f .l ...
```

- Making Lint Libraries from C, Yacc, or Lex programs `n.ln' is made from `n.c' by running `lint`. The precise command is `$(LINT) $(LINTFLAGS) $(CPPFLAGS) -i'. The same command is used on the C code produced from `n.y' or `n.l'.
- TeX and Web `n.dvi' is made from `n.tex' with the command `$(TEX)'. `n.tex' is made from `n.web' with `$(WEAVE)', or from `n.w' (and from `n.ch' if it exists or can be made) with `$(CWEAVE)'. `n.p' is made from `n.web' with `$(TANGLE)' and `n.c' is made from `n.w' (and from `n.ch' if it exists or can be made) with `$(CTANGLE)'.
- Texinfo and Info `n.dvi' is made from `n.texinfo', `n.texi', or `n.txinfo', with the

command `$(TEXI2DVI) $(TEXI2DVI_FLAGS)'. `n.info' is made from `n.texinfo', `n.texi', or `n.txinfo', with the command `$(MAKEINFO) $(MAKEINFO_FLAGS)'.

- RCS Any file `n' is extracted if necessary from an RCS file named either `n,v' or `RCS/n,v'. The precise command used is `$(CO) $(COFLAGS)'. `n' will not be extracted from RCS if it already exists, even if the RCS file is newer. The rules for RCS are terminal (see section Match-Anything Pattern Rules), so RCS files cannot be generated from another source; they must actually exist.

- SCCS Any file `n' is extracted if necessary from an SCCS file named either `s.n' or `SCCS/s.n'. The precise command used is `$(GET) $(GFLAGS)'. The rules for SCCS are terminal (see section Match-Anything Pattern Rules), so SCCS files cannot be generated from another source; they must actually exist.

For the benefit of SCCS, a file `n' is copied from `n.sh' and made executable (by everyone). This is for shell scripts that are checked into SCCS. Since RCS preserves the execution permission of a file, you do not need to use this feature with RCS.

We recommend that you avoid using of SCCS. RCS is widely held to be superior, and is also free. By choosing free software in place of comparable (or inferior) proprietary software, you support the free software movement.

Usually, you want to change only the variables listed in the table above, which are documented in the following section.

However, the commands in built-in implicit rules actually use variables such as COMPILE.c, LINK.p, and PREPROCESS.S, whose values contain the commands listed above.

make follows the convention that the rule to compile a `.x' source file uses the variable COMPILE.x. Similarly, the rule to produce an executable from a `.x' file uses LINK.x; and the rule to preprocess a `.x' file uses PREPROCESS.x.

Every rule that produces an object file uses the variable OUTPUT_OPTION. make defines this variable either to contain `-o $@', or to be empty, depending on a compile-time option. You need the `-o' option to ensure that the output goes into the right file when the source file is in a different directory, as when using VPATH (see section Searching Directories for Dependencies). However, compilers on some systems do not accept a `-o' switch for object files. If you use such a system, and use VPATH, some compilations will put their output in the wrong place. A possible workaround for this problem is to give OUTPUT_OPTION the value `; mv $*.o $@'.

Variables Used by Implicit Rules

The commands in built-in implicit rules make liberal use of certain predefined variables. You can alter these variables in the makefile, with arguments to make, or in the environment to alter how the implicit rules work without redefining the rules themselves.

For example, the command used to compile a C source file actually says `$(CC) -c $(CFLAGS) $(CPPFLAGS)'. The default values of the variables used are `cc' and nothing, resulting in the command `cc -c'. By redefining `CC' to `ncc', you could cause `ncc' to be used for all C compilations performed by

the implicit rule. By redefining `CFLAGS' to be `-g', you could pass the `-g' option to each compilati
All implicit rules that do C compilation use `$(CC)' to get the program name for the compiler and *all* include `$(CFLAGS)' among the arguments given to the compiler.

The variables used in implicit rules fall into two classes: those that are names of programs (like `CC`) and those that contain arguments for the programs (like `CFLAGS`). (The "name of a program" may also contain some command arguments, but it must start with an actual executable program name.) If a variable value contains more than one argument, separate them with spaces.

Here is a table of variables used as names of programs in built-in rules:

`AR`
: Archive-maintaining program; default `ar'.

`AS`
: Program for doing assembly; default `as'.

`CC`
: Program for compiling C programs; default `cc'.

`CXX`
: Program for compiling C++ programs; default `g++'.

`CO`
: Program for extracting a file from RCS; default `co'.

`CPP`
: Program for running the C preprocessor, with results to standard output; default `$(CC) -E'.

`FC`
: Program for compiling or preprocessing Fortran and Ratfor programs; default `f77'.

`GET`
: Program for extracting a file from SCCS; default `get'.

`LEX`
: Program to use to turn Lex grammars into C programs or Ratfor programs; default `lex'.

`PC`
: Program for compiling Pascal programs; default `pc'.

`YACC`
: Program to use to turn Yacc grammars into C programs; default `yacc'.

`YACCR`
: Program to use to turn Yacc grammars into Ratfor programs; default `yacc -r'.

`MAKEINFO`
: Program to convert a Texinfo source file into an Info file; default `makeinfo'.

`TEX`
: Program to make TeX DVI files from TeX source; default `tex'.

`TEXI2DVI`

Program to make TeX DVI files from Texinfo source; default `texi2dvi'.

`WEAVE`

Program to translate Web into TeX; default `weave'.

`CWEAVE`

Program to translate C Web into TeX; default `cweave'.

`TANGLE`

Program to translate Web into Pascal; default `tangle'.

`CTANGLE`

Program to translate C Web into C; default `ctangle'.

`RM`

Command to remove a file; default `rm -f'.

Here is a table of variables whose values are additional arguments for the programs above. The default values for all of these is the empty string, unless otherwise noted.

`ARFLAGS`

Flags to give the archive-maintaining program; default `rv'.

`ASFLAGS`

Extra flags to give to the assembler (when explicitly invoked on a `.s' or `.S' file).

`CFLAGS`

Extra flags to give to the C compiler.

`CXXFLAGS`

Extra flags to give to the C++ compiler.

`COFLAGS`

Extra flags to give to the RCS `co` program.

`CPPFLAGS`

Extra flags to give to the C preprocessor and programs that use it (the C and Fortran compilers).

`FFLAGS`

Extra flags to give to the Fortran compiler.

`GFLAGS`

Extra flags to give to the SCCS `get` program.

`LDFLAGS`

Extra flags to give to compilers when they are supposed to invoke the linker, `ld'.

`LFLAGS`

Extra flags to give to Lex.

`PFLAGS`

Extra flags to give to the Pascal compiler.

`RFLAGS`

Extra flags to give to the Fortran compiler for Ratfor programs.

YFLAGS

Extra flags to give to Yacc.

Chains of Implicit Rules

Sometimes a file can be made by a sequence of implicit rules. For example, a file `n.o' could be made from `n.y' by running first Yacc and then cc. Such a sequence is called a chain.

If the file `n.c' exists, or is mentioned in the makefile, no special searching is required: make finds that the object file can be made by C compilation from `n.c'; later on, when considering how to make `n.c', the rule for running Yacc is used. Ultimately both `n.c' and `n.o' are updated.

However, even if `n.c' does not exist and is not mentioned, make knows how to envision it as the missing link between `n.o' and `n.y'! In this case, `n.c' is called an intermediate file. Once make has decided to use the intermediate file, it is entered in the data base as if it had been mentioned in the makefile, along with the implicit rule that says how to create it.

Intermediate files are remade using their rules just like all other files. The difference is that the intermediate file is deleted when make is finished. Therefore, the intermediate file which did not exist before make also does not exist after make. The deletion is reported to you by printing a `rm -f' command that shows what make is doing. (You can list the target pattern of an implicit rule (such as `%.o') as a dependency of the special target .PRECIOUS to preserve intermediate files made by implicit rules whose target patterns match that file's name; see section Interrupting or Killing make.)

A chain can involve more than two implicit rules. For example, it is possible to make a file `foo' from `RCS/foo.y,v' by running RCS, Yacc and cc. Then both `foo.y' and `foo.c' are intermediate files that are deleted at the end.

No single implicit rule can appear more than once in a chain. This means that make will not even consider such a ridiculous thing as making `foo' from `foo.o.o' by running the linker twice. This constraint has the added benefit of preventing any infinite loop in the search for an implicit rule chain.

There are some special implicit rules to optimize certain cases that would otherwise be handled by rule chains. For example, making `foo' from `foo.c' could be handled by compiling and linking with separate chained rules, using `foo.o' as an intermediate file. But what actually happens is that a special rule for this case does the compilation and linking with a single cc command. The optimized rule is used in preference to the step-by-step chain because it comes earlier in the ordering of rules.

Defining and Redefining Pattern Rules

You define an implicit rule by writing a pattern rule. A pattern rule looks like an ordinary rule, except that its target contains the character `%' (exactly one of them). The target is considered a pattern for matching file names; the `%' can match any nonempty substring, while other characters match only themselves. The dependencies likewise use `%' to show how their names relate to the target name.

Thus, a pattern rule `%.o : %.c' says how to make any file `stem.o' from another file `stem.c'.

Note that expansion using `%' in pattern rules occurs **after** any variable or function expansions, which take place when the makefile is read. See section How to Use Variables, and section Functions for Transforming Text.

Introduction to Pattern Rules

A pattern rule contains the character `%' (exactly one of them) in the target; otherwise, it looks exactly like an ordinary rule. The target is a pattern for matching file names; the `%' matches any nonempty substring, while other characters match only themselves.

For example, `%.c' as a pattern matches any file name that ends in `.c'. `s.%.c' as a pattern matches any file name that starts with `s.', ends in `.c' and is at least five characters long. (There must be at least one character to match the `%'.) The substring that the `%' matches is called the stem.

`%' in a dependency of a pattern rule stands for the same stem that was matched by the `%' in the target. In order for the pattern rule to apply, its target pattern must match the file name under consideration, and its dependency patterns must name files that exist or can be made. These files become dependencies of the target.

Thus, a rule of the form

```
%.o : %.c ; command...
```

specifies how to make a file `n.o', with another file `n.c' as its dependency, provided that `n.c' exists or can be made.

There may also be dependencies that do not use `%'; such a dependency attaches to every file made by this pattern rule. These unvarying dependencies are useful occasionally.

A pattern rule need not have any dependencies that contain `%', or in fact any dependencies at all. Such a rule is effectively a general wildcard. It provides a way to make any file that matches the target pattern. See section Defining Last-Resort Default Rules.

Pattern rules may have more than one target. Unlike normal rules, this does not act as many different rules with the same dependencies and commands. If a pattern rule has multiple targets, `make` knows that the rule's commands are responsible for making all of the targets. The commands are executed only once to make all the targets. When searching for a pattern rule to match a target, the target patterns of a rule other than the one that matches the target in need of a rule are incidental: `make` worries only about giving commands and dependencies to the file presently in question. However, when this file's commands are run, the other targets are marked as having been updated themselves.

The order in which pattern rules appear in the makefile is important since this is the order in which they are considered. Of equally applicable rules, only the first one found is used. The rules you write take precedence over those that are built in. Note however, that a rule whose dependencies actually exist or are mentioned always takes priority over a rule with dependencies that must be made by chaining other implicit rules.

Pattern Rule Examples

Here are some examples of pattern rules actually predefined in `make`. First, the rule that compiles `.c' files into `.o' files:

```
%.o : %.c
        $(CC) -c $(CFLAGS) $(CPPFLAGS) $< -o $@
```

defines a rule that can make any file `x.o' from `x.c'. The command uses the automatic variables `$@' and `$<' to substitute the names of the target file and the source file in each case where the rule applies (see section Automatic Variables).

Here is a second built-in rule:

```
% :: RCS/%,v
        $(CO) $(COFLAGS) $<
```

defines a rule that can make any file `x' whatsoever from a corresponding file `x,v' in the subdirectory `RCS'. Since the target is `%', this rule will apply to any file whatever, provided the appropriate dependency file exists. The double colon makes the rule terminal, which means that its dependency may not be an intermediate file (see section Match-Anything Pattern Rules).

This pattern rule has two targets:

```
%.tab.c %.tab.h: %.y
        bison -d $<
```

This tells `make` that the command `bison -d x.y' will make both `x.tab.c' and `x.tab.h'. If the file `foo' depends on the files `parse.tab.o' and `scan.o' and the file `scan.o' depends on the file `parse.tab.h', when `parse.y' is changed, the command `bison -d parse.y' will be executed only once, and the dependencies of both `parse.tab.o' and `scan.o' will be satisfied. (Presumably the file `parse.tab.o' will be recompiled from `parse.tab.c' and the file `scan.o' from `scan.c', while `foo' is linked from `parse.tab.o', `scan.o', and its other dependencies, and it will execute happily ever after.)

Automatic Variables

Suppose you are writing a pattern rule to compile a `.c' file into a `.o' file: how do you write the `cc' command so that it operates on the right source file name? You cannot write the name in the command, because the name is different each time the implicit rule is applied.

What you do is use a special feature of `make`, the automatic variables. These variables have values computed afresh for each rule that is executed, based on the target and dependencies of the rule. In this example, you would use `$@' for the object file name and `$<' for the source file name.

Here is a table of automatic variables:

$@

The file name of the target of the rule. If the target is an archive member, then `$@' is the name of the archive file. In a pattern rule that has multiple targets (see section Introduction to Pattern Rules), `$@' is the name of whichever target caused the rule's commands to be run.

$%

The target member name, when the target is an archive member. See section Using `make` to Update Archive Files. For example, if the target is `` `foo.a(bar.o)' `` then `$%' is `` `bar.o' `` and `$@' is `` `foo.a' ``. `$%' is empty when the target is not an archive member.

$<

The name of the first dependency. If the target got its commands from an implicit rule, this will be the first dependency added by the implicit rule (see section Using Implicit Rules).

$?

The names of all the dependencies that are newer than the target, with spaces between them. For dependencies which are archive members, only the member named is used (see section Using `make` to Update Archive Files).

$^

The names of all the dependencies, with spaces between them. For dependencies which are archive members, only the member named is used (see section Using `make` to Update Archive Files). A target has only one dependency on each other file it depends on, no matter how many times each file is listed as a dependency. So if you list a dependency more than once for a target, the value of $^ contains just one copy of the name.

$+

This is like `$^', but dependencies listed more than once are duplicated in the order they were listed in the makefile. This is primarily useful for use in linking commands where it is meaningful to repeat library file names in a particular order.

$*

The stem with which an implicit rule matches (see section How Patterns Match). If the target is `` `dir/a.foo.b' `` and the target pattern is `` `a.%.b' `` then the stem is `` `dir/foo' ``. The stem is useful for constructing names of related files.

In a static pattern rule, the stem is part of the file name that matched the `%' in the target pattern.

In an explicit rule, there is no stem; so `$*' cannot be determined in that way. Instead, if the target name ends with a recognized suffix (see section Old-Fashioned Suffix Rules), `$*' is set to the target name minus the suffix. For example, if the target name is `foo.c', then `$*' is set to `foo', since `.c' is a suffix. GNU `make` does this bizarre thing only for compatibility with other implementations of `make`. You should generally avoid using `$*' except in implicit rules or static pattern rules.

If the target name in an explicit rule does not end with a recognized suffix, `$*' is set to the empty string for that rule.

`$?' is useful even in explicit rules when you wish to operate on only the dependencies that have changed. For example, suppose that an archive named `lib' is supposed to contain copies of several object files. This rule copies just the changed object files into the archive:

```
lib: foo.o bar.o lose.o win.o
        ar r lib $?
```

Of the variables listed above, four have values that are single file names, and two have values that are lists of file names. These six have variants that get just the file's directory name or just the file name within the directory. The variant variables' names are formed by appending `D' or `F', respectively. These variants are semi-obsolete in GNU `make` since the functions `dir` and `notdir` can be used to get a similar effect (see section Functions for File Names). Note, however, that the `F' variants all omit the trailing slash which always appears in the output of the `dir` function. Here is a table of the variants:

`$(@D)'

The directory part of the file name of the target, with the trailing slash removed. If the value of `$@' is `dir/foo.o' then `$(@D)' is `dir'. This value is `.' if `$@' does not contain a slash.

`$(@F)'

The file-within-directory part of the file name of the target. If the value of `$@' is `dir/foo.o' then `$(@F)' is `foo.o'. `$(@F)' is equivalent to `$(notdir $@)'.

`$(*D)'

`$(*F)'

The directory part and the file-within-directory part of the stem; `dir' and `foo' in this example.

`$(%D)'

`$(%F)'

The directory part and the file-within-directory part of the target archive member name. This makes sense only for archive member targets of the form `archive(member)' and is useful only when member may contain a directory name. (See section Archive Members as Targets.)

`$(<D)'

`$(<F)'

The directory part and the file-within-directory part of the first dependency.

`$(^D)'

`$(^F)'

Lists of the directory parts and the file-within-directory parts of all dependencies.

`$(?D)'

`$(?F)'

Lists of the directory parts and the file-within-directory parts of all dependencies that are newer than the target.

Note that we use a special stylistic convention when we talk about these automatic variables; we write

"the value of `$<'", rather than "the variable `<'" as we would write for ordinary variables such as `objects` and `CFLAGS`. We think this convention looks more natural in this special case. Please do assume it has a deep significance; `$<' refers to the variable named `<` just as `$(CFLAGS)' refers to the variable named `CFLAGS`. You could just as well use `$(<)' in place of `$<'.

How Patterns Match

A target pattern is composed of a `%' between a prefix and a suffix, either or both of which may be empty. The pattern matches a file name only if the file name starts with the prefix and ends with the suffix, without overlap. The text between the prefix and the suffix is called the stem. Thus, when the pattern `%.o' matches the file name `test.o', the stem is `test'. The pattern rule dependencies are turned into actual file names by substituting the stem for the character `%'. Thus, if in the same example one of the dependencies is written as `%.c', it expands to `test.c'.

When the target pattern does not contain a slash (and it usually does not), directory names in the file names are removed from the file name before it is compared with the target prefix and suffix. After the comparison of the file name to the target pattern, the directory names, along with the slash that ends them, are added on to the dependency file names generated from the pattern rule's dependency patterns and the file name. The directories are ignored only for the purpose of finding an implicit rule to use, not in the application of that rule. Thus, `e%t' matches the file name `src/eat', with `src/a' as the stem. When dependencies are turned into file names, the directories from the stem are added at the front, while the rest of the stem is substituted for the `%'. The stem `src/a' with a dependency pattern `c%r' gives the file name `src/car'.

Match-Anything Pattern Rules

When a pattern rule's target is just `%', it matches any file name whatever. We call these rules match-anything rules. They are very useful, but it can take a lot of time for `make` to think about them, because it must consider every such rule for each file name listed either as a target or as a dependency.

Suppose the makefile mentions `foo.c'. For this target, `make` would have to consider making it by linking an object file `foo.c.o', or by C compilation-and-linking in one step from `foo.c.c', or by Pascal compilation-and-linking from `foo.c.p', and many other possibilities.

We know these possibilities are ridiculous since `foo.c' is a C source file, not an executable. If `make` did consider these possibilities, it would ultimately reject them, because files such as `foo.c.o' and `foo.c.p' would not exist. But these possibilities are so numerous that `make` would run very slowly if it had to consider them.

To gain speed, we have put various constraints on the way `make` considers match-anything rules. There are two different constraints that can be applied, and each time you define a match-anything rule you must choose one or the other for that rule.

One choice is to mark the match-anything rule as terminal by defining it with a double colon. When a rule is terminal, it does not apply unless its dependencies actually exist. Dependencies that could be made with other implicit rules are not good enough. In other words, no further chaining is allowed beyond a terminal rule.

For example, the built-in implicit rules for extracting sources from RCS and SCCS files are terminal; as a result, if the file `foo.c,v' does not exist, make will not even consider trying to make it as an intermediate file from `foo.c,v.o' or from `RCS/SCCS/s.foo.c,v'. RCS and SCCS files are generally ultimate source files, which should not be remade from any other files; therefore, make can save time by not looking for ways to remake them.

If you do not mark the match-anything rule as terminal, then it is nonterminal. A nonterminal match-anything rule cannot apply to a file name that indicates a specific type of data. A file name indicates a specific type of data if some non-match-anything implicit rule target matches it.

For example, the file name `foo.c' matches the target for the pattern rule `%.c : %.y' (the rule to run Yacc). Regardless of whether this rule is actually applicable (which happens only if there is a file `foo.y'), the fact that its target matches is enough to prevent consideration of any nonterminal match-anything rules for the file `foo.c'. Thus, make will not even consider trying to make `foo.c' as an executable file from `foo.c.o', `foo.c.c', `foo.c.p', etc.

The motivation for this constraint is that nonterminal match-anything rules are used for making files containing specific types of data (such as executable files) and a file name with a recognized suffix indicates some other specific type of data (such as a C source file).

Special built-in dummy pattern rules are provided solely to recognize certain file names so that nonterminal match-anything rules will not be considered. These dummy rules have no dependencies and no commands, and they are ignored for all other purposes. For example, the built-in implicit rule

```
%.p :
```

exists to make sure that Pascal source files such as `foo.p' match a specific target pattern and thereby prevent time from being wasted looking for `foo.p.o' or `foo.p.c'.

Dummy pattern rules such as the one for `%.p' are made for every suffix listed as valid for use in suffix rules (see section Old-Fashioned Suffix Rules).

Canceling Implicit Rules

You can override a built-in implicit rule (or one you have defined yourself) by defining a new pattern rule with the same target and dependencies, but different commands. When the new rule is defined, the built-in one is replaced. The new rule's position in the sequence of implicit rules is determined by where you write the new rule.

You can cancel a built-in implicit rule by defining a pattern rule with the same target and dependencies, but no commands. For example, the following would cancel the rule that runs the assembler:

```
%.o : %.s
```

Defining Last-Resort Default Rules

You can define a last-resort implicit rule by writing a terminal match-anything pattern rule with no dependencies (see section Match-Anything Pattern Rules). This is just like any other pattern rule; the only thing special about it is that it will match any target. So such a rule's commands are used for all targets and dependencies that have no commands of their own and for which no other implicit rule applies.

For example, when testing a makefile, you might not care if the source files contain real data, only that they exist. Then you might do this:

```
%::
        touch $@
```

to cause all the source files needed (as dependencies) to be created automatically.

You can instead define commands to be used for targets for which there are no rules at all, even ones which don't specify commands. You do this by writing a rule for the target `.DEFAULT`. Such a rule's commands are used for all dependencies which do not appear as targets in any explicit rule, and for which no implicit rule applies. Naturally, there is no `.DEFAULT` rule unless you write one.

If you use `.DEFAULT` with no commands or dependencies:

```
.DEFAULT:
```

the commands previously stored for `.DEFAULT` are cleared. Then `make` acts as if you had never defined `.DEFAULT` at all.

If you do not want a target to get the commands from a match-anything pattern rule or `.DEFAULT`, but you also do not want any commands to be run for the target, you can give it empty commands (see section Using Empty Commands).

You can use a last-resort rule to override part of another makefile. See section Overriding Part of Another Makefile.

Old-Fashioned Suffix Rules

Suffix rules are the old-fashioned way of defining implicit rules for `make`. Suffix rules are obsolete because pattern rules are more general and clearer. They are supported in GNU `make` for compatibility with old makefiles. They come in two kinds: double-suffix and single-suffix.

A double-suffix rule is defined by a pair of suffixes: the target suffix and the source suffix. It matches any file whose name ends with the target suffix. The corresponding implicit dependency is made by replacing the target suffix with the source suffix in the file name. A two-suffix rule whose target and source suffixes are `.o' and `.c' is equivalent to the pattern rule `%.o : %.c'.

A single-suffix rule is defined by a single suffix, which is the source suffix. It matches any file name, and the corresponding implicit dependency name is made by appending the source suffix. A single-suffix rule whose source suffix is `.c' is equivalent to the pattern rule `% : %.c'.

Suffix rule definitions are recognized by comparing each rule's target against a defined list of known suffixes. When `make` sees a rule whose target is a known suffix, this rule is considered a single-suffix rule. When `make` sees a rule whose target is two known suffixes concatenated, this rule is taken as a double-suffix rule.

For example, `.c' and `.o' are both on the default list of known suffixes. Therefore, if you define a rule whose target is `.c.o', `make` takes it to be a double-suffix rule with source suffix `.c' and target suffix `.o'. Here is the old-fashioned way to define the rule for compiling a C source file:

```
.c.o:
        $(CC) -c $(CFLAGS) $(CPPFLAGS) -o $@ $<
```

Suffix rules cannot have any dependencies of their own. If they have any, they are treated as normal files with funny names, not as suffix rules. Thus, the rule:

```
.c.o: foo.h
        $(CC) -c $(CFLAGS) $(CPPFLAGS) -o $@ $<
```

tells how to make the file `.c.o' from the dependency file `foo.h', and is not at all like the pattern rule:

```
%.o: %.c foo.h
        $(CC) -c $(CFLAGS) $(CPPFLAGS) -o $@ $<
```

which tells how to make `.o' files from `.c' files, and makes all `.o' files using this pattern rule also depend on `foo.h'.

Suffix rules with no commands are also meaningless. They do not remove previous rules as do pattern rules with no commands (see section Canceling Implicit Rules). They simply enter the suffix or pair of suffixes concatenated as a target in the data base.

The known suffixes are simply the names of the dependencies of the special target `.SUFFIXES`. You can add your own suffixes by writing a rule for `.SUFFIXES` that adds more dependencies, as in:

```
.SUFFIXES: .hack .win
```

which adds `.hack' and `.win' to the end of the list of suffixes.

If you wish to eliminate the default known suffixes instead of just adding to them, write a rule for `.SUFFIXES` with no dependencies. By special dispensation, this eliminates all existing dependencies of `.SUFFIXES`. You can then write another rule to add the suffixes you want. For example,

```
.SUFFIXES:            # Delete the default suffixes
```

```
.SUFFIXES: .c .o .h   # Define our suffix list
```

The `-r' or `--no-builtin-rules' flag causes the default list of suffixes to be empty.

The variable `SUFFIXES` is defined to the default list of suffixes before `make` reads any makefiles. You can change the list of suffixes with a rule for the special target `.SUFFIXES`, but that does not alter this variable.

Implicit Rule Search Algorithm

Here is the procedure `make` uses for searching for an implicit rule for a target t. This procedure is followed for each double-colon rule with no commands, for each target of ordinary rules none of which have commands, and for each dependency that is not the target of any rule. It is also followed recursively for dependencies that come from implicit rules, in the search for a chain of rules.

Suffix rules are not mentioned in this algorithm because suffix rules are converted to equivalent pattern rules once the makefiles have been read in.

For an archive member target of the form `archive(member)', the following algorithm is run twice, first using the entire target name t, and second using `(member)' as the target t if the first run found no rule.

1. Split t into a directory part, called d, and the rest, called n. For example, if t is `src/foo.o', then d is `src/' and n is `foo.o'.
2. Make a list of all the pattern rules one of whose targets matches t or n. If the target pattern contains a slash, it is matched against t; otherwise, against n.
3. If any rule in that list is *not* a match-anything rule, then remove all nonterminal match-anything rules from the list.
4. Remove from the list all rules with no commands.
5. For each pattern rule in the list:
    1. Find the stem s, which is the nonempty part of t or n matched by the `%' in the target pattern.
    2. Compute the dependency names by substituting s for `%'; if the target pattern does not contain a slash, append d to the front of each dependency name.
    3. Test whether all the dependencies exist or ought to exist. (If a file name is mentioned in the makefile as a target or as an explicit dependency, then we say it ought to exist.)

       If all dependencies exist or ought to exist, or there are no dependencies, then this rule applies.
6. If no pattern rule has been found so far, try harder. For each pattern rule in the list:
    1. If the rule is terminal, ignore it and go on to the next rule.
    2. Compute the dependency names as before.
    3. Test whether all the dependencies exist or ought to exist.
    4. For each dependency that does not exist, follow this algorithm recursively to see if the dependency can be made by an implicit rule.

5. If all dependencies exist, ought to exist, or can be made by implicit rules, then this rule applies.

7. If no implicit rule applies, the rule for `.DEFAULT`, if any, applies. In that case, give t the same commands that `.DEFAULT` has. Otherwise, there are no commands for t.

Once a rule that applies has been found, for each target pattern of the rule other than the one that matched t or n, the `%' in the pattern is replaced with s and the resultant file name is stored until the commands to remake the target file t are executed. After these commands are executed, each of these stored file names are entered into the data base and marked as having been updated and having the same update status as the file t.

When the commands of a pattern rule are executed for t, the automatic variables are set corresponding to the target and dependencies. See section Automatic Variables.

Using make to Update Archive Files

Archive files are files containing named subfiles called members; they are maintained with the program `ar` and their main use is as subroutine libraries for linking.

Archive Members as Targets

An individual member of an archive file can be used as a target or dependency in `make`. You specify the member named member in archive file archive as follows:

```
archive(member)
```

This construct is available only in targets and dependencies, not in commands! Most programs that you might use in commands do not support this syntax and cannot act directly on archive members. Only `ar` and other programs specifically designed to operate on archives can do so. Therefore, valid commands to update an archive member target probably must use `ar`. For example, this rule says to create a member `` `hack.o' `` in archive `` `foolib' `` by copying the file `` `hack.o' ``:

```
foolib(hack.o) : hack.o
        ar cr foolib hack.o
```

In fact, nearly all archive member targets are updated in just this way and there is an implicit rule to do it for you. **Note:** The `c' flag to `ar` is required if the archive file does not already exist.

To specify several members in the same archive, you can write all the member names together between the parentheses. For example:

```
foolib(hack.o kludge.o)
```

is equivalent to:

```
foolib(hack.o) foolib(kludge.o)
```

You can also use shell-style wildcards in an archive member reference. See section Using Wildcard Characters in File Names. For example, `foolib(*.o)' expands to all existing members of the `` `foolib' `` archive whose names end in `.o'; perhaps `foolib(hack.o) foolib(kludge.o)'.

Implicit Rule for Archive Member Targets

Recall that a target that looks like `a(m)' stands for the member named m in the archive file a.

When make looks for an implicit rule for such a target, as a special feature it considers implicit rules that match `(m)', as well as those that match the actual target `a(m)'.

This causes one special rule whose target is `(%)' to match. This rule updates the target `a(m)' by copying the file m into the archive. For example, it will update the archive member target `foo.a(bar.o)' by copying the *file* `bar.o' into the archive `foo.a' as a *member* named `bar.o'.

When this rule is chained with others, the result is very powerful. Thus, `make "foo.a(bar.o)"' (the quotes are needed to protect the `(' and `)' from being interpreted specially by the shell) in the presence of a file `bar.c' is enough to cause the following commands to be run, even without a makefile:

```
cc -c bar.c -o bar.o
ar r foo.a bar.o
rm -f bar.o
```

Here make has envisioned the file `bar.o' as an intermediate file. See section Chains of Implicit Rules.

Implicit rules such as this one are written using the automatic variable `$%'. See section Automatic Variables.

An archive member name in an archive cannot contain a directory name, but it may be useful in a makefile to pretend that it does. If you write an archive member target `foo.a(dir/file.o)', make will perform automatic updating with this command:

```
ar r foo.a dir/file.o
```

which has the effect of copying the file `dir/file.o' into a member named `file.o'. In connection with such usage, the automatic variables %D and %F may be useful.

Updating Archive Symbol Directories

An archive file that is used as a library usually contains a special member named `__.SYMDEF' that contains a directory of the external symbol names defined by all the other members. After you update any other members, you need to update `__.SYMDEF' so that it will summarize the other members properly. This is done by running the ranlib program:

```
ranlib archivefile
```

Normally you would put this command in the rule for the archive file, and make all the members of the archive file dependencies of that rule. For example,

```
libfoo.a: libfoo.a(x.o) libfoo.a(y.o) ...
        ranlib libfoo.a
```

The effect of this is to update archive members `x.o', `y.o', etc., and then update the symbol directory member `__.SYMDEF' by running `ranlib`. The rules for updating the members are not shown here; most likely you can omit them and use the implicit rule which copies files into the archive, as described in the preceding section.

This is not necessary when using the GNU `ar` program, which updates the `__.SYMDEF' member automatically.

Dangers When Using Archives

It is important to be careful when using parallel execution (the `-j` switch; see section Parallel Execution) and archives. If multiple `ar` commands run at the same time on the same archive file, they will not know about each other and can corrupt the file.

Possibly a future version of `make` will provide a mechanism to circumvent this problem by serializing all commands that operate on the same archive file. But for the time being, you must either write your makefiles to avoid this problem in some other way, or not use `-j`.

Suffix Rules for Archive Files

You can write a special kind of suffix rule for dealing with archive files. See section Old-Fashioned Suffix Rules, for a full explanation of suffix rules. Archive suffix rules are obsolete in GNU `make`, because pattern rules for archives are a more general mechanism (see section Implicit Rule for Archive Member Targets). But they are retained for compatibility with other `make`s.

To write a suffix rule for archives, you simply write a suffix rule using the target suffix `.a' (the usual suffix for archive files). For example, here is the old-fashioned suffix rule to update a library archive from C source files:

```
.c.a:
        $(CC) $(CFLAGS) $(CPPFLAGS) -c $< -o $*.o
        $(AR) r $@ $*.o
        $(RM) $*.o
```

This works just as if you had written the pattern rule:

```
(%.o): %.c
        $(CC) $(CFLAGS) $(CPPFLAGS) -c $< -o $*.o
        $(AR) r $@ $*.o
        $(RM) $*.o
```

In fact, this is just what `make` does when it sees a suffix rule with `.a' as the target suffix. Any double-suffix rule `.x.a' is converted to a pattern rule with the target pattern `(%.o)' and a dependency pattern of `%.x'.

Since you might want to use `.a' as the suffix for some other kind of file, `make` also converts archive suffix rules to pattern rules in the normal way (see section Old-Fashioned Suffix Rules). Thus a double-suffix rule `.x.a' produces two pattern rules: `(%.o): %.x' and `%.a: %.x'.

Go to the previous, next section.

Go to the previous, next section.

Features of GNU `make`

Here is a summary of the features of GNU `make`, for comparison with and credit to other versions of `make`. We consider the features of `make` in 4.2 BSD systems as a baseline. If you are concerned with writing portable makefiles, you should use only the features of `make` *not* listed here or in section Incompatibilities and Missing Features.

Many features come from the version of `make` in System V.

- The `VPATH` variable and its special meaning. See section Searching Directories for Dependencies. This feature exists in System V `make`, but is undocumented. It is documented in 4.3 BSD `make` (which says it mimics System V's `VPATH` feature).
- Included makefiles. See section Including Other Makefiles. Allowing multiple files to be included with a single directive is a GNU extension.
- Variables are read from and communicated via the environment. See section Variables from the Environment.
- Options passed through the variable `MAKEFLAGS` to recursive invocations of `make`. See section Communicating Options to a Sub-`make`.
- The automatic variable `$%` is set to the member name in an archive reference. See section Automatic Variables.
- The automatic variables `$@`, `$*`, `$<`, `$%`, and `$?` have corresponding forms like `$(@F)` and `$(@D)`. We have generalized this to `$^` as an obvious extension. See section Automatic Variables.
- Substitution variable references. See section Basics of Variable References.
- The command-line options `-b' and `-m', accepted and ignored. In System V `make`, these options actually do something.
- Execution of recursive commands to run `make` via the variable `MAKE` even if `-n', `-q' or `-t' is specified. See section Recursive Use of `make`.
- Support for suffix `.a' in suffix rules. See section Suffix Rules for Archive Files. This feature is obsolete in GNU `make`, because the general feature of rule chaining (see section Chains of Implicit Rules) allows one pattern rule for installing members in an archive (see section Implicit Rule for Archive Member Targets) to be sufficient.
- The arrangement of lines and backslash-newline combinations in commands is retained when the commands are printed, so they appear as they do in the makefile, except for the stripping of initial whitespace.

The following features were inspired by various other versions of `make`. In some cases it is unclear exactly which versions inspired which others.

- Pattern rules using `%'. This has been implemented in several versions of `make`. We're not sure who invented it first, but it's been spread around a bit. See section Defining and Redefining Pattern

Rules.

- Rule chaining and implicit intermediate files. This was implemented by Stu Feldman in his version of `make` for AT&T Eighth Edition Research Unix, and later by Andrew Hume of AT&T Bell Labs in his `mk` program (where he terms it "transitive closure"). We do not really know if we got this from either of them or thought it up ourselves at the same time. See section Chains of Implicit Rules.
- The automatic variable `$^` containing a list of all dependencies of the current target. We did not invent this, but we have no idea who did. See section Automatic Variables. The automatic variable `$+` is a simple extension of `$^`.
- The "what if" flag (`-W' in GNU `make`) was (as far as we know) invented by Andrew Hume in `mk`. See section Instead of Executing the Commands.
- The concept of doing several things at once (parallelism) exists in many incarnations of `make` and similar programs, though not in the System V or BSD implementations. See section Command Execution.
- Modified variable references using pattern substitution come from SunOS 4. See section Basics of Variable References. This functionality was provided in GNU `make` by the `patsubst` function before the alternate syntax was implemented for compatibility with SunOS 4. It is not altogether clear who inspired whom, since GNU `make` had `patsubst` before SunOS 4 was released.
- The special significance of `+' characters preceding command lines (see section Instead of Executing the Commands) is mandated by IEEE Standard 1003.2-1992 (POSIX.2).
- The `+=' syntax to append to the value of a variable comes from SunOS 4 `make`. See section Appending More Text to Variables.
- The syntax `archive(mem1 mem2...)' to list multiple members in a single archive file comes from SunOS 4 `make`. See section Archive Members as Targets.
- The `-include` directive to include makefiles with no error for a nonexistent file comes from SunOS 4 `make`. (But note that SunOS 4 `make` does not allow multiple makefiles to be specified in one `-include` directive.)

The remaining features are inventions new in GNU `make`:

- Use the `-v' or `--version' option to print version and copyright information.
- Use the `-h' or `--help' option to summarize the options to `make`.
- Simply-expanded variables. See section The Two Flavors of Variables.
- Pass command-line variable assignments automatically through the variable `MAKE` to recursive `make` invocations. See section Recursive Use of `make`.
- Use the `-C' or `--directory' command option to change directory. See section Summary of Options.
- Make verbatim variable definitions with `define`. See section Defining Variables Verbatim.
- Declare phony targets with the special target `.PHONY`.

  Andrew Hume of AT&T Bell Labs implemented a similar feature with a different syntax in his `mk`

program. This seems to be a case of parallel discovery. See section Phony Targets.

- Manipulate text by calling functions. See section Functions for Transforming Text.
- Use the `-o' or `--old-file' option to pretend a file's modification-time is old. See section Avoiding Recompilation of Some Files.
- Conditional execution.

  This feature has been implemented numerous times in various versions of `make`; it seems a natural extension derived from the features of the C preprocessor and similar macro languages and is not a revolutionary concept. See section Conditional Parts of Makefiles.
- Specify a search path for included makefiles. See section Including Other Makefiles.
- Specify extra makefiles to read with an environment variable. See section The Variable `MAKEFILES`.
- Strip leading sequences of `./' from file names, so that `` `./file' `` and `` `file' `` are considered to be the same file.
- Use a special search method for library dependencies written in the form `-lname'. See section Directory Search for Link Libraries.
- Allow suffixes for suffix rules (see section Old-Fashioned Suffix Rules) to contain any characters. In other versions of `make`, they must begin with `.' and not contain any `/' characters.
- Keep track of the current level of `make` recursion using the variable `MAKELEVEL`. See section Recursive Use of `make`.
- Specify static pattern rules. See section Static Pattern Rules.
- Provide selective `vpath` search. See section Searching Directories for Dependencies.
- Provide computed variable references. See section Basics of Variable References.
- Update makefiles. See section How Makefiles Are Remade. System V `make` has a very, very limited form of this functionality in that it will check out SCCS files for makefiles.
- Various new built-in implicit rules. See section Catalogue of Implicit Rules.
- The built-in variable `MAKE_VERSION' gives the version number of `make`.

Go to the previous, next section.

Go to the previous, next section.

Incompatibilities and Missing Features

The `make` programs in various other systems support a few features that are not implemented in GNU `make`. The POSIX.2 standard (IEEE Standard 1003.2-1992) which specifies `make` does not require any of these features.

- A target of the form `file((entry))' stands for a member of archive file file. The member is chosen, not by name, but by being an object file which defines the linker symbol entry.

  This feature was not put into GNU `make` because of the nonmodularity of putting knowledge into `make` of the internal format of archive file symbol tables. See section Updating Archive Symbol Directories.

- Suffixes (used in suffix rules) that end with the character `~' have a special meaning to System V `make`; they refer to the SCCS file that corresponds to the file one would get without the `~'. For example, the suffix rule `.c~.o' would make the file `n.o' from the SCCS file `s.n.c'. For complete coverage, a whole series of such suffix rules is required. See section Old-Fashioned Suffix Rules.

  In GNU `make`, this entire series of cases is handled by two pattern rules for extraction from SCCS, in combination with the general feature of rule chaining. See section Chains of Implicit Rules.

- In System V `make`, the string `$$@' has the strange meaning that, in the dependencies of a rule with multiple targets, it stands for the particular target that is being processed.

  This is not defined in GNU `make` because `$$' should always stand for an ordinary `$'.

  It is possible to get this functionality through the use of static pattern rules (see section Static Pattern Rules). The System V `make` rule:

  ```
  $(targets): $$@.o lib.a
  ```

  can be replaced with the GNU `make` static pattern rule:

  ```
  $(targets): %: %.o lib.a
  ```

- In System V and 4.3 BSD `make`, files found by `VPATH` search (see section Searching Directories for Dependencies) have their names changed inside command strings. We feel it is much cleaner to always use automatic variables and thus make this feature obsolete.

- In some Unix `make`s, the automatic variable `$*` appearing in the dependencies of a rule has the amazingly strange "feature" of expanding to the full name of the *target of that rule*. We cannot imagine what went on in the minds of Unix `make` developers to do this; it is utterly inconsistent with the normal definition of `$*`.

- In some Unix `make`s, implicit rule search (see section Using Implicit Rules) is apparently done for *all* targets, not just those without commands. This means you can do:

```
foo.o:
        cc -c foo.c
```

and Unix `make` will intuit that `` `foo.o' `` depends on `` `foo.c' ``.

We feel that such usage is broken. The dependency properties of `make` are well-defined (for GNU `make`, at least), and doing such a thing simply does not fit the model.

- GNU `make` does not include any built-in implicit rules for compiling or preprocessing EFL programs. If we hear of anyone who is using EFL, we will gladly add them.
- It appears that in SVR4 `make`, a suffix rule can be specified with no commands, and it is treated as if it had empty commands (see section Using Empty Commands). For example:

```
.c.a:
```

will override the built-in `` `.c.a' `` suffix rule.

We feel that it is cleaner for a rule without commands to always simply add to the dependency list for the target. The above example can be easily rewritten to get the desired behavior in GNU `make`:

```
.c.a: ;
```

- Some versions of `make` invoke the shell with the `-e' flag, except under `-k' (see section Testing the Compilation of a Program). The `-e' flag tells the shell to exit as soon as any program it runs returns a nonzero status. We feel it is cleaner to write each shell command line to stand on its own and not require this special treatment.

Go to the previous, next section.

Go to the previous, next section.

Makefile Conventions

This chapter describes conventions for writing the Makefiles for GNU programs.

General Conventions for Makefiles

Every Makefile should contain this line:

```
SHELL = /bin/sh
```

to avoid trouble on systems where the `SHELL` variable might be inherited from the environment. (This is never a problem with GNU `make`.)

Different `make` programs have incompatible suffix lists and implicit rules, and this sometimes creates confusion or misbehavior. So it is a good idea to set the suffix list explicitly using only the suffixes you need in the particular Makefile, like this:

```
.SUFFIXES:
.SUFFIXES: .c .o
```

The first line clears out the suffix list, the second introduces all suffixes which may be subject to implicit rules in this Makefile.

Don't assume that `.' is in the path for command execution. When you need to run programs that are a part of your package during the make, please make sure that it uses `./' if the program is built as part of the make or `$(srcdir)/' if the file is an unchanging part of the source code. Without one of these prefixes, the current search path is used.

The distinction between `./' and `$(srcdir)/' is important when using the `--srcdir' option to `configure'. A rule of the form:

```
foo.1 : foo.man sedscript
        sed -e sedscript foo.man > foo.1
```

will fail when the current directory is not the source directory, because `foo.man' and `sedscript' are not in the current directory.

When using GNU `make`, relying on `VPATH' to find the source file will work in the case where there is a single dependency file, since the `make' automatic variable `$<' will represent the source file wherever it is. (Many versions of `make` set `$<' only in implicit rules.) A makefile target like

```
foo.o : bar.c
        $(CC) -I. -I$(srcdir) $(CFLAGS) -c bar.c -o foo.o
```

should instead be written as

```
foo.o : bar.c
        $(CC) -I. -I$(srcdir) $(CFLAGS) -c $< -o $@
```

in order to allow `VPATH' to work correctly. When the target has multiple dependencies, using an explicit `$(srcdir)' is the easiest way to make the rule work well. For example, the target above for `foo.1' is best written as:

```
foo.1 : foo.man sedscript
        sed -e $(srcdir)/sedscript $(srcdir)/foo.man > $@
```

Utilities in Makefiles

Write the Makefile commands (and any shell scripts, such as `configure`) to run in `sh`, not in `csh`. Don't use any special features of `ksh` or `bash`.

The `configure` script and the Makefile rules for building and installation should not use any utilities directly except these:

```
cat cmp cp echo egrep expr grep
ln mkdir mv pwd rm rmdir sed test touch
```

Stick to the generally supported options for these programs. For example, don't use `mkdir -p', convenient as it may be, because most systems don't support it.

The Makefile rules for building and installation can also use compilers and related programs, but should do so via `make` variables so that the user can substitute alternatives. Here are some of the programs we mean:

```
ar bison cc flex install ld lex
make makeinfo ranlib texi2dvi yacc
```

Use the following `make` variables:

```
$(AR) $(BISON) $(CC) $(FLEX) $(INSTALL) $(LD) $(LEX)
$(MAKE) $(MAKEINFO) $(RANLIB) $(TEXI2DVI) $(YACC)
```

When you use `ranlib`, you should make sure nothing bad happens if the system does not have `ranlib`. Arrange to ignore an error from that command, and print a message before the command to tell the user that failure of the `ranlib` command does not mean a problem.

If you use symbolic links, you should implement a fallback for systems that don't have symbolic links.

It is ok to use other utilities in Makefile portions (or scripts) intended only for particular systems where you know those utilities to exist.

Standard Targets for Users

All GNU programs should have the following targets in their Makefiles:

`all'

Compile the entire program. This should be the default target. This target need not rebuild any documentation files; Info files should normally be included in the distribution, and DVI files should be made only when explicitly asked for.

`install'

Compile the program and copy the executables, libraries, and so on to the file names where they should reside for actual use. If there is a simple test to verify that a program is properly installed, this target should run that test.

If possible, write the `install` target rule so that it does not modify anything in the directory where the program was built, provided `make all' has just been done. This is convenient for building the program under one user name and installing it under another.

The commands should create all the directories in which files are to be installed, if they don't already exist. This includes the directories specified as the values of the variables `prefix` and `exec_prefix`, as well as all subdirectories that are needed. One way to do this is by means of an `installdirs` target as described below.

Use `-' before any command for installing a man page, so that `make` will ignore any errors. This is in case there are systems that don't have the Unix man page documentation system installed.

The way to install Info files is to copy them into `$(infodir)' with `$(INSTALL_DATA)` (see section Variables for Specifying Commands), and then run the `install-info` program if it is present. `install-info` is a script that edits the Info `dir' file to add or update the menu entry for the given Info file; it will be part of the Texinfo package. Here is a sample rule to install an Info file:

```
$(infodir)/foo.info: foo.info
# There may be a newer info file in . than in srcdir.
        -if test -f foo.info; then d=.; \
         else d=$(srcdir); fi; \
        $(INSTALL_DATA) $$d/foo.info $@; \
# Run install-info only if it exists.
# Use `if' instead of just prepending `-' to the
# line so we notice real errors from install-info.
# We use `$(SHELL) -c' because some shells do not
# fail gracefully when there is an unknown command.
        if $(SHELL) -c 'install-info --version' \
           >/dev/null 2>&1; then \
          install-info --infodir=$(infodir) $$d/foo.info; \
        else true; fi
```

`uninstall'

Delete all the installed files that the `install' target would create (but not the noninstalled files su as `make all' would create).

This rule should not modify the directories where compilation is done, only the directories where files are installed.

`clean'

Delete all files from the current directory that are normally created by building the program. Don't delete the files that record the configuration. Also preserve files that could be made by building, but normally aren't because the distribution comes with them.

Delete `.dvi' files here if they are not part of the distribution.

`distclean'

Delete all files from the current directory that are created by configuring or building the program. If you have unpacked the source and built the program without creating any other files, `make distclean' should leave only the files that were in the distribution.

`mostlyclean'

Like `clean', but may refrain from deleting a few files that people normally don't want to recompile. For example, the `mostlyclean' target for GCC does not delete `libgcc.a', because recompiling it is rarely necessary and takes a lot of time.

`maintainer-clean'

Delete almost everything from the current directory that can be reconstructed with this Makefile. This typically includes everything deleted by `distclean`, plus more: C source files produced by Bison, tags tables, Info files, and so on.

The reason we say "almost everything" is that `make maintainer-clean' should not delete `configure' even if `configure' can be remade using a rule in the Makefile. More generally, `make maintainer-clean' should not delete anything that needs to exist in order to run `configure' and then begin to build the program. This is the only exception; `maintainer-clean` should delete everything else that can be rebuilt.

The `maintainer-clean' is intended to be used by a maintainer of the package, not by ordinary users. You may need special tools to reconstruct some of the files that `make maintainer-clean' deletes. Since these files are normally included in the distribution, we don't take care to make them easy to reconstruct. If you find you need to unpack the full distribution again, don't blame us.

To help make users aware of this, the commands for `maintainer-clean` should start with these two:

```
@echo "This command is intended for maintainers to use;"
@echo "it deletes files that may require special tools to rebuild."
```

`TAGS'

Update a tags table for this program.

`info'

Generate any Info files needed. The best way to write the rules is as follows:

```
info: foo.info

foo.info: foo.texi chap1.texi chap2.texi
        $(MAKEINFO) $(srcdir)/foo.texi
```

You must define the variable `MAKEINFO` in the Makefile. It should run the `makeinfo` program, which is part of the Texinfo distribution.

`dvi'

Generate DVI files for all TeXinfo documentation. For example:

```
dvi: foo.dvi

foo.dvi: foo.texi chap1.texi chap2.texi
        $(TEXI2DVI) $(srcdir)/foo.texi
```

You must define the variable `TEXI2DVI` in the Makefile. It should run the program `texi2dvi`, which is part of the Texinfo distribution. Alternatively, write just the dependencies, and allow GNU Make to provide the command.

`dist'

Create a distribution tar file for this program. The tar file should be set up so that the file names in the tar file start with a subdirectory name which is the name of the package it is a distribution for. This name can include the version number.

For example, the distribution tar file of GCC version 1.40 unpacks into a subdirectory named `` `gcc-1.40' ``.

The easiest way to do this is to create a subdirectory appropriately named, use `ln` or `cp` to install the proper files in it, and then `tar` that subdirectory.

The `dist` target should explicitly depend on all non-source files that are in the distribution, to make sure they are up to date in the distribution. See section 'Making Releases' in GNU Coding Standards.

`check'

Perform self-tests (if any). The user must build the program before running the tests, but need not install the program; you should write the self-tests so that they work when the program is built but not installed.

The following targets are suggested as conventional names, for programs in which they are useful.

`installcheck`

Perform installation tests (if any). The user must build and install the program before running the tests. You should not assume that `` `$(bindir)' `` is in the search path.

`installdirs`

It's useful to add a target named `installdirs' to create the directories where files are installed, and their parent directories. There is a script called `` `mkinstalldirs' `` which is convenient for this;

find it in the Texinfo package. You can use a rule like this:

```
# Make sure all installation directories (e.g. $(bindir))
# actually exist by making them if necessary.
installdirs: mkinstalldirs
        $(srcdir)/mkinstalldirs $(bindir) $(datadir) \
                                $(libdir) $(infodir) \
                                $(mandir)
```

This rule should not modify the directories where compilation is done. It should do nothing but create installation directories.

Variables for Specifying Commands

Makefiles should provide variables for overriding certain commands, options, and so on.

In particular, you should run most utility programs via variables. Thus, if you use Bison, have a variable named `BISON` whose default value is set with `BISON = bison', and refer to it with `$(BISON)` whenever you need to use Bison.

File management utilities such as `ln`, `rm`, `mv`, and so on, need not be referred to through variables in this way, since users don't need to replace them with other programs.

Each program-name variable should come with an options variable that is used to supply options to the program. Append `FLAGS' to the program-name variable name to get the options variable name--for example, `BISONFLAGS`. (The name `CFLAGS` is an exception to this rule, but we keep it because it is standard.) Use `CPPFLAGS` in any compilation command that runs the preprocessor, and use `LDFLAGS` in any compilation command that does linking as well as in any direct use of `ld`.

If there are C compiler options that *must* be used for proper compilation of certain files, do not include them in `CFLAGS`. Users expect to be able to specify `CFLAGS` freely themselves. Instead, arrange to pass the necessary options to the C compiler independently of `CFLAGS`, by writing them explicitly in the compilation commands or by defining an implicit rule, like this:

```
CFLAGS = -g
ALL_CFLAGS = -I. $(CFLAGS)
.c.o:
        $(CC) -c $(CPPFLAGS) $(ALL_CFLAGS) $<
```

Do include the `-g' option in `CFLAGS`, because that is not *required* for proper compilation. You can consider it a default that is only recommended. If the package is set up so that it is compiled with GCC by default, then you might as well include `-O' in the default value of `CFLAGS` as well.

Put `CFLAGS` last in the compilation command, after other variables containing compiler options, so the user can use `CFLAGS` to override the others.

Every Makefile should define the variable `INSTALL`, which is the basic command for installing a file into the system.

Every Makefile should also define the variables `INSTALL_PROGRAM` and `INSTALL_DATA`. (The default for each of these should be `$(INSTALL)`.) Then it should use those variables as the commands for actual installation, for executables and nonexecutables respectively. Use these variables as follows:

```
$(INSTALL_PROGRAM) foo $(bindir)/foo
$(INSTALL_DATA) libfoo.a $(libdir)/libfoo.a
```

Always use a file name, not a directory name, as the second argument of the installation commands. Use a separate command for each file to be installed.

Variables for Installation Directories

Installation directories should always be named by variables, so it is easy to install in a nonstandard place. The standard names for these variables are described below. They are based on a standard filesystem layout; variants of it are used in SVR4, 4.4BSD, Linux, Ultrix v4, and other modern operating systems.

These two variables set the root for the installation. All the other installation directories should be subdirectories of one of these two, and nothing should be directly installed into these two directories.

`prefix'

A prefix used in constructing the default values of the variables listed below. The default value of `prefix` should be `` `/usr/local' `` When building the complete GNU system, the prefix will be empty and `` `/usr' `` will be a symbolic link to `` `/' ``.

`exec_prefix'

A prefix used in constructing the default values of some of the variables listed below. The default value of `exec_prefix` should be `$(prefix)`.

Generally, `$(exec_prefix)` is used for directories that contain machine-specific files (such as executables and subroutine libraries), while `$(prefix)` is used directly for other directories.

Executable programs are installed in one of the following directories.

`bindir'

The directory for installing executable programs that users can run. This should normally be `` `/usr/local/bin' ``, but write it as `` `$(exec_prefix)/bin' ``.

`sbindir'

The directory for installing executable programs that can be run from the shell, but are only generally useful to system administrators. This should normally be `` `/usr/local/sbin' ``, but write it as `` `$(exec_prefix)/sbin' ``.

`libexecdir'

The directory for installing executable programs to be run by other programs rather than by users. This directory should normally be `` `/usr/local/libexec' ``, but write it as `` `$(exec_prefix)/libexec' ``.

Data files used by the program during its execution are divided into categories in two ways.

- Some files are normally modified by programs; others are never normally modified (though users

may edit some of these).

- Some files are architecture-independent and can be shared by all machines at a site; some are architecture-dependent and can be shared only by machines of the same kind and operating system; others may never be shared between two machines.

This makes for six different possibilities. However, we want to discourage the use of architecture-dependent files, aside from of object files and libraries. It is much cleaner to make other data files architecture-independent, and it is generally not hard.

Therefore, here are the variables makefiles should use to specify directories:

`datadir'

The directory for installing read-only architecture independent data files. This should normally be `/usr/local/share', but write it as `$(prefix)/share'. As a special exception, see `$(infodir)' and `$(includedir)' below.

`sysconfdir'

The directory for installing read-only data files that pertain to a single machine--that is to say, files for configuring a host. Mailer and network configuration files, `/etc/passwd', and so forth belong here. All the files in this directory should be ordinary ASCII text files. This directory should normally be `/usr/local/etc', but write it as `$(prefix)/etc'.

Do not install executables in this directory (they probably belong in `$(libexecdir)' or `$(sbindir))'. Also do not install files that are modified in the normal course of their use (programs whose purpose is to change the configuration of the system excluded). Those probably belong in `$(localstatedir)'.

`sharedstatedir'

The directory for installing architecture-independent data files which the programs modify while they run. This should normally be `/usr/local/com', but write it as `$(prefix)/com'.

`localstatedir'

The directory for installing data files which the programs modify while they run, and that pertain to one specific machine. Users should never need to modify files in this directory to configure the package's operation; put such configuration information in separate files that go in `datadir' or `$(sysconfdir)'. `$(localstatedir)' should normally be `/usr/local/var', but write it as `$(prefix)/var'.

`libdir'

The directory for object files and libraries of object code. Do not install executables here, they probably belong in `$(libexecdir)' instead. The value of `libdir' should normally be `/usr/local/lib', but write it as `$(exec_prefix)/lib'.

`infodir'

The directory for installing the Info files for this package. By default, it should be `/usr/local/info', but it should be written as `$(prefix)/info'.

`includedir'

The directory for installing header files to be included by user programs with the C `#include' preprocessor directive. This should normally be `/usr/local/include', but write it as

`$(prefix)/include'.

Most compilers other than GCC do not look for header files in `/usr/local/include'. So installing the header files this way is only useful with GCC. Sometimes this is not a problem because some libraries are only really intended to work with GCC. But some libraries are intended to work with other compilers. They should install their header files in two places, one specified by `includedir` and one specified by `oldincludedir`.

`oldincludedir'

The directory for installing `#include' header files for use with compilers other than GCC. This should normally be `/usr/include'.

The Makefile commands should check whether the value of `oldincludedir` is empty. If it is, they should not try to use it; they should cancel the second installation of the header files.

A package should not replace an existing header in this directory unless the header came from the same package. Thus, if your Foo package provides a header file `foo.h', then it should install the header file in the `oldincludedir` directory if either (1) there is no `foo.h' there or (2) the `foo.h' that exists came from the Foo package.

To tell whether `foo.h' came from the Foo package, put a magic string in the file--part of a comment--and grep for that string.

Unix-style man pages are installed in one of the following:

`mandir'

The directory for installing the man pages (if any) for this package. It should include the suffix for the proper section of the manual--usually `1' for a utility. It will normally be `/usr/local/man/man1', but you should write it as `$(prefix)/man/man1'.

`man1dir'

The directory for installing section 1 man pages.

`man2dir'

The directory for installing section 2 man pages.

`...'

Use these names instead of `mandir' if the package needs to install man pages in more than one section of the manual.

Don't make the primary documentation for any GNU software be a man page. Write a manual in Texinfo instead. Man pages are just for the sake of people running GNU software on Unix, which is a secondary application only.

`manext'

The file name extension for the installed man page. This should contain a period followed by the appropriate digit; it should normally be `.1'.

`man1ext'

The file name extension for installed section 1 man pages.

`man2ext'

The file name extension for installed section 2 man pages.

`...'

Use these names instead of `manext' if the package needs to install man pages in more than one section of the manual.

And finally, you should set the following variable:

`srcdir'

The directory for the sources being compiled. The value of this variable is normally inserted by the `configure` shell script.

For example:

```
# Common prefix for installation directories.
# NOTE: This directory must exist when you start the install.
prefix = /usr/local
exec_prefix = $(prefix)
# Where to put the executable for the command `gcc'.
bindir = $(exec_prefix)/bin
# Where to put the directories used by the compiler.
libexecdir = $(exec_prefix)/libexec
# Where to put the Info files.
infodir = $(prefix)/info
```

If your program installs a large number of files into one of the standard user-specified directories, it might be useful to group them into a subdirectory particular to that program. If you do this, you should write the `install` rule to create these subdirectories.

Do not expect the user to include the subdirectory name in the value of any of the variables listed above. The idea of having a uniform set of variable names for installation directories is to enable the user to specify the exact same values for several different GNU packages. In order for this to be useful, all the packages must be designed so that they will work sensibly when the user does so.

Quick Reference

This appendix summarizes the directives, text manipulation functions, and special variables which GNU `make` understands. See section Special Built-in Target Names, section Catalogue of Implicit Rules, and section Summary of Options, for other summaries.

Here is a summary of the directives GNU `make` recognizes:

`define variable`
`endef`

Define a multi-line, recursively-expanded variable.
See section Defining Canned Command Sequences.

`ifdef variable`
`ifndef variable`
`ifeq (a,b)`
`ifeq "a" "b"`
`ifeq 'a' 'b'`
`ifneq (a,b)`
`ifneq "a" "b"`
`ifneq 'a' 'b'`
`else`
`endif`

Conditionally evaluate part of the makefile.
See section Conditional Parts of Makefiles.

`include file`

Include another makefile.
See section Including Other Makefiles.

`override variable = value`
`override variable := value`
`override variable += value`
`override define variable`
`endef`

Define a variable, overriding any previous definition, even one from the command line.
See section The `override` Directive.

`export`

Tell `make` to export all variables to child processes by default.
See section Communicating Variables to a Sub-`make`.

`export variable`

`export variable = value`

`export variable := value`

`export variable += value`

`unexport variable`

Tell `make` whether or not to export a particular variable to child processes.
See section Communicating Variables to a Sub-`make`.

`vpath pattern path`

Specify a search path for files matching a `%' pattern.
See section The `vpath` Directive.

`vpath pattern`

Remove all search paths previously specified for pattern.

`vpath`

Remove all search paths previously specified in any `vpath` directive.

Here is a summary of the text manipulation functions (see section Functions for Transforming Text):

`$(subst from,to,text)`

Replace from with to in text.
See section Functions for String Substitution and Analysis.

`$(patsubst pattern,replacement,text)`

Replace words matching pattern with replacement in text.
See section Functions for String Substitution and Analysis.

`$(strip string)`

Remove excess whitespace characters from string.
See section Functions for String Substitution and Analysis.

`$(findstring find,text)`

Locate find in text.
See section Functions for String Substitution and Analysis.

`$(filter pattern...,text)`

Select words in text that match one of the pattern words.
See section Functions for String Substitution and Analysis.

`$(filter-out pattern...,text)`

Select words in text that *do not* match any of the pattern words.
See section Functions for String Substitution and Analysis.

`$(sort list)`

Sort the words in list lexicographically, removing duplicates.

See section Functions for String Substitution and Analysis.

`$(dir names...)`

Extract the directory part of each file name.
See section Functions for File Names.

`$(notdir names...)`

Extract the non-directory part of each file name.
See section Functions for File Names.

`$(suffix names...)`

Extract the suffix (the last `.' and following characters) of each file name.
See section Functions for File Names.

`$(basename names...)`

Extract the base name (name without suffix) of each file name.
See section Functions for File Names.

`$(addsuffix suffix,names...)`

Append suffix to each word in names.
See section Functions for File Names.

`$(addprefix prefix,names...)`

Prepend prefix to each word in names.
See section Functions for File Names.

`$(join list1,list2)`

Join two parallel lists of words.
See section Functions for File Names.

`$(word n,text)`

Extract the nth word (one-origin) of text.
See section Functions for File Names.

`$(words text)`

Count the number of words in text.
See section Functions for File Names.

`$(firstword names...)`

Extract the first word of names.
See section Functions for File Names.

`$(wildcard pattern...)`

Find file names matching a shell file name pattern (*not* a `%' pattern).
See section The Function `wildcard`.

`$(shell command)`

Execute a shell command and return its output.
See section The `shell` Function.

`$(origin variable)`

Return a string describing how the `make` variable variable was defined.
See section The `origin` Function.

`$(foreach var,words,text)`

Evaluate text with var bound to each word in words, and concatenate the results.
See section The `foreach` Function.

Here is a summary of the automatic variables. See section Automatic Variables, for full information.

`$@`

The file name of the target.

`$%`

The target member name, when the target is an archive member.

`$<`

The name of the first dependency.

`$?`

The names of all the dependencies that are newer than the target, with spaces between them. For dependencies which are archive members, only the member named is used (see section Using `make` to Update Archive Files).

`$^`

`$+`

The names of all the dependencies, with spaces between them. For dependencies which are archive members, only the member named is used (see section Using `make` to Update Archive Files). The value of `$^` omits duplicate dependencies, while `$+` retains them and preserves their order.

`$*`

The stem with which an implicit rule matches (see section How Patterns Match).

`$(@D)`

`$(@F)`

The directory part and the file-within-directory part of `$@`.

`$(*D)`

`$(*F)`

The directory part and the file-within-directory part of `$*`.

`$(%D)`

`$(%F)`

The directory part and the file-within-directory part of `$%`.

`$(<D)`

`$(<F)`

The directory part and the file-within-directory part of `$<`.

`$(^D)`
`$(^F)`

The directory part and the file-within-directory part of `$^`.

`$(+D)`
`$(+F)`

The directory part and the file-within-directory part of `$+`.

`$(?D)`
`$(?F)`

The directory part and the file-within-directory part of `$?`.

These variables are used specially by GNU `make`:

`MAKEFILES`

Makefiles to be read on every invocation of `make`.
See section The Variable `MAKEFILES`.

`VPATH`

Directory search path for files not found in the current directory.
See section `VPATH`: Search Path for All Dependencies.

`SHELL`

The name of the system default command interpreter, usually `` `/bin/sh' ``. You can set `SHELL` in the makefile to change the shell used to run commands. See section Command Execution.

`MAKE`

The name with which `make` was invoked. Using this variable in commands has special meaning.
See section How the `MAKE` Variable Works.

`MAKELEVEL`

The number of levels of recursion (sub-`make`s).
See section Communicating Variables to a Sub-`make`.

`MAKEFLAGS`

The flags given to `make`. You can set this in the environment or a makefile to set flags.
See section Communicating Options to a Sub-`make`.

`SUFFIXES`

The default list of suffixes before `make` reads any makefiles.

Go to the previous, next section.

Go to the previous, next section.

Complex Makefile Example

Here is the makefile for the GNU `tar` program. This is a moderately complex makefile.

Because it is the first target, the default goal is `all'. An interesting feature of this makefile is that `` `testpad.h' `` is a source file automatically created by the `testpad` program, itself compiled from `` `testpad.c' ``.

If you type `make' or `make all', then `make` creates the `` `tar' `` executable, the `` `rmt' `` daemon that provides remote tape access, and the `` `tar.info' `` Info file.

If you type `make install', then `make` not only creates `` `tar' ``, `` `rmt' ``, and `` `tar.info' ``, but also installs them.

If you type `make clean', then `make` removes the `.o' files, and the `` `tar' ``, `` `rmt' ``, `` `testpad' ``, `` `testpad.h' ``, and `` `core' `` files.

If you type `make distclean', then `make` not only removes the same files as does `make clean' but also the `` `TAGS' ``, `` `Makefile' ``, and `` `config.status' `` files. (Although it is not evident, this makefile (and `` `config.status' ``) is generated by the user with the `configure` program, which is provided in the `tar` distribution, but is not shown here.)

If you type `make realclean', then `make` removes the same files as does `make distclean' and also removes the Info files generated from `` `tar.texinfo' ``.

In addition, there are targets `shar` and `dist` that create distribution kits.

# Things you might add to DEFS:
# -DSTDC_HEADERS        If you have ANSI C headers and
#                       libraries.
# -DPOSIX               If you have POSIX.1 headers and
#                       libraries.
# -DBSD42               If you have sys/dir.h (unless
#                       you use -DPOSIX), sys/file.h,
#                       and st_blocks in `struct stat'.
# -DUSG                 If you have System V/ANSI C
#                       string and memory functions
#                       and headers, sys/sysmacros.h,
#                       fcntl.h, getcwd, no valloc,
#                       and ndir.h (unless
#                       you use -DDIRENT).
# -DNO_MEMORY_H         If USG or STDC_HEADERS but do not
#                       include memory.h.
# -DDIRENT              If USG and you have dirent.h
#                       instead of ndir.h.
# -DSIGTYPE=int         If your signal handlers
#                       return int, not void.
# -DNO_MTIO             If you lack sys/mtio.h
#                       (magtape ioctls).
# -DNO_REMOTE           If you do not have a remote shell
#                       or rexec.
# -DUSE_REXEC           To use rexec for remote tape
#                       operations instead of
#                       forking rsh or remsh.
# -DVPRINTF_MISSING     If you lack vprintf function
#                       (but have _doprnt).
# -DDOPRNT_MISSING      If you lack _doprnt function.
#                       Also need to define
#                       -DVPRINTF_MISSING.
# -DFTIME_MISSING       If you lack ftime system call.
# -DSTRSTR_MISSING      If you lack strstr function.
# -DVALLOC_MISSING      If you lack valloc function.
# -DMKDIR_MISSING       If you lack mkdir and
#                       rmdir system calls.
# -DRENAME_MISSING      If you lack rename system call.
```

```
# -DFTRUNCATE_MISSING   If you lack ftruncate
#                       system call.
# -DV7                  On Version 7 Unix (not
#                       tested in a long time).
# -DEMUL_OPEN3          If you lack a 3-argument version
#                       of open, and want to emulate it
#                       with system calls you do have.
# -DNO_OPEN3            If you lack the 3-argument open
#                       and want to disable the tar -k
#                       option instead of emulating open.
# -DXENIX               If you have sys/inode.h
#                       and need it 94 to be included.

Gnus 5.3 Manual

Go to the next section.

Starting Gnus

If your system administrator has set things up properly, starting Gnus and reading news is extremely easy--you just type M-x gnus in your Emacs.

If you want to start Gnus in a different frame, you can use the command M-x gnus-other-frame instead.

If things do not go smoothly at startup, you have to twiddle some variables.

Finding the News

The `gnus-select-method` variable says where Gnus should look for news. This variable should be a list where the first element says how and the second element says where. This method is your native method. All groups that are not fetched with this method are foreign groups.

For instance, if the `news.somewhere.edu' NNTP server is where you want to get your daily dosage of news from, you'd say:

```
(setq gnus-select-method '(nntp "news.somewhere.edu"))
```

If you want to read directly from the local spool, say:

```
(setq gnus-select-method '(nnspool ""))
```

If you can use a local spool, you probably should, as it will almost certainly be much faster.

If this variable is not set, Gnus will take a look at the `NNTPSERVER` environment variable. If that variable isn't set, Gnus will see whether `gnus-nntpserver-file` (`/etc/nntpserver' by default) has any opinions on the matter. If that fails as well, Gnus will will try to use the machine that is running Emacs as an NNTP server. That's a long-shot, though.

If `gnus-nntp-server` is set, this variable will override `gnus-select-method`. You should therefore set `gnus-nntp-server` to `nil`, which is what it is by default.

You can also make Gnus prompt you interactively for the name of an NNTP server. If you give a non-numerical prefix to `gnus` (i.e., C-u M-x gnus), Gnus will let you choose between the servers in the `gnus-secondary-servers` list (if any). You can also just type in the name of any server you feel like visiting.

However, if you use one NNTP server regularly and are just interested in a couple of groups from a different server, you would be better served by using the B command in the group buffer. It will let you have a look at what groups are available, and you can subscribe to any of the groups you want to. This also makes `.newsrc' maintenance much tidier. See section Foreign Groups.

A slightly different approach to foreign groups is to set the `gnus-secondary-select-methoc` variable. The select methods listed in this variable are in many ways just as native as the `gnus-select-method` server. They will also be queried for active files during startup (if that's required), and new newsgroups that appear on these servers will be subscribed (or not) just as native groups are.

For instance, if you use the `nnmbox` backend to read your mail, you would typically set this variable to

```
(setq gnus-secondary-select-methods '((nnmbox "")))
```

The First Time

If no startup files exist, Gnus will try to determine what groups should be subscribed by default.

If the variable `gnus-default-subscribed-newsgroups` is set, Gnus will subscribe you to just those groups in that list, leaving the rest killed. Your system administrator should have set this variable to something useful.

Since she hasn't, Gnus will just subscribe you to a few arbitrarily picked groups (i.e., `*.newusers'). (Arbitrary is here defined as whatever Lars thinks you should read.)

You'll also be subscribed to the Gnus documentation group, which should help you with most common problems.

If `gnus-default-subscribed-newsgroups` is `t`, Gnus will just use the normal functions for handling new groups, and not do anything special.

The Server is Down

If the default server is down, Gnus will understandably have some problems starting. However, if you have some mail groups in addition to the news groups, you may want to start Gnus anyway.

Gnus, being the trusting sort of program, will ask whether to proceed without a native select method if that server can't be contacted. This will happen whether the server doesn't actually exist (i.e., you have given the wrong address) or the server has just momentarily taken ill for some reason or other. If you decide to continue and have no foreign groups, you'll find it difficult to actually do anything in the group buffer. But, hey, that's your problem. Blllrph!

If you know that the server is definitely down, or you just want to read your mail without bothering with the server at all, you can use the `gnus-no-server` command to start Gnus. That might come in handy if you're in a hurry as well.

Slave Gnusiï

You might want to run more than one Emacs with more than one Gnus at the same time. If you are using different `.newsrc' files (eg., if you are using the two different Gnusiï to read from two different servers), that is no problem whatsoever. You just do it.

The problem appears when you want to run two Gnusiï that use the same `.newsrc` file.

To work around that problem some, we here at the Think-Tank at the Gnus Towers have come up with a new concept: Masters and servants. (We have applied for a patent on this concept, and have taken out a copyright on those words. If you wish to use those words in conjunction with each other, you have to send $1 per usage instance to me. Usage of the patent (Master/Slave Relationships In Computer Applications) will be much more expensive, of course.)

Anyways, you start one Gnus up the normal way with M-x gnus (or however you do it). Each subsequent slave Gnusiï should be started with M-x gnus-slave. These slaves won't save normal `.newsrc' files, but instead save slave files that contains information only on what groups have been read in the slave session. When a master Gnus starts, it will read (and delete) these slave files, incorporating all information from them. (The slave files will be read in the sequence they were created, so the latest changes will have precedence.)

Information from the slave files has, of course, precedence over the information in the normal (i. e., master) `.newsrc` file.

Fetching a Group

It it sometime convenient to be able to just say "I want to read this group and I don't care whether Gnus has been started or not". This is perhaps more useful for people who write code than for users, but the command `gnus-fetch-group` provides this functionality in any case. It takes the group name as a parameter.

New Groups

What Gnus does when it encounters a new group is determined by the `gnus-subscribe-newsgroup-method` variable.

This variable should contain a function. Some handy pre-fab values are:

`gnus-subscribe-zombies`

> Make all new groups zombies. You can browse the zombies later (with A z) and either kill them all off properly, or subscribe to them. This is the default.

`gnus-subscribe-randomly`

> Subscribe all new groups randomly.

`gnus-subscribe-alphabetically`

> Subscribe all new groups alphabetically.

`gnus-subscribe-hierarchically`

Subscribe all new groups hierarchically.

`gnus-subscribe-interactively`

Subscribe new groups interactively. This means that Gnus will ask you about **all** new groups.

`gnus-subscribe-killed`

Kill all new groups.

A closely related variable is `gnus-subscribe-hierarchical-interactive`. (That's quite a mouthful.) If this variable is non-`nil`, Gnus will ask you in a hierarchical fashion whether to subscribe to new groups or not. Gnus will ask you for each sub-hierarchy whether you want to descend the hierarchy or not.

One common mistake is to set the variable a few paragraphs above to `gnus-subscribe-hierarchical-interactive`. This is an error. This will not work. This is ga-ga. So don't do it.

A nice and portable way to control which new newsgroups should be subscribed (or ignored) is to put an options line at the start of the `` `.newsrc' `` file. Here's an example:

```
options -n !alt.all !rec.all sci.all
```

This line obviously belongs to a serious-minded intellectual scientific person (or she may just be plain old boring), because it says that all groups that have names beginning with `alt' and `rec' should be ignored, and all groups with names beginning with `sci' should be subscribed. Gnus will not use the normal subscription method for subscribing these groups. `gnus-subscribe-options-newsgroup-method` is used instead. This variable defaults to `gnus-subscribe-alphabetically`.

If you don't want to mess with your `` `.newsrc' `` file, you can just set the two variables `gnus-options-subscribe` and `gnus-options-not-subscribe`. These two variables do exactly the same as the `` `.newsrc' ``options -n' trick. Both are regexps, and if the the new group matches the former, it will be unconditionally subscribed, and if it matches the latter, it will be ignored.

Yet another variable that meddles here is `gnus-auto-subscribed-groups`. It works exactly like `gnus-options-subscribe`, and is therefore really superfluous, but I thought it would be nice to have two of these. This variable is more meant for setting some ground rules, while the other variable is used more for user fiddling. By default this variable makes all new groups that come from mail backends (`nnml`, `nnbabyl`, `nnfolder`, `nnmbox`, and `nnmh`) subscribed. If you don't like that, just set this variable to `nil`.

If you are satisfied that you really never want to see any new groups, you could set `gnus-check-new-newsgroups` to `nil`. This will also save you some time at startup. Even if this variable is `nil`, you can always subscribe to the new groups just by pressing U in the group buffer (see section Group Maintenance). This variable is `t` by default.

Gnus normally determines whether a group is new or not by comparing the list of groups from the active file(s) with the lists of subscribed and dead groups. This isn't a particularly fast method. If

`gnus-check-new-newsgroups` is `ask-server`, Gnus will ask the server for new groups since the last time. This is both faster & cheaper. This also means that you can get rid of the list of killed groups altogether, so you may set `gnus-save-killed-list` to `nil`, which will save time both at startup, at exit, and all over. Saves disk space, too. Why isn't this the default, then? Unfortunately, not all servers support this command.

I bet I know what you're thinking now: How do I find out whether my server supports `ask-server`? No? Good, because I don't have a fail-safe answer. I would suggest just setting this variable to `ask-server` and see whether any new groups appear within the next few days. If any do, then it works. If any don't, then it doesn't work. I could write a function to make Gnus guess whether the server supports `ask-server`, but it would just be a guess. So I won't. You could `telnet` to the server and say `HELP` and see whether it lists `NEWGROUPS' among the commands it understands. If it does, then it might work. (But there are servers that lists `NEWGROUPS' without supporting the function properly.)

This variable can also be a list of select methods. If so, Gnus will issue an `ask-server` command to each of the select methods, and subscribe them (or not) using the normal methods. This might be handy if you are monitoring a few servers for new groups. A side effect is that startup will take much longer, so you can meditate while waiting. Use the mantra "dingnusdingnusdingnus" to achieve permanent bliss.

Startup Files

Now, you all know about the `` `.newsrc' `` file. All subscription information is traditionally stored in this file.

Things got a bit more complicated with GNUS. In addition to keeping the `` `.newsrc' `` file updated, it also used a file called `` `.newsrc.el' `` for storing all the information that didn't fit into the `` `.newsrc' `` file. (Actually, it also duplicated everything in the `` `.newsrc' `` file.) GNUS would read whichever one of these files was the most recently saved, which enabled people to swap between GNUS and other newsreaders.

That was kinda silly, so Gnus went one better: In addition to the `` `.newsrc' `` and `` `.newsrc.el' `` files, Gnus also has a file called `` `.newsrc.eld' ``. It will read whichever of these files that are most recent, but it will never write a `` `.newsrc.el' `` file.

You can turn off writing the `` `.newsrc' `` file by setting `gnus-save-newsrc-file` to `nil`, which means you can delete the file and save some space, as well as making exit from Gnus faster. However, this will make it impossible to use other newsreaders than Gnus. But hey, who would want to, right?

If `gnus-save-killed-list` (default `t`) is `nil`, Gnus will not save the list of killed groups to the startup file. This will save both time (when starting and quitting) and space (on disk). It will also means that Gnus has no record of what groups are new or old, so the automatic new groups subscription methods become meaningless. You should always set `gnus-check-new-newsgroups` to `nil` or `ask-server` if you set this variable to `nil` (see section New Groups).

The `gnus-startup-file` variable says where the startup files are. The default value is `` `~/.newsrc' ``, with the Gnus (El Dingo) startup file being whatever that one is with a `.eld' appended.

`gnus-save-newsrc-hook` is called before saving any of the newsrc files, while `gnus-save-quick-newsrc-hook` is called just before saving the `.newsrc.eld' file, and `gnus-save-standard-newsrc-hook` is called just before saving the `.newsrc' file. The latter two are commonly used to turn version control on or off. Version control is off by default when saving the startup files.

Auto Save

Whenever you do something that changes the Gnus data (reading articles, catching up, killing/subscribing groups), the change is added to a special dribble buffer. This buffer is auto-saved the normal Emacs way. If your Emacs should crash before you have saved the `.newsrc' files, all changes you have made can be recovered from this file.

If Gnus detects this file at startup, it will ask the user whether to read it. The auto save file is deleted whenever the real startup file is saved.

If `gnus-use-dribble-file` is `nil`, Gnus won't create and maintain a dribble buffer. The default is `t`.

Gnus will put the dribble file(s) in `gnus-dribble-directory`. If this variable is `nil`, which it is by default, Gnus will dribble into the directory where the `.newsrc' file is located. (This is normally the user's home directory.) The dribble file will get the same file permissions as the `.newsrc` file.

The Active File

When Gnus starts, or indeed whenever it tries to determine whether new articles have arrived, it reads the active file. This is a very large file that lists all the active groups and articles on the server.

Before examining the active file, Gnus deletes all lines that match the regexp `gnus-ignored-newsgroups`. This is done primarily to reject any groups with bogus names, but you can use this variable to make Gnus ignore hierarchies you aren't ever interested in. However, this is not recommended. In fact, it's highly discouraged. Instead, see section New Groups for an overview of other variables that can be used instead.

The active file can be rather Huge, so if you have a slow network, you can set `gnus-read-active-file` to `nil` to prevent Gnus from reading the active file. This variable is `t` by default.

Gnus will try to make do by getting information just on the groups that you actually subscribe to.

Note that if you subscribe to lots and lots of groups, setting this variable to `nil` will probably make Gnus slower, not faster. At present, having this variable `nil` will slow Gnus down considerably, unless you read news over a 2400 baud modem.

This variable can also have the value `some`. Gnus will then attempt to read active info only on the subscribed groups. On some servers this is quite fast (on sparkling, brand new INN servers that support the `LIST ACTIVE group` command), on others this isn't fast at all. In any case, `some` should be

faster than `nil`, and is certainly faster than `t` over slow lines.

If this variable is `nil`, Gnus will ask for group info in total lock-step, which isn't very fast. If it is `some` and you use an NNTP server, Gnus will pump out commands as fast as it can, and read all the replies in one swoop. This will normally result in better performance, but if the server does not support the aforementioned `LIST ACTIVE group` command, this isn't very nice to the server.

In any case, if you use `some` or `nil`, you should definitely kill all groups that you aren't interested in to speed things up.

Startup Variables

`gnus-load-hook`

A hook that is run while Gnus is being loaded. Note that this hook will normally be run just once in each Emacs session, no matter how many times you start Gnus.

`gnus-startup-hook`

A hook that is run after starting up Gnus successfully.

`gnus-check-bogus-newsgroups`

If non-`nil`, Gnus will check for and delete all bogus groups at startup. A bogus group is a group that you have in your `` `.newsrc' `` file, but doesn't exist on the news server. Checking for bogus groups can take quite a while, so to save time and resources it's best to leave this option off, and do the checking for bogus groups once in a while from the group buffer instead (see section Group Maintenance).

`gnus-inhibit-startup-message`

If non-`nil`, the startup message won't be displayed. That way, your boss might not notice that you are reading news instead of doing your job as easily.

`gnus-no-groups-message`

Message displayed by Gnus when no groups are available.

Go to the next section.

Go to the previous, next section.

The Group Buffer

The group buffer lists all (or parts) of the available groups. It is the first buffer shown when Gnus starts, and will never be killed as long as Gnus is active.

Group Buffer Format

Group Line Specification

The default format of the group buffer is nice and dull, but you can make it as exciting and ugly as you feel like.

Here's a couple of example group lines:

```
     25: news.announce.newusers
 *    0: alt.fan.andrea-dworkin
```

Quite simple, huh?

You can see that there are 25 unread articles in `news.announce.newusers'. There are no unread articles, but some ticked articles, in `alt.fan.andrea-dworkin' (see that little asterisk at the beginning of the line?)

You can change that format to whatever you want by fiddling with the `gnus-group-line-format` variable. This variable works along the lines of a `format` specification, which is pretty much the same as a `printf` specifications, for those of you who use (feh!) C. See section Formatting Variables.

The default value that produced those lines above is `%M%S%5y: %(%g%)\n'.

There should always be a colon on the line; the cursor always moves to the colon after performing an operation. Nothing else is required--not even the group name. All displayed text is just window dressing, and is never examined by Gnus. Gnus stores all real information it needs using text properties.

(Note that if you make a really strange, wonderful, spreadsheet-like layout, everybody will believe you are hard at work with the accounting instead of wasting time reading news.)

Here's a list of all available format characters:

`M'

Only marked articles.

`S'

Whether the group is subscribed.

`L'

Level of subscribedness.

`N'
: Number of unread articles.

`I'
: Number of dormant articles.

`T'
: Number of ticked articles.

`R'
: Number of read articles.

`t'
: Total number of articles.

`y'
: Number of unread, unticked, non-dormant articles.

`i'
: Number of ticked and dormant articles.

`g'
: Full group name.

`G'
: Group name.

`D'
: Newsgroup description.

`o'
: `m' if moderated.

`O'
: `(m)' if moderated.

`s'
: Select method.

`n'
: Select from where.

`z'
: A string that looks like `<%s:%n>' if a foreign select method is used.

`P'
: Indentation based on the level of the topic (see section Group Topics).

`c'
: Short (collapsed) group name. The `gnus-group-uncollapsed-levels` variable says how many levels to leave at the end of the group name. The default is `1`.

`u'
: User defined specifier. The next character in the format string should be a letter. GNUS will call

the function `gnus-user-format-function-`X', where `X' is the letter following `%u'. The function will be passed the current headers as argument. The function should return a string, which will be inserted into the buffer just like information from any other specifier.

All the "number-of" specs will be filled with an asterisk (`*') if no info is available--for instance, if it is a non-activated foreign group, or a bogus (or semi-bogus) native group.

Group Modeline Specification

The mode line can be changed by setting (`gnus-group-mode-line-format`). It doesn't understand that many format specifiers:

`S'

The native news server.

`M'

The native select method.

Group Highlighting

Highlighting in the group buffer is controlled by the `gnus-group-highlight` variable. This is an alist with elements that look like (form . face). If form evaluates to something non-`nil`, the face will be used on the line.

Here's an example value for this variable that might look nice if the background is dark:

```
(setq gnus-group-highlight
    `(((> unread 200) .
       ,(custom-face-lookup "Red" nil nil t nil nil))
      ((and (< level 3) (zerop unread)) .
       ,(custom-face-lookup "SeaGreen" nil nil t nil nil))
      ((< level 3) .
       ,(custom-face-lookup "SpringGreen" nil nil t nil nil))
      ((zerop unread) .
       ,(custom-face-lookup "SteelBlue" nil nil t nil nil))
      (t .
       ,(custom-face-lookup "SkyBlue" nil nil t nil nil))
      ))
```

Variables that are dynamically bound when the forms are evaluated include:

`group`

The group name.

`unread`

The number of unread articles in the group.

`method`

The select method.

`mailp`
: Whether the group is a mail group.

`level`
: The level of the group.

`score`
: The score of the group.

`ticked`
: The number of ticked articles in the group.

`topic`
: When using the topic minor mode, this variable is bound to the current topic being inserted.

When the forms are `eval`ed, point is at the beginning of the line of the group in question, so you can use many of the normal Gnus functions for snarfing info on the group.

`gnus-group-update-hook` is called when a group line is changed. It will not be called when `gnus-visual` is `nil`. This hook calls `gnus-group-highlight-line` by default.

Group Maneuvering

All movement commands understand the numeric prefix and will behave as expected, hopefully.

n
: Go to the next group that has unread articles (`gnus-group-next-unread-group`).

p

DEL
: Go to the previous group group that has unread articles (`gnus-group-prev-unread-group`).

N
: Go to the next group (`gnus-group-next-group`).

P
: Go to the previous group (`gnus-group-prev-group`).

M-p
: Go to the next unread group on the same level (or lower) (`gnus-group-next-unread-group-same-level`).

M-n
: Go to the previous unread group on the same level (or lower) (`gnus-group-prev-unread-group-same-level`).

Three commands for jumping to groups:

j
: Jump to a group (and make it visible if it isn't already) (`gnus-group-jump-to-group`).

Killed groups can be jumped to, just like living groups.

,

Jump to the unread group with the lowest level (`gnus-group-best-unread-group`).

.

Jump to the first group with unread articles (`gnus-group-first-unread-group`).

If `gnus-group-goto-unread` is `nil`, all the movement commands will move to the next group, not the next unread group. Even the commands that say they move to the next unread group. The default is `t`.

Selecting a Group

SPACE

Select the current group, switch to the summary buffer and display the first unread article (`gnus-group-read-group`). If there are no unread articles in the group, or if you give a non-numerical prefix to this command, Gnus will offer to fetch all the old articles in this group from the server. If you give a numerical prefix N, Gnus will fetch N number of articles. If N is positive, fetch the N newest articles, if N is negative, fetch the abs(N) oldest articles.

RET

Select the current group and switch to the summary buffer (`gnus-group-select-group`). Takes the same arguments as `gnus-group-read-group`---the only difference is that this command does not display the first unread article automatically upon group entry.

M-RET

This does the same as the command above, but tries to do it with the minimum amount off fuzz (`gnus-group-quick-select-group`). No scoring/killing will be performed, there will be no highlights and no expunging. This might be useful if you're in a real hurry and have to enter some humongous group.

M-SPACE

This is yet one more command that does the same as the one above, but this one does it without expunging and hiding dormants (`gnus-group-visible-select-group`).

c

Mark all unticked articles in this group as read (`gnus-group-catchup-current`). `gnus-group-catchup-group-hook` is when catching up a group from the group buffer.

C

Mark all articles in this group, even the ticked ones, as read (`gnus-group-catchup-current-all`).

The `gnus-large-newsgroup` variable says what Gnus should consider to be a big group. This is 200 by default. If the group has more unread articles than this, Gnus will query the user before entering the group. The user can then specify how many articles should be fetched from the server. If the user specifies a negative number (`-n`), the `n` oldest articles will be fetched. If it is positive, the `n` articles that have arrived most recently will be fetched.

`gnus-auto-select-first` control whether any articles are selected automatically when entering a group.

`nil`

Don't select any articles when entering the group. Just display the full summary buffer.

`t`

Select the first unread article when entering the group.

`best`

Select the most high-scored article in the group when entering the group.

If you want to prevent automatic selection in some group (say, in a binary group with Huge articles) you can set this variable to `nil` in `gnus-select-group-hook`, which is called when a group is selected.

Subscription Commands

S t

u

Toggle subscription to the current group (`gnus-group-unsubscribe-current-group`).

S s

U

Prompt for a group to subscribe, and then subscribe it. If it was subscribed already, unsubscribe it instead (`gnus-group-unsubscribe-group`).

S k

C-k

Kill the current group (`gnus-group-kill-group`).

S y

C-y

Yank the last killed group (`gnus-group-yank-group`).

C-x C-t

Transpose two groups (`gnus-group-transpose-groups`). This isn't really a subscription command, but you can use it instead of a kill-and-yank sequence sometimes.

S w

C-w

Kill all groups in the region (`gnus-group-kill-region`).

S z

Kill all zombie groups (`gnus-group-kill-all-zombies`).

S C-k

Kill all groups on a certain level (`gnus-group-kill-level`). These groups can't be yanked back after killing, so this command should be used with some caution. The only thing where this

command comes in really handy is when you have a `.newsrc' with lots of unsubscribed groups that you want to get rid off. S C-k on level 7 will kill off all unsubscribed groups that do not have message numbers in the `.newsrc' file.

Also see section Group Levels.

Group Levels

All groups have a level of subscribedness. For instance, if a group is on level 2, it is more subscribed than a group on level 5. You can ask Gnus to just list groups on a given level or lower (see section Listing Groups), or to just check for new articles in groups on a given level or lower (see section Scanning New Messages).

Remember: The higher the level of the group, the less important it is.

S l

Set the level of the current group. If a numeric prefix is given, the next n groups will have their levels set. The user will be prompted for a level.

Gnus considers groups on between levels 1 and `gnus-level-subscribed` (inclusive) (default 5) to be subscribed, `gnus-level-subscribed` (exclusive) and `gnus-level-unsubscribed` (inclusive) (default 7) to be unsubscribed, `gnus-level-zombie` to be zombies (walking dead) (default 8) and `gnus-level-killed` to be killed (default 9), completely dead. Gnus treats subscribed and unsubscribed groups exactly the same, but zombie and killed groups have no information on what articles you have read, etc, stored. This distinction between dead and living groups isn't done because it is nice or clever, it is done purely for reasons of efficiency.

It is recommended that you keep all your mail groups (if any) on quite low levels (eg. 1 or 2).

If you want to play with the level variables, you should show some care. Set them once, and don't touch them ever again. Better yet, don't touch them at all unless you know exactly what you're doing.

Two closely related variables are `gnus-level-default-subscribed` (default 3) and `gnus-level-default-unsubscribed` (default 6), which are the levels that new groups will be put on if they are (un)subscribed. These two variables should, of course, be inside the relevant legal ranges.

If `gnus-keep-same-level` is non-`nil`, some movement commands will only move to groups that are of the same level (or lower). In particular, going from the last article in one group to the next group will go to the next group of the same level (or lower). This might be handy if you want to read the most important groups before you read the rest.

All groups with a level less than or equal to `gnus-group-default-list-level` will be listed in the group buffer by default.

If `gnus-group-list-inactive-groups` is non-`nil`, non-active groups will be listed along with the unread groups. This variable is `t` by default. If it is `nil`, inactive groups won't be listed.

If `gnus-group-use-permanent-levels` is non-`nil`, once you give a level prefix to g or l, all

subsequent commands will use this level as the "work" level.

Gnus will normally just activate groups that are on level `gnus-activate-level` or less. If you don't want to activate unsubscribed groups, for instance, you might set this variable to `5`.

Group Score

You would normally keep important groups on high levels, but that scheme is somewhat restrictive. Don't you wish you could have Gnus sort the group buffer according to how often you read groups, perhaps? Within reason?

This is what group score is for. You can assign a score to each group. You can then sort the group buffer based on this score. Alternatively, you can sort on score and then level. (Taken together, the level and the score is called the rank of the group. A group that is on level 4 and has a score of 1 has a higher rank than a group on level 5 that has a score of 300. (The level is the most significant part and the score is the least significant part.)

If you want groups you read often to get higher scores than groups you read seldom you can add the `gnus-summary-bubble-group` function to the `gnus-summary-exit-hook` hook. This will result (after sorting) in a bubbling sort of action. If you want to see that in action after each summary exit, you can add `gnus-group-sort-groups-by-rank` or `gnus-group-sort-groups-by-score` to the same hook, but that will slow things down somewhat.

Marking Groups

If you want to perform some command on several groups, and they appear subsequently in the group buffer, you would normally just give a numerical prefix to the command. Most group commands will then do your bidding on those groups.

However, if the groups are not in sequential order, you can still perform a command on several groups. You simply mark the groups first with the process mark and then execute the command.

#

M m

Set the mark on the current group (`gnus-group-mark-group`).

M-#

M u

Remove the mark from the current group (`gnus-group-unmark-group`).

M U

Remove the mark from all groups (`gnus-group-unmark-all-groups`).

M w

Mark all groups between point and mark (`gnus-group-mark-region`).

M b

Mark all groups in the buffer (`gnus-group-mark-buffer`).

M r

Mark all groups that match some regular expression (`gnus-group-mark-regexp`).

Also see section Process/Prefix.

If you want to execute some command on all groups that have been marked with the process mark, you can use the M-& (`gnus-group-universal-argument`) command. It will prompt you for the command to be executed.

Foreign Groups

Here are some group mode commands for making and editing general foreign groups, as well as commands to ease the creation of a few special-purpose groups:

G m

Make a new group (`gnus-group-make-group`). Gnus will prompt you for a name, a method and possibly an address. For an easier way to subscribe to NNTP groups, see section Browse Foreign Server.

G r

Rename the current group to something else (`gnus-group-rename-group`). This is legal only on some groups -- mail groups mostly. This command might very well be quite slow on some backends.

G e

Enter a buffer where you can edit the select method of the current group (`gnus-group-edit-group-method`).

G p

Enter a buffer where you can edit the group parameters (`gnus-group-edit-group-parameters`).

G E

Enter a buffer where you can edit the group info (`gnus-group-edit-group`).

G d

Make a directory group. You will be prompted for a directory name (`gnus-group-make-directory-group`).

G h

Make the Gnus help group (`gnus-group-make-help-group`).

G a

Make a Gnus archive group (`gnus-group-make-archive-group`). By default a group pointing to the most recent articles will be created (`gnus-group-recent-archive-directory`), but given a prefix, a full group will be created from from `gnus-group-archive-directory`.

G k

Make a kiboze group. You will be prompted for a name, for a regexp to match groups to be "included" in the kiboze group, and a series of strings to match on headers (`gnus-group-make-kiboze-group`). See section Kibozed Groups

G D

Read an arbitrary directory as if with were a newsgroup with the `nneething` backend (`gnus-group-enter-directory`).

G f

Make a group based on some file or other (`gnus-group-make-doc-group`). If you give a prefix to this command, you will be prompted for a file name and a file type. Currently supported types are `babyl`, `mbox`, `digest`, `mmdf`, `news`, `rnews`, `clari-briefs`, and `forward`. If you run this command without a prefix, Gnus will guess at the file type.

G DEL

This function will delete the current group (`gnus-group-delete-group`). If given a prefix, this function will actually delete all the articles in the group, and forcibly remove the group itself from the face of the Earth. Use a prefix only if you are absolutely sure of what you are doing.

G V

Make a new, fresh, empty `nnvirtual` group (`gnus-group-make-empty-virtual`).

G v

Add the current group to an `nnvirtual` group (`gnus-group-add-to-virtual`). Uses the process/prefix convention.

See section Select Methods for more information on the various select methods.

If the `gnus-activate-foreign-newsgroups` is a positive number, Gnus will check all foreign groups with this level or lower at startup. This might take quite a while, especially if you subscribe to lots of groups from different NNTP servers.

Group Parameters

Gnus stores all information on a group in a list that is usually known as the group info. This list has from three to six elements. Here's an example info.

```
("nnml:mail.ding" 3 ((1 . 232) 244 (256 . 270)) ((tick 246 249))
                  (nnml "private") ((to-address . "ding@ifi.uio.no")))
```

The first element is the group name, as Gnus knows the group, anyway. The second element is the subscription level, which normally is a small integer. The third element is a list of ranges of read articles. The fourth element is a list of lists of article marks of various kinds. The fifth element is the select method (or virtual server, if you like). The sixth element is a list of group parameters, which is what this section is about.

Any of the last three elements may be missing if they are not required. In fact, the vast majority of groups

will normally only have the first three elements, which saves quite a lot of cons cells.

The group parameters store information local to a particular group:

`to-address`

If the group parameter list contains an element that looks like `(to-address . "some@where.com")`, that address will be used by the backend when doing followups and posts. This is primarily useful in mail groups that represent closed mailing lists--mailing lists where it's expected that everybody that writes to the mailing list is subscribed to it. Since using this parameter ensures that the mail only goes to the mailing list itself, it means that members won't receive two copies of your followups.

Using `to-address` will actually work whether the group is foreign or not. Let's say there's a group on the server that is called `fa.4ad-l'. This is a real newsgroup, but the server has gotten the articles from a mail-to-news gateway. Posting directly to this group is therefore impossible--you have to send mail to the mailing list address instead.

`to-list`

If the group parameter list has an element that looks like `(to-list . "some@where.com")`, that address will be used when doing a a in any group. It is totally ignored when doing a followup--except that if it is present in a news group, you'll get mail group semantics when doing f.

`broken-reply-to`

Elements like `(broken-reply-to . t)` signals that `Reply-To` headers in this group are to be ignored. This can be useful if you're reading a mailing list group where the listserv has inserted `Reply-To` headers that point back to the listserv itself. This is broken behavior. So there!

`to-group`

If the group parameter list contains an element like `(to-group . "some.group.name")`, all posts will be sent to that group.

`auto-expire`

If this symbol is present in the group parameter list, all articles that are read will be marked as expirable. For an alternative approach, see section Expiring Mail.

`total-expire`

If this symbol is present, all read articles will be put through the expiry process, even if they are not marked as expirable. Use with caution.

`expiry-wait`

If the group parameter has an element that looks like `(expiry-wait . 10)`, this value will override any `nnmail-expiry-wait` and `nnmail-expiry-wait-function` when expiring expirable messages. The value can either be a number of days (not necessarily an integer) or the symbols `never` or `immediate`.

`score-file`

Elements that look like `(score-file . "file")` will make `file' into the current score file for the group in question. This means that all score commands you issue will end up in that file.

`admin-address`

When unsubscribing to a mailing list you should never send the unsubscription notice to the mailing list itself. Instead, you'd send messages to the administrative address. This parameter allows you to put the admin address somewhere convenient.

`comment`

This parameter allows you to enter a arbitrary comment on the group.

`(variable form)`

You can use the group parameters to set variables local to the group you are entering. Say you want to turn threading off in `news.answers'. You'd then put `(gnus-show-threads nil)` in the group parameters of that group. `gnus-show-threads` will be made into a local variable in the summary buffer you enter, and the form `nil` will be `eval`ed there.

This can also be used as a group-specific hook function, if you'd like. If you want to hear a beep when you enter the group `alt.binaries.pictures.furniture', you could put something like `(dummy-variable (ding))` in the parameters of that group. `dummy-variable` will be set to the result of the `(ding)` form, but who cares?

If you want to change the group info you can use the G E command to enter a buffer where you can edit it.

You usually don't want to edit the entire group info, so you'd be better off using the G p command to just edit the group parameters.

Listing Groups

These commands all list various slices of the groups that are available.

l

A s

List all groups that have unread articles (`gnus-group-list-groups`). If the numeric prefix is used, this command will list only groups of level ARG and lower. By default, it only lists groups of level five or lower (i.e., just subscribed groups).

L

A u

List all groups, whether they have unread articles or not (`gnus-group-list-all-groups`). If the numeric prefix is used, this command will list only groups of level ARG and lower. By default, it lists groups of level seven or lower (i.e., just subscribed and unsubscribed groups).

A l

List all unread groups on a specific level (`gnus-group-list-level`). If given a prefix, also list the groups with no unread articles.

A k

List all killed groups (`gnus-group-list-killed`). If given a prefix argument, really list all groups that are available, but aren't currently (un)subscribed. This could entail reading the active file from the server.

A z

List all zombie groups (`gnus-group-list-zombies`).

A m

List all subscribed groups with unread articles that match a regexp (`gnus-group-list-matching`).

A M

List groups that match a regexp (`gnus-group-list-all-matching`).

A A

List absolutely all groups that are in the active file(s) of the server(s) you are connected to (`gnus-group-list-active`). This might very well take quite a while. It might actually be a better idea to do a A m to list all matching, and just give `.' as the thing to match on.

A a

List all groups that have names that match a regexp (`gnus-group-apropos`).

A d

List all groups that have names or descriptions that match a regexp (`gnus-group-description-apropos`).

Groups that match the `gnus-permanently-visible-groups` regexp will always be shown, whether they have unread articles or not. You can also add the `visible` element to the group parameters in question to get the same effect.

Groups that have just ticked articles in it are normally listed in the group buffer. If `gnus-list-groups-with-ticked-articles` is `nil`, these groups will be treated just like totally empty groups. It is `t` by default.

Sorting Groups

The C-c C-s (`gnus-group-sort-groups`) command sorts the group buffer according to the function(s) given by the `gnus-group-sort-function` variable. Available sorting functions include:

`gnus-group-sort-by-alphabet`

Sort the group names alphabetically. This is the default.

`gnus-group-sort-by-level`

Sort by group level.

`gnus-group-sort-by-score`

Sort by group score.

`gnus-group-sort-by-rank`

Sort by group score and then the group level. The level and the score are, when taken together, the group's rank.

`gnus-group-sort-by-unread`

Sort by number of unread articles.

`gnus-group-sort-by-method`

Sort by alphabetically on the select method.

`gnus-group-sort-function` can also be a list of sorting functions. In that case, the most significant sort key function must be the last one.

There are also a number of commands for sorting directly according to some sorting criteria:

G S a

Sort the group buffer alphabetically by group name (`gnus-group-sort-groups-by-alphabet`).

G S u

Sort the group buffer by the number of unread articles (`gnus-group-sort-groups-by-unread`).

G S l

Sort the group buffer by group level (`gnus-group-sort-groups-by-level`).

G S v

Sort the group buffer by group score (`gnus-group-sort-groups-by-score`).

G S r

Sort the group buffer by group level (`gnus-group-sort-groups-by-rank`).

G S m

Sort the group buffer alphabetically by backend name (`gnus-group-sort-groups-by-method`).

When given a prefix, all these commands will sort in reverse order.

Group Maintenance

b

Find bogus groups and delete them (`gnus-group-check-bogus-groups`).

F

Find new groups and process them (`gnus-find-new-newsgroups`). If given a prefix, use the `ask-server` method to query the server for new groups.

C-c C-x

Run all expirable articles in the current group through the expiry process (if any) (`gnus-group-expire-articles`).

C-c M-C-x

Run all articles in all groups through the expiry process (`gnus-group-expire-all-groups`).

Browse Foreign Server

B

You will be queried for a select method and a server name. Gnus will then attempt to contact this server and let you browse the groups there (`gnus-group-browse-foreign-server`).

A new buffer with a list of available groups will appear. This buffer will be use the `gnus-browse-mode`. This buffer looks a bit (well, a lot) like a normal group buffer, but with one major difference - you can't enter any of the groups. If you want to read any of the news available on that server, you have to subscribe to the groups you think may be interesting, and then you have to exit this buffer. The new groups will be added to the group buffer, and then you can read them as you would any other group.

Future versions of Gnus may possibly permit reading groups straight from the browse buffer.

Here's a list of keystrokes available in the browse mode:

n

Go to the next group (`gnus-group-next-group`).

p

Go to the previous group (`gnus-group-prev-group`).

SPACE

Enter the current group and display the first article (`gnus-browse-read-group`).

RET

Enter the current group (`gnus-browse-select-group`).

u

Unsubscribe to the current group, or, as will be the case here, subscribe to it (`gnus-browse-unsubscribe-current-group`).

l

q

Exit browse mode (`gnus-browse-exit`).

?

Describe browse mode briefly (well, there's not much to describe, is there) (`gnus-browse-describe-briefly`).

Exiting Gnus

Yes, Gnus is ex(c)iting.

z

Suspend Gnus (`gnus-group-suspend`). This doesn't really exit Gnus, but it kills all buffers except the Group buffer. I'm not sure why this is a gain, but then who am I to judge?

q
: Quit Gnus (`gnus-group-exit`).

Q
: Quit Gnus without saving any startup files (`gnus-group-quit`).

`gnus-suspend-gnus-hook` is called when you suspend Gnus and `gnus-exit-gnus-hook` is called when you quit Gnus, while `gnus-after-exiting-gnus-hook` is called as the final item when exiting Gnus.

If you wish to completely unload Gnus and all its adherents, you can use the `gnus-unload` command. This command is also very handy when trying to customize meta-variables.

Note:

> Miss Lisa Cannifax, while sitting in English class, feels her feet go numbly heavy and herself fall into a hazy trance as the boy sitting behind her drew repeated lines with his pencil across the back of her plastic chair.

Group Topics

If you read lots and lots of groups, it might be convenient to group them hierarchically according to topics. You put your Emacs groups over here, your sex groups over there, and the rest (what, two groups or so?) you put in some misc section that you never bother with anyway. You can even group the Emacs sex groups as a sub-topic to either the Emacs groups or the sex groups--or both! Go wild!

To get this *fab* functionality you simply turn on (ooh!) the `gnus-topic` minor mode--type t in the group buffer. (This is a toggling command.)

Go ahead, just try it. I'll still be here when you get back. La de dum... Nice tune, that... la la la... What, you're back? Yes, and now press l. There. All your groups are now listed under `misc'. Doesn't that make you feel all warm and fuzzy? Hot and bothered?

If you want this permanently enabled, you should add that minor mode to the hook for the group mode:

```
(add-hook 'gnus-group-mode-hook 'gnus-topic-mode)
```

Topic Variables

Now, if you select a topic, if will fold/unfold that topic, which is really neat, I think.

The topic lines themselves are created according to the `gnus-topic-line-format` variable. See section Formatting Variables. Elements allowed are:

`i'
: Indentation.

`n'
: Topic name.

`v'

Visibility.

`l'

Level.

`g'

Number of groups in the topic.

`a'

Number of unread articles in the topic.

`A'

Number of unread articles in the topic and all its subtopics.

Each sub-topic (and the groups in the sub-topics) will be indented with `gnus-topic-indent-level` times the topic level number of spaces. The default is `2`.

`gnus-topic-mode-hook` is called in topic minor mode buffers.

Topic Commands

When the topic minor mode is turned on, a new T submap will be available. In addition, a few of the standard keys change their definitions slightly.

T n

Prompt for a new topic name and create it (`gnus-topic-create-topic`).

T m

Move the current group to some other topic (`gnus-topic-move-group`). This command understands the process/prefix convention (see section Process/Prefix).

T c

Copy the current group to some other topic (`gnus-topic-copy-group`). This command understands the process/prefix convention (see section Process/Prefix).

T D

Remove a group from the current topic (`gnus-topic-remove-group`). This command understands the process/prefix convention (see section Process/Prefix).

T M

Move all groups that match some regular expression to a topic (`gnus-topic-move-matching`).

T C

Copy all groups that match some regular expression to a topic (`gnus-topic-copy-matching`).

T #

Mark all groups in the current topic with the process mark (`gnus-topic-mark-topic`).

T M-#

Remove the process mark from all groups in the current topic (`gnus-topic-unmark-top`).

RET

SPACE

Either select a group or fold a topic (`gnus-topic-select-group`). When you perform this command on a group, you'll enter the group, as usual. When done on a topic line, the topic will be folded (if it was visible) or unfolded (if it was folded already). So it's basically a toggling command on topics. In addition, if you give a numerical prefix, group on that level (and lower) will be displayed.

T TAB

"Indent" the current topic so that it becomes a sub-topic of the previous topic (`gnus-topic-indent`). If given a prefix, "un-indent" the topic instead.

C-k

Kill a group or topic (`gnus-topic-kill-group`).

C-y

Yank the previously killed group or topic (`gnus-topic-yank-group`). Note that all topics will be yanked before all groups.

T r

Rename a topic (`gnus-topic-rename`).

T DEL

Delete an empty topic (`gnus-topic-delete`).

A T

List all groups that Gnus knows about in a topics-ified way (`gnus-topic-list-active`).

Topic Topology

So, let's have a look at an example group buffer:

```
Gnus
  Emacs -- I wuw it!
       3: comp.emacs
       2: alt.religion.emacs
    Naughty Emacs
     452: alt.sex.emacs
       0: comp.talk.emacs.recovery
  Misc
       8: comp.binaries.fractals
      13: comp.sources.unix
```

So, here we have one top-level topic, two topics under that, and one sub-topic under one of the sub-topics. (There is always just one (1) top-level topic). This topology can be expressed as follows:

```
(("Gnus" visible)
 (("Emacs -- I wuw it!" visible)
  (("Naughty Emacs" visible)))
 (("Misc" visible)))
```

This is in fact how the variable `gnus-topic-topology` would look for the display above. That variable is saved in the `.newsrc.eld' file, and shouldn't be messed with manually--unless you really want to. Since this variable is read from the `.newsrc.eld' file, setting it in any other startup files will have no effect.

This topology shows what topics are sub-topics of what topics (right), and which topics are visible. Two settings are currently allowed---`visible` and `invisible`.

Misc Group Stuff

^

Enter the server buffer (`gnus-group-enter-server-mode`). See section The Server Buffer.

a

Post an article to a group (`gnus-group-post-news`). The current group name will be used as the default.

m

Mail a message somewhere (`gnus-group-mail`).

Variables for the group buffer:

`gnus-group-mode-hook`

`gnus-group-mode-hook` is called after the group buffer has been created.

`gnus-group-prepare-hook`

`gnus-group-prepare-hook` is called after the group buffer is generated. It may be used to modify the buffer in some strange, unnatural way.

`gnus-permanently-visible-groups`

Groups matching this regexp will always be listed in the group buffer, whether they are empty or not.

Scanning New Messages

g

Check the server(s) for new articles. If the numerical prefix is used, this command will check only groups of level arg and lower (`gnus-group-get-new-news`). If given a non-numerical prefix, this command will force a total rereading of the active file(s) from the backend(s).

M-g

Check whether new articles have arrived in the current group (`gnus-group-get-new-news-this-group`). The

`gnus-goto-next-group-when-activating` variable controls whether this command moves point to the next group or not. It is `t` by default.

C-c M-g

Activate absolutely all groups (`gnus-activate-all-groups`).

R

Restart Gnus (`gnus-group-restart`).

`gnus-get-new-news-hook` is run just before checking for new news.

`gnus-after-getting-new-news-hook` is run after checking for new news.

Group Information

M-f

Try to fetch the FAQ for the current group (`gnus-group-fetch-faq`). Gnus will try to get the FAQ from `gnus-group-faq-directory`, which is usually a directory on a remote machine. `ange-ftp` will be used for fetching the file.

D

Describe the current group (`gnus-group-describe-group`). If given a prefix, force Gnus to re-read the description from the server.

M-d

Describe all groups (`gnus-group-describe-all-groups`). If given a prefix, force Gnus to re-read the description file from the server.

V

Display current Gnus version numbers (`gnus-version`).

?

Give a very short help message (`gnus-group-describe-briefly`).

C-c C-i

Go to the Gnus info node (`gnus-info-find-node`).

File Commands

r

Read the init file (`gnus-init-file`, which defaults to `` `~/.gnus' ``) (`gnus-group-read-init-file`).

s

Save the `` `.newsrc.eld' `` file (and `` `.newsrc' `` if wanted) (`gnus-group-save-newsrc`). If given a prefix, force saving the file(s) whether Gnus thinks it is necessary or not.

Go to the previous, next section.

Go to the previous, next section.

The Summary Buffer

A line for each article is displayed in the summary buffer. You can move around, read articles, post articles and reply to articles.

Summary Buffer Format

Gnus will use the value of the `gnus-extract-address-components` variable as a function for getting the name and address parts of a `From` header. Two pre-defined function exist: `gnus-extract-address-components`, which is the default, quite fast, and too simplistic solution; and `mail-extract-address-components`, which works very nicely, but is slower. The default function will return the wrong answer in 5% of the cases. If this is unacceptable to you, use the other function instead.

`gnus-summary-same-subject` is a string indicating that the current article has the same subject as the previous. This string will be used with those specs that require it. The default is `'.

Summary Buffer Lines

You can change the format of the lines in the summary buffer by changing the `gnus-summary-line-format` variable. It works along the same lines a a normal `format` string, with some extensions.

The default string is `%U%R%z%I%(%[%4L: %-20,20n%]%) %s\n'.

The following format specification characters are understood:

`N'
: Article number.

`S'
: Subject string.

`s'
: Subject if the article is the root, `gnus-summary-same-subject` otherwise.

`F'
: Full `From` line.

`n'
: The name (from the `From` header).

`a'
: The name (from the `From` header). This differs from the `n` spec in that it uses `gnus-extract-address-components`, which is slower, but may be more thorough.

`A'

The address (from the `From` header). This works the same way as the `a` spec.

`L'

Number of lines in the article.

`c'

Number of characters in the article.

`I'

Indentation based on thread level (see section Customizing Threading).

`T'

Nothing if the article is a root and lots of spaces if it isn't (it pushes everything after it off the screen).

`\['

Opening bracket, which is normally `\[', but can also be `<' for adopted articles.

`\]'

Closing bracket, which is normally `\]', but can also be `>' for adopted articles.

`>'

One space for each thread level.

`<'

Twenty minus thread level spaces.

`U'

Unread.

`R'

Replied.

`i'

Score as a number.

`z'

Zcore, `+' if above the default level and `-' if below the default level. If the difference between `gnus-summary-default-level` and the score is less than `gnus-summary-zcore-fuzz`, this spec will not be used.

`V'

Total thread score.

`x'

`Xref`.

`D'

`Date`.

`M'

`Message-ID`.

`r'

`References`.

`t'

Number of articles in the current sub-thread. Using this spec will slow down summary buffer generation somewhat.

`e'

A single character will be displayed if the article has any children.

`u'

User defined specifier. The next character in the format string should be a letter. GNUS will call the function `gnus-user-format-function-`X', where `X' is the letter following `%u'. The function will be passed the current header as argument. The function should return a string, which will be inserted into the summary just like information from any other summary specifier.

The `%U' (status), `%R' (replied) and `%z' (zcore) specs have to be handled with care. For reasons of efficiency, Gnus will compute what column these characters will end up in, and "hard-code" that. This means that it is illegal to have these specs after a variable-length spec. Well, you might not be arrested, but your summary buffer will look strange, which is bad enough.

The smart choice is to have these specs as far to the left as possible. (Isn't that the case with everything, though? But I digress.)

This restriction may disappear in later versions of Gnus.

Summary Buffer Mode Line

You can also change the format of the summary mode bar. Set `gnus-summary-mode-line-format` to whatever you like. Here are the elements you can play with:

`G'

Group name.

`p'

Unprefixed group name.

`A'

Current article number.

`V'

Gnus version.

`U'

Number of unread articles in this group.

`e'

Number of unselected articles in this group.

`Z'

A string with the number of unread and unselected articles represented either as `<%U(+%u) more>' if there are both unread and unselected articles, and just as `<%U more>' if there are just unread articles and no unselected ones.

`g'

Shortish group name. For instance, `rec.arts.anime' will be shortened to `r.a.anime'.

`S'

Subject of the current article.

`u'

Used-defined spec.

`s'

Name of the current score file.

`d'

Number of dormant articles.

`t'

Number of ticked articles.

`r'

Number of articles that have been marked as read in this session.

`E'

Number of articles expunged by the score files.

Summary Highlighting

`gnus-visual-mark-article-hook`

This hook is run after selecting an article. It is meant to be used for highlighting the article in some way. It is not run if `gnus-visual` is `nil`.

`gnus-summary-update-hook`

This hook is called when a summary line is changed. It is not run if `gnus-visual` is `nil`.

`gnus-summary-selected-face`

This is the face (or font as some people call it) that is used to highlight the current article in the summary buffer.

`gnus-summary-highlight`

Summary lines are highlighted according to this variable, which is a list where the elements are on the format `(FORM . FACE)`. If you would, for instance, like ticked articles to be italic and high-scored articles to be bold, you could set this variable to something like

```
(((eq mark gnus-ticked-mark) . italic)
 ((> score default) . bold))
```

As you may have guessed, if FORM returns a non-`nil` value, FACE will be applied to the line.

Summary Maneuvering

All the straight movement commands understand the numeric prefix and behave pretty much as you'd expect.

None of these commands select articles.

G M-n

M-n

Go to the next summary line of an unread article (`gnus-summary-next-unread-subject`).

G M-p

M-p

Go to the previous summary line of an unread article (`gnus-summary-prev-unread-subject`).

G j

j

Ask for an article number and then go that article (`gnus-summary-goto-article`).

G g

Ask for an article number and then go the summary line of that article (`gnus-summary-goto-subject`).

If Gnus asks you to press a key to confirm going to the next group, you can use the C-n and C-p keys to move around the group buffer, searching for the next group to read without actually returning to the group buffer.

Variables related to summary movement:

`gnus-auto-select-next`

If you are at the end of the group and issue one of the movement commands, Gnus will offer to go to the next group. If this variable is `t` and the next group is empty, Gnus will exit summary mode and return to the group buffer. If this variable is neither `t` nor `nil`, Gnus will select the next group, no matter whether it has any unread articles or not. As a special case, if this variable is `quietly`, Gnus will select the next group without asking for confirmation. If this variable is `almost-quietly`, the same will happen only if you are located on the last article in the group. Finally, if this variable is `slightly-quietly`, the Z n command will go to the next group without confirmation. Also see section Group Levels.

`gnus-auto-select-same`

If non-`nil`, all the movement commands will try to go to the next article with the same subject as the current. This variable is not particularly useful if you use a threaded display.

`gnus-summary-check-current`

If non-`nil`, all the "unread" movement commands will not proceed to the next (or previous) article if the current article is unread. Instead, they will choose the current article.

`gnus-auto-center-summary`

If non-`nil`, Gnus will keep the point in the summary buffer centered at all times. This makes things quite tidy, but if you have a slow network connection, or simply do not like this un-Emacsism, you can set this variable to `nil` to get the normal Emacs scrolling action. This will also inhibit horizontal re-centering of the summary buffer, which might make it more inconvenient to read extremely long threads.

Choosing Articles

None of the following movement commands understand the numeric prefix, and they all select and display an article.

SPACE

Select the current article, or, if that one's read already, the next unread article (`gnus-summary-next-page`).

G n

n

Go to next unread article (`gnus-summary-next-unread-article`).

G p

p

Go to previous unread article (`gnus-summary-prev-unread-article`).

G N

N

Go to the next article (`gnus-summary-next-article`).

G P

P

Go to the previous article (`gnus-summary-prev-article`).

G C-n

Go to the next article with the same subject (`gnus-summary-next-same-subject`).

G C-p

Go to the previous article with the same subject (`gnus-summary-prev-same-subject`).

G f

.

Go to the first unread article (`gnus-summary-first-unread-article`).

G b

,

Go to the article with the highest score (`gnus-summary-best-unread-article`).

G l

l

Go to the previous article read (`gnus-summary-goto-last-article`).

G p

Pop an article off the summary history and go to this article (`gnus-summary-pop-article`). This command differs from the command above in that you can pop as many previous articles off the history as you like.

Some variables that are relevant for moving and selecting articles:

`gnus-auto-extend-newsgroup`

All the movement commands will try to go to the previous (or next) article, even if that article isn't displayed in the Summary buffer if this variable is non-`nil`. Gnus will then fetch the article from the server and display it in the article buffer.

`gnus-select-article-hook`

This hook is called whenever an article is selected. By default it exposes any threads hidden under the selected article.

`gnus-mark-article-hook`

This hook is called whenever an article is selected. It is intended to be used for marking articles as read. The default value is `gnus-summary-mark-read-and-unread-as-read`, and will change the mark of almost any article you read to `gnus-unread-mark`. The only articles not affected by this function are ticked, dormant, and expirable articles. If you'd instead like to just have unread articles marked as read, you can use `gnus-summary-mark-unread-as-read` instead. It will leave marks like `gnus-low-score-mark`, `gnus-del-mark` (and so on) alone.

Scrolling the Article

SPACE

Pressing SPACE will scroll the current article forward one page, or, if you have come to the end of the current article, will choose the next article (`gnus-summary-next-page`).

DEL

Scroll the current article back one page (`gnus-summary-prev-page`).

RET

Scroll the current article one line forward (`gnus-summary-scroll-up`).

A g

g

(Re)fetch the current article (`gnus-summary-show-article`). If given a prefix, fetch the current article, but don't run any of the article treatment functions. This will give you a "raw" article, just the way it came from the server.

A <

<

Scroll to the beginning of the article (`gnus-summary-beginning-of-article`).

A >

>

Scroll to the end of the article (`gnus-summary-end-of-article`).

A s

Perform an isearch in the article buffer (`gnus-summary-isearch-article`).

Reply, Followup and Post

Summary Mail Commands

Commands for composing a mail message:

S r

r

Mail a reply to the author of the current article (`gnus-summary-reply`).

S R

R

Mail a reply to the author of the current article and include the original message (`gnus-summary-reply-with-original`). This command uses the process/prefix convention.

S o m

Forward the current article to some other person (`gnus-summary-mail-forward`).

S o p

Forward the current article to a newsgroup (`gnus-summary-post-forward`).

S m

m

Send a mail to some other person (`gnus-summary-mail-other-window`).

S D b

If you have sent a mail, but the mail was bounced back to you for some reason (wrong address, transient failure), you can use this command to resend that bounced mail (`gnus-summary-resend-bounced-mail`). You will be popped into a mail buffer where you can edit the headers before sending the mail off again. If you give a prefix to this command, and the bounced mail is a reply to some other mail, Gnus will try to fetch that mail and display it for easy perusal of its headers. This might very well fail, though.

S D r

Not to be confused with the previous command, `gnus-summary-resend-message` will prompt you for an address to send the current message off to, and then send it to that place. The headers of the message won't be altered--but lots of headers that say `Resent-To`, `Resent-From` and so on will be added. This means that you actually send a mail to someone that has a `To` header that (probably) points to yourself. This will confuse people. So, natcherly you'll only do that if you're really eVIl.

This command is mainly used if you have several accounts and want to ship a mail to a different account of yours. (If you're both `root` and `postmaster` and get a mail for `postmaster` to the `root` account, you may want to resend it to `postmaster`. Ordnung muss sein!

S O m

Digest the current series and forward the result using mail (`gnus-uu-digest-mail-forward`). This command uses the process/prefix convention (see section Process/Prefix).

S O p

Digest the current series and forward the result to a newsgroup (`gnus-uu-digest-mail-forward`).

Summary Post Commands

Commands for posting an article:

S p

a

Post an article to the current group (`gnus-summary-post-news`).

S f

f

Post a followup to the current article (`gnus-summary-followup`).

S F

F

Post a followup to the current article and include the original message (`gnus-summary-followup-with-original`). This command uses the process/prefix convention.

S u

Uuencode a file, split it into parts, and post it as a series (`gnus-uu-post-news`). (see section Uuencoding and Posting).

Canceling Articles

Have you ever written something, and then decided that you really, really, really wish you hadn't posted that?

Well, you can't cancel mail, but you can cancel posts.

Find the article you wish to cancel (you can only cancel your own articles, so don't try any funny stuff). Then press C or S c (`gnus-summary-cancel-article`). Your article will be canceled--machines all over the world will be deleting your article.

Be aware, however, that not all sites honor cancels, so your article may live on here and there, while most sites will delete the article in question.

If you discover that you have made some mistakes and want to do some corrections, you can post a superseding article that will replace your original article.

Go to the original article and press S s (`gnus-summary-supersede-article`). You will be put in a buffer where you can edit the article all you want before sending it off the usual way.

The same goes for superseding as for canceling, only more so: Some sites do not honor superseding. On those sites, it will appear that you have posted almost the same article twice.

If you have just posted the article, and change your mind right away, there is a trick you can use to cancel/supersede the article without waiting for the article to appear on your site first. You simply return to the post buffer (which is called `*post-buf*`). There you will find the article you just posted, with all the headers intact. Change the `Message-ID` header to a `Cancel` or `Supersedes` header by substituting one of those words for `Message-ID`. Then just press C-c C-c to send the article as you would do normally. The previous article will be canceled/superseded.

Just remember, kids: There is no 'c' in 'supersede'.

Marking Articles

There are several marks you can set on an article.

You have marks that decide the readedness (whoo, neato-keano neologism ohoy!) of the article. Alphabetic marks generally mean read, while non-alphabetic characters generally mean unread.

In addition, you also have marks that do not affect readedness.

Unread Articles

The following marks mark articles as unread, in one form or other.

`!'

Ticked articles are articles that will remain visible always. If you see an article that you find interesting, or you want to put off reading it, or replying to it, until sometime later, you'd typically tick it. However, articles can be expired, so if you want to keep an article forever, you'll have to save it. Ticked articles have a `!' (`gnus-ticked-mark`) in the first column.

`?'

A dormant article is marked with a `?' (`gnus-dormant-mark`), and will only appear in the summary buffer if there are followups to it.

`SPACE'

An unread article is marked with a `SPACE' (`gnus-unread-mark`). These are articles that haven't been read at all yet.

Read Articles

All the following marks mark articles as read.

`r'

Articles that are marked as read. They have a `r' (`gnus-del-mark`) in the first column. These are articles that the user has marked as read more or less manually.

`R'

Articles that are actually read are marked with `R' (`gnus-read-mark`).

`O'

Articles that were marked as read in previous sessions are now old and marked with `O' (`gnus-ancient-mark`).

`K'

Marked as killed (`gnus-killed-mark`).

`X'

Marked as killed by kill files (`gnus-kill-file-mark`).

`Y'

Marked as read by having a too low score (`gnus-low-score-mark`).

`C'

Marked as read by a catchup (`gnus-catchup-mark`).

`G'

Canceled article (`gnus-canceled-mark`)

`F'

SOUPed article (`gnus-souped-mark`).

`Q'

Sparsely reffed article (`gnus-sparse-mark`).

All these marks just mean that the article is marked as read, really. They are interpreted differently by the adaptive scoring scheme, however.

One more special mark, though:

`E'

You can also mark articles as expirable (or have them marked as such automatically). That doesn't make much sense in normal groups, because a user does not control the expiring of news articles, but in mail groups, for instance, articles that are marked as expirable can be deleted by Gnus at any time. Expirable articles are marked with `E' (`gnus-expirable-mark`).

Other Marks

There are some marks that have nothing to do with whether the article is read or not.

- You can set a bookmark in the current article. Say you are reading a long thesis on cats' urinary tracts, and have to go home for dinner before you've finished reading the thesis. You can then set a bookmark in the article, and Gnus will jump to this bookmark the next time it encounters the article.
- All articles that you have replied to or made a followup to (i.e., have answered) will be marked with an `A' in the second column (`gnus-replied-mark`).
- Articles that are stored in the article cache will be marked with an `*' in the second column (`gnus-cached-mark`).
- Articles that are "saved" (in some manner or other; not necessarily religiously) are marked with an `S' in the second column (`gnus-saved-mark`.
- It the `%e' spec is used, the presence of threads or not will be marked with `gnus-not-empty-thread-mark` and `gnus-empty-thread-mark` in the third column, respectively.
- Finally we have the process mark (`gnus-process-mark`. A variety of commands react to the presence of the process mark. For instance, X u (`gnus-uu-decode-uu`) will uudecode and view all articles that have been marked with the process mark. Articles marked with the process mark have a `#' in the second column.

You might have noticed that most of these "non-readedness" marks appear in the second column by default. So if you have a cached, saved, replied article that you have process-marked, what will that look like?

Nothing much. The precedence rules go as follows: process -> cache -> replied -> saved. So if the article is in the cache and is replied, you'll only see the cache mark and not the replied mark.

Setting Marks

All the marking commands understand the numeric prefix.

M t

!

Tick the current article (`gnus-summary-tick-article-forward`).

M ?

?

Mark the current article as dormant (`gnus-summary-mark-as-dormant`).

M d

d

Mark the current article as read (`gnus-summary-mark-as-read-forward`).

M k

k

Mark all articles that have the same subject as the current one as read, and then select the next unread article (`gnus-summary-kill-same-subject-and-select`).

M K

C-k

Mark all articles that have the same subject as the current one as read (`gnus-summary-kill-same-subject`).

M C

Mark all unread articles in the group as read (`gnus-summary-catchup`).

M C-c

Mark all articles in the group as read--even the ticked and dormant articles (`gnus-summary-catchup-all`).

M H

Catchup the current group to point (`gnus-summary-catchup-to-here`).

C-w

Mark all articles between point and mark as read (`gnus-summary-mark-region-as-read`).

M V k

Kill all articles with scores below the default score (or below the numeric prefix) (`gnus-summary-kill-below`).

M c

M-u

Clear all readedness-marks from the current article (`gnus-summary-clear-mark-forward`).

M e

E

Mark the current article as expirable (`gnus-summary-mark-as-expirable`).

M b

Set a bookmark in the current article (`gnus-summary-set-bookmark`).

M B

Remove the bookmark from the current article (`gnus-summary-remove-bookmark`).

M V c

Clear all marks from articles with scores over the default score (or over the numeric prefix) (`gnus-summary-clear-above`).

M V u

Tick all articles with scores over the default score (or over the numeric prefix) (`gnus-summary-tick-above`).

M V m

Prompt for a mark, and mark all articles with scores over the default score (or over the numeric prefix) with this mark (`gnus-summary-clear-above`).

The `gnus-summary-goto-unread` variable controls what action should be taken after setting a mark. If non-`nil`, point will move to the next/previous unread article. If `nil`, point will just move one line up or down. As a special case, if this variable is `never`, all the marking commands as well as other commands (like SPACE) will move to the next article, whether it is unread or not. The default is `t`.

Setting Process Marks

M P p

#

Mark the current article with the process mark (`gnus-summary-mark-as-processable`).

M P u

M-#

Remove the process mark, if any, from the current article (`gnus-summary-unmark-as-processable`).

M P U

Remove the process mark from all articles (`gnus-summary-unmark-all-processable`).

M P R

Mark articles by a regular expression (`gnus-uu-mark-by-regexp`).

M P r

Mark articles in region (`gnus-uu-mark-region`).

M P t

Mark all articles in the current (sub)thread (`gnus-uu-mark-thread`).

M P T

Unmark all articles in the current (sub)thread (`gnus-uu-unmark-thread`).

M P v

Mark all articles that have a score above the prefix argument (`gnus-uu-mark-over`).

M P s

Mark all articles in the current series (`gnus-uu-mark-series`).

M P S

Mark all series that have already had some articles marked (`gnus-uu-mark-sparse`).

M P a

Mark all articles in series order (`gnus-uu-mark-series`).

M P b

Mark all articles in the buffer in the order they appear (`gnus-uu-mark-buffer`).

Limiting

It can be convenient to limit the summary buffer to just show some subset of the articles currently in the group. The effect most limit commands have is to remove a few (or many) articles from the summary buffer.

/ /

/ s

Limit the summary buffer to articles that match some subject (`gnus-summary-limit-to-subject`).

/ a

Limit the summary buffer to articles that match some author (`gnus-summary-limit-to-author`).

/ u

x

Limit the summary buffer to articles that are not marked as read (`gnus-summary-limit-to-unread`). If given a prefix, limit the buffer to articles that are strictly unread. This means that ticked and dormant articles will also be excluded.

/ m

Ask for a mark and then limit to all articles that have not been marked with that mark (`gnus-summary-limit-to-marks`).

/ n

Limit the summary buffer to the current article (`gnus-summary-limit-to-articles`). Uses the process/prefix convention (see section Process/Prefix).

/ w

Pop the previous limit off the stack and restore it (`gnus-summary-pop-limit`). If given a prefix, pop all limits off the stack.

/ v

Limit the summary buffer to articles that have a score at or above some score (`gnus-summary-limit-to-score`).

/ E

M S

Display all expunged articles (`gnus-summary-limit-include-expunged`).

/ D

Display all dormant articles (`gnus-summary-limit-include-dormant`).

/ d

Hide all dormant articles (`gnus-summary-limit-exclude-dormant`).

/ c

Hide all dormant articles that have no children (`gnus-summary-limit-exclude-childless-dormant`).

/ C

Mark all excluded unread articles as read (`gnus-summary-limit-mark-excluded-as-read`). If given a prefix, also mark excluded ticked and dormant articles as read.

Threading

Gnus threads articles by default. To thread is to put replies to articles directly after the articles they reply to--in a hierarchical fashion.

Customizing Threading

`gnus-show-threads`

If this variable is `nil`, no threading will be done, and all of the rest of the variables here will have no effect. Turning threading off will speed group selection up a bit, but it is sure to make reading slower and more awkward.

`gnus-fetch-old-headers`

If non-`nil`, Gnus will attempt to build old threads by fetching more old headers--headers to articles that are marked as read. If you would like to display as few summary lines as possible, but still connect as many loose threads as possible, you should set this variable to `some` or a number. If you set it to a number, no more than that number of extra old headers will be fetched. In either case, fetching old headers only works if the backend you are using carries overview files--this would normally be `nntp`, `nnspool` and `nnml`. Also remember that if the root of the thread has been expired by the server, there's not much Gnus can do about that.

`gnus-build-sparse-threads`

Fetching old headers can be slow. A low-rent similar effect can be gotten by setting this variable to `some`. Gnus will then look at the complete `References` headers of all articles and try to string articles that belong in the same thread together. This will leave gaps in the threading display where Gnus guesses that an article is missing from the thread. (These gaps appear like normal summary lines. If you select a gap, Gnus will try to fetch the article in question.) If this variable is `t`, Gnus will display all these "gaps" without regard for whether they are useful for completing the thread or not. Finally, if this variable is `more`, Gnus won't cut off sparse leaf nodes that don't lead anywhere. This variable is `nil` by default.

`gnus-summary-gather-subject-limit`

Loose threads are gathered by comparing subjects of articles. If this variable is `nil`, Gnus requires an exact match between the subjects of the loose threads before gathering them into one big super-thread. This might be too strict a requirement, what with the presence of stupid newsreaders that chop off long subjects lines. If you think so, set this variable to, say, 20 to require that only the first 20 characters of the subjects have to match. If you set this variable to a really low number, you'll find that Gnus will gather everything in sight into one thread, which isn't very helpful.

If you set this variable to the special value `fuzzy`, Gnus will use a fuzzy string comparison algorithm on the subjects.

`gnus-simplify-subject-fuzzy-regexp`

This can either be a regular expression or list of regular expressions that match strings that will be

removed from subjects if fuzzy subject simplification is used.

`gnus-simplify-ignored-prefixes`

If you set `gnus-summary-gather-subject-limit` to something as low as 10, you might consider setting this variable to something sensible:

```
(setq gnus-simplify-ignored-prefixes
      (concat
       "\\`\\[?\\("
       (mapconcat 'identity
                  '("looking"
                    "wanted" "followup" "summary\\( of\\)?"
                    "help" "query" "problem" "question"
                    "answer" "reference" "announce"
                    "How can I" "How to" "Comparison of"
                    ;; ...
                    )
                  "\\|")
       "\\)\\s *\\("
       (mapconcat 'identity
                  '("for" "for reference" "with" "about")
                  "\\|")
       "\\)?\\]?:?[ \t]*"))
```

All words that match this regexp will be removed before comparing two subjects.

`gnus-summary-gather-exclude-subject`

Since loose thread gathering is done on subjects only, that might lead to many false hits, especially with certain common subjects like `' and `(none)'. To make the situation slightly better, you can use the regexp `gnus-summary-gather-exclude-subject` to say what subjects should be excluded from the gathering process. The default is `^ *$\\|^(none)$'.

`gnus-summary-thread-gathering-function`

Gnus gathers threads by looking at `Subject` headers. This means that totally unrelated articles may end up in the same "thread", which is confusing. An alternate approach is to look at all the `Message-ID`s in all the `References` headers to find matches. This will ensure that no gathered threads ever includes unrelated articles, but it's also means that people who have posted with broken newsreaders won't be gathered properly. The choice is yours--plague or cholera:

`gnus-gather-threads-by-subject`

This function is the default gathering function and looks at `Subject`s exclusively.

`gnus-gather-threads-by-references`

This function looks at `References` headers exclusively.

If you want to test gathering by `References`, you could say something like:

```
(setq gnus-summary-thread-gathering-function
      'gnus-gather-threads-by-references)
```

- gnus-summary-make-false-root If non-`nil`, Gnus will gather all loose subtrees into one big tree and

create a dummy root at the top. (Wait a minute. Root at the top? Yup.) Loose subtrees occur when the real root has expired, or you've read or killed the root in a previous session.

When there is no real root of a thread, Gnus will have to fudge something. This variable says what fudging method Gnus should use. There are four possible values:

`adopt`

Gnus will make the first of the orphaned articles the parent. This parent will adopt all the other articles. The adopted articles will be marked as such by pointy brackets (`<>') instead of the standard square brackets (`[]'). This is the default method.

`dummy`

Gnus will create a dummy summary line that will pretend to be the parent. This dummy line does not correspond to any real article, so selecting it will just select the first real article after the dummy article. `gnus-summary-dummy-line-format` is used to specify the format of the dummy roots. It accepts only one format spec: `S', which is the subject of the article. See section Formatting Variables.

`empty`

Gnus won't actually make any article the parent, but simply leave the subject field of all orphans except the first empty. (Actually, it will use `gnus-summary-same-subject` as the subject (see section Summary Buffer Format).)

`none`

Don't make any article parent at all. Just gather the threads and display them after one another.

`nil`

Don't gather loose threads.

- gnus-thread-hide-subtree If non-`nil`, all threads will be hidden when the summary buffer is generated.
- gnus-thread-hide-killed if you kill a thread and this variable is non-`nil`, the subtree will be hidden.
- gnus-thread-ignore-subject Sometimes somebody changes the subject in the middle of a thread. If this variable is non-`nil`, the subject change is ignored. If it is `nil`, which is the default, a change in the subject will result in a new thread.
- gnus-thread-indent-level This is a number that says how much each sub-thread should be indented. The default is `4`.

Thread Commands

T k

M-C-k

Mark all articles in the current sub-thread as read (`gnus-summary-kill-thread`). If the prefix argument is positive, remove all marks instead. If the prefix argument is negative, tick articles instead.

T l

M-C-l

Lower the score of the current thread (`gnus-summary-lower-thread`).

T i

Increase the score of the current thread (`gnus-summary-raise-thread`).

T #

Set the process mark on the current thread (`gnus-uu-mark-thread`).

T M-#

Remove the process mark from the current thread (`gnus-uu-unmark-thread`).

T T

Toggle threading (`gnus-summary-toggle-threads`).

T s

Expose the thread hidden under the current article, if any (`gnus-summary-show-thread`).

T h

Hide the current (sub)thread (`gnus-summary-hide-thread`).

T S

Expose all hidden threads (`gnus-summary-show-all-threads`).

T H

Hide all threads (`gnus-summary-hide-all-threads`).

T t

Re-thread the thread the current article is part of (`gnus-summary-rethread-current`). This works even when the summary buffer is otherwise unthreaded.

T ^

Make the current article the child of the marked (or previous) article (`gnus-summary-reparent-thread`.

The following commands are thread movement commands. They all understand the numeric prefix.

T n

Go to the next thread (`gnus-summary-next-thread`).

T p

Go to the previous thread (`gnus-summary-prev-thread`).

T d

Descend the thread (`gnus-summary-down-thread`).

T u

Ascend the thread (`gnus-summary-up-thread`).

T o

Go to the top of the thread (`gnus-summary-top-thread`).

If you ignore subject while threading, you'll naturally end up with threads that have several different subjects in them. If you then issue a command like `T k' (`gnus-summary-kill-thread`) you might not wish to kill the entire thread, but just those parts of the thread that have the same subject as the current article. If you like this idea, you can fiddle with `gnus-thread-operation-ignore-subject`. If is non-`nil` (which it is by default), subjects will be ignored when doing thread commands. If this variable is `nil`, articles in the same thread with different subjects will not be included in the operation in question. If this variable is `fuzzy`, only articles that have subjects that are fuzzily equal will be included.

Sorting

If you are using a threaded summary display, you can sort the threads by setting `gnus-thread-sort-functions`, which is a list of functions. By default, sorting is done on article numbers. Ready-made sorting predicate functions include `gnus-thread-sort-by-number`, `gnus-thread-sort-by-author`, `gnus-thread-sort-by-subject`, `gnus-thread-sort-by-date`, `gnus-thread-sort-by-score`, and `gnus-thread-sort-by-total-score`.

Each function takes two threads and return non-`nil` if the first thread should be sorted before the other. Note that sorting really is normally done by looking only at the roots of each thread. If you use more than one function, the primary sort key should be the last function in the list. You should probably always include `gnus-thread-sort-by-number` in the list of sorting functions--preferably first. This will ensure that threads that are equal with respect to the other sort criteria will be displayed in ascending article order.

If you would like to sort by score, then by subject, and finally by number, you could do something like:

```
(setq gnus-thread-sort-functions
      '(gnus-thread-sort-by-number
        gnus-thread-sort-by-subject
        gnus-thread-sort-by-score))
```

The threads that have highest score will be displayed first in the summary buffer. When threads have the same score, they will be sorted alphabetically. The threads that have the same score and the same subject will be sorted by number, which is (normally) the sequence in which the articles arrived.

If you want to sort by score and then reverse arrival order, you could say something like:

```
(setq gnus-thread-sort-functions
      '((lambda (t1 t2)
          (not (gnus-thread-sort-by-number t1 t2)))
        gnus-thread-sort-by-score))
```

The function in the `gnus-thread-score-function` variable (default `+`) is used for calculating the total score of a thread. Useful functions might be `max`, `min`, or squared means, or whatever tickles your fancy.

If you are using an unthreaded display for some strange reason or other, you have to fiddle with the `gnus-article-sort-functions` variable. It is very similar to the `gnus-thread-sort-functions`, except that is uses slightly different functions for article comparison. Available sorting predicate functions are `gnus-article-sort-by-number`, `gnus-article-sort-by-author`, `gnus-article-sort-by-subject`, `gnus-article-sort-by-date`, and `gnus-article-sort-by-score`.

If you want to sort an unthreaded summary display by subject, you could say something like:

```
(setq gnus-article-sort-functions
      '(gnus-article-sort-by-number
```

```
gnus-article-sort-by-subject))
```

Asynchronous Article Fetching

If you read your news from an NNTP server that's far away, the network latencies may make reading articles a chore. You have to wait for a while after pressing n to go to the next article before the article appears. Why can't Gnus just go ahead and fetch the article while you are reading the previous one? Why not, indeed.

First, some caveats. There are some pitfalls to using asynchronous article fetching, especially the way Gnus does it.

Let's say you are reading article 1, which is short, and article 2 is quite long, and you are not interested in reading that. Gnus does not know this, so it goes ahead and fetches article 2. You decide to read article 3, but since Gnus is in the process of fetching article 2, the connection is blocked.

To avoid these situations, Gnus will open two (count 'em two) connections to the server. Some people may think this isn't a very nice thing to do, but I don't see any real alternatives. Setting up that extra connection takes some time, so Gnus startup will be slower.

Gnus will fetch more articles than you will read. This will mean that the link between your machine and the NNTP server will become more loaded than if you didn't use article pre-fetch. The server itself will also become more loaded--both with the extra article requests, and the extra connection.

Ok, so now you know that you shouldn't really use this thing... unless you really want to.

Here's how: Set `gnus-asynchronous` to `t`. The rest should happen automatically.

You can control how many articles that are to be pre-fetched by setting `nntp-async-number`. This is five by default, which means that when you read an article in the group, `nntp` will pre-fetch the next five articles. If this variable is `t`, `nntp` will pre-fetch all the articles that it can without bound. If it is `nil`, no pre-fetching will be made.

You may wish to create some sort of scheme for choosing which articles that `nntp` should consider as candidates for pre-fetching. For instance, you may wish to pre-fetch all articles with high scores, and not pre-fetch low-scored articles. You can do that by setting the `gnus-asynchronous-article-function`, which will be called with an alist where the keys are the article numbers. Your function should return an alist where the articles you are not interested in have been removed. You could also do sorting on article score and the like.

Article Caching

If you have an *extremely* slow NNTP connection, you may consider turning article caching on. Each article will then be stored locally under your home directory. As you may surmise, this could potentially use *huge* amounts of disk space, as well as eat up all your inodes so fast it will make your head swim. In vodka.

Used carefully, though, it could be just an easier way to save articles.

To turn caching on, set `gnus-use-cache` to `t`. By default, all articles that are ticked or marked as dormant will then be copied over to your local cache (`gnus-cache-directory`). Whether this cache is

flat or hierarchal is controlled by the `gnus-use-long-file-name` variable, as usual.

When re-select a ticked or dormant article, it will be fetched from the cache instead of from the server. As articles in your cache will never expire, this might serve as a method of saving articles while still keeping them where they belong. Just mark all articles you want to save as dormant, and don't worry.

When an article is marked as read, is it removed from the cache.

The entering/removal of articles from the cache is controlled by the `gnus-cache-enter-articles` and `gnus-cache-remove-articles` variables. Both are lists of symbols. The first is `(ticked dormant)` by default, meaning that ticked and dormant articles will be put in the cache. The latter is `(read)` by default, meaning that articles that are marked as read are removed from the cache. Possibly symbols in these two lists are `ticked`, `dormant`, `unread` and `read`.

So where does the massive article-fetching and storing come into the picture? The `gnus-jog-cache` command will go through all subscribed newsgroups, request all unread articles, and store them in the cache. You should only ever, ever ever ever, use this command if 1) your connection to the NNTP server is really, really, really slow and 2) you have a really, really, really huge disk. Seriously.

It is likely that you do not want caching on some groups. For instance, if your `nnml` mail is located under your home directory, it makes no sense to cache it somewhere else under your home directory. Unless you feel that it's neat to use twice as much space. To limit the caching, you could set the `gnus-uncacheable-groups` regexp to `^nnml', for instance. This variable is `nil` by default.

The cache stores information on what articles it contains in its active file (`gnus-cache-active-file`). If this file (or any other parts of the cache) becomes all messed up for some reason or other, Gnus offers two functions that will try to set things right. M-x gnus-cache-generate-nov-databases will (re)build all the NOV files, and gnus-cache-generate-active will (re)generate the active file.

Persistent Articles

Closely related to article caching, we have persistent articles. In fact, it's just a different way of looking at caching, and much more useful in my opinion.

Say you're reading a newsgroup, and you happen on to some valuable gem that you want to keep and treasure forever. You'd normally just save it (using one of the many saving commands) in some file. The problem with that is that it's just, well, yucky. Ideally you'd prefer just having the article remain in the group where you found it forever; untouched by the expiry going on at the news server.

This is what a persistent article is--an article that just won't be deleted. It's implemented using the normal cache functions, but you use two explicit commands for managing persistent articles:

*
: Make the current article persistent (`gnus-cache-enter-article`).

M-*
: Remove the current article from the persistent articles (`gnus-cache-remove-article`). This will normally delete the article.

Both these commands understand the process/prefix convention.

To avoid having all ticked articles (and stuff) entered into the cache, you should set `gnus-use-cache passive` if you're just interested in persistent articles:

```
(setq gnus-use-cache 'passive)
```

Article Backlog

If you have a slow connection, but the idea of using caching seems unappealing to you (and it is, really), you can help the situation some by switching on the backlog. This is where Gnus will buffer already read articles so that it doesn't have to re-fetch articles you've already read. This only helps if you are in the habit of re-selecting articles you've recently read, of course. If you never do that, turning the backlog on will slow Gnus down a little bit, and increase memory usage some.

If you set `gnus-keep-backlog` to a number n, Gnus will store at most n old articles in a buffer for later re-fetching. If this variable is non-`nil` and is not a number, Gnus will store *all* read articles, which means that your Emacs will grow without bound before exploding and taking your machine down with you. I put that in there just to keep y'all on your toes.

This variable is `nil` by default.

Saving Articles

Gnus can save articles in a number of ways. Below is the documentation for saving articles in a fairly straight-forward fashion (i.e., little processing of the article is done before it is saved). For a different approach (uudecoding, unsharing) you should use `gnus-uu` (see section Decoding Articles).

If `gnus-save-all-headers` is non-`nil`, Gnus will not delete unwanted headers before saving the article.

If the preceding variable is `nil`, all headers that match the `gnus-saved-headers` regexp will be kept, while the rest will be deleted before saving.

O o

o

Save the current article using the default article saver (`gnus-summary-save-article`).

O m

Save the current article in mail format (`gnus-summary-save-article-mail`).

O r

Save the current article in rmail format (`gnus-summary-save-article-rmail`).

O f

Save the current article in plain file format (`gnus-summary-save-article-file`).

O b

Save the current article body in plain file format (`gnus-summary-save-article-body-file`).

O h

Save the current article in mh folder format (`gnus-summary-save-article-folder`).

O v

Save the current article in a VM folder (`gnus-summary-save-article-vm`).

O p

Save the current article in a pipe. Uhm, like, what I mean is--Pipe the current article to a process (`gnus-summary-pipe-output`).

All these commands use the process/prefix convention (see section Process/Prefix). If you save bunches of articles using these functions, you might get tired of being prompted for files to save each and every article in. The prompting action is controlled by the `gnus-prompt-before-saving` variable, which is `always` by default, giving you that excessive prompting action you know and loathe. If you set this variable to `t` instead, you'll be prompted just once for each series of articles you save. If you like to really have Gnus do all your thinking for you, you can even set this variable to `nil`, which means that you will never be prompted for files to save articles in. Gnus will simply save all the articles in the default files.

You can customize the `gnus-default-article-saver` variable to make Gnus do what you want it to. You can use any of the four ready-made functions below, or you can create your own.

`gnus-summary-save-in-rmail`

This is the default format, babyl. Uses the function in the `gnus-rmail-save-name` variable to get a file name to save the article in. The default is `gnus-plain-save-name`.

`gnus-summary-save-in-mail`

Save in a Unix mail (mbox) file. Uses the function in the `gnus-mail-save-name` variable to get a file name to save the article in. The default is `gnus-plain-save-name`.

`gnus-summary-save-in-file`

Append the article straight to an ordinary file. Uses the function in the `gnus-file-save-name` variable to get a file name to save the article in. The default is `gnus-numeric-save-name`.

`gnus-summary-save-body-in-file`

Append the article body to an ordinary file. Uses the function in the `gnus-file-save-name` variable to get a file name to save the article in. The default is `gnus-numeric-save-name`.

`gnus-summary-save-in-folder`

Save the article to an MH folder using `rcvstore` from the MH library. Uses the function in the `gnus-folder-save-name` variable to get a file name to save the article in. The default is `gnus-folder-save-name`, but you can also use `gnus-Folder-save-name`. The former creates capitalized names, and the latter does not.

`gnus-summary-save-in-vm`

Save the article in a VM folder. You have to have the VM mail reader to use this setting.

All of these functions, except for the last one, will save the article in the `gnus-article-save-directory`, which is initialized from the `SAVEDIR` environment variable. This is `` `~/News/' `` by default.

As you can see above, the functions use different functions to find a suitable name of a file to save the article in. Below is a list of available functions that generate names:

`gnus-Numeric-save-name`

Generates file names that look like `~/News/Alt.andrea-dworkin/45'.

`gnus-numeric-save-name`

Generates file names that look like `~/News/alt.andrea-dworkin/45'.

`gnus-Plain-save-name`

Generates file names that look like `~/News/Alt.andrea-dworkin'.

`gnus-plain-save-name`

Generates file names that look like `~/News/alt.andrea-dworkin'.

You can have Gnus suggest where to save articles by plonking a regexp into the `gnus-split-methods` alist. For instance, if you would like to save articles related to Gnus in the file `gnus-stuff', and articles related to VM in `vm-stuff`, you could set this variable to something like:

```
(("^Subject:.*gnus\\|^Newsgroups:.*gnus" "gnus-stuff")
 ("^Subject:.*vm\\|^Xref:.*vm" "vm-stuff")
 (my-choosing-function "../other-dir/my-stuff")
 ((equal gnus-newsgroup-name "mail.misc") "mail-stuff"))
```

We see that this is a list where each element is a list that has two elements--the match and the file. The match can either be a string (in which case it is used as a regexp to match on the article head); it can be a symbol (which will be called as a function with the group name as a parameter); or it can be a list (which will be `eval`ed). If any of these actions have a non-`nil` result, the file will be used as a default prompt. In addition, the result of the operation itself will be used if the function or form called returns a string or a list of strings.

You basically end up with a list of file names that might be used when saving the current article. (All "matches" will be used.) You will then be prompted for what you really want to use as a name, with file name completion over the results from applying this variable.

This variable is `((gnus-article-archive-name))` by default, which means that Gnus will look at the articles it saves for an `Archive-name` line and use that as a suggestion for the file name.

Finally, you have the `gnus-use-long-file-name` variable. If it is `nil`, all the preceding functions will replace all periods (`.') in the group names with slashes (`/')---which means that the functions will generate hierarchies of directories instead of having all the files in the toplevel directory (`~/News/alt/andrea-dworkin' instead of `~/News/alt.andrea-dworkin'.) This variable is `t` by default on most systems. However, for historical reasons, this is `nil` on Xenix and usg-unix-v machines by default.

This function also affects kill and score file names. If this variable is a list, and the list contains the element `not-score`, long file names will not be used for score files, if it contains the element `not-save`, long file names will not be used for saving, and if it contains the element `not-kill`, long file names will not be used for kill files.

If you'd like to save articles in a hierarchy that looks something like a spool, you could

```
(setq gnus-use-long-file-name '(not-save)) ; to get a hierarchy
(setq gnus-default-article-save 'gnus-summary-save-in-file) ; no encoding
```

Then just save with o. You'd then read this hierarchy with ephemeral `nneething` groups---G D in the

group buffer, and the toplevel directory as the argument (`~/News/'). Then just walk around to the groups/directories with nneething.

Decoding Articles

Sometime users post articles (or series of articles) that have been encoded in some way or other. Gnus can decode them for you.

All these functions use the process/prefix convention (see section Process/Prefix) for finding out what articles to work on, with the extension that a "single article" means "a single series". Gnus can find out by itself what articles belong to a series, decode all the articles and unpack/view/save the resulting file(s).

Gnus guesses what articles are in the series according to the following simplish rule: The subjects must be (nearly) identical, except for the last two numbers of the line. (Spaces are largely ignored, however.)

For example: If you choose a subject called `cat.gif (2/3)', Gnus will find all the articles that match the regexp `^cat.gif ([0-9]+/[0-9]+).*$'.

Subjects that are nonstandard, like `cat.gif (2/3) Part 6 of a series', will not be properly recognized by any of the automatic viewing commands, and you have to mark the articles manually with #.

Uuencoded Articles

X u
: Uudecodes the current series (gnus-uu-decode-uu).

X U
: Uudecodes and saves the current series (gnus-uu-decode-uu-and-save).

X v u
: Uudecodes and views the current series (gnus-uu-decode-uu-view).

X v U
: Uudecodes, views and saves the current series (gnus-uu-decode-uu-and-save-view).

Remember that these all react to the presence of articles marked with the process mark. If, for instance, you'd like to decode and save an entire newsgroup, you'd typically do M P a (gnus-uu-mark-all) and then X U (gnus-uu-decode-uu-and-save).

All this is very much different from how gnus-uu worked with GNUS 4.1, where you had explicit keystrokes for everything under the sun. This version of gnus-uu generally assumes that you mark articles in some way (see section Setting Process Marks) and then press X u.

Note: When trying to decode articles that have names matching gnus-uu-notify-files, which is hard-coded to `[Cc][Ii][Nn][Dd][Yy][0-9]+.\\(gif\\|jpg\\)', gnus-uu will automatically post an article on `comp.unix.wizards' saying that you have just viewed the file in question. This feature can't be turned off.

Shared Articles

X s

Unshars the current series (`gnus-uu-decode-unshar`).

X S

Unshars and saves the current series (`gnus-uu-decode-unshar-and-save`).

X v s

Unshars and views the current series (`gnus-uu-decode-unshar-view`).

X v S

Unshars, views and saves the current series (`gnus-uu-decode-unshar-and-save-view`).

PostScript Files

X p

Unpack the current PostScript series (`gnus-uu-decode-postscript`).

X P

Unpack and save the current PostScript series (`gnus-uu-decode-postscript-and-save`).

X v p

View the current PostScript series (`gnus-uu-decode-postscript-view`).

X v P

View and save the current PostScript series (`gnus-uu-decode-postscript-and-save-view`).

Decoding Variables

Adjective, not verb.

Rule Variables

Gnus uses rule variables to decide how to view a file. All these variables are on the form

```
(list '(regexp1 command2)
      '(regexp2 command2)
      ...)
```

`gnus-uu-user-view-rules`

This variable is consulted first when viewing files. If you wish to use, for instance, `sox` to convert an `.au' sound file, you could say something like:

```
(setq gnus-uu-user-view-rules
  (list '(\"\\\\.au$\" \"sox %s -t .aiff > /dev/audio\")))
```

`gnus-uu-user-view-rules-end`

This variable is consulted if Gnus couldn't make any matches from the user and default view rules.

`gnus-uu-user-archive-rules`

This variable can be used to say what commands should be used to unpack archives.

Other Decode Variables

`gnus-uu-grabbed-file-functions`

All functions in this list will be called right each file has been successfully decoded--so that you can move or view files right away, and don't have to wait for all files to be decoded before you can do anything. Ready-made functions you can put in this list are:

`gnus-uu-grab-view`

View the file.

`gnus-uu-grab-move`

Move the file (if you're using a saving function.)

- gnus-uu-ignore-files-by-name Files with name matching this regular expression won't be viewed.
- gnus-uu-ignore-files-by-type Files with a MIME type matching this variable won't be viewed. Note that Gnus tries to guess what type the file is based on the name. `gnus-uu` is not a MIME package (yet), so this is slightly kludgey.
- gnus-uu-tmp-dir Where `gnus-uu` does its work.
- gnus-uu-do-not-unpack-archives Non-`nil` means that `gnus-uu` won't peek inside archives looking for files to display.
- gnus-uu-view-and-save Non-`nil` means that the user will always be asked to save a file after viewing it.
- gnus-uu-ignore-default-view-rules Non-`nil` means that `gnus-uu` will ignore the default viewing rules.
- gnus-uu-ignore-default-archive-rules Non-`nil` means that `gnus-uu` will ignore the default archive unpacking commands.
- gnus-uu-kill-carriage-return Non-`nil` means that `gnus-uu` will strip all carriage returns from articles.
- gnus-uu-unmark-articles-not-decoded Non-`nil` means that `gnus-uu` will mark articles that were unsuccessfully decoded as unread.
- gnus-uu-correct-stripped-uucode Non-`nil` means that `gnus-uu` will *try* to fix uuencoded files that have had trailing spaces deleted.
- gnus-uu-view-with-metamail Non-`nil` means that `gnus-uu` will ignore the viewing commands defined by the rule variables and just fudge a MIME content type based on the file name. The result will be fed to `metamail` for viewing.
- gnus-uu-save-in-digest Non-`nil` means that `gnus-uu`, when asked to save without decoding, will save in digests. If this variable is `nil`, `gnus-uu` will just save everything in a file without any embellishments. The digesting almost conforms to RFC1153--no easy way to specify any meaningful volume and issue numbers were found, so I simply dropped them.

Uuencoding and Posting

`gnus-uu-post-include-before-composing`

Non-`nil` means that `gnus-uu` will ask for a file to encode before you compose the article. If this variable is `t`, you can either include an encoded file with C-c C-i or have one included for you when

you post the article.

`gnus-uu-post-length`

Maximum length of an article. The encoded file will be split into how many articles it takes to post the entire file.

`gnus-uu-post-threaded`

Non-`nil` means that `gnus-uu` will post the encoded file in a thread. This may not be smart, as no other decoder I have seen are able to follow threads when collecting uuencoded articles. (Well, I have seen one package that does that---`gnus-uu`, but somehow, I don't think that counts...) Default is `nil`.

`gnus-uu-post-separate-description`

Non-`nil` means that the description will be posted in a separate article. The first article will typically be numbered (0/x). If this variable is `nil`, the description the user enters will be included at the beginning of the first article, which will be numbered (1/x). Default is `t`.

Viewing Files

After decoding, if the file is some sort of archive, Gnus will attempt to unpack the archive and see if any of the files in the archive can be viewed. For instance, if you have a gzipped tar file `` `pics.tar.gz' `` containing the files `` `pic1.jpg' `` and `` `pic2.gif' ``, Gnus will uncompress and de-tar the main file, and then view the two pictures. This unpacking process is recursive, so if the archive contains archives of archives, it'll all be unpacked.

Finally, Gnus will normally insert a pseudo-article for each extracted file into the summary buffer. If you go to these "articles", you will be prompted for a command to run (usually Gnus will make a suggestion), and then the command will be run.

If `gnus-view-pseudo-asynchronously` is `nil`, Emacs will wait until the viewing is done before proceeding.

If `gnus-view-pseudos` is `automatic`, Gnus will not insert the pseudo-articles into the summary buffer, but view them immediately. If this variable is `not-confirm`, the user won't even be asked for a confirmation before viewing is done.

If `gnus-view-pseudos-separately` is non-`nil`, one pseudo-article will be created for each file to be viewed. If `nil`, all files that use the same viewing command will be given as a list of parameters to that command.

If `gnus-insert-pseudo-articles` is non-`nil`, insert pseudo-articles when decoding. It is `t` by default.

So; there you are, reading your *pseudo-articles* in your *virtual newsgroup* from the *virtual server*; and you think: Why isn't anything real anymore? How did we get here?

Article Treatment

Reading through this huge manual, you may have quite forgotten that the object of newsreaders are to actually, like, read what people have written. Reading articles. Unfortunately, people are quite bad at writing, so there are tons of functions and variables to make reading these articles easier.

Article Highlighting

Not only do you want your article buffer to look like fruit salad, but you want it to look like technicolor fruit salad.

W H a

Highlight the current article (`gnus-article-highlight`).

W H h

Highlight the headers (`gnus-article-highlight-headers`). The highlighting will be done according to the `gnus-header-face-alist` variable, which is a list where each element has the form (regexp name content). regexp is a regular expression for matching the header, name is the face used for highlighting the header name and content is the face for highlighting the header value. The first match made will be used. Note that regexp shouldn't have `^' prepended--Gnus will add one.

W H c

Highlight cited text (`gnus-article-highlight-citation`).

Some variables to customize the citation highlights:

`gnus-cite-parse-max-size`

If the article size if bigger than this variable (which is 25000 by default), no citation highlighting will be performed.

`gnus-cite-prefix-regexp`

Regexp matching the longest possible citation prefix on a line.

`gnus-cite-max-prefix`

Maximum possible length for a citation prefix (default 20).

`gnus-cite-face-list`

List of faces used for highlighting citations. When there are citations from multiple articles in the same message, Gnus will try to give each citation from each article its own face. This should make it easier to see who wrote what.

`gnus-supercite-regexp`

Regexp matching normal Supercite attribution lines.

`gnus-supercite-secondary-regexp`

Regexp matching mangled Supercite attribution lines.

`gnus-cite-minimum-match-count`

Minimum number of identical prefixes we have to see before we believe that it's a citation.

`gnus-cite-attribution-prefix`

Regexp matching the beginning of an attribution line.

`gnus-cite-attribution-suffix`

Regexp matching the end of an attribution line.

`gnus-cite-attribution-face`

Face used for attribution lines. It is merged with the face for the cited text belonging to the attribution.

- W H s Highlight the signature (`gnus-article-highlight-signature`). Everything after `gnus-signature-separator` in an article will be considered a signature and will be highlighted with `gnus-signature-face`, which is `italic` by default.

Article Hiding

Or rather, hiding certain things in each article. There usually is much too much cruft in most articles.

W W a

Do maximum hiding on the summary buffer (gnus-article-hide).

W W h

Hide headers (`gnus-article-hide-headers`). See section Hiding Headers.

W W b

Hide headers that aren't particularly interesting (`gnus-article-hide-boring-headers`). See section Hiding Headers.

W W s

Hide signature (`gnus-article-hide-signature`).

W W p

Hide PGP signatures (`gnus-article-hide-pgp`).

W W c

Hide citation (`gnus-article-hide-citation`). Some variables for customizing the hiding:

`gnus-cite-hide-percentage`

If the cited text is of a bigger percentage than this variable (default 50), hide the cited text.

`gnus-cite-hide-absolute`

The cited text must be have at least this length (default 10) before it is hidden.

`gnus-cited-text-button-line-format`

Gnus adds buttons show where the cited text has been hidden, and to allow toggle hiding the text. The format of the variable is specified by this format-like variable. These specs are legal:

`b'

Start point of the hidden text.

`e'

End point of the hidden text.

`l'

Length of the hidden text.

- gnus-cited-lines-visible The number of lines at the beginning of the cited text to leave shown.

- W W C Hide cited text in articles that aren't roots (`gnus-article-hide-citation-in-followups`). This isn't very useful as an interactive command, but might be a handy function to stick in `gnus-article-display-hook` (see section Customizing Articles).

All these "hiding" commands are toggles, but if you give a negative prefix to these commands, they will

show what they have previously hidden. If you give a positive prefix, they will always hide.

Also see section Article Highlighting for further variables for citation customization.

`gnus-signature-limit` provides a limit to what is considered a signature. If it is a number, no signature may not be longer (in characters) than that number. If it is a function, the function will be called without any parameters, and if it returns `nil`, there is no signature in the buffer. If it is a string, it will be used as a regexp. If it matches, the text in question is not a signature.

Article Washing

We call this "article washing" for a really good reason. Namely, the A key was taken, so we had to use the W key instead.

Washing is defined by us as "changing something from something to something else", but normally results in something looking better. Cleaner, perhaps.

W l

Remove page breaks from the current article (`gnus-summary-stop-page-breaking`).

W r

Do a Caesar rotate (rot13) on the article buffer (`gnus-summary-caesar-message`).

W t

Toggle whether to display all headers in the article buffer (`gnus-summary-toggle-header`).

W v

Toggle whether to display all headers in the article buffer permanently (`gnus-summary-verbose-header`).

W m

Toggle whether to run the article through MIME before displaying (`gnus-summary-toggle-mime`).

W o

Treat overstrike (`gnus-article-treat-overstrike`).

W w

Do word wrap (`gnus-article-fill-cited-article`).

W c

Remove CR (`gnus-article-remove-cr`).

W L

Remove all blank lines at the end of the article (`gnus-article-remove-trailing-blank-lines`).

W q

Treat quoted-printable (`gnus-article-de-quoted-unreadable`).

W f

Look for and display any X-Face headers (`gnus-article-display-x-face`). The command executed by this function is given by the `gnus-article-x-face-command` variable. If this

variable is a string, this string will be executed in a sub-shell. If it is a function, this function will be called with the face as the argument. If the `gnus-article-x-face-too-ugly` (which is a regexp) matches the `From` header, the face will not be shown. The default action under Emacs is to fork off an `xv` to view the face; under XEmacs the default action is to display the face before the `From` header. (It's nicer if XEmacs has been compiled with X-Face support -- that will make display somewhat faster. If there's no native X-Face support, Gnus will try to convert the `X-Face` header using external programs from the `pbmplus` package and friends.) If you want to have this function in the display hook, it should probably come last.

W b

Add clickable buttons to the article (`gnus-article-add-buttons`).

W B

Add clickable buttons to the article headers (`gnus-article-add-buttons-to-head`).

Article Buttons

People often include references to other stuff in articles, and it would be nice if Gnus could just fetch whatever it is that people talk about with the minimum of fuzz.

Gnus adds buttons to certain standard references by default: Well-formed URLs, mail addresses and Message-IDs. This is controlled by two variables, one that handles article bodies and one that handles article heads:

`gnus-button-alist`

This is an alist where each entry has this form:

```
(REGEXP BUTTON-PAR USE-P FUNCTION DATA-PAR)
```

regexp

All text that match this regular expression will be considered an external reference. Here's a typical regexp that match embedded URLs: `<URL:\\([^\n\r>]*\\)>'.

button-par

Gnus has to know which parts of the match is to be highlighted. This is a number that says what sub-expression of the regexp that is to be highlighted. If you want it all highlighted, you use `0` here.

use-p

This form will be `eval`ed, and if the result is non-`nil`, this is considered a match. This is useful if you want extra sifting to avoid false matches.

function

This function will be called when you click on this button.

data-par

As with button-par, this is a sub-expression number, but this one says which part of the match is to be sent as data to function.

So the full entry for buttonizing URLs is then

```
("<URL:\\([^\n\r>]*\\)>" 0 t gnus-button-url 1)
```

- gnus-header-button-alist This is just like the other alist, except that it is applied to the article head only, and that each entry has an additional element that is used to say what headers to apply the buttonize coding to:

```
(HEADER REGEXP BUTTON-PAR USE-P FUNCTION DATA-PAR)
```

header is a regular expression.

- gnus-button-url-regexp A regular expression that matches embedded URLs. It is used in the default values of the variables above.
- gnus-article-button-face Face used on bottons.
- gnus-article-mouse-face Face is used when the mouse cursor is over a button.

Article Date

The date is most likely generated in some obscure timezone you've never heard of, so it's quite nice to be able to find out what the time was when the article was sent.

W T u
: Display the date in UT (aka. GMT, aka ZULU) (`gnus-article-date-ut`).

W T l
: Display the date in the local timezone (`gnus-article-date-local`).

W T e
: Say how much time has (e)lapsed between the article was posted and now (`gnus-article-date-lapsed`).

W T o
: Display the original date (`gnus-article-date-original`). This can be useful if you normally use some other conversion function and is worried that it might be doing something totally wrong. Say, claiming that the article was posted in 1854. Although something like that is *totally* impossible. Don't you trust me? *titter*

Summary Sorting

You can have the summary buffer sorted in various ways, even though I can't really see why you'd want that.

C-c C-s C-n
: Sort by article number (`gnus-summary-sort-by-number`).

C-c C-s C-a
: Sort by author (`gnus-summary-sort-by-author`).

C-c C-s C-s
: Sort by subject (`gnus-summary-sort-by-subject`).

C-c C-s C-d
: Sort by date (`gnus-summary-sort-by-date`).

C-c C-s C-i

Sort by score (`gnus-summary-sort-by-score`).

These functions will work both when you use threading and when you don't use threading. In the latter case, all summary lines will be sorted, line by line. In the former case, sorting will be done on a root-by-root basis, which might not be what you were looking for. To toggle whether to use threading, type T T (see section Thread Commands).

Finding the Parent

If you'd like to read the parent of the current article, and it is not displayed in the summary buffer, you might still be able to. That is, if the current group is fetched by NNTP, the parent hasn't expired and the `References` in the current article are not mangled, you can just press ^ or A r (`gnus-summary-refer-parent-article`). If everything goes well, you'll get the parent. If the parent is already displayed in the summary buffer, point will just move to this article.

You can have Gnus fetch all articles mentioned in the `References` header of the article by pushing A R (`gnus-summary-refer-references`).

You can also ask the NNTP server for an arbitrary article, no matter what group it belongs to. M-^ (`gnus-summary-refer-article`) will ask you for a `Message-ID`, which is one of those long thingies that look something like `<38o6up$6f2@hymir.ifi.uio.no>'. You have to get it all exactly right. No fuzzy searches, I'm afraid.

If the group you are reading is located on a backend that does not support fetching by `Message-ID` very well (like `nnspool`), you can set `gnus-refer-article-method` to an NNTP method. It would, perhaps, be best if the NNTP server you consult is the same as the one that keeps the spool you are reading from updated, but that's not really necessary.

Most of the mail backends support fetching by `Message-ID`, but do not do a particularly excellent job of it. That is, `nnmbox` and `nnbabyl` are able to locate articles from any groups, while `nnml` and `nnfolder` are only able to locate articles that have been posted to the current group. (Anything else would be too time consuming.) `nnmh` does not support this at all.

Alternative Approaches

Different people like to read news using different methods. This being Gnus, we offer a small selection of minor modes for the summary buffers.

Pick and Read

Some newsreaders (like `nn` and, uhm, `nn`) use a two-phased reading interface. The user first marks the articles she wants to read from a summary buffer. Then she starts reading the articles with just an article buffer displayed.

Gnus provides a summary buffer minor mode that allows this---`gnus-pick-mode`. This basically means that a few process mark commands become one-keystroke commands to allow easy marking, and it makes

one additional command for switching to the summary buffer available.

Here are the available keystrokes when using pick mode:

SPACE
: Pick the article (`gnus-summary-mark-as-processable`).

u
: Unpick the article (`gnus-summary-unmark-as-processable`).

U
: Unpick all articles (`gnus-summary-unmark-all-processable`).

t
: Pick the thread (`gnus-uu-mark-thread`).

T
: Unpick the thread (`gnus-uu-unmark-thread`).

r
: Pick the region (`gnus-uu-mark-region`).

R
: Unpick the region (`gnus-uu-unmark-region`).

e
: Pick articles that match a regexp (`gnus-uu-mark-by-regexp`).

E
: Unpick articles that match a regexp (`gnus-uu-unmark-by-regexp`).

b
: Pick the buffer (`gnus-uu-mark-buffer`).

B
: Unpick the buffer (`gnus-uu-unmark-buffer`).

RET
: Start reading the picked articles (`gnus-pick-start-reading`). If given a prefix, mark all unpicked articles as read first. If `gnus-pick-display-summary` is non-`nil`, the summary buffer will still be visible when you are reading.

If this sounds like a good idea to you, you could say:

```
(add-hook 'gnus-summary-mode-hook 'gnus-pick-mode)
```

`gnus-pick-mode-hook` is run in pick minor mode buffers.

Binary Groups

If you spend much time in binary groups, you may grow tired of hitting X u, n, RET all the time. M-x gnus-binary-mode is a minor mode for summary buffers that makes all ordinary Gnus article selection functions uudecode series of articles and display the result instead of just displaying the articles the normal way.

In fact, the only way to see the actual articles if you have turned this mode on is the g command (`gnus-binary-show-article`).

`gnus-binary-mode-hook` is called in binary minor mode buffers.

Tree Display

If you don't like the normal Gnus summary display, you might try setting `gnus-use-trees` to `t`. This will create (by default) an additional tree buffer. You can execute all summary mode commands in the tree buffer.

There are a few variables to customize the tree display, of course:

`gnus-tree-mode-hook`

A hook called in all tree mode buffers.

`gnus-tree-mode-line-format`

A format string for the mode bar in the tree mode buffers. The default is `Gnus: %%b [%A] %Z'. For a list of legal specs, see section Summary Buffer Mode Line.

`gnus-selected-tree-face`

Face used for highlighting the selected article in the tree buffer. The default is `modeline`.

`gnus-tree-line-format`

A format string for the tree nodes. The name is a bit of a misnomer, though--it doesn't define a line, but just the node. The default value is `%(%[%3,3n%]%)', which displays the first three characters of the name of the poster. It is vital that all nodes are of the same length, so you *must* use `%4,4n'-like specifiers.

Legal specs are:

`n'

The name of the poster.

`f'

The `From` header.

`N'

The number of the article.

`['

The opening bracket.

`]'

The closing bracket.

`s'

The subject.

See section Formatting Variables.

Variables related to the display are:

`gnus-tree-brackets`

This is used for differentiating between "real" articles and "sparse" articles. The format is ((real-open . real-close) (sparse-open . sparse-close) (dummy-open . dummy-close)), and the default is `((?[ . ?]) (?( . ?)) (?{ . ?}))`.

`gnus-tree-parent-child-edges`

This is a list that contains the characters used for connecting parent nodes to their children. The default is `(?- ?\\ ?|)`.

- gnus-tree-minimize-window If this variable is non-`nil`, Gnus will try to keep the tree buffer as small as possible to allow more room for the other Gnus windows. If this variable is a number, the tree buffer will never be higher than that number. The default is `t`.
- gnus-generate-tree-function The function that actually generates the thread tree. Two predefined functions are available: `gnus-generate-horizontal-tree` and `gnus-generate-vertical-tree` (which is the default).

Here's and example from a horizontal tree buffer:

```
{***}-(***)-[odd]-[Gun]
     |     \[Jan]
     |     \[odd]-[Eri]
     |     \(***)-[Eri]
     |           \[odd]-[Paa]
     \[Bjo]
     \[Gun]
     \[Gun]-[Jor]
```

Here's the same thread displayed in a vertical tree buffer:

```
{***}
  |--------------------------\-----\-----\
(***)                         [Bjo] [Gun] [Gun]
  |--\-----\-----\                           |
[odd] [Jan] [odd] (***)                    [Jor]
  |           |     |--\
[Gun]       [Eri] [Eri] [odd]
                          |
                        [Paa]
```

Mail Group Commands

Some commands only make sense in mail groups. If these commands are illegal in the current group, they will raise a hell and let you know.

All these commands (except the expiry and edit commands) use the process/prefix convention (see section Process/Prefix).

B e

Expire all expirable articles in the group (`gnus-summary-expire-articles`).

B M-C-e

Expunge all the expirable articles in the group (`gnus-summary-expire-articles-now`). This means that **all** articles that are eligible for expiry in the current group will disappear forever into that big `/dev/null' in the sky.

B DEL

Delete the mail article. This is "delete" as in "delete it from your disk forever and ever, never to return again." Use with caution. (`gnus-summary-delete-article`).

B m

Move the article from one mail group to another (`gnus-summary-move-article`).

B c

Copy the article from one group (mail group or not) to a mail group (`gnus-summary-copy-article`).

B C

Crosspost the current article to some other group (`gnus-summary-crosspost-article`). This will create a new copy of the article in the other group, and the Xref headers of the article will be properly updated.

B i

Import an arbitrary file into the current mail newsgroup (`gnus-summary-import-article`). You will be prompted for a file name, a `From` header and a `Subject` header.

B r

Respool the mail article (`gnus-summary-move-article`).

B w

e

Edit the current article (`gnus-summary-edit-article`). To finish editing and make the changes permanent, type C-c C-c (gnus-summary-edit-article-done).

B q

If you want to re-spool an article, you might be curious as to what group the article will end up in before you do the re-spooling. This command will tell you (`gnus-summary-respool-query`).

If you move (or copy) articles regularly, you might wish to have Gnus suggest where to put the articles. `gnus-move-split-methods` is a variable that uses the same syntax as `gnus-split-methods` (see section Saving Articles). You may customize that variable to create suggestions you find reasonable.

Various Summary Stuff

`gnus-summary-mode-hook`

This hook is called when creating a summary mode buffer.

`gnus-summary-generate-hook`

This is called as the last thing before doing the threading and the generation of the summary buffer. It's quite convenient for customizing the threading variables based on what data the newsgroup has. This

hook is called from the summary buffer after most summary buffer variables has been set.

`gnus-summary-prepare-hook`

Is is called after the summary buffer has been generated. You might use it to, for instance, highlight lines or modify the look of the buffer in some other ungodly manner. I don't care.

Summary Group Information

H f

Try to fetch the FAQ (list of frequently asked questions) for the current group (`gnus-summary-fetch-faq`). Gnus will try to get the FAQ from `gnus-group-faq-directory`, which is usually a directory on a remote machine. This variable can also be a list of directories. In that case, giving a prefix to this command will allow you to choose between the various sites. `ange-ftp` probably will be used for fetching the file.

H d

Give a brief description of the current group (`gnus-summary-describe-group`). If given a prefix, force rereading the description from the server.

H h

Give a very brief description of the most important summary keystrokes (`gnus-summary-describe-briefly`).

H i

Go to the Gnus info node (`gnus-info-find-node`).

Searching for Articles

M-s

Search through all subsequent articles for a regexp (`gnus-summary-search-article-forward`).

M-r

Search through all previous articles for a regexp (`gnus-summary-search-article-backward`).

&

This command will prompt you for a header field, a regular expression to match on this field, and a command to be executed if the match is made (`gnus-summary-execute-command`).

M-&

Perform any operation on all articles that have been marked with the process mark (`gnus-summary-universal-argument`).

Really Various Summary Commands

A D

If the current article is a collection of other articles (for instance, a digest), you might use this command to enter a group based on the that article (`gnus-summary-enter-digest-group`).

Gnus will try to guess what article type is currently displayed unless you give a prefix to this command, which forces a "digest" interpretation. Basically, whenever you see a message that is a collection of other messages on some format, you A D and read these messages in a more convenient fashion.

C-t

Toggle truncation of summary lines (`gnus-summary-toggle-truncation`).

=

Expand the summary buffer window (`gnus-summary-expand-window`). If given a prefix, force an `article` window configuration.

Exiting the Summary Buffer

Exiting from the summary buffer will normally update all info on the group and return you to the group buffer.

Z Z

q

Exit the current group and update all information on the group (`gnus-summary-exit`). `gnus-summary-prepare-exit-hook` is called before doing much of the exiting, and calls `gnus-summary-expire-articles` by default. `gnus-summary-exit-hook` is called after finishing the exiting process.

Z E

Q

Exit the current group without updating any information on the group (`gnus-summary-exit-no-update`).

Z c

c

Mark all unticked articles in the group as read and then exit (`gnus-summary-catchup-and-exit`).

Z C

Mark all articles, even the ticked ones, as read and then exit (`gnus-summary-catchup-all-and-exit`).

Z n

Mark all articles as read and go to the next group (`gnus-summary-catchup-and-goto-next-group`).

Z R

Exit this group, and then enter it again (`gnus-summary-reselect-current-group`). If given a prefix, select all articles, both read and unread.

Z G

M-g

Exit the group, check for new articles in the group, and select the group (`gnus-summary-rescan-group`). If given a prefix, select all articles, both read and unread.

Z N

Exit the group and go to the next group (`gnus-summary-next-group`).

Z P

Exit the group and go to the previous group (`gnus-summary-prev-group`).

`gnus-exit-group-hook` is called when you exit the current group.

If you're in the habit of exiting groups, and then changing your mind about it, you might set `gnus-kill-summary-on-exit` to `nil`. If you do that, Gnus won't kill the summary buffer when you exit it. (Quelle surprise!) Instead it will change the name of the buffer to something like `*Dead Summary ... *' and install a minor mode called `gnus-dead-summary-mode`. Now, if you switch back to this buffer, you'll find that all keys are mapped to a function called `gnus-summary-wake-up-the-dead`. So tapping any keys in a dead summary buffer will result in a live, normal summary buffer.

There will never be more than one dead summary buffer at any one time.

The data on the current group will be updated (which articles you have read, which articles you have replied to, etc.) when you exit the summary buffer. If the `gnus-use-cross-reference` variable is `t` (which is the default), articles that are cross-referenced to this group and are marked as read, will also be marked as read in the other subscribed groups they were cross-posted to. If this variable is neither `nil` nor `t`, the article will be marked as read in both subscribed and unsubscribed groups.

Marking cross-posted articles as read ensures that you'll never have to read the same article more than once. Unless, of course, somebody has posted it to several groups separately. Posting the same article to several groups (not cross-posting) is called spamming, and you are by law required to send nasty-grams to anyone who perpetrates such a heinous crime.

Remember: Cross-posting is kinda ok, but posting the same article separately to several groups is not. Massive cross-posting (aka. velveeta) is to be avoided.

One thing that may cause Gnus to not do the cross-posting thing correctly is if you use an NNTP server that supports XOVER (which is very nice, because it speeds things up considerably) which does not include the `Xref` header in its NOV lines. This is Evil, but all too common, alas, alack. Gnus tries to Do The Right Thing even with XOVER by registering the `Xref` lines of all articles you actually read, but if you kill the articles, or just mark them as read without reading them, Gnus will not get a chance to snoop the `Xref` lines out of these articles, and will be unable to use the cross reference mechanism.

To check whether your NNTP server includes the `Xref` header in its overview files, try `telnet your.nntp.server nntp', `MODE READER' on `inn` servers, and then say `LIST overview.fmt'. This may not work, but if it does, and the last line you get does not read `Xref:full', then you should shout and whine at your news admin until she includes the `Xref` header in the overview files.

If you want Gnus to get the `Xref`s right all the time, you have to set `gnus-nov-is-evil` to `t`, which slows things down considerably.

C'est la vie.

Go to the previous, next section.

Go to the previous, next section.

The Article Buffer

The articles are displayed in the article buffer, of which there is only one. All the summary buffers share the same article buffer unless you tell Gnus otherwise.

Hiding Headers

The top section of each article is the head. (The rest is the body, but you may have guessed that already.)

There is a lot of useful information in the head: the name of the person who wrote the article, the date it was written and the subject of the article. That's well and nice, but there's also lots of information most people do not want to see--what systems the article has passed through before reaching you, the `Message-ID`, the `References`, etc. ad nauseum--and you'll probably want to get rid of some of those lines. If you want to keep all those lines in the article buffer, you can set `gnus-show-all-headers` to `t`.

Gnus provides you with two variables for sifting headers:

`gnus-visible-headers`

> If this variable is non-`nil`, it should be a regular expression that says what headers you wish to keep in the article buffer. All headers that do not match this variable will be hidden.
>
> For instance, if you only want to see the name of the person who wrote the article and the subject, you'd say:
>
> ```
> (setq gnus-visible-headers "^From:\\|^Subject:")
> ```
>
> This variable can also be a list of regexps to match headers that are to remain visible.

`gnus-ignored-headers`

> This variable is the reverse of `gnus-visible-headers`. If this variable is set (and `gnus-visible-headers` is `nil`), it should be a regular expression that matches all lines that you want to hide. All lines that do not match this variable will remain visible.
>
> For instance, if you just want to get rid of the `References` line and the `Xref` line, you might say:
>
> ```
> (setq gnus-ignored-headers "^References:\\|^Xref:")
> ```
>
> This variable can also be a list of regexps to match headers that are to be removed.
>
> Note that if `gnus-visible-headers` is non-`nil`, this variable will have no effect.

Gnus can also sort the headers for you. (It does this by default.) You can control the sorting by setting the `gnus-sorted-header-list` variable. It is a list of regular expressions that says in what order the

headers are to be displayed.

For instance, if you want the name of the author of the article first, and then the subject, you might say something like:

```
(setq gnus-sorted-header-list '("^From:" "^Subject:"))
```

Any headers that are to remain visible, but are not listed in this variable, will be displayed in random order after all the headers that are listed in this variable.

You can hide further boring headers by entering `gnus-article-hide-boring-headers` into `gnus-article-display-hook`. What this function does depends on the `gnus-boring-article-headers` variable. It's a list, but this list doesn't actually contain header names. Instead is lists various boring conditions that Gnus can check and remove from sight.

These conditions are:

`empty`
: Remove all empty headers.

`newsgroups`
: Remove the `Newsgroups` header if it only contains the current group name.

`followup-to`
: Remove the `Followup-To` header if it is identical to the `Newsgroups` header.

`reply-to`
: Remove the `Reply-To` header if it lists the same address as the `From` header.

`date`
: Remove the `Date` header if the article is less than three days old.

To include the four first elements, you could say something like;

```
(setq gnus-boring-article-headers
      '(empty newsgroups followup-to reply-to))
```

This is also the default value for this variable.

Using MIME

Mime is a standard for waving your hands through the air, aimlessly, while people stand around yawning.

MIME, however, is a standard for encoding your articles, aimlessly, while all newsreaders die of fear.

MIME may specify what character set the article uses, the encoding of the characters, and it also makes it possible to embed pictures and other naughty stuff in innocent-looking articles.

Gnus handles MIME by shoving the articles through `gnus-show-mime-method`, which is

`metamail-buffer` by default. Set `gnus-show-mime` to `t` if you want to use MIME all the tim
However, if `gnus-strict-mime` is non-`nil`, the MIME method will only be used if there are M
headers in the article.

It might be best to just use the toggling functions from the summary buffer to avoid getting nasty surprises. (For instance, you enter the group `alt.sing-a-long' and, before you know it, MIME has decoded the sound file in the article and some horrible sing-a-long song comes streaming out out your speakers, and you can't find the volume button, because there isn't one, and people are starting to look at you, and you try to stop the program, but you can't, and you can't find the program to control the volume, and everybody else in the room suddenly decides to look at you disdainfully, and you'll feel rather stupid.)

Any similarity to real events and people is purely coincidental. Ahem.

Customizing Articles

The `gnus-article-display-hook` is called after the article has been inserted into the article buffer. It is meant to handle all treatment of the article before it is displayed.

By default it contains `gnus-article-hide-headers`, `gnus-article-treat-overstrike`, and `gnus-article-maybe-highlight`, but there are thousands, nay millions, of functions you can put in this hook. For an overview of functions see section Article Highlighting, see section Article Hiding, see section Article Washing, see section Article Buttons and see section Article Date.

You can, of course, write your own functions. The functions are called from the article buffer, and you can do anything you like, pretty much. There is no information that you have to keep in the buffer--you can change everything. However, you shouldn't delete any headers. Instead make them invisible if you want to make them go away.

Article Keymap

Most of the keystrokes in the summary buffer can also be used in the article buffer. They should behave as if you typed them in the summary buffer, which means that you don't actually have to have a summary buffer displayed while reading. You can do it all from the article buffer.

A few additional keystrokes are available:

SPACE
: Scroll forwards one page (`gnus-article-next-page`).

DEL
: Scroll backwards one page (`gnus-article-prev-page`).

C-c ^
: If point is in the neighborhood of a `Message-ID` and you press r, Gnus will try to get that article from the server (`gnus-article-refer-article`).

C-c C-m

Send a reply to the address near point (`gnus-article-mail`). If given a prefix, include th mail.

s

Reconfigure the buffers so that the summary buffer becomes visible (`gnus-article-show-summary`).

?

Give a very brief description of the available keystrokes (`gnus-article-describe-briefly`).

TAB

Go to the next button, if any (`gnus-article-next-button`. This only makes sense if you have buttonizing turned on.

M-TAB

Go to the previous button, if any (`gnus-article-prev-button`.

Misc Article

`gnus-single-article-buffer`

If non-`nil`, use the same article buffer for all the groups. (This is the default.) If `nil`, each group will have its own article buffer.

`gnus-article-prepare-hook`

This hook is called right after the article has been inserted into the article buffer. It is mainly intended for functions that do something depending on the contents; it should probably not be used for changing the contents of the article buffer.

`gnus-article-display-hook`

This hook is called as the last thing when displaying an article, and is intended for modifying the contents of the buffer, doing highlights, hiding headers, and the like.

`gnus-article-mode-hook`

Hook called in article mode buffers.

`gnus-article-mode-line-format`

This variable is a format string along the same lines as `gnus-summary-mode-line-format`. It accepts exactly the same format specifications as that variable.

`gnus-break-pages`

Controls whether page breaking is to take place. If this variable is non-`nil`, the articles will be divided into pages whenever a page delimiter appears in the article. If this variable is `nil`, paging will not be done.

`gnus-page-delimiter`

This is the delimiter mentioned above. By default, it is `^L' (form linefeed).

Go to the previous, next section.

Go to the previous, next section.

Composing Messages

All commands for posting and mailing will put you in a message buffer where you can edit the article all you like, before you send the article by pressing C-c C-c. See section 'Top' in The Message Manual. If you are in a foreign news group, and you wish to post the article using the foreign server, you can give a prefix to C-c C-c to make Gnus try to post using the foreign server.

Also see see section Canceling Articles for information on how to remove articles you shouldn't have posted.

Mail

Variables for customizing outgoing mail:

`gnus-uu-digest-headers`

> List of regexps to match headers included in digested messages. The headers will be included in the sequence they are matched.

Post

Variables for composing news articles:

`gnus-sent-message-ids-file`

> Gnus will keep a `Message-ID` history file of all the mails it has sent. If it discovers that it has already sent a mail, it will ask the user whether to re-send the mail. (This is primarily useful when dealing with SOUP packets and the like where one is apt to sent the same packet multiple times.) This variable says what the name of this history file is. It is `` `~/News/Sent-Message-IDs' `` by default. Set this variable to `nil` if you don't want Gnus to keep a history file.

`gnus-sent-message-ids-length`

> This variable says how many `Message-ID`s to keep in the history file. It is 1000 by default.

Posting Server

When you press those magical C-c C-c keys to ship off your latest (extremely intelligent, of course) article, where does it go?

Thank you for asking. I hate you.

It can be quite complicated. Normally, Gnus will use the same native server. However. If your native server doesn't allow posting, just reading, you probably want to use some other server to post your (extremely intelligent and fabulously interesting) articles. You can then set the `gnus-post-method`

to some other method:

```
(setq gnus-post-method '(nnspool ""))
```

Now, if you've done this, and then this server rejects your article, or this server is down, what do you do then? To override this variable you can use a non-zero prefix to the C-c C-c command to force using the "current" server for posting.

If you give a zero prefix (i. e., C-u 0 C-c C-c) to that command, Gnus will prompt you for what method to use for posting.

You can also set `gnus-post-method` to a list of select methods. If that's the case, Gnus will always prompt you for what method to use for posting.

Mail and Post

Here's a list of variables that are relevant to both mailing and posting:

`gnus-mailing-list-groups`

> If your news server offers groups that are really mailing lists that are gatewayed to the NNTP server, you can read those groups without problems, but you can't post/followup to them without some difficulty. One solution is to add a `to-address` to the group parameters (see section Group Parameters). An easier thing to do is set the `gnus-mailing-list-groups` to a regexp that match the groups that really are mailing lists. Then, at least, followups to the mailing lists will work most of the time. Posting to these groups (a) is still a pain, though.

You may want to do spell-checking on messages that you send out. Or, if you don't want to spell-check by hand, you could add automatic spell-checking via the `ispell` package:

```
(add-hook 'message-send-hook 'ispell-message)
```

Archived Messages

Gnus provides a few different methods for storing the mail you send. The default method is to use the archive virtual server to store the mail. If you want to disable this completely, you should set `gnus-message-archive-group` to `nil`.

`gnus-message-archive-method` says what virtual server Gnus is to use to store sent messages. It is `(nnfolder "archive" (nnfolder-directory "~/Mail/archive/"))` by default, but you can use any mail select method (`nnml`, `nnmbox`, etc.). However, `nnfolder` is a quite likeable select method for doing this sort of thing. If you don't like the default directory chosen, you could say something like:

```
(setq gnus-message-archive-method
      '(nnfolder "archive"
```

```
                (nnfolder-inhibit-expiry t)
                (nnfolder-active-file "~/News/sent-mail/active")
                (nnfolder-directory "~/News/sent-mail/")))
```

Gnus will insert `Gcc` headers in all outgoing messages that point to one or more group(s) on that server. Which group to use is determined by the `gnus-message-archive-group` variable.

This variable can be:

- a string Messages will be saved in that group.
- a list of strings Messages will be saved in all those groups.
- an alist of regexps, functions and forms When a key "matches", the result is used.

Let's illustrate:

Just saving to a single group called `MisK':

```
(setq gnus-message-archive-group "MisK")
```

Saving to two groups, `MisK' and `safe':

```
(setq gnus-message-archive-group '("MisK" "safe"))
```

Save to different groups based on what group you are in:

```
(setq gnus-message-archive-group
      '(("^alt" "sent-to-alt")
        ("mail" "sent-to-mail")
        (".*" "sent-to-misc")))
```

More complex stuff:

```
(setq gnus-message-archive-group
      '((if (message-news-p)
            "misc-news"
          "misc-mail")))
```

This is the default.

How about storing all news messages in one file, but storing all mail messages in one file per month:

```
(setq gnus-message-archive-group
      '((if (message-news-p)
            "misc-news"
          (concat "mail." (format-time-string
                           "%Y-%m" (current-time))))))
```

Now, when you send a message off, it will be stored in the appropriate group. (If you want to disable

storing for just one particular message, you can just remove the `Gcc` header that has been inserted.) The archive group will appear in the group buffer the next time you start Gnus, or the next time you press g in the group buffer. You can enter it and read the articles in it just like you'd read any other group. If the group gets really big and annoying, you can simply rename if (using G r in the group buffer) to something nice -- `misc-mail-september-1995', or whatever. New messages will continue to be stored in the old (now empty) group.

That's the default method of archiving sent mail. Gnus also offers two other variables for the people who don't like the default method. In that case you should set `gnus-message-archive-group` to `nil`; this will disable archiving.

XEmacs 19.13 doesn't have `format-time-string`, so you'll have to use a different value for `gnus-message-archive-group` there.

`gnus-outgoing-message-group`

> All outgoing messages will be put in this group. If you want to store all your outgoing mail and articles in the group `nnml:archive', you set this variable to that value. This variable can also be a list of group names.
>
> If you want to have greater control over what group to put each message in, you can set this variable to a function that checks the current newsgroup name and then returns a suitable group name (or list of names).

Go to the previous, next section.

Go to the previous, next section.

Select Methods

A foreign group is a group that is not read by the usual (or default) means. It could be, for instance, a group from a different NNTP server, it could be a virtual group, or it could be your own personal mail group.

A foreign group (or any group, really) is specified by a name and a select method. To take the latter first, a select method is a list where the first element says what backend to use (eg. `nntp`, `nnspool`, `nnml`) and the second element is the server name. There may be additional elements in the select method, where the value may have special meaning for the backend in question.

One could say that a select method defines a virtual server---so we do just that (see section The Server Buffer).

The name of the group is the name the backend will recognize the group as.

For instance, the group `soc.motss' on the NNTP server `some.where.edu' will have the name `soc.motss' and select method `(nntp "some.where.edu")`. Gnus will call this group, in all circumstances, `nntp+some.where.edu:soc.motss', even though the `nntp` backend just knows this group as `soc.motss'.

The different methods all have their peculiarities, of course.

The Server Buffer

Traditionally, a server is a machine or a piece of software that one connects to, and then requests information from. Gnus does not connect directly to any real servers, but does all transactions through one backend or other. But that's just putting one layer more between the actual media and Gnus, so we might just as well say that each backend represents a virtual server.

For instance, the `nntp` backend may be used to connect to several different actual NNTP servers, or, perhaps, to many different ports on the same actual NNTP server. You tell Gnus which backend to use, and what parameters to set by specifying a select method.

These select methods specifications can sometimes become quite complicated--say, for instance, that you want to read from the NNTP server `news.funet.fi' on port number `13`, which hangs if queried for NOV headers and has a buggy select. Ahem. Anyways, if you had to specify that for each group that used this server, that would be too much work, so Gnus offers a way of naming select methods, which is what you do in the server buffer.

To enter the server buffer, user the ^ (`gnus-group-enter-server-mode`) command in the group buffer.

`gnus-server-mode-hook` is run when creating the server buffer.

Server Buffer Format

You can change the look of the server buffer lines by changing the `gnus-server-line-format` variable. This is a `format`-like variable, with some simple extensions:

`h'
: How the news is fetched--the backend name.

`n'
: The name of this server.

`w'
: Where the news is to be fetched from--the address.

`s'
: The opened/closed/denied status of the server.

The mode line can also be customized by using the `gnus-server-mode-line-format` variable. The following specs are understood:

`S'
: Server name.

`M'
: Server method.

Also see section Formatting Variables.

Server Commands

a
: Add a new server (`gnus-server-add-server`).

e
: Edit a server (`gnus-server-edit-server`).

SPACE
: Browse the current server (`gnus-server-read-server`).

q
: Return to the group buffer (`gnus-server-exit`).

k
: Kill the current server (`gnus-server-kill-server`).

y
: Yank the previously killed server (`gnus-server-yank-server`).

c
: Copy the current server (`gnus-server-copy-server`).

l

List all servers (`gnus-server-list-servers`).

Example Methods

Most select methods are pretty simple and self-explanatory:

```
(nntp "news.funet.fi")
```

Reading directly from the spool is even simpler:

```
(nnspool "")
```

As you can see, the first element in a select method is the name of the backend, and the second is the address, or name, if you will.

After these two elements, there may be a arbitrary number of (variable form) pairs.

To go back to the first example--imagine that you want to read from port `15` from that machine. This is what the select method should look like then:

```
(nntp "news.funet.fi" (nntp-port-number 15))
```

You should read the documentation to each backend to find out what variables are relevant, but here's an `nnmh` example.

`nnmh` is a mail backend that reads a spool-like structure. Say you have two structures that you wish to access: One is your private mail spool, and the other is a public one. Here's the possible spec for you private mail:

```
(nnmh "private" (nnmh-directory "~/private/mail/"))
```

(This server is then called `private', but you may have guessed that.)

Here's the method for a public spool:

```
(nnmh "public"
      (nnmh-directory "/usr/information/spool/")
      (nnmh-get-new-mail nil))
```

Creating a Virtual Server

If you're saving lots of articles in the cache by using persistent articles, you may want to create a virtual server to read the cache.

First you need to add a new server. The a command does that. It would probably be best to use `nnspool` to read the cache. You could also use `nnml` or `nnmh`, though.

Type a nnspool RET cache RET.

You should now have a brand new `nnspool` virtual server called `cache'. You now need to edit it to the right definitions. Type e to edit the server. You'll be entered into a buffer that will contain the following:

```
(nnspool "cache")
```

Change that to:

```
(nnspool "cache"
         (nnspool-spool-directory "~/News/cache/")
         (nnspool-nov-directory "~/News/cache/")
         (nnspool-active-file "~/News/cache/active"))
```

Type C-c C-c to return to the server buffer. If you now press RET over this virtual server, you should be entered into a browse buffer, and you should be able to enter any of the groups displayed.

Servers and Methods

Wherever you would normally use a select method (eg. `gnus-secondary-select-method`, in the group select method, when browsing a foreign server) you can use a virtual server name instead. This could potentially save lots of typing. And it's nice all over.

Unavailable Servers

If a server seems to be unreachable, Gnus will mark that server as `denied`. That means that any subsequent attempt to make contact with that server will just be ignored. "It can't be opened," Gnus will tell you, without making the least effort to see whether that is actually the case or not.

That might seem quite naughty, but it does make sense most of the time. Let's say you have 10 groups subscribed to the server `nepholococcygia.com'. This server is located somewhere quite far away from you, the machine is quite, so it takes 1 minute just to find out that it refuses connection from you today. If Gnus were to attempt to do that 10 times, you'd be quite annoyed, so Gnus won't attempt to do that. Once it has gotten a single "connection refused", it will regard that server as "down".

So, what happens if the machine was only feeling unwell temporarily? How do you test to see whether the machine has come up again?

You jump to the server buffer (see section The Server Buffer) and poke it with the following commands:

O
: Try to establish connection to the server on the current line (`gnus-server-open-server`).

C
: Close the connection (if any) to the server (`gnus-server-close-server`).

D
: Mark the current server as unreachable (`gnus-server-deny-server`).

R

Remove all marks to whether Gnus was denied connection from all servers (`gnus-server-remove-denials`).

Getting News

A newsreader is normally used for reading news. Gnus currently provides only two methods of getting news -- it can read from an NNTP server, or it can read from a local spool.

NNTP

Subscribing to a foreign group from an NNTP server is rather easy. You just specify `nntp` as method and the address of the NNTP server as the, uhm, address.

If the NNTP server is located at a non-standard port, setting the third element of the select method to this port number should allow you to connect to the right port. You'll have to edit the group info for that (see section Foreign Groups).

The name of the foreign group can be the same as a native group. In fact, you can subscribe to the same group from as many different servers you feel like. There will be no name collisions.

The following variables can be used to create a virtual `nntp` server:

`nntp-server-opened-hook`

`nntp-server-opened-hook` is run after a connection has been made. It can be used to send commands to the NNTP server after it has been contacted. By default is sends the command `MODE READER` to the server with the `nntp-send-mode-reader` function. Another popular function is `nntp-send-authinfo`, which will prompt you for an NNTP password and stuff.

`nntp-server-action-alist`

This is an list of regexps to match on server types and actions to be taken when matches are made. For instance, if you want Gnus to beep every time you connect to innd, you could say something like:

```
(setq nntp-server-action-alist
      '(("innd" (ding))))
```

You probably don't want to do that, though.

The default value is

```
'(("nntpd 1\\.5\\.11t"
   (remove-hook 'nntp-server-opened-hook nntp-send-mode-reader)))
```

This ensures that Gnus doesn't send the `MODE READER` command to nntpd 1.5.11t, since that command chokes that server, I've been told.

`nntp-maximum-request`

If the NNTP server doesn't support NOV headers, this backend will collect headers by sending a

series of `head` commands. To speed things up, the backend sends lots of these commands without waiting for reply, and then reads all the replies. This is controlled by the `nntp-maximum-request` variable, and is 400 by default. If your network is buggy, you should set this to 1.

`nntp-connection-timeout`

If you have lots of foreign `nntp` groups that you connect to regularly, you're sure to have problems with NNTP servers not responding properly, or being too loaded to reply within reasonable time. This is can lead to awkward problems, which can be helped somewhat by setting `nntp-connection-timeout`. This is an integer that says how many seconds the `nntp` backend should wait for a connection before giving up. If it is `nil`, which is the default, no timeouts are done.

`nntp-command-timeout`

If you're running Gnus on a machine that has a dynamically assigned address, Gnus may become confused. If the address of your machine changes after connecting to the NNTP server, Gnus will simply sit waiting forever for replies from the server. To help with this unfortunate problem, you can set this command to a number. Gnus will then, if it sits waiting longer than that number of seconds for a reply from the server, shut down the connection, start a new one, and resend the command. This should hopefully be transparent to the user. A likely number is 30 seconds.

`nntp-retry-on-break`

If this variable is non-`nil`, you can also C-g if Gnus hangs. This will have much the same effect as the command timeout described above.

`nntp-server-hook`

This hook is run as the last step when connecting to an NNTP server.

`nntp-open-server-function`

This function is used to connect to the remote system. Two pre-made functions are `nntp-open-network-stream`, which is the default, and simply connects to some port or other on the remote system. The other is `nntp-open-rlogin`, which does an rlogin on the remote system, and then does a telnet to the NNTP server available there.

`nntp-rlogin-parameters`

If you use `nntp-open-rlogin` as the `nntp-open-server-function`, this list will be used as the parameter list given to `rsh`.

`nntp-end-of-line`

String to use as end-of-line markers when talking to the NNTP server. This is `\r\n' by default, but should be `\n' when using `rlogin` to talk to the server.

`nntp-rlogin-user-name`

User name on the remote system when using the `rlogin` connect function.

`nntp-address`

The address of the remote system running the NNTP server.

`nntp-port-number`

Port number to connect to when using the `nntp-open-network-stream` connect function.

`nntp-buggy-select`

Set this to non-`nil` if your select routine is buggy.

`nntp-nov-is-evil`

If the NNTP server does not support NOV, you could set this variable to `t`, but `nntp` usually checks whether NOV can be used automatically.

`nntp-xover-commands`

List of strings that are used as commands to fetch NOV lines from a server. The default value of this variable is `("XOVER" "XOVERVIEW")`.

`nntp-nov-gap`

`nntp` normally sends just one big request for NOV lines to the server. The server responds with one huge list of lines. However, if you have read articles 2-5000 in the group, and only want to read article 1 and 5001, that means that `nntp` will fetch 4999 NOV lines that you do not want, and will not use. This variable says how big a gap between two consecutive articles is allowed to be before the `XOVER` request is split into several request. Note that if your network is fast, setting this variable to a really small number means that fetching will probably be slower. If this variable is `nil`, `nntp` will never split requests.

`nntp-prepare-server-hook`

A hook run before attempting to connect to an NNTP server.

`nntp-async-number`

How many articles should be pre-fetched when in asynchronous mode. If this variable is `t`, `nntp` will pre-fetch all the articles that it can without bound. If it is `nil`, no pre-fetching will be made.

`nntp-warn-about-losing-connection`

If this variable is non-`nil`, some noise will be made when a server closes connection.

News Spool

Subscribing to a foreign group from the local spool is extremely easy, and might be useful, for instance, to speed up reading groups like `alt.binaries.pictures.furniture'.

Anyways, you just specify `nnspool` as the method and `' (or anything else) as the address.

If you have access to a local spool, you should probably use that as the native select method (see section Finding the News). It is normally faster than using an `nntp` select method, but might not be. It depends. You just have to try to find out what's best at your site.

`nnspool-inews-program`

Program used to post an article.

`nnspool-inews-switches`

Parameters given to the inews program when posting an article.

`nnspool-spool-directory`

Where `nnspool` looks for the articles. This is normally `` `/usr/spool/news/' ``.

`nnspool-nov-directory`

Where `nnspool` will look for NOV files. This is normally

`/usr/spool/news/over.view/'.

`nnspool-lib-dir`
: Where the news lib dir is (`/usr/lib/news/' by default).

`nnspool-active-file`
: The path of the active file.

`nnspool-newsgroups-file`
: The path of the group descriptions file.

`nnspool-history-file`
: The path of the news history file.

`nnspool-active-times-file`
: The path of the active date file.

`nnspool-nov-is-evil`
: If non-`nil`, `nnspool` won't try to use any NOV files that it finds.

`nnspool-sift-nov-with-sed`
: If non-`nil`, which is the default, use `sed` to get the relevant portion from the overview file. If nil, `nnspool` will load the entire file into a buffer and process it there.

Getting Mail

Reading mail with a newsreader--isn't that just plain WeIrD? But of course.

Getting Started Reading Mail

It's quite easy to use Gnus to read your new mail. You just plonk the mail backend of your choice into `gnus-secondary-select-methods`, and things will happen automatically.

For instance, if you want to use `nnml` (which is a one file per mail backend), you could put the following in your `.gnus' file:

```
(setq gnus-secondary-select-methods
      '((nnml "private")))
```

Now, the next time you start Gnus, this backend will be queried for new articles, and it will move all the messages in your spool file to its directory, which is `~/Mail/` by default. The new group that will be created (`mail.misc') will be subscribed, and you can read it like any other group.

You will probably want to split the mail into several groups, though:

```
(setq nnmail-split-methods
  '(("junk" "^From:.*Lars Ingebrigtsen")
    ("crazy" "^Subject:.*die\\|^Organization:.*flabby")
    ("other" "")))
```

This will result in three new mail groups being created: `nnml:junk', `nnml:crazy', and `nnml:other'. A the mail that doesn't fit into the first two groups will be placed in the latter group.

This should be sufficient for reading mail with Gnus. You might want to give the other sections in this part of the manual a perusal, though, especially see section Choosing a Mail Backend and see section Expiring Mail.

Splitting Mail

The `nnmail-split-methods` variable says how the incoming mail is to be split into groups.

```
(setq nnmail-split-methods
  '(("mail.junk" "^From:.*Lars Ingebrigtsen")
    ("mail.crazy" "^Subject:.*die\\|^Organization:.*flabby")
    ("mail.other" "")))
```

This variable is a list of lists, where the first element of each of these lists is the name of the mail group (they do not have to be called something beginning with `mail', by the way), and the second element is a regular expression used on the header of each mail to determine if it belongs in this mail group.

The second element can also be a function. In that case, it will be called narrowed to the headers with the first element of the rule as the argument. It should return a non-`nil` value if it thinks that the mail belongs in that group.

The last of these groups should always be a general one, and the regular expression should *always* be `' so that it matches any mails that haven't been matched by any of the other regexps.

If you like to tinker with this yourself, you can set this variable to a function of your choice. This function will be called without any arguments in a buffer narrowed to the headers of an incoming mail message. The function should return a list of groups names that it thinks should carry this mail message.

Note that the mail backends are free to maul the poor, innocent incoming headers all they want to. They all add `Lines` headers; some add `X-Gnus-Group` headers; most rename the Unix mbox `From<SPACE>` line to something else.

The mail backends all support cross-posting. If several regexps match, the mail will be "cross-posted" to all those groups. `nnmail-crosspost` says whether to use this mechanism or not. Note that no articles are crossposted to the general (`') group.

`nnmh` and `nnml` makes crossposts by creating hard links to the crossposted articles. However, not all files systems support hard links. If that's the case for you, set `nnmail-crosspost-link-function` to `copy-file`. (This variable is `add-name-to-file` by default.)

Gnus gives you all the opportunity you could possibly want for shooting yourself in the foot. Let's say you create a group that will contain all the mail you get from your boss. And then you accidentally unsubscribe from the group. Gnus will still put all the mail from your boss in the unsubscribed group, and so, when your boss mails you "Have that report ready by Monday or you're fired!", you'll never see it and, come Tuesday, you'll still believe that you're gainfully employed while you really should be out collecting empty bottles to save up for next month's rent money.

Mail Backend Variables

These variables are (for the most part) pertinent to all the various mail backends.

`nnmail-read-incoming-hook`

The mail backends all call this hook after reading new mail. You can use this hook to notify any mail watch programs, if you want to.

`nnmail-spool-file`

The backends will look for new mail in this file. If this variable is `nil`, the mail backends will never attempt to fetch mail by themselves. If you are using a POP mail server and your name is `larsi', you should set this variable to `po:larsi'. If your name is not `larsi', you should probably modify that slightly, but you may have guessed that already, you smart & handsome devil! You can also set this variable to `pop`, and Gnus will try to figure out the POP mail string by itself. In any case, Gnus will call `movemail` which will contact the POP server named in the `MAILHOST` environment variable. If the POP server needs a password, you can either set `nnmail-pop-password-required` to `t` and be prompted for the password, or set `nnmail-pop-password` to the password itself.

When you use a mail backend, Gnus will slurp all your mail from your inbox and plonk it down in your home directory. Gnus doesn't move any mail if you're not using a mail backend--you have to do a lot of magic invocations first. At the time when you have finished drawing the pentagram, lightened the candles, and sacrificed the goat, you really shouldn't be too surprised when Gnus moves your mail.

`nnmail-use-procmail`

If non-`nil`, the mail backends will look in `nnmail-procmail-directory` for incoming mail. All the files in that directory that have names ending in `nnmail-procmail-suffix` will be considered incoming mailboxes, and will be searched for new mail.

`nnmail-crash-box`

When the mail backends read a spool file, it is first moved to this file, which is `` `~/.gnus-crash-box' `` by default. If this file already exists, it will always be read (and incorporated) before any other spool files.

`nnmail-prepare-incoming-hook`

This is run in a buffer that holds all the new incoming mail, and can be used for, well, anything, really.

`nnmail-pre-get-new-mail-hook`

`nnmail-post-get-new-mail-hook`

These are two useful hooks executed when treating new incoming mail---`nnmail-pre-get-new-mail-hook` (is called just before starting to handle the new mail) and `nnmail-post-get-new-mail-hook` (is called when the mail handling is done). Here's and example of using these two hooks to change the default file modes the new mail files get:

```
(add-hook 'gnus-pre-get-new-mail-hook
```

```
            (lambda () (set-default-file-modes 511)))

    (add-hook 'gnus-post-get-new-mail-hook
            (lambda () (set-default-file-modes 551)))
```

`nnmail-tmp-directory`

This variable says where to move the incoming mail to while processing it. This is usually done in the same directory that the mail backend inhabits (i.e., `` `~/Mail/' ``), but if this variable is non-`nil`, it will be used instead.

`nnmail-movemail-program`

This program is executed to move mail from the user's inbox to her home directory. The default is `movemail'.

`nnmail-delete-incoming`

If non-`nil`, the mail backends will delete the temporary incoming file after splitting mail into the proper groups. This is `nil` by default for reasons of security.

`nnmail-use-long-file-names`

If non-`nil`, the mail backends will use long file and directory names. Groups like `mail.misc' will end up in directories like `` `mail.misc/' ``. If it is `nil`, the same group will end up in `` `mail/misc/' ``.

`nnmail-delete-file-function`

Function called to delete files. It is `delete-file` by default.

Fancy Mail Splitting

If the rather simple, standard method for specifying how to split mail doesn't allow you to do what you want, you can set `nnmail-split-methods` to `nnmail-split-fancy`. Then you can play with the `nnmail-split-fancy` variable.

Let's look at an example value of this variable first:

```
;; Messages from the mailer daemon are not crossposted to any of
;; the ordinary groups.  Warnings are put in a separate group
;; from real errors.
(| ("from" mail (| ("subject" "warn.*" "mail.warning")
                   "mail.misc"))
   ;; Non-error messages are crossposted to all relevant
   ;; groups, but we don't crosspost between the group for the
   ;; (ding) list and the group for other (ding) related mail.
   (& (| (any "ding@ifi\\.uio\\.no" "ding.list")
         ("subject" "ding" "ding.misc"))
      ;; Other mailing lists...
      (any "procmail@informatik\\.rwth-aachen\\.de" "procmail.list")
      (any "SmartList@informatik\\.rwth-aachen\\.de" "SmartList.list")
      ;; People...
```

```
    (any "larsi@ifi\\.uio\\.no" "people.Lars Magne Ingebrigtsen"))
  ;; Unmatched mail goes to the catch all group.
  "misc.misc"))")
```

This variable has the format of a split. A split is a (possibly) recursive structure where each split may contain other splits. Here are the four possible split syntaxes:

GROUP

If the split is a string, that will be taken as a group name.

(FIELD VALUE SPLIT)

If the split is a list, and the first element is a string, then that means that if header FIELD (a regexp) contains VALUE (also a regexp), then store the message as specified by SPLIT.

(| SPLIT...)

If the split is a list, and the first element is `|` (vertical bar), then process each SPLIT until one of them matches. A SPLIT is said to match if it will cause the mail message to be stored in one or more groups.

(& SPLIT...)

If the split is a list, and the first element is &, then process all SPLITs in the list.

In these splits, FIELD must match a complete field name. VALUE must match a complete word according to the fundamental mode syntax table. You can use `.*` in the regexps to match partial field names or words.

FIELD and VALUE can also be lisp symbols, in that case they are expanded as specified by the variable `nnmail-split-abbrev-alist`. This is an alist of cons cells, where the car of the cells contains the key, and the cdr contains a string.

`nnmail-split-fancy-syntax-table` is the syntax table in effect when all this splitting is performed.

Mail and Procmail

Many people use `procmail` (or some other mail filter program or external delivery agent---`slocal`, `elm`, etc) to split incoming mail into groups. If you do that, you should set `nnmail-spool-file` to `procmail` to ensure that the mail backends never ever try to fetch mail by themselves.

This also means that you probably don't want to set `nnmail-split-methods` either, which has some, perhaps, unexpected side effects.

When a mail backend is queried for what groups it carries, it replies with the contents of that variable, along with any groups it has figured out that it carries by other means. None of the backends (except `nnmh`) actually go out to the disk and check what groups actually exist. (It's not trivial to distinguish between what the user thinks is a basis for a newsgroup and what is just a plain old file or directory.)

This means that you have to tell Gnus (and the backends) what groups exist by hand.

Let's take the `nnmh` backend as an example.

The folders are located in `nnmh-directory`, say, `~/Mail/'. There are three folders, `foo', `bar' and `mail.baz'.

Go to the group buffer and type G m. When prompted, answer `foo' for the name and `nnmh' for the method. Repeat twice for the two other groups, `bar' and `mail.baz'. Be sure to include all your mail groups.

That's it. You are now set to read your mail. An active file for this method will be created automatically.

If you use `nnfolder` or any other backend that store more than a single article in each file, you should never have procmail add mails to the file that Gnus sees. Instead, procmail should put all incoming mail in `nnmail-procmail-directory`. To arrive at the file name to put the incoming mail in, append `nnmail-procmail-suffix` to the group name. The mail backends will read the mail from these files.

When Gnus reads a file called `mail.misc.spool', this mail will be put in the `mail.misc`, as one would expect. However, if you want Gnus to split the mail the normal way, you could set `nnmail-resplit-incoming` to `t`.

If you use `procmail` to split things directory into an `nnmh` directory (which you shouldn't do), you should set `nnmail-keep-last-article` to non-`nil` to prevent Gnus from ever expiring the final article in a mail newsgroup. This is quite, quite important.

Incorporating Old Mail

Most people have lots of old mail stored in various file formats. If you have set up Gnus to read mail using one of the spiffy Gnus mail backends, you'll probably wish to have that old mail incorporated into your mail groups.

Doing so can be quite easy.

To take an example: You're reading mail using `nnml` (see section Mail Spool), and have set `nnmail-split-methods` to a satisfactory value (see section Splitting Mail). You have an old Unix mbox file filled with important, but old, mail. You want to move it into your `nnml` groups.

Here's how:

1. Go to the group buffer.
2. Type `G f' and give the path of the mbox file when prompted to create an `nndoc` group from the mbox file (see section Foreign Groups).
3. Type `SPACE' to enter the newly created group.
4. Type `M P b' to process-mark all articles in this group (see section Setting Process Marks).
5. Type `B r' to respool all the process-marked articles, and answer `nnml' when prompted (see section Mail Group Commands).

All the mail messages in the mbox file will now also be spread out over all your `nnml` groups. Try entering them and check whether things have gone without a glitch. If things look ok, you may consider deleting the mbox file, but I wouldn't do that unless I was absolutely sure that all the mail has ended up where it should be.

Respooling is also a handy thing to do if you're switching from one mail backend to another. Just resp all the mail in the old mail groups using the new mail backend.

Expiring Mail

Traditional mail readers have a tendency to remove mail articles when you mark them as read, in some way. Gnus takes a fundamentally different approach to mail reading.

Gnus basically considers mail just to be news that has been received in a rather peculiar manner. It does not think that it has the power to actually change the mail, or delete any mail messages. If you enter a mail group, and mark articles as "read", or kill them in some other fashion, the mail articles will still exist on the system. I repeat: Gnus will not delete your old, read mail. Unless you ask it to, of course.

To make Gnus get rid of your unwanted mail, you have to mark the articles as expirable. This does not mean that the articles will disappear right away, however. In general, a mail article will be deleted from your system if, 1) it is marked as expirable, AND 2) it is more than one week old. If you do not mark an article as expirable, it will remain on your system until hell freezes over. This bears repeating one more time, with some spurious capitalizations: IF you do NOT mark articles as EXPIRABLE, Gnus will NEVER delete those ARTICLES.

You do not have to mark articles as expirable by hand. Groups that match the regular expression `gnus-auto-expirable-newsgroups` will have all articles that you read marked as expirable automatically. All articles that are marked as expirable have an `E' in the first column in the summary buffer.

Let's say you subscribe to a couple of mailing lists, and you want the articles you have read to disappear after a while:

```
(setq gnus-auto-expirable-newsgroups
      "mail.nonsense-list\\|mail.nice-list")
```

Another way to have auto-expiry happen is to have the element `auto-expire` in the group parameters of the group.

The `nnmail-expiry-wait` variable supplies the default time an expirable article has to live. The default is seven days.

Gnus also supplies a function that lets you fine-tune how long articles are to live, based on what group they are in. Let's say you want to have one month expiry period in the `mail.private' group, a one day expiry period in the `mail.junk' group, and a six day expiry period everywhere else:

```
(setq nnmail-expiry-wait-function
      (lambda (group)
       (cond ((string= group "mail.private")
              31)
             ((string= group "mail.junk")
              1)
             ((string= group "important")
```

```
          'never)
        (t
          6))))
```

The group names that this function is fed are "unadorned" group names--no `nnml:' prefixes and the like.

The `nnmail-expiry-wait` variable and `nnmail-expiry-wait-function` function can be either a number (not necessarily an integer) or the symbols `immediate` or `never`.

You can also use the `expiry-wait` group parameter to selectively change the expiry period (see section Group Parameters).

If `nnmail-keep-last-article` is non-`nil`, Gnus will never expire the final article in a mail newsgroup. This is to make life easier for procmail users.

By the way, that line up there about Gnus never expiring non-expirable articles is a lie. If you put `total-expire` in the group parameters, articles will not be marked as expirable, but all read articles will be put through the expiry process. Use with extreme caution. Even more dangerous is the `gnus-total-expirable-newsgroups` variable. All groups that match this regexp will have all read articles put through the expiry process, which means that *all* old mail articles in the groups in question will be deleted after a while. Use with extreme caution, and don't come crying to me when you discover that the regexp you used matched the wrong group and all your important mail has disappeared. Be a *man*! Or a *woman*! Whatever you feel more comfortable with! So there!

Duplicates

If you are a member of a couple of mailing list, you will sometime receive two copies of the same mail. This can be quite annoying, so `nnmail` checks for and treats any duplicates it might find. To do this, it keeps a cache of old `Message-ID`s - `nnmail-message-id-cache-file`, which is `` `~/.nnmail-cache' `` by default. The approximate maximum number of `Message-ID`s stored there is controlled by the `nnmail-message-id-cache-length` variable, which is 1000 by default. (So 1000 `Message-ID`s will be stored.) If all this sounds scary to you, you can set `nnmail-treat-duplicates` to `warn` (which is what it is by default), and `nnmail` won't delete duplicate mails. Instead it will generate a brand new `Message-ID` for the mail and insert a warning into the head of the mail saying that it thinks that this is a duplicate of a different message.

This variable can also be a function. If that's the case, the function will be called from a buffer narrowed to the message in question with the `Message-ID` as a parameter. The function must return either `nil`, `warn`, or `delete`.

You can turn this feature off completely by setting the variable to `nil`.

If you want all the duplicate mails to be put into a special duplicates group, you could do that using the normal mail split methods:

```
(setq nnmail-split-fancy
      '(| ;; Messages duplicates go to a separate group.
          ("gnus-warning" "duplication of message" "duplicate")
```

```
          ;; Message from daemons, postmaster, and the like to anoth
          (any mail "mail.misc")
          ;; Other rules.
          [ ... ] ))
```

Or something like:

```
(setq nnmail-split-methods
      '(("duplicates" "^Gnus-Warning:")
        ;; Other rules.
        [...]))
```

Here's a neat feature: If you know that the recipient reads her mail with Gnus, and that she has `nnmail-treat-duplicates` set to `delete`, you can send her as many insults as you like, just by using a `Message-ID` of a mail that you know that she's already received. Think of all the fun! She'll never see any of it! Whee!

Not Reading Mail

If you start using any of the mail backends, they have the annoying habit of assuming that you want to read mail with them. This might not be unreasonable, but it might not be what you want.

If you set `nnmail-spool-file` to `nil`, none of the backends will ever attempt to read incoming mail, which should help.

This might be too much, if, for instance, you are reading mail quite happily with `nnml` and just want to peek at some old RMAIL file you have stashed away with `nnbabyl`. All backends have variables called backend-`get-new-mail`. If you want to disable the `nnbabyl` mail reading, you edit the virtual server for the group to have a setting where `nnbabyl-get-new-mail` to `nil`.

All the mail backends will call `nn*-prepare-save-mail-hook` narrowed to the article to be saved before saving it when reading incoming mail.

Choosing a Mail Backend

Gnus will read the mail spool when you activate a mail group. The mail file is first copied to your home directory. What happens after that depends on what format you want to store your mail in.

Unix Mail Box

The nnmbox backend will use the standard Un*x mbox file to store mail. `nnmbox` will add extra headers to each mail article to say which group it belongs in.

Virtual server settings:

`nnmbox-mbox-file`

The name of the mail box in the user's home directory.

`nnmbox-active-file`

The name of the active file for the mail box.

`nnmbox-get-new-mail`

If non-`nil`, `nnmbox` will read incoming mail and split it into groups.

Rmail Babyl

The nnbabyl backend will use a babyl mail box (aka. rmail mbox) to store mail. `nnbabyl` will add extra headers to each mail article to say which group it belongs in.

Virtual server settings:

`nnbabyl-mbox-file`

The name of the rmail mbox file.

`nnbabyl-active-file`

The name of the active file for the rmail box.

`nnbabyl-get-new-mail`

If non-`nil`, `nnbabyl` will read incoming mail.

Mail Spool

The nnml spool mail format isn't compatible with any other known format. It should be used with some caution.

If you use this backend, Gnus will split all incoming mail into files; one file for each mail, and put the articles into the correct directories under the directory specified by the `nnml-directory` variable. The default value is `` `~/Mail/' ``.

You do not have to create any directories beforehand; Gnus will take care of all that.

If you have a strict limit as to how many files you are allowed to store in your account, you should not use this backend. As each mail gets its own file, you might very well occupy thousands of inodes within a few weeks. If this is no problem for you, and it isn't a problem for you having your friendly systems administrator walking around, madly, shouting "Who is eating all my inodes?! Who? Who!?!", then you should know that this is probably the fastest format to use. You do not have to trudge through a big mbox file just to read your new mail.

`nnml` is probably the slowest backend when it comes to article splitting. It has to create lots of files, and it also generates NOV databases for the incoming mails. This makes is the fastest backend when it comes to reading mail.

Virtual server settings:

`nnml-directory`

All `nnml` directories will be placed under this directory.

`nnml-active-file`

The active file for the `nnml` server.

`nnml-newsgroups-file`

The `nnml` group descriptions file. See section Newsgroups File Format.

`nnml-get-new-mail`

If non-`nil`, `nnml` will read incoming mail.

`nnml-nov-is-evil`

If non-`nil`, this backend will ignore any NOV files.

`nnml-nov-file-name`

The name of the NOV files. The default is `` `.overview' ``.

`nnml-prepare-save-mail-hook`

Hook run narrowed to an article before saving.

If your `nnml` groups and NOV files get totally out of whack, you can do a complete update by typing M-x nnml-generate-nov-databases. This command will trawl through the entire `nnml` hierarchy, looking at each and every article, so it might take a while to complete.

MH Spool

`nnmh` is just like `nnml`, except that is doesn't generate NOV databases and it doesn't keep an active file. This makes `nnmh` a *much* slower backend than `nnml`, but it also makes it easier to write procmail scripts for.

Virtual server settings:

`nnmh-directory`

All `nnmh` directories will be located under this directory.

`nnmh-get-new-mail`

If non-`nil`, `nnmh` will read incoming mail.

`nnmh-be-safe`

If non-`nil`, `nnmh` will go to ridiculous lengths to make sure that the articles in the folder are actually what Gnus thinks they are. It will check date stamps and stat everything in sight, so setting this to `t` will mean a serious slow-down. If you never use anything but Gnus to read the `nnmh` articles, you do not have to set this variable to `t`.

Mail Folders

`nnfolder` is a backend for storing each mail group in a separate file. Each file is in the standard Un*x mbox format. `nnfolder` will add extra headers to keep track of article numbers and arrival dates.

Virtual server settings:

`nnfolder-directory`

All the `nnfolder` mail boxes will be stored under this directory.

`nnfolder-active-file`

The name of the active file.

`nnfolder-newsgroups-file`

The name of the group descriptions file. See section Newsgroups File Format.

`nnfolder-get-new-mail`

If non-`nil`, `nnfolder` will read incoming mail.

If you have lots of `nnfolder`-like files you'd like to read with `nnfolder`, you can use the M-x nnfolder-generate-active-file command to make `nnfolder` aware of all likely files in `nnfolder-directory`.

Other Sources

Gnus can do more than just read news or mail. The methods described below allow Gnus to view directories and files as if they were newsgroups.

Directory Groups

If you have a directory that has lots of articles in separate files in it, you might treat it as a newsgroup. The files have to have numerical names, of course.

This might be an opportune moment to mention `ange-ftp`, that most wonderful of all wonderful Emacs packages. When I wrote `nndir`, I didn't think much about it--a backend to read directories. Big deal.

`ange-ftp` changes that picture dramatically. For instance, if you enter `` `"/ftp.hpc.uh.edu:/pub/emacs/ding-list/"' `` as the the directory name, ange-ftp will actually allow you to read this directory over at `sina' as a newsgroup. Distributed news ahoy!

`nndir` will use NOV files if they are present.

`nndir` is a "read-only" backend--you can't delete or expire articles with this method. You can use `nnmh` or `nnml` for whatever you use `nndir` for, so you could switch to any of those methods if you feel the need to have a non-read-only `nndir`.

Anything Groups

From the `nndir` backend (which reads a single spool-like directory), it's just a hop and a skip to `nneething`, which pretends that any arbitrary directory is a newsgroup. Strange, but true.

When `nneething` is presented with a directory, it will scan this directory and assign article numbers to each file. When you enter such a group, `nneething` must create "headers" that Gnus can use. After all, Gnus is a newsreader, in case you're forgetting. `nneething` does this in a two-step process. First, it snoops each file in question. If the file looks like an article (i.e., the first few lines look like headers), it will use this as the head. If this is just some arbitrary file without a head (eg. a C source file), `nneething` will cobble up a header out of thin air. It will use file ownership, name and date and do whatever it can with these elements.

All this should happen automatically for you, and you will be presented with something that looks very much like a newsgroup. Totally like a newsgroup, to be precise. If you select an article, it will be displayed in the article buffer, just as usual.

If you select a line that represents a directory, Gnus will pop you into a new summary buffer for this `nneething` group. And so on. You can traverse the entire disk this way, if you feel like, but remember that Gnus is not dired, really, and does not intend to be, either.

There are two overall modes to this action--ephemeral or solid. When doing the ephemeral thing (i.e., G D from the group buffer), Gnus will not store information on what files you have read, and what files are new, and so on. If you create a solid `nneething` group the normal way with G m, Gnus will store a mapping table between article numbers and file names, and you can treat this group like any other groups. When you activate a solid `nneething` group, you will be told how many unread articles it contains, etc., etc.

Some variables:

`nneething-map-file-directory`

All the mapping files for solid `nneething` groups will be stored in this directory, which defaults to `` `~/.nneething/' ``.

`nneething-exclude-files`

All files that match this regexp will be ignored. Nice to use to exclude auto-save files and the like, which is what it does by default.

`nneething-map-file`

Name of the map files.

Document Groups

`nndoc` is a cute little thing that will let you read a single file as a newsgroup. Several files types are supported:

`babyl`

The babyl (rmail) mail box.

`mbox`

The standard Unix mbox file.

`mmdf`

The MMDF mail box format.

`news`

Several news articles appended into a file.

`rnews`

The rnews batch transport format.

`forward`

Forwarded articles.

`mime-digest`

MIME (RFC 1341) digest format.

`standard-digest`

The standard (RFC 1153) digest format.

`slack-digest`

Non-standard digest format--matches most things, but does it badly.

You can also use the special "file type" `guess`, which means that `nndoc` will try to guess what file type it is looking at. `digest` means that `nndoc` should guess what digest type the file is.

`nndoc` will not try to change the file or insert any extra headers into it--it will simply, like, let you use the file as the basis for a group. And that's it.

If you have some old archived articles that you want to insert into your new & spiffy Gnus mail backend, `nndoc` can probably help you with that. Say you have an old `` `RMAIL' `` file with mail that you now want to split into your new `nnml` groups. You look at that file using `nndoc`, set the process mark on all the articles in the buffer (M P b, for instance), and then re-spool (B r) using `nnml`. If all goes well, all the mail in the `` `RMAIL' `` file is now also stored in lots of `nnml` directories, and you can delete that pesky `` `RMAIL' `` file. If you have the guts!

Virtual server variables:

`nndoc-article-type`

This should be one of `mbox`, `babyl`, `digest`, `mmdf`, `forward`, `news`, `rnews`, `mime-digest`, `clari-briefs`, or `guess`.

`nndoc-post-type`

This variable says whether Gnus is to consider the group a news group or a mail group. There are two legal values: `mail` (the default) and `news`.

SOUP

In the PC world people often talk about "offline" newsreaders. These are thingies that are combined reader/news transport monstrosities. With built-in modem programs. Yecchh!

Of course, us Unix Weenie types of human beans use things like `uucp` and, like, `nntpd` and set up proper news and mail transport things like Ghod intended. And then we just use normal newsreaders.

However, it can sometimes be convenient to do something a that's a bit easier on the brain if you have a very slow modem, and you're not really that interested in doing things properly.

A file format called SOUP has been developed for transporting news and mail from servers to home machines and back again. It can be a bit fiddly.

1. You log in on the server and create a SOUP packet. You can either use a dedicated SOUP thingie, or you can use Gnus to create the packet with the O s command.
2. You transfer the packet home. Rail, boat, car or modem will do fine.
3. You put the packet in your home directory.
4. You fire up Gnus using the `nnsoup` backend as the native server.
5. You read articles and mail and answer and followup to the things you want.
6. You do the G s r command to pack these replies into a SOUP packet.
7. You transfer this packet to the server.

8. You use Gnus to mail this packet out with the G s s command.
9. You then repeat until you die.

So you basically have a bipartite system--you use `nnsoup` for reading and Gnus for packing/sending these SOUP packets.

SOUP Commands

G s b

Pack all unread articles in the current group (`gnus-group-brew-soup`). This command understands the process/prefix convention.

G s w

Save all data files (`gnus-soup-save-areas`).

G s s

Send all replies from the replies packet (`gnus-soup-send-replies`).

G s p

Pack all files into a SOUP packet (`gnus-soup-pack-packet`).

G s r

Pack all replies into a replies packet (`nnsoup-pack-replies`).

O s

This summary-mode command adds the current article to a SOUP packet (`gnus-soup-add-article`). It understands the process/prefix convention.

There are a few variables to customize where Gnus will put all these thingies:

`gnus-soup-directory`

Directory where Gnus will save intermediate files while composing SOUP packets. The default is `` `~/SoupBrew/' ``.

`gnus-soup-replies-directory`

This is what Gnus will use as a temporary directory while sending our reply packets. The default is `` `~/SoupBrew/SoupReplies/' ``.

`gnus-soup-prefix-file`

Name of the file where Gnus stores the last used prefix. The default is `gnus-prefix'.

`gnus-soup-packer`

A format string command for packing a SOUP packet. The default is `tar cf - %s | gzip > $HOME/Soupout%d.tgz'.

`gnus-soup-unpacker`

Format string command for unpacking a SOUP packet. The default is `gunzip -c %s | tar xvf -'.

`gnus-soup-packet-directory`

Where Gnus will look for reply packets. The default is `` `~/' ``.

`gnus-soup-packet-regexp`

TOC

Regular expression matching SOUP reply packets in `gnus-soup-packet-directory`.

SOUP Groups

`nnsoup` is the backend for reading SOUP packets. It will read incoming packets, unpack them, and put them in a directory where you can read them at leisure.

These are the variables you can use to customize its behavior:

`nnsoup-tmp-directory`

When `nnsoup` unpacks a SOUP packet, it does it in this directory. (`` `/tmp/' `` by default.)

`nnsoup-directory`

`nnsoup` then moves each message and index file to this directory. The default is `` `~/SOUP/' ``.

`nnsoup-replies-directory`

All replies will stored in this directory before being packed into a reply packet. The default is `` `~/SOUP/replies/"' ``.

`nnsoup-replies-format-type`

The SOUP format of the replies packets. The default is `?n' (rnews), and I don't think you should touch that variable. I probably shouldn't even have documented it. Drats! Too late!

`nnsoup-replies-index-type`

The index type of the replies packet. The is `?n', which means "none". Don't fiddle with this one either!

`nnsoup-active-file`

Where `nnsoup` stores lots of information. This is not an "active file" in the `nntp` sense; it's an Emacs Lisp file. If you lose this file or mess it up in any way, you're dead. The default is `` `~/SOUP/active' ``.

`nnsoup-packer`

Format string command for packing a reply SOUP packet. The default is `tar cf - %s | gzip > $HOME/Soupin%d.tgz'.

`nnsoup-unpacker`

Format string command for unpacking incoming SOUP packets. The default is `gunzip -c %s | tar xvf -'.

`nnsoup-packet-directory`

Where `nnsoup` will look for incoming packets. The default is `` `~/' ``.

`nnsoup-packet-regexp`

Regular expression matching incoming SOUP packets. The default is `Soupout'.

SOUP Replies

Just using `nnsoup` won't mean that your postings and mailings end up in SOUP reply packets automagically. You have to work a bit more for that to happen.

The `nnsoup-set-variables` command will set the appropriate variables to ensure that all your

followups and replies end up in the SOUP system.

In specific, this is what it does:

```
(setq gnus-inews-article-function 'nnsoup-request-post)
(setq send-mail-function 'nnsoup-request-mail)
```

And that's it, really. If you only want news to go into the SOUP system you just use the first line. If you only want mail to be SOUPed you use the second.

Combined Groups

Gnus allows combining a mixture of all the other group types into bigger groups.

Virtual Groups

An nnvirtual group is really nothing more than a collection of other groups.

For instance, if you are tired of reading many small group, you can put them all in one big group, and then grow tired of reading one big, unwieldy group. The joys of computing!

You specify `nnvirtual` as the method. The address should be a regexp to match component groups.

All marks in the virtual group will stick to the articles in the component groups. So if you tick an article in a virtual group, the article will also be ticked in the component group from whence it came. (And vice versa--marks from the component groups will also be shown in the virtual group.)

Here's an example `nnvirtual` method that collects all Andrea Dworkin newsgroups into one, big, happy newsgroup:

```
(nnvirtual "^alt\\.fan\\.andrea-dworkin$\\|^rec\\.dworkin.*")
```

The component groups can be native or foreign; everything should work smoothly, but if your computer explodes, it was probably my fault.

Collecting the same group from several servers might actually be a good idea if users have set the Distribution header to limit distribution. If you would like to read `soc.motss' both from a server in Japan and a server in Norway, you could use the following as the group regexp:

```
"^nntp+some.server.jp:soc.motss$\\|^nntp+some.server.no:soc.motss$"
```

This should work kinda smoothly--all articles from both groups should end up in this one, and there should be no duplicates. Threading (and the rest) will still work as usual, but there might be problems with the sequence of articles. Sorting on date might be an option here (see section Selecting a Group.

One limitation, however--all groups that are included in a virtual group has to be alive (i.e., subscribed or unsubscribed). Killed or zombie groups can't be component groups for `nnvirtual` groups.

If the `nnvirtual-always-rescan` is non-`nil`, `nnvirtual` will always scan groups for unread articles when entering a virtual group. If this variable is `nil` (which is the default) and you read articles in a component group after the virtual group has been activated, the read articles from the component group will show up when you enter the virtual group. You'll also see this effect if you have two virtual groups that contain the same component group. If that's the case, you should set this variable to `t`. Or you can just tap `M-g` on the virtual group every time before you enter it--it'll have much the same effect.

Kibozed Groups

Kibozing is defined by OED as "grepping through (parts of) the news feed". `nnkiboze` is a backend that will do this for you. Oh joy! Now you can grind any NNTP server down to a halt with useless requests! Oh happiness!

To create a kibozed group, use the G k command in the group buffer.

The address field of the `nnkiboze` method is, as with `nnvirtual`, a regexp to match groups to be "included" in the `nnkiboze` group. There most similarities between `nnkiboze` and `nnvirtual` ends.

In addition to this regexp detailing component groups, an `nnkiboze` group must have a score file to say what articles that are to be included in the group (see section Scoring).

You must run M-x nnkiboze-generate-groups after creating the `nnkiboze` groups you want to have. This command will take time. Lots of time. Oodles and oodles of time. Gnus has to fetch the headers from all the articles in all the components groups and run them through the scoring process to determine if there are any articles in the groups that are to be part of the `nnkiboze` groups.

Please limit the number of component groups by using restrictive regexps. Otherwise your sysadmin may become annoyed with you, and the NNTP site may throw you off and never let you back in again. Stranger things have happened.

`nnkiboze` component groups do not have to be alive--they can be dead, and they can be foreign. No restrictions.

The generation of an `nnkiboze` group means writing two files in `nnkiboze-directory`, which is `` `~/News/' `` by default. One contains the NOV header lines for all the articles in the group, and the other is an additional `` `.newsrc' `` file to store information on what groups that have been searched through to find component articles.

Articles that are marked as read in the `nnkiboze` group will have their NOV lines removed from the NOV file.

Go to the previous, next section.

Go to the previous, next section.

Scoring

Other people use kill files, but we here at Gnus Towers like scoring better than killing, so we'd rather switch than fight. They do something completely different as well, so sit up straight and pay attention!

All articles have a default score (`gnus-summary-default-score`), which is 0 by default. This score may be raised or lowered either interactively or by score files. Articles that have a score lower than `gnus-summary-mark-below` are marked as read.

Gnus will read any score files that apply to the current group before generating the summary buffer.

There are several commands in the summary buffer that insert score entries based on the current article. You can, for instance, ask Gnus to lower or increase the score of all articles with a certain subject.

There are two sorts of scoring entries: Permanent and temporary. Temporary score entries are self-expiring entries. Any entries that are temporary and have not been used for, say, a week, will be removed silently to help keep the sizes of the score files down.

Summary Score Commands

The score commands that alter score entries do not actually modify real score files. That would be too inefficient. Gnus maintains a cache of previously loaded score files, one of which is considered the current score file alist. The score commands simply insert entries into this list, and upon group exit, this list is saved.

The current score file is by default the group's local score file, even if no such score file actually exists. To insert score commands into some other score file (eg. `` `all.SCORE' ``), you must first make this score file the current one.

General score commands that don't actually change the score file:

V s
: Set the score of the current article (`gnus-summary-set-score`).

V S
: Display the score of the current article (`gnus-summary-current-score`).

V t
: Display all score rules that have been used on the current article (`gnus-score-find-trace`).

V R
: Run the current summary through the scoring process (`gnus-summary-rescore`). This might be useful if you're playing around with your score files behind Gnus' back and want to see the effect you're having.

V a
: Add a new score entry, and allow specifying all elements (`gnus-summary-score-entry`).

V c
: Make a different score file the current (`gnus-score-change-score-file`).

V e

Edit the current score file (`gnus-score-edit-current-scores`). You will be popped into a `gnus-score-mode` buffer (see section Score File Editing).

V f

Edit a score file and make this score file the current one (`gnus-score-edit-file`).

V F

Flush the score cahe (`gnus-score-flush-cache`). This is useful after editing score files.

V C

Customize a score file in a visually pleasing manner (`gnus-score-customize`).

I C-i

Increase the score of the current article (`gnus-summary-raise-score`).

L C-l

Lower the score of the current article (`gnus-summary-lower-score`).

The rest of these commands modify the local score file.

V m

Prompt for a score, and mark all articles with a score below this as read (`gnus-score-set-mark-below`).

V E

Expunge all articles with a score below the default score (or the numeric prefix) (`gnus-score-set-expunge-below`).

The keystrokes for actually making score entries follow a very regular pattern, so there's no need to list all the commands. (Hundreds of them.)

1. The first key is either I (upper case i) for increasing the score or L for lowering the score.
2. The second key says what header you want to score on. The following keys are available:

   a

   Score on the author name.

   s

   Score on the subject line.

   x

   Score on the Xref line--i.e., the cross-posting line.

   t

   Score on thread--the References line.

   d

   Score on the date.

   l

   Score on the number of lines.

   i

   Score on the Message-ID.

   f

Score on followups.

b

Score on the body.

h

Score on the head.

3. The third key is the match type. Which match types are legal depends on what headers you are scoring on.

`strings`

e

Exact matching.

s

Substring matching.

f

Fuzzy matching.

r

Regexp matching

- date

b

Before date.

a

At date.

n

This date.

- number

<

Less than number.

=

Equal to number.

>

Greater than number.

4. The fourth and final key says whether this is a temporary (i.e., expiring) score entry, or a permanent (i.e., non-expiring) score entry, or whether it is to be done immediately, without adding to the score file.

t

Temporary score entry.

p

Permanent score entry.

i

Immediately scoring.

So, let's say you want to increase the score on the current author with exact matching permanently: I a e p. If you want to lower the score based on the subject line, using substring matching, and make a temporary score entry:

L s s t. Pretty easy.

To make things a bit more complicated, there are shortcuts. If you use a capital letter on either the second or third keys, Gnus will use defaults for the remaining one or two keystrokes. The defaults are "substring" and "temporary". So I A is the same as I a s t, and I a R is the same as I a r t.

The `gnus-score-mimic-keymap` says whether these commands will pretend they are keymaps or not.

Group Score Commands

There aren't many of these as yet, I'm afraid.

W f

> Gnus maintains a cache of score alists to avoid having to reload them all the time. This command will flush the cache (`gnus-score-flush-cache`).

Score Variables

`gnus-use-scoring`

> If `nil`, Gnus will not check for score files, and will not, in general, do any score-related work. This is `t` by default.

`gnus-kill-killed`

> If this variable is `nil`, Gnus will never apply score files to articles that have already been through the kill process. While this may save you lots of time, it also means that if you apply a kill file to a group, and then change the kill file and want to run it over you group again to kill more articles, it won't work. You have to set this variable to `t` to do that. (It is `t` by default.)

`gnus-kill-files-directory`

> All kill and score files will be stored in this directory, which is initialized from the `SAVEDIR` environment variable by default. This is `` `~/News/' `` by default.

`gnus-score-file-suffix`

> Suffix to add to the group name to arrive at the score file name (`SCORE' by default.)

`gnus-score-uncacheable-files`

> All score files are normally cached to avoid excessive re-loading of score files. However, if this might make you Emacs grow big and bloated, so this regexp can be used to weed out score files that are unlikely to be needed again. It would be a bad idea to deny caching of `` `all.SCORE' ``, while it might be a good idea to not cache `` `comp.infosystems.www.authoring.misc.ADAPT' ``. In fact, this variable is `ADAPT$' by default, so no adaptive score files will be cached.

`gnus-save-score`

> If you have really complicated score files, and do lots of batch scoring, then you might set this variable to `t`. This will make Gnus save the scores into the `` `.newsrc.eld' `` file.

`gnus-score-interactive-default-score`

> Score used by all the interactive raise/lower commands to raise/lower score with. Default is 1000, which may seem excessive, but this is to ensure that the adaptive scoring scheme gets enough room to play with. We don't want the small changes from the adaptive scoring to overwrite manually entered data.

`gnus-summary-default-score`

Default score of an article, which is 0 by default.

`gnus-score-over-mark`

Mark (in the third column) used for articles with a score over the default. Default is `+'.

`gnus-score-below-mark`

Mark (in the third column) used for articles with a score below the default. Default is `-'.

`gnus-score-find-score-files-function`

Function used to find score files for the current group. This function is called with the name of the group as the argument.

Predefined functions available are:

`gnus-score-find-single`

Only apply the group's own score file.

`gnus-score-find-bnews`

Apply all score files that match, using bnews syntax. This is the default. For instance, if the current group is `gnu.emacs.gnus', `all.emacs.all.SCORE', `not.alt.all.SCORE' and `gnu.all.SCORE' would all apply. In short, the instances of `all' in the score file names are translated into `.*', and then a regexp match is done.

This means that if you have some score entries that you want to apply to all groups, then you put those entries in the `all.SCORE' file.

`gnus-score-find-hierarchical`

Apply all score files from all the parent groups. This means that you can't have score files like `all.SCORE' or `all.emacs.SCORE', but you can have `SCORE', `comp.SCORE' and `comp.emacs.SCORE'.

This variable can also be a list of functions. In that case, all these functions will be called, and all the returned lists of score files will be applied. These functions can also return lists of score alists directly. In that case, the functions that return these non-file score alists should probably be placed before the "real" score file functions, to ensure that the last score file returned is the local score file. Phu.

- gnus-score-expiry-days This variable says how many days should pass before an unused score file entry is expired. If this variable is `nil`, no score file entries are expired. It's 7 by default.
- gnus-update-score-entry-dates If this variable is non-`nil`, matching score entries will have their dates updated. (This is how Gnus controls expiry--all non-matching entries will become too old while matching entries will stay fresh and young.) However, if you set this variable to `nil`, even matching entries will grow old and will have to face that oh-so grim reaper.
- gnus-score-after-write-file-function Function called with the name of the score file just written.

Score File Format

A score file is an `emacs-lisp` file that normally contains just a single form. Casual users are not expected to edit these files; everything can be changed from the summary buffer.

Anyway, if you'd like to dig into it yourself, here's an example:

```
(("from"
  ("Lars Ingebrigtsen" -10000)
```

```
 ("Per Abrahamsen")
 ("larsi\\|lmi" -50000 nil R))
("subject"
 ("Ding is Badd" nil 728373))
("xref"
 ("alt.politics" -1000 728372 s))
("lines"
 (2 -100 nil <))
(mark 0)
(expunge -1000)
(mark-and-expunge -10)
(read-only nil)
(orphan -10)
(adapt t)
(files "/hom/larsi/News/gnu.SCORE")
(exclude-files "all.SCORE")
(local (gnus-newsgroup-auto-expire t)
       (gnus-summary-make-false-root 'empty))
(eval (ding)))
```

This example demonstrates absolutely everything about a score file.

Even though this looks much like lisp code, nothing here is actually `eval`ed. The lisp reader is used to read this form, though, so it has to be legal syntactically, if not semantically.

Six keys are supported by this alist:

`STRING`

If the key is a string, it is the name of the header to perform the match on. Scoring can only be performed on these eight headers: `From`, `Subject`, `References`, `Message-ID`, `Xref`, `Lines`, `Chars` and `Date`. In addition to these headers, there are three strings to tell Gnus to fetch the entire article and do the match on larger parts of the article: `Body` will perform the match on the body of the article, `Head` will perform the match on the head of the article, and `All` will perform the match on the entire article. Note that using any of these last three keys will slow down group entry *considerably*. The final "header" you can score on is `Followup`. These score entries will result in new score entries being added for all follow-ups to articles that matches these score entries.

Following this key is a arbitrary number of score entries, where each score entry has one to four elements.

The first element is the match element. On most headers this will be a string, but on the Lines and Chars headers, this must be an integer.

If the second element is present, it should be a number--the score element. This number should be an integer in the neginf to posinf interval. This number is added to the score of the article if the match is successful. If this element is not present, the `gnus-score-interactive-default-score` number will be used instead. This is 1000 by default.

If the third element is present, it should be a number--the date element. This date says when the last time this score entry matched, which provides a mechanism for expiring the score entries. It this element is not present, the score entry is permanent. The date is represented by the number of days since December 31, 1 ce.

If the fourth element is present, it should be a symbol--the type element. This element

specifies what function should be used to see whether this score entry matches the article. Wha match types that can be used depends on what header you wish to perform the match on.

From, Subject, References, Xref, Message-ID

For most header types, there are the `r` and `R` (regexp) as well as `s` and `S` (substring) types and `e` and `E` (exact match) types. If this element is not present, Gnus will assume that substring matching should be used. `R` and `S` differ from the other two in that the matches will be done in a case-sensitive manner. All these one-letter types are really just abbreviations for the `regexp`, `string` and `exact` types, which you can use instead, if you feel like.

Lines, Chars

These two headers use different match types: <, >, =, >= and <=.

Date

For the Date header we have three match types: `before`, `at` and `after`. I can't really imagine this ever being useful, but, like, it would feel kinda silly not to provide this function. Just in case. You never know. Better safe than sorry. Once burnt, twice shy. Don't judge a book by its cover. Never not have sex on a first date.

Head, Body, All

These three match keys use the same match types as the `From` (etc) header uses.

Followup

This match key will add a score entry on all articles that followup to some author. Uses the same match types as the `From` header uses.

Thread

This match key will add a score entry on all articles that are part of a thread. Uses the same match types as the `References` header uses.

- mark The value of this entry should be a number. Any articles with a score lower than this number will be marked as read.
- expunge The value of this entry should be a number. Any articles with a score lower than this number will be removed from the summary buffer.
- mark-and-expunge The value of this entry should be a number. Any articles with a score lower than this number will be marked as read and removed from the summary buffer.
- thread-mark-and-expunge The value of this entry should be a number. All articles that belong to a thread that has a total score below this number will be marked as read and removed from the summary buffer. `gnus-thread-score-function` says how to compute the total score for a thread.
- files The value of this entry should be any number of file names. These files are assumed to be score files as well, and will be loaded the same way this one was.
- exclude-files The clue of this entry should be any number of files. This files will not be loaded, even though they would normally be so, for some reason or other.
- eval The value of this entry will be `eval`el. This element will be ignored when handling global score files.
- read-only Read-only score files will not be updated or saved. Global score files should feature this atom (see section Global Score Files).
- orphan The value of this entry should be a number. Articles that do not have parents will get this number added to their scores. Imagine you follow some high-volume newsgroup, like `comp.lang.c'. Most likely you will only follow a few of the threads, also want to see any new threads.

You can do this with the following two score file entries:

```
(orphan -500)
(mark-and-expunge -100)
```

When you enter the group the first time, you will only see the new threads. You then raise the score of the threads that you find interesting (with I T or I S), and ignore (C y) the rest. Next time you enter the group, you will see new articles in the interesting threads, plus any new threads.

I.e. -- the orphan score atom is for high-volume groups where there exist a few interesting threads which can't be found automatically by ordinary scoring rules.

- adapt This entry controls the adaptive scoring. If it is `t`, the default adaptive scoring rules will be used. If it is `ignore`, no adaptive scoring will be performed on this group. If it is a list, this list will be used as the adaptive scoring rules. If it isn't present, or is something other than `t` or `ignore`, the default adaptive scoring rules will be used. If you want to use adaptive scoring on most groups, you'd set `gnus-use-adaptive-scoring` to `t`, and insert an `(adapt ignore)` in the groups where you do not want adaptive scoring. If you only want adaptive scoring in a few groups, you'd set `gnus-use-adaptive-scoring` to `nil`, and insert `(adapt t)` in the score files of the groups where you want it.
- adapt-file All adaptive score entries will go to the file named by this entry. It will also be applied when entering the group. This atom might be handy if you want to adapt on several groups at once, using the same adaptive file for a number of groups.
- local The value of this entry should be a list of `(VAR VALUE)` pairs. Each var will be made buffer-local to the current summary buffer, and set to the value specified. This is a convenient, if somewhat strange, way of setting variables in some groups if you don't like hooks much.

Score File Editing

You normally enter all scoring commands from the summary buffer, but you might feel the urge to edit them by hand as well, so we've supplied you with a mode for that.

It's simply a slightly customized `emacs-lisp` mode, with these additional commands:

C-c C-c

> Save the changes you have made and return to the summary buffer (`gnus-score-edit-done`).

C-c C-d

> Insert the current date in numerical format (`gnus-score-edit-insert-date`). This is really the day number, if you were wondering.

C-c C-p

> The adaptive score files are saved in an unformatted fashion. If you intend to read one of these files, you want to pretty print it first. This command (`gnus-score-pretty-print`) does that for you.

Type M-x gnus-score-mode to use this mode.

`gnus-score-menu-hook` is run in score mode buffers.

In the summary buffer you can use commands like V f and V e to begin editing score files.

Adaptive Scoring

If all this scoring is getting you down, Gnus has a way of making it all happen automatically--as if by magic. Or rather, as if by artificial stupidity, to be precise.

When you read an article, or mark an article as read, or kill an article, you leave marks behind. On exit from the group, Gnus can sniff these marks and add score elements depending on what marks it finds. You turn on this ability by setting `gnus-use-adaptive-scoring` to `t`.

To give you complete control over the scoring process, you can customize the `gnus-default-adaptive-score-alist` variable. For instance, it might look something like this:

```
(defvar gnus-default-adaptive-score-alist
  '((gnus-unread-mark)
    (gnus-ticked-mark (from 4))
    (gnus-dormant-mark (from 5))
    (gnus-del-mark (from -4) (subject -1))
    (gnus-read-mark (from 4) (subject 2))
    (gnus-expirable-mark (from -1) (subject -1))
    (gnus-killed-mark (from -1) (subject -3))
    (gnus-kill-file-mark)
    (gnus-ancient-mark)
    (gnus-low-score-mark)
    (gnus-catchup-mark (from -1) (subject -1))))
```

As you see, each element in this alist has a mark as a key (either a variable name or a "real" mark--a character). Following this key is a arbitrary number of header/score pairs. If there are no header/score pairs following the key, no adaptive scoring will be done on articles that have that key as the article mark. For instance, articles with `gnus-unread-mark` in the example above will not get adaptive score entries.

Each article can have only one mark, so just a single of these rules will be applied to each article.

To take `gnus-del-mark` as an example--this alist says that all articles that have that mark (i.e., are marked with `D') will have a score entry added to lower based on the `From` header by -4, and lowered by `Subject` by -1. Change this to fit your prejudices.

If you have marked 10 articles with the same subject with `gnus-del-mark`, the rule for that mark will be applied ten times. That means that that subject will get a score of ten times -1, which should be, unless I'm much mistaken, -10.

The headers you can score on are `from`, `subject`, `message-id`, `references`, `xref`, `lines`, `chars` and `date`. In addition, you can score on `followup`, which will create an adaptive score entry that matches on the `References` header using the `Message-ID` of the current article, thereby matching the following thread.

You can also score on `thread`, which will try to score all articles that appear in a thread. `thread` matches uses a `Message-ID` to match on the `References` header of the article. If the match is made, the `Message-ID` of the article is added to the `thread` rule. (Think about it. I'd recommend two aspirins afterwards.)

If you use this scheme, you should set the score file atom `mark` to something small--like -300, perhaps, to avoid having small random changes result in articles getting marked as read.

After using adaptive scoring for a week or so, Gnus should start to become properly trained and enhance the authors you like best, and kill the authors you like least, without you having to say so explicitly.

You can control what groups the adaptive scoring is to be performed on by using the score files (see section Score File Format). This will also let you use different rules in different groups.

The adaptive score entries will be put into a file where the name is the group name with `gnus-adaptive-file-suffix` appended. The default is `ADAPT'.

When doing adaptive scoring, substring or fuzzy matching would probably give you the best results in most cases. However, if the header one matches is short, the possibility for false positives is great, so if the length of the match is less than `gnus-score-exact-adapt-limit`, exact matching will be used. If this variable is `nil`, exact matching will always be used to avoid this problem.

Followups To Yourself

Gnus offers two commands for picking out the `Message-ID` header in the current buffer. Gnus will then add a score rule that scores using this `Message-ID` on the `References` header of other articles. This will, in effect, increase the score of all articles that respond to the article in the current buffer. Quite useful if you want to easily note when people answer what you've said.

`gnus-score-followup-article`

This will add a score to articles that directly follow up your own article.

`gnus-score-followup-thread`

This will add a score to all articles that appear in a thread "below" your own article.

These two functions are both primarily meant to be used in hooks like `gnus-inews-article-hook`.

Scoring Tips

Crossposts

If you want to lower the score of crossposts, the line to match on is the `Xref` header.

```
("xref" (" talk.politics.misc:" -1000))
```

Multiple crossposts

If you want to lower the score of articles that have been crossposted to more than, say, 3 groups:

```
("xref" ("[^:\n]+:[0-9]+ +[^:\n]+:[0-9]+ +[^:\n]+:[0-9]+" -1000 nil r))
```

Matching on the body

This is generally not a very good idea--it takes a very long time. Gnus actually has to fetch each individual article from the server. But you might want to anyway, I guess. Even though there are three match keys (`Head`, `Body` and `All`), you should choose one and stick with it in each score file. If you use any two, each article will be fetched *twice*. If you want to match a bit on the `Head` and a bit on the `Body`, just use `All` for all the matches.

Marking as read

You will probably want to mark articles that has a score below a certain number as read. This is most

easily achieved by putting the following in your `all.SCORE' file:

```
((mark -100))
```

You may also consider doing something similar with `expunge`.

Negated character classes

If you say stuff like `[^abcd]*`, you may get unexpected results. That will match newlines, which might lead to, well, The Unknown. Say `[^abcd\n]*` instead.

Reverse Scoring

If you want to keep just articles that have `Sex with Emacs' in the subject header, and expunge all other articles, you could put something like this in your score file:

```
(("subject"
  ("Sex with Emacs" 2))
 (mark 1)
 (expunge 1))
```

So, you raise all articles that match `Sex with Emacs' and mark the rest as read, and expunge them to boot.

Global Score Files

Sure, other newsreaders have "global kill files". These are usually nothing more than a single kill file that applies to all groups, stored in the user's home directory. Bah! Puny, weak newsreaders!

What I'm talking about here are Global Score Files. Score files from all over the world, from users everywhere, uniting all nations in one big, happy score file union! Ange-score! New and untested!

All you have to do to use other people's score files is to set the `gnus-global-score-files` variable. One entry for each score file, or each score file directory. Gnus will decide by itself what score files are applicable to which group.

Say you want to use all score files in the `/ftp@ftp.some-where:/pub/score' directory and the single score file `/ftp@ftp.ifi.uio.no:/pub/larsi/ding/score/soc.motss.SCORE':

```
(setq gnus-global-score-files
      '("/ftp@ftp.ifi.uio.no:/pub/larsi/ding/score/soc.motss.SCORE"
        "/ftp@ftp.some-where:/pub/score/"))
```

Simple, eh? Directory names must end with a `/'. These directories are typically scanned only once during each Gnus session. If you feel the need to manually re-scan the remote directories, you can use the `gnus-score-search-global-directories` command.

Note that, at present, using this option will slow down group entry somewhat. (That is--a lot.)

If you want to start maintaining score files for other people to use, just put your score file up for anonymous ftp and announce it to the world. Become a retro-moderator! Participate in the retro-moderator wars sure to ensue, where retro-moderators battle it out for the sympathy of the people, luring them to use their score files on false

premises! Yay! The net is saved!

Here are some tips for the would-be retro-moderator, off the top of my head:

- Articles that are heavily crossposted are probably junk.
- To lower a single inappropriate article, lower by `Message-ID`.
- Particularly brilliant authors can be raised on a permanent basis.
- Authors that repeatedly post off-charter for the group can safely be lowered out of existence.
- Set the `mark` and `expunge` atoms to obliterate the nastiest articles completely.
- Use expiring score entries to keep the size of the file down. You should probably have a long expiry period, though, as some sites keep old articles for a long time.

... I wonder whether other newsreaders will support global score files in the future. *Snicker*. Yup, any day now, newsreaders like Blue Wave, xrn and 1stReader are bound to implement scoring. Should we start holding our breath yet?

Kill Files

Gnus still supports those pesky old kill files. In fact, the kill file entries can now be expiring, which is something I wrote before Daniel Quinlan thought of doing score files, so I've left the code in there.

In short, kill processing is a lot slower (and I do mean *a lot*) than score processing, so it might be a good idea to rewrite your kill files into score files.

Anyway, a kill file is a normal `emacs-lisp` file. You can put any forms into this file, which means that you can use kill files as some sort of primitive hook function to be run on group entry, even though that isn't a very good idea.

XCNormal kill files look like this:

```
(gnus-kill "From" "Lars Ingebrigtsen")
(gnus-kill "Subject" "ding")
(gnus-expunge "X")
```

This will mark every article written by me as read, and remove them from the summary buffer. Very useful, you'll agree.

Other programs use a totally different kill file syntax. If Gnus encounters what looks like a `rn` kill file, it will take a stab at interpreting it.

Two summary functions for editing a GNUS kill file:

M-k

Edit this group's kill file (`gnus-summary-edit-local-kill`).

M-K

Edit the general kill file (`gnus-summary-edit-global-kill`).

Two group mode functions for editing the kill files:

M-k

Edit this group's kill file (`gnus-group-edit-local-kill`).

M-K

Edit the general kill file (`gnus-group-edit-global-kill`).

Kill file variables:

`gnus-kill-file-name`

A kill file for the group `soc.motss' is normally called `soc.motss.KILL'. The suffix appended to the group name to get this file name is detailed by the `gnus-kill-file-name` variable. The "global" kill file (not in the score file sense of "global", of course) is called just `KILL'.

`gnus-kill-save-kill-file`

If this variable is non-`nil`, Gnus will save the kill file after processing, which is necessary if you use expiring kills.

`gnus-apply-kill-hook`

A hook called to apply kill files to a group. It is `(gnus-apply-kill-file)` by default. If you want to ignore the kill file if you have a score file for the same group, you can set this hook to `(gnus-apply-kill-file-unless-scored)`. If you don't want kill files to be processed, you should set this variable to `nil`.

`gnus-kill-file-mode-hook`

A hook called in kill-file mode buffers.

GroupLens

GroupLens is a collaborative filtering system that helps you work together with other people to find the quality news articles out of the huge volume of news articles generated every day.

To accomplish this the GroupLens system combines your opinions about articles you have already read with the opinions of others who have done likewise and gives you a personalized prediction for each unread news article. Think of GroupLens as a matchmaker. GroupLens watches how you rate articles, and finds other people that rate articles the same way. Once it has found for you some people you agree with it tells you, in the form of a prediction, what they thought of the article. You can use this prediction to help you decide whether or not you want to read the article.

Using GroupLens

To use GroupLens you must register a pseudonym with your local Better Bit Bureau (BBB). At the moment the only better bit in town is at `http://www.cs.umn.edu/Research/GroupLens/bbb.html'.

Once you have registered you'll need to set a couple of variables.

`gnus-use-grouplens`

Setting this variable to a non-`nil` value will make Gnus hook into all the relevant GroupLens functions.

`grouplens-pseudonym`

This variable should be set to the pseudonum you got when registering with the Better Bit Bureau.

`grouplens-newsgroups`

A list of groups that you want to get GroupLens predictions for.

Thats the minimum of what you need to get up and running with GroupLens. Once you've registered,

TOC

GroupLens will start giving you scores for articles based on the average of what other people think. But, to the real benefit of GroupLens you need to start rating articles yourself. Then the scores GroupLens gives you will be personalized for you, based on how the people you usually agree with have already rated.

Rating Articles

In GroupLens, an article is rated on a scale from 1 to 5, inclusive. Where 1 means something like this article is a waste of bandwidth and 5 means that the article was really good. The basic question to ask yourself is, "on a scale from 1 to 5 would I like to see more articles like this one?"

There are four ways to enter a rating for an article in GroupLens.

r

This function will prompt you for a rating on a scale of one to five.

k

This function will prompt you for a rating, and rate all the articles in the thread. This is really useful for some of those long running giant threads in rec.humor.

The next two commands, n and , take a numerical prefix to be the score of the article you're reading.

1-5 n

Rate the article and go to the next unread article.

1-5 ,

Rate the article and go to the next unread article with the highest score.

If you want to give the current article a score of 4 and then go to the next article, just type 4 n.

Displaying Predictions

GroupLens makes a prediction for you about how much you will like a news article. The predictions from GroupLens are on a scale from 1 to 5, where 1 is the worst and 5 is the best. You can use the predictions from GroupLens in one of three ways controlled by the variable `gnus-grouplens-override-scoring`.

There are three ways to display predictions in grouplens. You may choose to have the GroupLens scores contribute to, or override the regular gnus scoring mechanism. override is the default; however, some people prefer to see the Gnus scores plus the grouplens scores. To get the separate scoring behavior you need to set `gnus-grouplens-override-scoring` to `'separate`. To have the GroupLens predictions combined with the grouplens scores set it to `'override` and to combine the scores set `gnus-grouplens-override-scoring` to `'combine`. When you use the combine option you will also want to set the values for `grouplens-prediction-offset` and `grouplens-score-scale-factor`.

In either case, GroupLens gives you a few choices for how you would like to see your predictions displayed. The display of predictions is controlled by the `grouplens-prediction-display` variable.

The following are legal values for that variable.

`prediction-spot`

The higher the prediction, the further to the right an `*' is displayed.

`confidence-interval`

A numeric confidence interval.

`prediction-bar`
: The higher the prediction, the longer the bar.

`confidence-bar`
: Numerical confidence.

`confidence-spot`
: The spot gets bigger with more confidence.

`prediction-num`
: Plain-old numeric value.

`confidence-plus-minus`
: Prediction +/i confidence.

GroupLens Variables

`gnus-summary-grouplens-line-format`
: The summary line format used in summary buffers that are GroupLens enhanced. It accepts the same specs as the normal summary line format (see section Summary Buffer Lines). The default is `%U%R%z%l%I%(%[%4L: %-20,20n%]%) %s\n'.

`grouplens-bbb-host`
: Host running the bbbd server. The default is `grouplens.cs.umn.edu'.

`grouplens-bbb-port`
: Port of the host running the bbbd server. The default is 9000.

`grouplens-score-offset`
: Offset the prediction by this value. In other words, subtract the prediction value by this number to arrive at the effective score. The default is 0.

`grouplens-score-scale-factor`
: This variable allows the user to magnify the effect of GroupLens scores. The scale factor is applied after the offset. The default is 1.

Go to the previous, next section.

Go to the previous, next section.

Various

Process/Prefix

Many functions, among them functions for moving, decoding and saving articles, use what is known as the Process/Prefix convention.

This is a method for figuring out what articles that the user wants the command to be performed on.

It goes like this:

If the numeric prefix is N, perform the operation on the next N articles, starting with the current one. If the numeric prefix is negative, perform the operation on the previous N articles, starting with the current one.

If `transient-mark-mode` in non-`nil` and the region is active, all articles in the region will be worked upon.

If there is no numeric prefix, but some articles are marked with the process mark, perform the operation on the articles that are marked with the process mark.

If there is neither a numeric prefix nor any articles marked with the process mark, just perform the operation on the current article.

Quite simple, really, but it needs to be made clear so that surprises are avoided.

One thing that seems to shock & horrify lots of people is that, for instance, 3 d does exactly the same as d d d. Since each d (which marks the current article as read) by default goes to the next unread article after marking, this means that 3 d will mark the next three unread articles as read, no matter what the summary buffer looks like. Set `gnus-summary-goto-unread` to `nil` for a more straightforward action.

Interactive

`gnus-novice-user`

> If this variable is non-`nil`, you are either a newcomer to the World of Usenet, or you are very cautious, which is a nice thing to be, really. You will be given questions of the type "Are you sure you want to do this?" before doing anything dangerous. This is `t` by default.

`gnus-expert-user`

> If this variable is non-`nil`, you will never ever be asked any questions by Gnus. It will simply assume you know what you're doing, no matter how strange.

`gnus-interactive-catchup`

> Require confirmation before catching up a group if non-`nil`. It is `t` by default.

`gnus-interactive-exit`

> Require confirmation before exiting Gnus. This variable is `t` by default.

Formatting Variables

Throughout this manual you've probably noticed lots of variables that are called things like `gnus-group-line-format` and `gnus-summary-mode-line-format`. These control how Gnus is to output lines in the various buffers. There's quite a lot of them. Fortunately, they all use the same syntax, so there's not that much to be annoyed by.

Here's an example format spec (from the group buffer): `%M%S%5y: %(%g%)\n'. We see that it is indeed extremely ugly, and that there are lots of percentages everywhere.

Each `%' element will be replaced by some string or other when the buffer in question is generated. `%5y' means "insert the `y' spec, and pad with spaces to get a 5-character field". Just like a normal format spec, almost.

You can also say `%6,4y', which means that the field will never be more than 6 characters wide and never less than 4 characters wide.

There are also specs for highlighting, and these are shared by all the format variables. Text inside the `%(' and `%)' specifiers will get the special `mouse-face` property set, which means that it will be highlighted (with `gnus-mouse-face`) when you put the mouse pointer over it.

Text inside the `%[' and `%]' specifiers will have their normal faces set using `gnus-face-0`, which is `bold` by default. If you say `%1[' instead, you'll get `gnus-face-1` instead, and so on. Create as many faces as you wish. The same goes for the `mouse-face` specs--you can say `%3(hello%)' to have `hello' mouse-highlighted with `gnus-mouse-face-3`.

Here's an alternative recipe for the group buffer:

```
;; Create three face types.
(setq gnus-face-1 'bold)
(setq gnus-face-3 'italic)

;; We want the article count to be in
;; a bold and green face.  So we create
;; a new face called `my-green-bold'.
(copy-face 'bold 'my-green-bold)
;; Set the color.
(set-face-foreground 'my-green-bold "ForestGreen")
(setq gnus-face-2 'my-green-bold)

;; Set the new & fancy format.
(setq gnus-group-line-format
      "%M%S%3{%5y%}%2[:%] %(%1{%g%}%)\n")
```

I'm sure you'll be able to use this scheme to create totally unreadable and extremely vulgar displays. Have fun!

Currently Gnus uses the following formatting variables: `gnus-group-line-format`, `gnus-summary-line-format`, `gnus-server-line-format`, `gnus-topic-line-format`,

`gnus-group-mode-line-format`, `gnus-summary-mode-line-format`, `gnus-article-mode-line-format`, `gnus-server-mode-line-format`.

Note that the `%(' specs (and friends) do not make any sense on the mode-line variables.

All these format variables can also be arbitrary elisp forms. In that case, they will be `eval`ed to insert the required lines.

Gnus includes a command to help you while creating your own format specs. M-x gnus-update-format will `eval` the current form, update the spec in question and pop you to a buffer where you can examine the resulting lisp code to be run to generate the line.

Windows Configuration

No, there's nothing here about X, so be quiet.

If `gnus-use-full-window` non-`nil`, Gnus will delete all other windows and occupy the entire Emacs screen by itself. It is `t` by default.

`gnus-buffer-configuration` describes how much space each Gnus buffer should be given. Here's an excerpt of this variable:

```
((group (vertical 1.0 (group 1.0 point)
                      (if gnus-carpal (group-carpal 4))))
 (article (vertical 1.0 (summary 0.25 point)
                        (article 1.0))))
```

This is an alist. The key is a symbol that names some action or other. For instance, when displaying the group buffer, the window configuration function will use `group` as the key. A full list of possible names is listed below.

The value (i. e., the split) says how much space each buffer should occupy. To take the `article` split as an example -

```
(article (vertical 1.0 (summary 0.25 point)
                       (article 1.0)))
```

This split says that the summary buffer should occupy 25% of upper half of the screen, and that it is placed over the article buffer. As you may have noticed, 100% + 25% is actually 125% (yup, I saw y'all reaching for that calculator there). However, the special number `1.0` is used to signal that this buffer should soak up all the rest of the space available after the rest of the buffers have taken whatever they need. There should be only one buffer with the `1.0` size spec per split.

Point will be put in the buffer that has the optional third element `point`.

Here's a more complicated example:

```
(article (vertical 1.0 (group 4)
                       (summary 0.25 point)
```

```
                (if gnus-carpal (summary-carpal 4))
                (article 1.0)))
```

If the size spec is an integer instead of a floating point number, then that number will be used to say how many lines a buffer should occupy, not a percentage.

If the split looks like something that can be `eval`ed (to be precise--if the `car` of the split is a function or a subr), this split will be `eval`ed. If the result is non-`nil`, it will be used as a split. This means that there will be three buffers if `gnus-carpal` is `nil`, and four buffers if `gnus-carpal` is non-`nil`.

Not complicated enough for you? Well, try this on for size:

```
(article (horizontal 1.0
             (vertical 0.5
                 (group 1.0)
                 (gnus-carpal 4))
             (vertical 1.0
                 (summary 0.25 point)
                 (summary-carpal 4)
                 (article 1.0))))
```

Whoops. Two buffers with the mystery 100% tag. And what's that `horizontal` thingie?

If the first element in one of the split is `horizontal`, Gnus will split the window horizontally, giving you two windows side-by-side. Inside each of these strips you may carry on all you like in the normal fashion. The number following `horizontal` says what percentage of the screen is to be given to this strip.

For each split, there *must* be one element that has the 100% tag. The splitting is never accurate, and this buffer will eat any leftover lines from the splits.

To be slightly more formal, here's a definition of what a legal split may look like:

```
split       = frame | horizontal | vertical | buffer | form
frame       = "(frame " size *split ")"
horizontal  = "(horizontal " size *split ")"
vertical    = "(vertical " size *split ")"
buffer      = "(" buffer-name " " size *[ "point" ] ")"
size        = number | frame-params
buffer-name = group | article | summary ...
```

The limitations are that the `frame` split can only appear as the top-level split. form should be an Emacs Lisp form that should return a valid split. We see that each split is fully recursive, and may contain any number of `vertical` and `horizontal` splits.

Finding the right sizes can be a bit complicated. No window may be less than `gnus-window-min-height` (default 2) characters high, and all windows must be at least `gnus-window-min-width` (default 1) characters wide. Gnus will try to enforce this before applying the splits. If you want to use the normal Emacs window width/height limit, you can just set these two variables to `nil`.

If you're not familiar with Emacs terminology, `horizontal` and `vertical` splits may work the opp way of what you'd expect. Windows inside a `horizontal` split are shown side-by-side, and windows within a `vertical` split are shown above each other.

If you want to experiment with window placement, a good tip is to call `gnus-configure-frame` directly with a split. This is the function that does all the real work when splitting buffers. Below is a pretty nonsensical configuration with 5 windows; two for the group buffer and three for the article buffer. (I said it was nonsensical.) If you `eval` the statement below, you can get an idea of how that would look straight away, without going through the normal Gnus channels. Play with it until you're satisfied, and then use `gnus-add-configuration` to add your new creation to the buffer configuration list.

```
(gnus-configure-frame
 '(horizontal 1.0
    (vertical 10
      (group 1.0)
      (article 0.3 point))
    (vertical 1.0
      (article 1.0)
      (horizontal 4
        (group 1.0)
        (article 10)))))
```

You might want to have several frames as well. No prob--just use the `frame` split:

```
(gnus-configure-frame
 '(frame 1.0
         (vertical 1.0
                   (summary 0.25 point)
                   (article 1.0))
         (vertical ((height . 5) (width . 15)
                    (user-position . t)
                    (left . -1) (top . 1))
                   (picon 1.0))))
```

This split will result in the familiar summary/article window configuration in the first (or "main") frame, while a small additional frame will be created where picons will be shown. As you can see, instead of the normal `1.0` top-level spec, each additional split should have a frame parameter alist as the size spec. See section 'Frame Parameters' in The GNU Emacs Lisp Reference Manual.

Here's a list of all possible keys for `gnus-buffer-configuration`:

`group`, `summary`, `article`, `server`, `browse`, `group-mail`, `summary-mail`, `summary-reply`, `info`, `summary-faq`, `edit-group`, `edit-server`, `reply`, `reply-yank`, `followup`, `followup-yank`, `edit-score`.

Since the `gnus-buffer-configuration` variable is so long and complicated, there's a function you can use to ease changing the config of a single setting: `gnus-add-configuration`. If, for instance, you want to change the `article` setting, you could say:

```
(gnus-add-configuration
 '(article (vertical 1.0
             (group 4)
             (summary .25 point)
             (article 1.0))))
```

You'd typically stick these `gnus-add-configuration` calls in your `.gnus' file or in some startup hook -- they should be run after Gnus has been loaded.

Compilation

Remember all those line format specification variables? `gnus-summary-line-format`, `gnus-group-line-format`, and so on. Now, Gnus will of course heed whatever these variables are, but, unfortunately, changing them will mean a quite significant slow-down. (The default values of these variables have byte-compiled functions associated with them, while the user-generated versions do not, of course.)

To help with this, you can run M-x gnus-compile after you've fiddled around with the variables and feel that you're (kind of) satisfied. This will result in the new specs being byte-compiled, and you'll get top speed again.

Mode Lines

`gnus-updated-mode-lines` says what buffers should keep their mode lines updated. It is a list of symbols. Supported symbols include `group`, `article`, `summary`, `server`, `browse`, and `tree`. If the corresponding symbol is present, Gnus will keep that mode line updated with information that may be pertinent. If this variable is `nil`, screen refresh may be quicker.

By default, Gnus displays information on the current article in the mode lines of the summary and article buffers. The information Gnus wishes to display (eg. the subject of the article) is often longer than the mode lines, and therefore have to be cut off at some point. The `gnus-mode-non-string-length` variable says how long the other elements on the line is (i.e., the non-info part). If you put additional elements on the mode line (eg. a clock), you should modify this variable:

```
(add-hook 'display-time-hook
          (lambda () (setq gnus-mode-non-string-length
                           (+ 21
                              (if line-number-mode 5 0)
                              (if column-number-mode 4 0)
                              (length display-time-string)))))
```

If this variable is `nil` (which is the default), the mode line strings won't be chopped off, and they won't be padded either.

Highlighting and Menus

The `gnus-visual` variable controls most of the prettifying Gnus aspects. If `nil`, Gnus won't attempt to create menus or use fancy colors or fonts. This will also inhibit loading the `` `gnus-vis.el' `` file.

This variable can be a list of visual properties that are enabled. The following elements are legal, and are all included by default:

`group-highlight`
: Do highlights in the group buffer.

`summary-highlight`
: Do highlights in the summary buffer.

`article-highlight`
: Do highlights in the article buffer.

`highlight`
: Turn on highlighting in all buffers.

`group-menu`
: Create menus in the group buffer.

`summary-menu`
: Create menus in the summary buffers.

`article-menu`
: Create menus in the article buffer.

`browse-menu`
: Create menus in the browse buffer.

`server-menu`
: Create menus in the server buffer.

`score-menu`
: Create menus in the score buffers.

`menu`
: Create menus in all buffers.

So if you only want highlighting in the article buffer and menus in all buffers, you could say something like:

```
(setq gnus-visual '(article-highlight menu))
```

If you want only highlighting and no menus whatsoever, you'd say:

```
(setq gnus-visual '(highlight))
```

If `gnus-visual` is `t`, highlighting and menus will be used in all Gnus buffers.

Other general variables that influence the look of all buffers include:

`gnus-mouse-face`

This is the face (i.e., font) used for mouse highlighting in Gnus. No mouse highlights will be done if `gnus-visual` is `nil`.

`gnus-display-type`

This variable is symbol indicating the display type Emacs is running under. The symbol should be one of `color`, `grayscale` or `mono`. If Gnus guesses this display attribute wrongly, either set this variable in your `` `~/.emacs' `` or set the resource `Emacs.displayType` in your `` `~/.Xdefaults' ``.

`gnus-background-mode`

This is a symbol indicating the Emacs background brightness. The symbol should be one of `light` or `dark`. If Gnus guesses this frame attribute wrongly, either set this variable in your `` `~/.emacs' `` or set the resource `Emacs.backgroundMode` in your `` `~/.Xdefaults' ``. `gnus-display-type'.

There are hooks associated with the creation of all the different menus:

`gnus-article-menu-hook`

Hook called after creating the article mode menu.

`gnus-group-menu-hook`

Hook called after creating the group mode menu.

`gnus-summary-menu-hook`

Hook called after creating the summary mode menu.

`gnus-server-menu-hook`

Hook called after creating the server mode menu.

`gnus-browse-menu-hook`

Hook called after creating the browse mode menu.

`gnus-score-menu-hook`

Hook called after creating the score mode menu.

Buttons

Those new-fangled mouse contraptions is very popular with the young, hep kids who don't want to learn the proper way to do things these days. Why, I remember way back in the summer of '89, when I was using Emacs on a Tops 20 system. Three hundred users on one single machine, and every user was running Simula compilers. Bah!

Right.

Well, you can make Gnus display bufferfuls of buttons you can click to do anything by setting `gnus-carpal` to `t`. Pretty simple, really. Tell the chiropractor I sent you.

`gnus-carpal-mode-hook`

Hook run in all carpal mode buffers.

`gnus-carpal-button-face`

Face used on buttons.

`gnus-carpal-header-face`

Face used on carpal buffer headers.

`gnus-carpal-group-buffer-buttons`

Buttons in the group buffer.

`gnus-carpal-summary-buffer-buttons`

Buttons in the summary buffer.

`gnus-carpal-server-buffer-buttons`

Buttons in the server buffer.

`gnus-carpal-browse-buffer-buttons`

Buttons in the browse buffer.

All the `buttons` variables are lists. The elements in these list is either a cons cell where the car contains a text to be displayed and the cdr contains a function symbol, or a simple string.

Daemons

Gnus, being larger than any program ever written (allegedly), does lots of strange stuff that you may wish to have done while you're not present. For instance, you may want it to check for new mail once in a while. Or you may want it to close down all connections to all servers when you leave Emacs idle. And stuff like that.

Gnus will let you do stuff like that by defining various handlers. Each handler consists of three elements: A function, a time, and an idle parameter.

Here's an example of a handler that closes connections when Emacs has been idle for thirty minutes:

```
(gnus-demon-close-connections nil 30)
```

Here's a handler that scans for PGP headers every hour when Emacs is idle:

```
(gnus-demon-scan-pgp 60 t)
```

This time parameter and than idle parameter works together in a strange, but wonderful fashion. Basically, if idle is `nil`, then the function will be called every time minutes.

If idle is `t`, then the function will be called after time minutes only if Emacs is idle. So if Emacs is never idle, the function will never be called. But once Emacs goes idle, the function will be called every time minutes.

If idle is a number and time is a number, the function will be called every time minutes only when Emacs has been idle for idle minutes.

If idle is a number and time is `nil`, the function will be called once every time Emacs has been idle for idle minutes.

And if time is a string, it should look like `07:31', and the function will then be called once every day somewhere near that time. Modified by the idle parameter, of course.

(When I say "minute" here, I really mean `gnus-demon-timestep` seconds. This is `60` by default. If you change that variable, all the timings in the handlers will be affected.)

To set the whole thing in motion, though, you have to set `gnus-use-demon` to `t`.

So, if you want to add a handler, you could put something like this in your `.gnus' file:

```
(gnus-demon-add-handler 'gnus-demon-close-connections nil 30)
```

Some ready-made functions to do this has been created: `gnus-demon-add-nocem`, `gnus-demon-add-disconnection`, and `gnus-demon-add-scanmail`. Just put those functions in your `.gnus' if you want those abilities.

If you add handlers to `gnus-demon-handlers` directly, you should run `gnus-demon-init` to make the changes take hold. To cancel all daemons, you can use the `gnus-demon-cancel` function.

Note that adding daemons can be pretty naughty if you overdo it. Adding functions that scan all news and mail from all servers every two seconds is a sure-fire way of getting booted off any respectable system. So behave.

NoCeM

Spamming is posting the same article lots and lots of times. Spamming is bad. Spamming is evil.

Spamming is usually canceled within a day or so by various anti-spamming agencies. These agencies usually also send out NoCeM messages. NoCeM is pronounced "no see-'em", and means what the name implies--these are messages that make the offending articles, like, go away.

What use are these NoCeM messages if the articles are canceled anyway? Some sites do not honor cancel messages and some sites just honor cancels from a select few people. Then you may wish to make use of the NoCeM messages, which are distributed in the `alt.nocem.misc' newsgroup.

Gnus can read and parse the messages in this group automatically, and this will make spam disappear.

There are some variables to customize, of course:

`gnus-use-nocem`

Set this variable to `t` to set the ball rolling. It is `nil` by default.

`gnus-nocem-groups`

Gnus will look for NoCeM messages in the groups in this list. The default is `("alt.nocem.misc" "news.admin.net-abuse.announce")`.

`gnus-nocem-issuers`

There are many people issuing NoCeM messages. This list says what people you want to listen to. The default is `("Automoose-1" "clewis@ferret.ocunix.on.ca;" "jem@xpat.com;" "red@redpoll.mrfs.oh.us (Richard E. Depew)")`; fine, upstanding citizens all of them.

Known despammers that you can put in this list include:

`clewis@ferret.ocunix.on.ca;'

Chris Lewis--Major Canadian despammer who has probably canceled more usenet abuse than anybody else.

`Automoose-1'

The CancelMoose[tm] on autopilot. The CancelMoose[tm] is reputed to be Norwegian, and was the person(s) who invented NoCeM.

`jem@xpat.com;'

Jem--Korean despammer who is getting very busy these days.

`red@redpoll.mrfs.oh.us (Richard E. Depew)'

Richard E. Depew--lone American despammer. He mostly cancels binary postings to non-binary groups and removes spews (regurgitated articles).

You do not have to heed NoCeM messages from all these people--just the ones you want to listen to.

- gnus-nocem-directory This is where Gnus will store its NoCeM cache files. The default is `~/News/NoCeM/'.
- gnus-nocem-expiry-wait The number of days before removing old NoCeM entries from the cache. The default is 15. If you make it shorter Gnus will be faster, but you might then see old spam.

Picons

So... You want to slow down your news reader even more! This is a good way to do so. Its also a great way to impress people staring over your shoulder as you read news.

Picon Basics

What are Picons? To quote directly from the Picons Web site (`http://www.cs.indiana.edu/picons/ftp/index.html'):

> Picons is short for "personal icons". They're small, constrained images used to represent users and domains on the net, organized into databases so that the appropriate image for a given e-mail address can be found. Besides users and domains, there are picon databases for Usenet newsgroups and weather forecasts. The picons are in either monochrome `XBM` format or color `XPM` and `GIF` formats.

Please see the above mentioned web site for instructions on obtaining and installing the picons databases, or the following ftp site: `http://www.cs.indiana.edu/picons/ftp/index.html'.

Gnus expects picons to be installed into a location pointed to by `gnus-picons-database`.

Picon Requirements

To use have Gnus display Picons for you, you must be running XEmacs 19.13 or greater since all other versions of Emacs aren't yet able to display images.

Additionally, you must have `xpm` support compiled into XEmacs.

If you want to display faces from `X-Face` headers, you must have the `netpbm` utilities installed, or munge the `gnus-picons-convert-x-face` variable to use something else.

Easy Picons

To enable displaying picons, simply put the following line in your `~/.gnus' file and start Gnus.

```
(setq gnus-use-picons t)
(add-hook 'gnus-article-display-hook 'gnus-article-display-picons t)
(add-hook 'gnus-summary-prepare-hook 'gnus-group-display-picons t)
(add-hook 'gnus-article-display-hook 'gnus-picons-article-display-x-face)
```

Hard Picons

Gnus can display picons for you as you enter and leave groups and articles. It knows how to interact with three sections of the picons database. Namely, it can display the picons newsgroup pictures, author's face picture(s), and the authors domain. To enable this feature, you need to first decide where to display them.

`gnus-picons-display-where`

> Where the picon images should be displayed. It is `picons` by default (which by default maps to the buffer `*Picons*'). Other valid places could be `article`, `summary`, or `'"*scratch*"' for all I care. Just make sure that you've made the buffer visible using the standard Gnus window configuration routines -- See section Windows Configuration.

Note: If you set `gnus-use-picons` to `t`, it will set up your window configuration for you to include the `picons` buffer.

Now that you've made that decision, you need to add the following functions to the appropriate hooks so these pictures will get displayed at the right time.

`gnus-article-display-picons`

> Looks up and display the picons for the author and the author's domain in the `gnus-picons-display-where` buffer. Should be added to the `gnus-article-display-hook`.

`gnus-group-display-picons`

> Displays picons representing the current group. This function should be added to the `gnus-summary-prepare-hook` or to the `gnus-article-display-hook` if `gnus-picons-display-where` is set to `article`.

`gnus-picons-article-display-x-face`

> Decodes and displays the X-Face header if present. This function should be added to `gnus-article-display-hook`.

Note: You must append them to the hook, so make sure to specify 't' to the append flag of `add-hook`:

```
(add-hook 'gnus-article-display-hook 'gnus-article-display-picons t)
```

Picon Configuration

The following variables offer further control over how things are done, where things are located, and other useless stuff you really don't need to worry about.

`gnus-picons-database`

The location of the picons database. Should point to a directory containing the `` `news' ``, `` `domains' ``, `` `users' `` (and so on) subdirectories. Defaults to `` `/usr/local/faces' ``.

`gnus-picons-news-directory`

Sub-directory of the faces database containing the icons for newsgroups.

`gnus-picons-user-directories`

List of subdirectories to search in `gnus-picons-database` for user faces. Defaults to `("local" "users" "usenix" "misc/MISC")`.

`gnus-picons-domain-directories`

List of subdirectories to search in `gnus-picons-database` for domain name faces. Defaults to `("domains")`. Some people may want to add `unknown' to this list.

`gnus-picons-convert-x-face`

The command to use to convert the `X-Face` header to an X bitmap (`xbm`). Defaults to `(format "{ echo '/* Width=48, Height=48 */'; uncompface; } | icontopbm | pbmtoxbm > %s" gnus-picons-x-face-file-name)`

`gnus-picons-x-face-file-name`

Names a temporary file to store the `X-Face` bitmap in. Defaults to `(format "/tmp/picon-xface.%s.xbm" (user-login-name))`.

`gnus-picons-buffer`

The name of the buffer that `picons` points to. Defaults to `*Icon Buffer*'.

Various Various

`gnus-verbose`

This variable is an integer between zero and ten. The higher the value, the more messages will be displayed. If this variable is zero, Gnus will never flash any messages, if it is seven (which is the default), most important messages will be shown, and if it is ten, Gnus won't ever shut up, but will flash so many messages it will make your head swim.

`gnus-verbose-backends`

This variable works the same way as `gnus-verbose`, but it applies to the Gnus backends instead of Gnus proper.

`nnheader-max-head-length`

When the backends read straight heads of articles, they all try to read as little as possible. This variable (default `4096`) specifies the absolute max length the backends will try to read before giving up on finding a separator line between the head and the body. If this variable is `nil`, there is no upper read bound. If it is `t`, the backends won't try to read the articles piece by piece, but read the entire articles. This makes sense with some versions of `ange-ftp`.

`nnheader-file-name-translation-alist`

This is an alist that says how to translate characters in file names. For instance, if `:' is illegal as a file character in file names on your system (you OS/2 user you), you could say something like:

```
(setq nnheader-file-name-translation-alist
      '((?: . ?_)))
```

In fact, this is the default value for this variable on OS/2 and MS Windows (phooey) systems.

`gnus-hidden-properties`

This is a list of properties to use to hide "invisible" text. It is `(invisible t intangible t)` by default on most systems, which makes invisible text invisible and intangible.

`gnus-parse-headers-hook`

A hook called before parsing headers. It can be used, for instance, to gather statistics on the headers fetched, or perhaps you'd like to prune some headers. I don't see why you'd want that, though.

Go to the previous, next section.

Go to the previous, next section.

The End

Well, that's the manual--you can get on with your life now. Keep in touch. Say hello to your cats from me.

My **ghod**---I just can't stand goodbyes. Sniffle.

Ol' Charles Reznikoff said it pretty well, so I leave the floor to him:

> **Te Deum**
>
> Not because of victories
> I sing,
> having none,
> but for the common sunshine,
> the breeze,
> the largess of the spring.
>
> Not for victory
> but for the day's work done
> as well as I was able;
> not for a seat upon the dais
> but at the common table.

Go to the previous, next section.

TOC

Appendices

History

GNUS was written by Masanobu UMEDA. When autumn crept up in '94, Lars Magne Ingebrigtsen grew bored and decided to rewrite Gnus.

If you want to investigate the person responsible for this outrage, you can point your (feh!) web browser to `http://www.ifi.uio.no/~larsi/'. This is also the primary distribution point for the new and spiffy versions of Gnus, and is known as The Site That Destroys Newsrcs And Drives People Mad.

During the first extended alpha period of development, the new Gnus was called "(ding) Gnus". (ding), is, of course, short for ding is not Gnus, which is a total and utter lie, but who cares? (Besides, the "Gnus" in this abbreviation should probably be pronounced "news" as UMEDA intended, which makes it a more appropriate name, don't you think?)

In any case, after spending all that energy on coming up with a new and spunky name, we decided that the name was *too* spunky, so we renamed it back again to "Gnus". But in mixed case. "Gnus" vs. "GNUS". New vs. old.

The first "proper" release of Gnus 5 was done in November 1995 when it was included in the Emacs 19.30 distribution.

In May 1996 the next Gnus generation (aka. "September Gnus") was released under the name "Gnus 5.2".

Why?

What's the point of Gnus?

I want to provide a "rad", "happening", "way cool" and "hep" newsreader, that lets you do anything you can think of. That was my original motivation, but while working on Gnus, it has become clear to me that this generation of newsreaders really belong in the stone age. Newsreaders haven't developed much since the infancy of the net. If the volume continues to rise with the current rate of increase, all current newsreaders will be pretty much useless. How do you deal with newsgroups that have thousands of new articles each day? How do you keep track of millions of people who post?

Gnus offers no real solutions to these questions, but I would very much like to see Gnus being used as a testing ground for new methods of reading and fetching news. Expanding on UMEDA-san's wise decision to separate the newsreader from the backends, Gnus now offers a simple interface for anybody who wants to write new backends for fetching mail and news from different sources. I have added hooks for customizations everywhere I could imagine useful. By doing so, I'm inviting every one of you to explore and invent.

May Gnus never be complete. C-u 100 M-x hail-emacs.

Compatibility

Gnus was designed to be fully compatible with GNUS. Almost all key bindings have been kept. More key bindings have been added, of course, but only in one or two obscure cases have old bindings been changed.

Our motto is:

> In a cloud bones of steel.

All commands have kept their names. Some internal functions have changed their names.

The `gnus-uu` package has changed drastically. see section Decoding Articles.

One major compatibility question is the presence of several summary buffers. All variables that are relevant while reading a group are buffer-local to the summary buffer they belong in. Although many important variables have their values copied into their global counterparts whenever a command is executed in the summary buffer, this change might lead to incorrect values being used unless you are careful.

All code that relies on knowledge of GNUS internals will probably fail. To take two examples: Sorting `gnus-newsrc-alist` (or changing it in any way, as a matter of fact) is strictly verboten. Gnus maintains a hash table that points to the entries in this alist (which speeds up many functions), and changing the alist directly will lead to peculiar results.

Old hilit19 code does not work at all. In fact, you should probably remove all hilit code from all Gnus hooks (`gnus-group-prepare-hook` and `gnus-summary-prepare-hook`). Gnus provides various integrated functions for highlighting. These are faster and more accurate. To make life easier for everybody, Gnus will by default remove all hilit calls from all hilit hooks. Uncleanliness! Away!

Packages like `expire-kill` will no longer work. As a matter of fact, you should probably remove all old GNUS packages (and other code) when you start using Gnus. More likely than not, Gnus already does what you have written code to make GNUS do. (Snicker.)

Even though old methods of doing things are still supported, only the new methods are documented in this manual. If you detect a new method of doing something while reading this manual, that does not mean you have to stop doing it the old way.

Gnus understands all GNUS startup files.

Overall, a casual user who hasn't written much code that depends on GNUS internals should suffer no problems. If problems occur, please let me know by issuing that magic command M-x gnus-bug.

Conformity

No rebels without a clue here, ma'am. We conform to all standards known to (wo)man. Except for those standards and/or conventions we disagree with, of course.

RFC 822

There are no known breaches of this standard.

RFC 1036

There are no known breaches of this standard, either.

Usenet Seal of Approval

Gnus hasn't been formally through the Seal process, but I have read through the Seal text and I think Gnus would pass.

Son-of-RFC 1036

We do have some breaches to this one.

MIME

Gnus does no MIME handling, and this standard-to-be seems to think that MIME is the bees' knees, so we have major breakage here.

X-Newsreader

This is considered to be a "vanity header", while I consider it to be consumer information. After seeing so many badly formatted articles coming from `tin` and `Netscape` I know not to use either of those for posting articles. I would not have known that if it wasn't for the `X-Newsreader` header.

References

Gnus does line breaking on this header. I infer from RFC1036 that being conservative in what you output is not creating 5000-character lines, so it seems like a good idea to me. However, this standard-to-be says that whitespace in the `References` header is to be preserved, so... It doesn't matter one way or the other to Gnus, so if somebody tells me what The Way is, I'll change it. Or not.

If you ever notice Gnus acting non-compliantly with regards to the texts mentioned above, don't hesitate to drop a note to Gnus Towers and let us know.

Emacsen

Gnus should work on :

- Emacs 19.30 and up.
- XEmacs 19.13 and up.
- Mule versions based on Emacs 19.30 and up.

Gnus will absolutely not work on any Emacsen older than that. Not reliably, at least.

There are some vague differences between Gnus on the various platforms:

- The mouse-face on Gnus lines under Emacs and Mule is delimited to certain parts of the lines while they cover the entire line under XEmacs.
- The same with current-article marking--XEmacs puts an underline under the entire summary line while Emacs and Mule are nicer

and kinder.

- XEmacs features more graphics--a logo and a toolbar.
- Citation highlighting us better under Emacs and Mule than under XEmacs.
- Emacs 19.26-19.28 have tangible hidden headers, which can be a bit confusing.

Contributors

The new Gnus version couldn't have been done without the help of all the people on the (ding) mailing list. Every day for over a year I have gotten billions of nice bug reports from them, filling me with joy, every single one of them. Smooches. The people on the list have been tried beyond endurance, what with my "oh, that's a neat idea <type type>, yup, I'll release it right away <ship off> no wait, that doesn't work at all <type type>, yup, I'll ship that one off right away <ship off> no, wait, that absolutely does not work" policy for releases. Micro$oft--bah. Amateurs. I'm *much* worse. (Or is that "worser"? "much worser"? "worsest"?)

I would like to take this opportunity to thank the Academy for... oops, wrong show.

- Kevin Davidson Came up with the name ding, so blame him.

Peter Arius, Stainless Steel Rat, Ulrik Dickow, Jack Vinson, Daniel Quinlan, Frank D. Cringle, Geoffrey T. Dairiki, Fabrice Popineau and Andrew Eskilsson have all contributed code and suggestions.

New Features

- The look of all buffers can be changed by setting format-like variables (see section Group Buffer Format and see section Summary Buffer Format).
- Local spool and several NNTP servers can be used at once (see section Select Methods).
- You can combine groups into virtual groups (see section Virtual Groups).
- You can read a number of different mail formats (see section Getting Mail). All the mail backends implement a convenient mail expiry scheme (see section Expiring Mail).
- Gnus can use various strategies for gathering threads that have lost their roots (thereby gathering loose sub-threads into one thread) or it can go back and retrieve enough headers to build a complete thread (see section Customizing Threading).
- Killed groups can be displayed in the group buffer, and you can read them as well (see section Listing Groups).
- Gnus can do partial group updates--you do not have to retrieve the entire active file just to check for new articles in a few groups (see section The Active File).
- Gnus implements a sliding scale of subscribedness to groups (see section Group Levels).
- You can score articles according to any number of criteria (see section Scoring). You can even get Gnus to find out how to score articles for you (see section Adaptive Scoring).

- Gnus maintains a dribble buffer that is auto-saved the normal Emacs manner, so it should be difficult to lose much data on v you have read if your machine should go down (see section Auto Save).
- Gnus now has its own startup file (`.gnus') to avoid cluttering up the `.emacs' file.
- You can set the process mark on both groups and articles and perform operations on all the marked items (see section Process/Prefix).
- You can grep through a subset of groups and create a group from the results (see section Kibozed Groups).
- You can list subsets of groups according to, well, anything (see section Listing Groups).
- You can browse foreign servers and subscribe to groups from those servers (see section Browse Foreign Server).
- Gnus can fetch articles asynchronously on a second connection to the server (see section Asynchronous Article Fetching).
- You can cache articles locally (see section Article Caching).
- The uudecode functions have been expanded and generalized (see section Decoding Articles).
- You can still post uuencoded articles, which was a little-known feature of GNUS' past (see section Uuencoding and Posting).
- Fetching parents (and other articles) now actually works without glitches (see section Finding the Parent).
- Gnus can fetch FAQs and group descriptions (see section Group Information).
- Digests (and other files) can be used as the basis for groups (see section Document Groups).
- Articles can be highlighted and customized (see section Customizing Articles).
- URLs and other external references can be buttonized (see section Article Buttons).
- You can do lots of strange stuff with the Gnus window & frame configuration (see section Windows Configuration).
- You can click on buttons instead of using the keyboard (see section Buttons).
- Gnus can use NoCeM files to weed out spam (see section NoCeM).

This is, of course, just a *short* overview of the *most* important new features. No, really. There are tons more. Yes, we have feeping creaturism in full effect, but nothing too gratuitous, I would hope.

Newest Features

Also known as the todo list. Sure to be implemented before the next millennium.

Be afraid. Be very afraid.

- Native MIME support is something that should be done.
- A better and simpler method for specifying mail composing methods.
- Allow posting through mail-to-news gateways.
- Really do unbinhexing.

And much, much, much more. There is more to come than has already been implemented. (But that's always true, isn't it?)

<URL:http://www.ifi.uio.no/~larsi/sgnus/todo> is where the actual up-to-the-second todo list is located, so if you're really curious, you could point your Web browser over that-a-way.

Terminology

news

This is what you are supposed to use this thing for--reading news. News is generally fetched from a nearby NNTP server, and is generally publicly available to everybody. If you post news, the entire world is likely to read just what you have written, and they'll all snigger mischievously. Behind your back.

mail

Everything that's delivered to you personally is mail. Some news/mail readers (like Gnus) blur the distinction between mail and news, but there is a difference. Mail is private. News is public. Mailing is not posting, and replying is not following up.

reply

Send a mail to the person who has written what you are reading.

follow up

Post an article to the current newsgroup responding to the article you are reading.

backend

Gnus gets fed articles from a number of backends, both news and mail backends. Gnus does not handle the underlying media, so to speak--this is all done by the backends.

native

Gnus will always use one method (and backend) as the native, or default, way of getting news.

foreign

You can also have any number of foreign groups active at the same time. These are groups that use different backends for getting news.

secondary

Secondary backends are somewhere half-way between being native and being foreign, but they mostly act like they are native.

article

A nessage that has been posted as news.

mail message

A message that has been mailed.

message

A mail message or news article

head

The top part of a message, where administrative information (etc.) is put.

body

The rest of an article. Everything that is not in the head is in the body.

header

A line from the head of an article.

headers

A collection of such lines, or a collection of heads. Or even a collection of NOV lines.

NOV

When Gnus enters a group, it asks the backend for the headers of all unread articles in the group. Most servers support the News OverView format, which is more compact and much faster to read and parse than the normal HEAD format.

level

Each group is subscribed at some level or other (1-9). The ones that have a lower level are "more" subscribed than the groups with a higher level. In fact, groups on levels 1-5 are considered subscribed; 6-7 are unsubscribed; 8 are zombies; and 9 are killed. Commands for listing groups and scanning for new articles will all use the numeric prefix as working level.

killed groups

No information on killed groups is stored or updated, which makes killed groups much easier to handle than subscribed groups.

zombie groups

Just like killed groups, only slightly less dead.

active file

The news server has to keep track of what articles it carries, and what groups exist. All this information in stored in the active file, which is rather large, as you might surmise.

bogus groups

A group that exists in the `.newsrc' file, but isn't known to the server (i. e., it isn't in the active file), is a *bogus group*. This means that the group probably doesn't exist (any more).

server

A machine than one can connect to and get news (or mail) from.

select method

A structure that specifies the backend, the server and the virtual server parameters.

virtual server

A named select method. Since a select methods defines all there is to know about connecting to a (physical) server, taking the who things as a whole is a virtual server.

Customization

All variables are properly documented elsewhere in this manual. This section is designed to give general pointers on how to customize Gnus for some quite common situations.

Slow/Expensive NNTP Connection

If you run Emacs on a machine locally, and get your news from a machine over some very thin strings, you want to cut down on the amount of data Gnus has to get from the NNTP server.

`gnus-read-active-file`

Set this to `nil`, which will inhibit Gnus from requesting the entire active file from the server. This file is often v. large. You also have to set `gnus-check-new-news` and `gnus-check-bogus-newsgroups` to `nil` to make sure that Gnus doesn't suddenly decide to fetch the active file anyway.

`gnus-nov-is-evil`

This one has to be `nil`. If not, grabbing article headers from the NNTP server will not be very fast. Not all NNTP servers support XOVER; Gnus will detect this by itself.

Slow Terminal Connection

Let's say you use your home computer for dialing up the system that runs Emacs and Gnus. If your modem is slow, you want to reduce the amount of data that is sent over the wires as much as possible.

`gnus-auto-center-summary`

Set this to `nil` to inhibit Gnus from re-centering the summary buffer all the time. If it is `vertical`, do only vertical re-centering. If it is neither `nil` nor `vertical`, do both horizontal and vertical recentering.

`gnus-visible-headers`

Cut down on the headers that are included in the articles to the minimum. You can, in fact, make do without them altogether--most of the useful data is in the summary buffer, anyway. Set this variable to `^NEVVVVER' or `From:', or whatever you feel you need.

`gnus-article-display-hook`

Set this hook to all the available hiding commands:

```
(setq gnus-article-display-hook
      '(gnus-article-hide-headers gnus-article-hide-signature
        gnus-article-hide-citation))
```

`gnus-use-full-window`

By setting this to `nil`, you can make all the windows smaller. While this doesn't really cut down much generally, it means that you have to see smaller portions of articles before deciding that you didn't want to read them anyway.

`gnus-thread-hide-subtree`

If this is non-`nil`, all threads in the summary buffer will be hidden initially.

`gnus-updated-mode-lines`

If this is `nil`, Gnus will not put information in the buffer mode lines, which might save some time.

Little Disk Space

The startup files can get rather large, so you may want to cut their sizes a bit if you are running out of space.

`gnus-save-newsrc-file`

If this is `nil`, Gnus will never save `.newsrc'---it will only save `.newsrc.eld'. This means that you will not be able to use any other newsreaders than Gnus. This variable is `t` by default.

`gnus-save-killed-list`

If this is `nil`, Gnus will not save the list of dead groups. You should also set `gnus-check-new-newsgroups` to `ask-server` and `gnus-check-bogus-newsgroups` to `nil` if you set this variable to `nil`. This variable is `t` by default.

Slow Machine

If you have a slow machine, or are just really impatient, there are a few things you can do to make Gnus run faster.

Set`gnus-check-new-newsgroups` and `gnus-check-bogus-newsgroups` to `nil` to make startup faster.

Set `gnus-show-threads`, `gnus-use-cross-reference` and `gnus-nov-is-evil` to `nil` to make entering and exiting the summary buffer faster.

Set `gnus-article-display-hook` to `nil` to make article processing a bit faster.

Troubleshooting

Gnus works *so* well straight out of the box--I can't imagine any problems, really.

Ahem.

1. Make sure your computer is switched on.
2. Make sure that you really load the current Gnus version. If you have been running GNUS, you need to exit Emacs and start it up again before Gnus will work.
3. Try doing an M-x gnus-version. If you get something that looks like `Gnus v5.46; nntp 4.0' you have the right files loaded. If, on the other hand, you get something like `NNTP 3.x' or `nntp flee', you have some old `` `.el' `` files lying around. Delete these.
4. Read the help group (G h in the group buffer) for a FAQ and a how-to.

If all else fails, report the problem as a bug.

If you find a bug in Gnus, you can report it with the M-x gnus-bug command. M-x set-variable RET debug-on-error RET t RET, and send me the backtrace. I will fix bugs, but I can only fix them if you send me a precise description as to how to reproduce the bug.

You really can never be too detailed in a bug report. Always use the M-x gnus-bug command when you make bug reports, even if it creates a 10Kb mail each time you use it, and even if you have sent me your environment 500 times before. I don't care. I want the full info each time.

It is also important to remember that I have no memory whatsoever. If you send a bug report, and I send you a reply, and then you send back just "No, it's not! Moron!", I will have no idea what you are insulting me about. Always over-explain everything. It's much easier for all of us--if I don't have all the information I need, I will just mail you and ask for more info, and everything takes more time.

If the problem you're seeing is very visual, and you can't quite explain it, copy the Emacs window to a file (with `xwd`, for instance), put it somewhere it can be reached, and include the URL of the picture in the bug report.a

If you just need help, you are better off asking on `gnu.emacs.gnus'. I'm not very helpful.

You can also ask on the ding mailing list---`ding@ifi.uio.no'. Write to `ding-request@ifi.uio.no' to subscribe.

A Programmer's Guide to Gnus

It is my hope that other people will figure out smart stuff that Gnus can do, and that other people will write those smart things as well. To facilitate that I thought it would be a good idea to describe the inner workings of Gnus. And some of the not-so-inner workings, while I'm at it.

You can never expect the internals of a program not to change, but I will be defining (in some details) the interface between Gnus and its backends (this is written in stone), the format of the score files (ditto), data structures (some are less likely to change than others) and general method of operations.

Backend Interface

Gnus doesn't know anything about NNTP, spools, mail or virtual groups. It only knows how to talk to virtual servers. A virtual server is a backend and some backend variables. As examples of the first, we have `nntp`, `nnspool` and `nnmbox`. As examples of the latter we have `nntp-port-number` and `nnmbox-directory`.

When Gnus asks for information from a backend--say `nntp`---on something, it will normally include a virtual server name in the function parameters. (If not, the backend should use the "current" virtual server.) For instance, `nntp-request-list` takes a virtual

server as its only (optional) parameter. If this virtual server hasn't been opened, the function should fail.

Note that a virtual server name has no relation to some physical server name. Take this example:

```
(nntp "odd-one"
      (nntp-address "ifi.uio.no")
      (nntp-port-number 4324))
```

Here the virtual server name is `odd-one' while the name of the physical server is `ifi.uio.no'.

The backends should be able to switch between several virtual servers. The standard backends implement this by keeping an alist of virtual server environments that it pulls down/pushes up when needed.

There are two groups of interface functions: required functions, which must be present, and optional functions, which Gnus will always check whether are present before attempting to call.

All these functions are expected to return data in the buffer `nntp-server-buffer` (` *nntpd*'), which is somewhat unfortunately named, but we'll have to live with it. When I talk about "resulting data", I always refer to the data in that buffer. When I talk about "return value", I talk about the function value returned by the function call.

Some backends could be said to be server-forming backends, and some might be said to not be. The latter are backends that generally only operate on one group at a time, and have no concept of "server" -- they have a group, and they deliver info on that group and nothing more.

In the examples and definitions I will refer to the imaginary backend `nnchoke`.

Required Backend Functions

`(nnchoke-retrieve-headers ARTICLES &optional GROUP SERVER FETCH-OLD)`

articles is either a range of article numbers or a list of `Message-ID`s. Current backends do not fully support either--only sequences (lists) of article numbers, and most backends do not support retrieval of `Message-ID`s. But they should try for both.

The result data should either be HEADs or NOV lines, and the result value should either be `headers` or `nov` to reflect this. This might later be expanded to `various`, which will be a mixture of HEADs and NOV lines, but this is currently not supported by Gnus.

If fetch-old is non-`nil` it says to try to fetch "extra headers, in some meaning of the word. This is generally done by fetching (at most) fetch-old extra headers less than the smallest article number in `articles`, and fill in the gaps as well. The presence of this parameter can be ignored if the backend finds it cumbersome to follow the request. If this is non-`nil` and not a number, do maximum fetches.

Here's an example HEAD:

```
221 1056 Article retrieved.
Path: ifi.uio.no!sturles
From: sturles@ifi.uio.no (Sturle Sunde)
Newsgroups: ifi.discussion
Subject: Re: Something very droll
Date: 27 Oct 1994 14:02:57 +0100
Organization: Dept. of Informatics, University of Oslo, Norway
Lines: 26
Message-ID: <38o8e1$a0o@holmenkollen.ifi.uio.no>
References: <38jdmq$4qu@visbur.ifi.uio.no>
NNTP-Posting-Host: holmenkollen.ifi.uio.no
.
```

So a `headers` return value would imply that there's a number of these in the data buffer.

Here's a BNF definition of such a buffer:

```
headers        = *head
head           = error / valid-head
```

```
error-message  = [ "4" / "5" ] 2number " " <error message> eol
valid-head     = valid-message *header "." eol
valid-message  = "221 " <number> " Article retrieved." eol
header         = <text> eol
```

If the return value is `nov`, the data buffer should contain network overview database lines. These are basically fields separated by tabs.

```
nov-buffer = *nov-line
nov-line   = 8*9 [ field <TAB> ] eol
field      = <text except TAB>
```

For a closer explanation what should be in those fields, see section Headers.

`(nnchoke-open-server SERVER &optional DEFINITIONS)`

server is here the virtual server name. definitions is a list of `(VARIABLE VALUE)` pairs that defines this virtual server.

If the server can't be opened, no error should be signaled. The backend may then choose to refuse further attempts at connecting to this server. In fact, it should do so.

If the server is opened already, this function should return a non-`nil` value. There should be no data returned.

`(nnchoke-close-server &optional SERVER)`

Close connection to server and free all resources connected to it. Return `nil` if the server couldn't be closed for some reason.

There should be no data returned.

`(nnchoke-request-close)`

Close connection to all servers and free all resources that the backend have reserved. All buffers that have been created by that backend should be killed. (Not the `nntp-server-buffer`, though.) This function is generally only called when Gnus is shutting down.

There should be no data returned.

`(nnchoke-server-opened &optional SERVER)`

If server is the current virtual server, and the connection to the physical server is alive, then this function should return a non-`nil` vlue. This function should under no circumstances attempt to reconnect to a server that is has lost connection to.

There should be no data returned.

`(nnchoke-status-message &optional SERVER)`

This function should return the last error message from server.

There should be no data returned.

`(nnchoke-request-article ARTICLE &optional GROUP SERVER TO-BUFFER)`

The result data from this function should be the article specified by article. This might either be a `Message-ID` or a number. It is optional whether to implement retrieval by `Message-ID`, but it would be nice if that were possible.

If to-buffer is non-`nil`, the result data should be returned in this buffer instead of the normal data buffer. This is to make it possible to avoid copying large amounts of data from one buffer to another, and Gnus mainly request articles to be inserted directly into its article buffer.

If it is at all possible, this function should return a cons cell where the car is the group name the article was fetched from, and the cdr is the article number. This will enable Gnus to find out what the real group and article numbers are when fetching articles by `Message-ID`. If this isn't possible, `t` should be returned on successful article retrievement.

`(nnchoke-open-group GROUP &optional SERVER)`

Make group the current group.

There should be no data returned by this function.

`(nnchoke-request-group GROUP &optional SERVER)`

Get data on group. This function also has the side effect of making group the current group.

Here's an example of some result data and a definition of the same:

```
211 56 1000 1059 ifi.discussion
```

The first number is the status, which should be `211`. Next is the total number of articles in the group, the lowest article number, the highest article number, and finally the group name. Note that the total number of articles may be less than one might think while just considering the highest and lowest article numbers, but some articles may have been canceled. Gnus just discards the total-number, so whether one should take the bother to generate it properly (if that is a problem) is left as an exercise to the reader.

```
group-status = [ error / info ] eol
error        = [ "4" / "5" ] 2<number> " " <Error message>
info         = "211 " 3* [ <number> " " ] <string>
```

`(nnchoke-close-group GROUP &optional SERVER)`

Close group and free any resources connected to it. This will be a no-op on most backends.

There should be no data returned.

`(nnchoke-request-list &optional SERVER)`

Return a list of all groups available on server. And that means *all*.

Here's an example from a server that only carries two groups:

```
ifi.test 0000002200 0000002000 y
ifi.discussion 3324 3300 n
```

On each line we have a group name, then the highest article number in that group, the lowest article number, and finally a flag.

```
active-file = *active-line
active-line = name " " <number> " " <number> " " flags eol
name        = <string>
flags       = "n" / "y" / "m" / "x" / "j" / "=" name
```

The flag says whether the group is read-only (`n'), is moderated (`m'), is dead (`x'), is aliased to some other group (`=other-group' or none of the above (`y').

`(nnchoke-request-post &optional SERVER)`

This function should post the current buffer. It might return whether the posting was successful or not, but that's not required. If, for instance, the posting is done asynchronously, it has generally not been completed by the time this function concludes. In that case, this function should set up some kind of sentinel to beep the user loud and clear if the posting could not be completed.

There should be no result data from this function.

Optional Backend Functions

`(nnchoke-retrieve-groups GROUPS &optional SERVER)`

groups is a list of groups, and this function should request data on all those groups. How it does it is of no concern to Gnus, but it should attempt to do this in a speedy fashion.

The return value of this function can be either `active` or `group`, which says what the format of the result data is. The former is in the same format as the data from `nnchoke-request-list`, while the latter is a buffer full of lines in the same format as `nnchoke-request-group` gives.

```
group-buffer = *active-line / *group-status
```

`(nnchoke-request-update-info GROUP INFO &optional SERVER)`

A Gnus group info (see section Group Info) is handed to the backend for alterations. This comes in handy if the backend really carries all the information (as is the case with virtual an imap groups). This function may alter the info in any manner it sees fit, and should return the (altered) group info. This function may alter the group info destructively, so no copying is needed before boogeying.

There should be no result data from this function.

`(nnchoke-request-type GROUP &optional ARTICLE)`

When the user issues commands for "sending news" (F in the summary buffer, for instance), Gnus has to know whether the article the user is following up is news or mail. This function should return `news` if article in group is news, `mail` if it is mail and `unknown` if the type can't be decided. (The article parameter is necessary in `nnvirtual` groups which might very well combine mail groups and news groups.)

There should be no result data from this function.

`(nnchoke-request-update-mark GROUP ARTICLE MARK)`

If the user tries to set a mark that the backend doesn't like, this function may change the mark. Gnus will use whatever this function returns as the mark for article instead of the original mark. If the backend doesn't care, it must return the original mark, and not `nil` or any other type of garbage.

The only use for this that I can see is what `nnvirtual` does with it--if a component group is auto-expirable, marking an article as read in the virtual group should result in the article being marked as expirable.

There should be no result data from this function.

`(nnchoke-request-scan &optional GROUP SERVER)`

This function may be called at any time (by Gnus or anything else) to request that the backend check for incoming articles, in one way or another. A mail backend will typically read the spool file or query the POP server when this function is invoked. The group doesn't have to be heeded--if the backend decides that it is too much work just scanning for a single group, it may do a total scan of all groups. It would be nice, however, to keep things local if that's practical.

There should be no result data from this function.

`(nnchoke-request-asynchronous GROUP &optional SERVER ARTICLES)`

This is a request to fetch articles asynchronously later. articles is an alist of (article-number line-number). One would generally expect that if one later fetches article number 4, for instance, some sort of asynchronous fetching of the articles after 4 (which might be 5, 6, 7 or 11, 3, 909 depending on the order in that alist) would be fetched asynchronously, but that is left up to the backend. Gnus doesn't care.

There should be no result data from this function.

`(nnchoke-request-group-description GROUP &optional SERVER)`

The result data from this function should be a description of group.

```
description-line = name <TAB> description eol
name             = <string>
description      = <text>
```

`(nnchoke-request-list-newsgroups &optional SERVER)`

The result data from this function should be the description of all groups available on the server.

```
description-buffer = *description-line
```

`(nnchoke-request-newgroups DATE &optional SERVER)`

The result data from this function should be all groups that were created after `date', which is in normal human-readable date format. The data should be in the active buffer format.

`(nnchoke-request-create-group GROUP &optional SERVER)`

This function should create an empty group with name group.

There should be no return data.

`(nnchoke-request-expire-articles ARTICLES &optional GROUP SERVER FORCE)`

This function should run the expiry process on all articles in the articles range (which is currently a simple list of article numbers.) It is left up to the backend to decide how old articles should be before they are removed by this function. If force is non-`nil`, all articles should be deleted, no matter how new they are.

This function should return a list of articles that it did not/was not able to delete.

There should be no result data returned.

`(nnchoke-request-move-article ARTICLE GROUP SERVER ACCEPT-FORM &optional LAST)`

This function should move article (which is a number) from group by calling accept-form.

This function should ready the article in question for moving by removing any header lines it has added to the article, and generally should "tidy up" the article. Then it should `eval` accept-form in the buffer where the "tidy" article is. This will do the actual copying. If this `eval` returns a non-`nil` value, the article should be removed.

If last is `nil`, that means that there is a high likelihood that there will be more requests issued shortly, so that allows some optimizations.

The function should return a cons where the car is the group name and the cdr is the article number that the article was entered as.

There should be no data returned.

`(nnchoke-request-accept-article GROUP &optional SERVER LAST)`

This function takes the current buffer and inserts it into group. If last in `nil`, that means that there will be more calls to this function in short order.

The function should return a cons where the car is the group name and the cdr is the article number that the article was entered as.

There should be no data returned.

`(nnchoke-request-replace-article ARTICLE GROUP BUFFER)`

This function should remove article (which is a number) from group and insert buffer there instead.

There should be no data returned.

`(nnchoke-request-delete-group GROUP FORCE &optional SERVER)`

This function should delete group. If force, it should really delete all the articles in the group, and then delete the group itself. (If there is such a thing as "the group itself".)

There should be no data returned.

`(nnchoke-request-rename-group GROUP NEW-NAME &optional SERVER)`

This function should rename group into new-name. All articles that are in group should move to new-name.

There should be no data returned.

Writing New Backends

The various backends share many similarities. `nnml` is just like `nnspool`, but it allows you to edit the articles on the server. `nnmh` is just like `nnml`, but it doesn't use an active file, and it doesn't maintain overview databases. `nndir` is just like `nnml`, but it has no concept of "groups", and it doesn't allow editing articles.

It would make sense if it were possible to "inherit" functions from backends when writing new backends. And, indeed, you can do that if you want to. (You don't have to if you don't want to, of course.)

All the backends declare their public variables and functions by using a package called `nnoo`.

To inherit functions from other backends (and allow other backends to inherit functions from the current backend), you should use the following macros: following.

`nnoo-declare`

This macro declares the first parameter to be a child of the subsequent parameters. For instance:

```
(nnoo-declare nndir
  nnml nnmh)
```

`nndir` has here declared that it intends to inherit functions from both `nnml` and `nnmh`.

`defvoo`

This macro is equivalent to `defvar`, but registers the variable as a public server variable. Most state-oriented variables sho declared with `defvoo` instead of `defvar`.

In addition to the normal `defvar` parameters, it takes a list of variables in the parent backends to map the variable to when executing a function in those backends.

```
(defvoo nndir-directory nil
  "Where nndir will look for groups."
  nnml-current-directory nnmh-current-directory)
```

This means that `nnml-current-directory` will be set to `nndir-directory` when an `nnml` function is called on behalf of `nndir`. (The same with `nnmh`.)

`nnoo-define-basics`

This macro defines some common functions that almost all backends should have.

```
(nnoo-define-basics nndir)
```

`deffoo`

This macro is just like `defun` and takes the same parameters. In addition to doing the normal `defun` things, it registers the function as being public so that other backends can inherit it.

`nnoo-map-functions`

This macro allows mapping of functions from the current backend to functions from the parent backends.

```
(nnoo-map-functions nndir
  (nnml-retrieve-headers 0 nndir-current-group 0 0)
  (nnmh-request-article 0 nndir-current-group 0 0))
```

This means that when `nndir-retrieve-headers` is called, the first, third, and fourth parameters will be passed on to `nnml-retrieve-headers`, while the second parameter is set to the value of `nndir-current-group`.

`nnoo-import`

This macro allows importing functions from backends. It should be the last thing in the source file, since it will only define functions that haven't already been defined.

```
(nnoo-import nndir
  (nnmh
   nnmh-request-list
   nnmh-request-newgroups)
  (nnml))
```

This means that calls to `nndir-request-list` should just be passed on to `nnmh-request-list`, while all public functions from `nnml` that haven't been defined in `nndir` yet should be defined now.

Below is a slightly shortened version of the `nndir` backend.

```
;;; nndir.el -- single directory newsgroup access for Gnus

```

Score File Syntax

Score files are meant to be easily parsable, but yet extremely mallable. It was decided that something that had the same read syntax as an Emacs Lisp list would fit that spec.

Here's a typical score file:

```
(("summary"
  ("win95" -10000 nil s)
  ("Gnus"))
 ("from"
  ("Lars" -1000))
 (mark -100))
```

BNF definition of a score file:

```
score-file       = "" / "(" *element ")"
element          = rule / atom
rule             = string-rule / number-rule / date-rule
string-rule      = "(" quote string-header quote space *string-match ")"
number-rule      = "(" quote number-header quote space *number-match ")"
date-rule        = "(" quote date-header quote space *date-match ")"
quote            = <ascii 34>
string-header    = "subject" / "from" / "references" / "message-id" /
                   "xref" / "body" / "head" / "all" / "followup"
number-header    = "lines" / "chars"
date-header      = "date"
string-match     = "(" quote <string> quote [ "" / [ space score [ "" /
                   space date [ "" / [ space string-match-t ] ] ] ] ] ")"
score            = "nil" / <integer>
date             = "nil" / <natural number>
string-match-t   = "nil" / "s" / "substring" / "S" / "Substring" /
                   "r" / "regex" / "R" / "Regex" /
                   "e" / "exact" / "E" / "Exact" /
                   "f" / "fuzzy" / "F" / "Fuzzy"
number-match     = "(" <integer> [ "" / [ space score [ "" /
                   space date [ "" / [ space number-match-t ] ] ] ] ] ")"
number-match-t   = "nil" / "=" / "<" / ">" / ">=" / "<="
date-match       = "(" quote <string> quote [ "" / [ space score [ "" /
                   space date [ "" / [ space date-match-t ] ] ] ] ")"
date-match-t     = "nil" / "at" / "before" / "after"
atom             = "(" [ required-atom / optional-atom ] ")"
required-atom    = mark / expunge / mark-and-expunge / files /
                   exclude-files / read-only / touched
optional-atom    = adapt / local / eval
mark             = "mark" space nil-or-number
nil-or-number    = "nil" / <integer>
expunge          = "expunge" space nil-or-number
mark-and-expunge = "mark-and-expunge" space nil-or-number
files            = "files" *[ space <string> ]
exclude-files    = "exclude-files" *[ space <string> ]
read-only        = "read-only" [ space "nil" / space "t" ]
adapt            = "adapt" [ space "nil" / space "t" / space adapt-rule ]
adapt-rule       = "(" *[ <string> *[ "(" <string> <integer> ")" ] ")"
local            = "local" *[ space "(" <string> space <form> ")" ]
eval             = "eval" space <form>
space            = *[ " " / <TAB> / <NEWLINE> ]
```

Any unrecognized elements in a score file should be ignored, but not discarded.

As you can see, white space is needed, but the type and amount of white space is irrelevant. This means that formatting of the score file is left up to the programmer--if it's simpler to just spew it all out on one looong line, then that's ok.

The meaning of the various atoms are explained elsewhere in this manual.

Headers

Gnus uses internally a format for storing article headers that corresponds to the NOV format in a mysterious fashion. One could almost suspect that the author looked at the NOV specification and just shamelessly *stole* the entire thing, and one would be right.

Header is a severely overloaded term. "Header" is used in RFC1036 to talk about lines in the head of an article (eg., `From`). It is used by many people as a synonym for "head"---"the header and the body". (That should be avoided, in my opinion.) And Gnus uses a format internally that it calls "header", which is what I'm talking about here. This is a 9-element vector, basically, with each header (ouch) having one slot.

These slots are, in order: `number`, `subject`, `from`, `date`, `id`, `references`, `chars`, `lines`, `xref`. There are macros for accessing and setting these slots -- they all have predictable names beginning with `mail-header-` and `mail-header-set-`, respectively.

The `xref` slot is really a `misc` slot. Any extra info will be put in there.

Ranges

GNUS introduced a concept that I found so useful that I've started using it a lot and have elaborated on it greatly.

The question is simple: If you have a large amount of objects that are identified by numbers (say, articles, to take a *wild* example) that you want to callify as being "included", a normal sequence isn't very useful. (A 200,000 length sequence is a bit long-winded.)

The solution is as simple as the question: You just collapse the sequence.

```
(1 2 3 4 5 6 10 11 12)
```

is transformed into

```
((1 . 6) (10 . 12))
```

To avoid having those nasty `(13 . 13)' elements to denote a lonesome object, a `13' is a valid element:

```
((1 . 6) 7 (10 . 12))
```

This means that comparing two ranges to find out whether they are equal is slightly tricky:

```
((1 . 5) 7 8 (10 . 12))
```

and

```
((1 . 5) (7 . 8) (10 . 12))
```

are equal. In fact, any non-descending list is a range:

```
(1 2 3 4 5)
```

is a perfectly valid range, although a pretty long-winded one. This is also legal:

```
(1 . 5)
```

and is equal to the previous range.

Here's a BNF definition of ranges. Of course, one must remember the semantic requirement that the numbers are non-descending. (Any number of repetition of the same number is allowed, but apt to disappear in range handling.)

```
range           = simple-range / normal-range
simple-range    = "(" number " . " number ")"
normal-range    = "(" start-contents ")"
contents        = "" / simple-range *[ " " contents ] /
                  number *[ " " contents ]
```

Gnus currently uses ranges to keep track of read articles and article marks. I plan on implementing a number of range operators in C if The Powers That Be are willing to let me. (I haven't asked yet, because I need to do some more thinking on what operators I need to make life totally range-based without ever having to convert back to normal sequences.)

Group Info

Gnus stores all permanent info on groups in a group info list. This list is from three to six elements (or more) long and exhaustively describes the group.

Here are two example group infos; one is a very simple group while the second is a more complex one:

```
("no.group" 5 (1 . 54324))

("nnml:my.mail" 3 ((1 . 5) 9 (20 . 55))
                ((tick (15 . 19)) (replied 3 6 (19 . 3)))
                (nnml "")
                (auto-expire (to-address "ding@ifi.uio.no")))
```

The first element is the group name as Gnus knows the group; the second is the group level; the third is the read articles in range format; the fourth is a list of article marks lists; the fifth is the select method; and the sixth contains the group parameters.

Here's a BNF definition of the group info format:

```
info          = "(" group space level space read
                [ "" / [ space marks-list [ "" / [ space method [ "" /
                space parameters ] ] ] ] ] ")"
group         = quote <string> quote
level         = <integer in the range of 1 to inf>
read          = range
marks-lists   = nil / "(" *marks ")"
marks         = "(" <string> range ")"
method        = "(" <string> *elisp-forms ")"
parameters    = "(" *elisp-forms ")"
```

Actually that `marks' rule is a fib. A `marks' is a `<string>' consed on to a `range', but that's a bitch to say in pseudo-BNF.

Emacs/XEmacs Code

While Gnus runs under Emacs, XEmacs and Mule, I decided that one of the platforms must be the primary one. I chose Emacs. Not because I don't like XEmacs or Mule, but because it comes first alphabetically.

This means that Gnus will byte-compile under Emacs with nary a warning, while XEmacs will pump out gigabytes of warnings while byte-compiling. As I use byte-compilation warnings to help me root out trivial errors in Gnus, that's very useful.

I've also consistently used Emacs function interfaces, but have used Gnusey aliases for the functions. To take an example: Emacs defines a `run-at-time` function while XEmacs defines a `start-itimer` function. I then define a function called `gnus-run-at-time` that takes the same parameters as the Emacs `run-at-time`. When running Gnus under Emacs, the former function is just an alias for the latter. However, when running under XEmacs, the former is an alias for the following function:

```
(defun gnus-xmas-run-at-time (time repeat function &rest args)
  (start-itimer
   "gnus-run-at-time"
   `(lambda ()
      (,function ,@args))
   time repeat))
```

This sort of thing has been done for bunches of functions. Gnus does not redefine any native Emacs functions while running under XEmacs -- it does this `defalias` thing with Gnus equivalents instead. Cleaner all over.

Of course, I could have chosen XEmacs as my native platform and done mapping functions the other way around. But I didn't. The performance hit these indirections impose on Gnus under XEmacs should be slight.

Various File Formats

Active File Format

The active file lists all groups that are available on the server in question. It also lists the highest and lowest current article numbers in each group.

Here's an excerpt from a typical active file:

```
soc.motss 296030 293865 y
alt.binaries.pictures.fractals 3922 3913 n
comp.sources.unix 1605 1593 m
comp.binaries.ibm.pc 5097 5089 y
no.general 1000 900 y
```

Here's a pseudo-BNF definition of this file:

```
active      = *group-line
group-line  = group space high-number space low-number space flag <NEWLINE>
group       = <non-white-space string>
space       = " "
high-number = <non-negative integer>
low-number  = <positive integer>
flag        = "y" / "n" / "m" / "j" / "x" / "=" group
```

Newsgroups File Format

The newsgroups file lists groups along with their descriptions. Not all groups on the server have to be listed, and not all groups in the file have to exist on the server. The file is meant purely as information to the user.

The format is quite simple; a group name, a tab, and the description. Here's the definition:

```
newsgroups    = *line
line          = group tab description <NEWLINE>
group         = <non-white-space string>
tab           = <TAB>
description   = <string>
```

Emacs for Heathens

Believe it or not, but some people who use Gnus haven't really used Emacs much before they embarked on their journey on the Gnus Love Boat. If you are one of those unfortunates whom "M-C-a", "kill the region", and "set `gnus-flargblossen` to an alist where the key is a regexp that is used for matching on the group name" are magical phrases with little or no meaning, then this appendix is for you. If you are already familiar with Emacs, just ignore this and go fondle your cat instead.

Keystrokes

- Q: What is an experienced Emacs user?
- A: A person who wishes that the terminal had pedals.

Yes, when you use Emacs, you are apt to use the control key, the shift key and the meta key a lot. This is very annoying to some people (notably `vi`le users), and the rest of us just love the hell out of it. Just give up and submit. Emacs really does stand for "Escape-Meta-Alt-Control-Shift", and not "Editing Macros", as you may have heard from other disreputable sources (like the Emacs author).

The shift key is normally located near your pinky fingers, and are normally used to get capital letters and stuff. You probably use it all the time. The control key is normally marked "CTRL" or something like that. The meta key is, funnily enough, never marked as such on any keyboards. The one I'm currently at has a key that's marked "Alt", which is the meta key on this keyboard. It's usually located somewhere to the left hand side of the keyboard, usually on the bottom row.

Now, us Emacs people doesn't say "press the meta-control-m key", because that's just too inconvenient. We say "press the M-C-m key". M- is the prefix that means "meta" and "C-" is the prefix that means "control". So "press C-k" means "press down the control key, and hold it down while you press k". "Press M-C-k" means "press down and hold down the meta key and the control key and then press k". Simple, ay?

This is somewhat complicated by the fact that not all keyboards have a meta key. In that case you can use the "escape" key. Then M-k means "press escape, release escape, press k". That's much more work than if you have a meta key, so if that's the case, I respectfully suggest you get a real keyboard with a meta key. You can't live without it.

Emacs Lisp

Emacs is the King of Editors because it's really a Lisp interpreter. Each and every key you tap runs some Emacs Lisp code snippet, and since Emacs Lisp is an interpreted language, that means that you can configure any key to run any arbitrary code. You just, like, do it.

Gnus is written in Emacs Lisp, and is run as a bunch of interpreted functions. (These are byte-compiled for speed, but it's still interpreted.) If you decide that you don't like the way Gnus does certain things, it's trivial to have it do something a different way. (Well, at least if you know how to write Lisp code.) However, that's beyond the scope of this manual, so we are simply going to talk about some common constructs that you normally use in your `.emacs' file to customize Gnus.

If you want to set the variable `gnus-florgbnize` to four (4), you write the following:

```
(setq gnus-florgbnize 4)
```

This function (really "special form") `setq` is the one that can set a variable to some value. This is really all you need to know. Now you can go and fill your `.emacs` file with lots of these to change how Gnus works.

If you have put that thing in your `.emacs` file, it will be read and `eval`ed (which is lisp-ese for "run") the next time you start Emacs. If you want to change the variable right away, simply say C-x C-e after the closing parenthesis. That will `eval` the previous "form", which here is a simple `setq` statement.

Go ahead--just try it, if you're located at your Emacs. After you C-x C-e, you will see `4' appear in the echo area, which is the return value of the form you `eval`ed.

Some pitfalls:

If the manual says "set `gnus-read-active-file` to `some`", that means:

```
(setq gnus-read-active-file 'some)
```

On the other hand, if the manual says "set `gnus-nntp-server` to `nntp.ifi.uio.no'", that means:

```
(setq gnus-nntp-server "nntp.ifi.uio.no")
```

So be careful not to mix up strings (the latter) with symbols (the former). The manual is unambiguous, but it can be confusing.

\input texinfo

Frequently Asked Questions

This is the Gnus Frequently Asked Questions list. If you have a Web browser, the official hypertext version is at `http://www.miranova.com/~steve/gnus-faq.html>', and has probably been updated since you got this manual.

Installation

- Q1.1 What is the latest version of Gnus?

  The latest (and greatest) version is 5.0.10. You might also run across something called *September Gnus*. September Gnus is the alpha version of the next major release of Gnus. It is currently not stable enough to run unless you are prepared to debug lisp.

- Q1.2 Where do I get Gnus?

  Any of the following locations:
  - `ftp://ftp.ifi.uio.no/pub/emacs/gnus/gnus.tar.gz'
  - `ftp://ftp.pilgrim.umass.edu/pub/misc/ding/'
  - `gopher://gopher.pilgrim.umass.edu/11/pub/misc/ding/'
  - `ftp://aphrodite.nectar.cs.cmu.edu/pub/ding-gnus/'
  - `ftp://ftp.solace.mh.se:/pub/gnu/elisp/'

- Q1.3 Which version of Emacs do I need?

  At least GNU Emacs 19.28, or XEmacs 19.12 is recommended. GNU Emacs 19.25 has been reported to work under certain

circumstances, but it doesn't *officially* work on it. 19.27 has also been reported to work. Gnus has been reported to work under OS/2 as well as Unix.

- Q1.4 Where is timezone.el?

  Upgrade to XEmacs 19.13. In earlier versions of XEmacs this file was placed with Gnus 4.1.3, but that has been corrected.

- Q1.5 When I run Gnus on XEmacs 19.13 I get weird error messages.

  You're running an old version of Gnus. Upgrade to at least version 5.0.4.

- Q1.6 How do I unsubscribe from the Mailing List?

  Send an e-mail message to `` `ding-request@ifi.uio.no' `` with the magic word *unsubscribe* somewhere in it, and you will be removed.

  If you are reading the digest version of the list, send an e-mail message to `` `ding-rn-digests-d-request@moe.shore.net' `` with *unsubscribe* as the subject and you will be removed.

- Q1.7 How do I run Gnus on both Emacs and XEmacs?

  The basic answer is to byte-compile under XEmacs, and then you can run under either Emacsen. There is, however, a potential version problem with easymenu.el with Gnu Emacs prior to 19.29.

  Per Abrahamsen <abraham@dina.kvl.dk> writes :
  The internal easymenu.el interface changed between 19.28 and 19.29 in order to make it possible to create byte compiled files that can be shared between Gnu Emacs and XEmacs. The change is upward compatible, but not downward compatible. This gives the following compatibility table:

```
Compiled with:  | Can be used with:
----------------+-----------------------------------
19.28           | 19.28         19.29
19.29           |               19.29          XEmacs
XEmacs          |               19.29          XEmacs
```

  If you have Gnu Emacs 19.28 or earlier, or XEmacs 19.12 or earlier, get a recent version of auc-menu.el from `` `ftp://ftp.iesd.auc.dk/pub/emacs-lisp/auc-menu.el' ``, and install it under the name easymenu.el somewhere early in your load path.

- Q1.8 What resources are available?

  There is the newsgroup Gnu.emacs.gnus. Discussion of Gnus 5.x is now taking place there. There is also a mailing list, send mail to `` `ding-request@ifi.uio.no' `` with the magic word *subscribe* somewhere in it.

  NOTE: the traffic on this list is heavy so you may not want to be on it (unless you use Gnus as your mailer reader, that is). The mailing list is mainly for developers and testers.

  Gnus has a home World Wide Web page at `` `http://www.ifi.uio.no/~larsi/ding.html' ``. Gnus has a write up in the X Windows Applications FAQ at `` `http://www.ee.ryerson.ca:8080/~elf/xapps/Q-III.html' ``. The Gnus manual is also available on the World Wide Web. The canonical source is in Norway at `` `http://www.ifi.uio.no/~larsi/ding-manual/gnus_toc.html' ``.

  There are three mirrors in the United States:

  1. `` `http://www.miranova.com/gnus-man/' ``
  2. `` `http://www.pilgrim.umass.edu/pub/misc/ding/manual/gnus_toc.html' ``
  3. `` `http://www.rtd.com/~woo/gnus/' ``

  PostScript copies of the Gnus Reference card are available from `` `ftp://ftp.cs.ualberta.ca/pub/oolog/gnus/' ``. They are mirrored at `` `ftp://ftp.pilgrim.umass.edu/pub/misc/ding/refcard/' `` in the United States. And `` `ftp://marvin.fkphy.uni-duesseldorf.de/pub/gnus/' `` in Germany. An online version of the Gnus FAQ is available at `` `http://www.miranova.com/~steve/gnus-faq.html' ``. Off-line formats are also available:
  ASCII: `` `ftp://ftp.miranova.com/pub/gnus/gnus-faq' ``
  PostScript: `` `ftp://ftp.miranova.com/pub/gnus/gnus-faq.ps' ``.

- Q1.9 Gnus hangs on connecting to NNTP server

  I am running XEmacs on SunOS and Gnus prints a message about Connecting to NNTP server and then just hangs.

  Ben Wing <wing@netcom.com> writes :
  I wonder if you're hitting the infamous *libresolv* problem. The basic problem is that under SunOS you can compile either with DNS or NIS name lookup libraries but not both. Try substituting the IP address and see if that works; if so, you need to download the sources and recompile.

- Q1.10 Mailcrypt 3.4 doesn't work

  This problem is verified to still exist in Gnus 5.0.9 and MailCrypt 3.4. The answer comes from Peter Arius <arius@immd2.informatik.uni-erlangen.de>.

  I found out that mailcrypt uses `gnus-eval-in-buffer-window`, which is a macro. It seems as if you have compiled mailcrypt with plain old GNUS in load path, and the XEmacs byte compiler has inserted that macro definition into `` `mc-toplev.elc' ``. The solution is to recompile `` `mc-toplev.el' `` with Gnus 5 in load-path, and it works fine.

  Steve Baur <steve@miranova.com> adds :
  The problem also manifests itself if neither GNUS 4 nor Gnus 5 is in the load-path.

- Q1.11 What other packages work with Gnus?
  - Mailcrypt.

    Mailcrypt is an Emacs interface to PGP. It works, it installs without hassle, and integrates very easily. Mailcrypt can be obtained from
    `` `ftp://cag.lcs.mit.edu/pub/patl/mailcrypt-3.4.tar.gz' ``.
  - Tiny Mime.

    Tiny Mime is an Emacs MUA interface to MIME. Installation is a two-step process unlike most other packages, so you should be prepared to move the byte-compiled code somewhere. There are currently two versions of this package available. It can be obtained from
    `` `ftp://ftp.jaist.ac.jp/pub/GNU/elisp/' ``. Be sure to apply the supplied patch. It works with Gnus through version 5.0.9. In order for all dependencies to work correctly the load sequence is as follows:

    ```
    (load "tm-setup")
    (load "gnus")
    (load "mime-compose")
    ```

    NOTE: Loading the package disables citation highlighting by default. To get the old behavior back, use the M-t command.

Customization

- Q2.1 Custom Edit does not work under XEmacs

  The custom package has not been ported to XEmacs.

- Q2.2 How do I quote messages?

  I see lots of messages with quoted material in them. I am wondering how to have Gnus do it for me.

  This is Gnus, so there are a number of ways of doing this. You can use the built-in commands to do this. There are the F and R keys from the summary buffer which automatically include the article being responded to. These commands are also selectable as *Followup and Yank* and *Reply and Yank* in the Post menu.

  C-c C-y grabs the previous message and prefixes each line with `ail-indentation-spaces` spaces or `mail-yank-prefix` if that is non-nil, unless you have set your own `mail-citation-hook`, which will be called to to do the job.

  You might also consider the Supercite package, which allows for pretty arbitrarily complex quoting styles. Some people love it, some people hate it.

- Q2.3 How can I keep my nnvirtual:* groups sorted?

  How can I most efficiently arrange matters so as to keep my nnvirtual:* (etc) groups at the top of my group selection buffer, whilst keeping everything sorted in alphabetical order. If you don't subscribe often to new groups then the easiest way is to first sort the groups and then manually kill and yank the virtuals wherever you want them.

- Q2.4 Any good suggestions on stuff for an all.SCORE file?

  Here is a collection of suggestions from the Gnus mailing list.

  1. From "Dave Disser" <disser@sdd.hp.com>
     I like blasting anything without lowercase letters. Weeds out most of the make $$ fast, as well as the lame titles like "IBM" and "HP-UX" with no further description.

     ```
     (("Subject"
      ("^\\(Re: \\)?[^a-z]*$" -200 nil R)))
     ```

  2. From "Peter Arius" <arius@immd2.informatik.uni-erlangen.de>
     The most vital entries in my (still young) all.SCORE:

     ```
     (("xref"
       ("alt.fan.oj-simpson" -1000 nil s))
      ("subject"
       ("\\<\\(make\\|fast\\|big\\)\\s-*\\(money\\|cash\\|bucks?\\)\\>" -1000 nil r)
       ("$$$$" -1000 nil s)))
     ```

  3. From "Per Abrahamsen" <abraham@dina.kvl.dk>

     ```
     (("subject"
       ;; CAPS OF THE WORLD, UNITE
       ("^..[^a-z]+$" -1 nil R)
       ;; $$$ Make Money $$$ (Try work)
       ("$" -1 nil s)
       ;; I'm important! And I have exclamation marks to prove it!
       ("!" -1 nil s)))
     ```

  4. From "heddy boubaker" <boubaker@cenatls.cena.dgac.fr>
     I would like to contribute with mine.

     ```
     (
      (read-only t)
      ("subject"
       ;; ALL CAPS SUBJECTS
       ("^\\([Rr][Ee]: +\\)?[^a-z]+$" -1 nil R)
       ;; $$$ Make Money $$$
       ("$$" -10 nil s)
       ;; Empty subjects are worthless!
       ("^ *\\([(<]none[>)]\\|(no subject\\( given\\)?)\\)? *$" -10 nil r)
       ;; Sometimes interesting announces occur!
       ("ANN?OU?NC\\(E\\|ING\\)" +10 nil r)
       ;; Some people think they're on mailing lists
       ("\\(un\\)?sub?scribe" -100 nil r)
       ;; Stop Micro$oft NOW!!
       ("\\(m\\(icro\\)?[s$]\\(oft\\|lot\\)?-?\\)?wind?\\(ows\\|aube\\|oze\\)?[-
     ]*\\('?95\\|NT\\|3[.]1\\|32\\)" -1001 nil r)
       ;; I've nothing to buy
       ("\\(for\\|4\\)[- ]*sale" -100 nil r)
       ;; SELF-DISCIPLINED people
       ("\\[[^a-z0-9 \t\n][^a-z0-9 \t\n]\\]" +100 nil r)
       )
      ("from"
       ;; To keep track of posters from my site
       (".dgac.fr" +1000 nil s))
      ("followup"
       ;; Keep track of answers to my posts
       ("boubaker" +1000 nil s))
      ("lines"
     ```

```
 ;; Some people have really nothing to say!!
 (1 -10 nil <=))
(mark -100)
(expunge -1000)
)
```

5. From "Christopher Jones" <cjones@au.oracle.com>
   The sample `all.SCORE' files from Per and boubaker could be augmented with:

```
(("subject"
  ;; No junk mail please!
  ("please ignore" -500 nil s)
  ("test" -500 nil e))
)
```

6. From "Brian Edmonds" <edmonds@cs.ubc.ca>
   Augment any of the above with a fast method of scoring down excessively cross posted articles.

```
 ("xref"
  ;; the more cross posting, the exponentially worse the article
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+" -1 nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+" -2 nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+" -4 nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+" -8 nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+" -16 nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+" -32 nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+" -64 nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+" -128
nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+"
-256 nil r)
  ("^xref: \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+ \\S-+
\\S-+" -512 nil r))
```

- Q2.5 What do I use to yank-through when replying?

  You should probably reply and followup with R and F, instead of r and f, which solves your problem. But you could try something like:

```
(defconst mail-yank-ignored-headers
  "^.*:"
  "Delete these headers from old message when it's inserted in a reply.")
```

- Q2.6 I don't like the default WWW browser

  Now when choosing an URL Gnus starts up a W3 buffer, I would like it to always use Netscape (I don't browse in text-mode ;-).

  1. Activate `Customize...' from the `Help' menu.
  2. Scroll down to the `WWW Browser' field.
  3. Click `mouse-2' on `WWW Browser'.
  4. Select `Netscape' from the pop up menu.
  5. Press `C-c C-c'

  If you are using XEmacs then to specify Netscape do

```
(setq gnus-button-url 'gnus-netscape-open-url)
```

- Q2.7 What, if any, relation is between "ask-server" and "(setq gnus-read-active-file 'some)"?

  In order for Gnus to show you the complete list of newsgroups, it will either have to either store the list locally, or ask the server to transmit the list. You enable the first with

```
(setq gnus-save-killed-list t)
```

and the second with

```
(setq gnus-read-active-file t)
```

If both are disabled, Gnus will not know what newsgroups exists. There is no option to get the list by casting a spell.

- Q2.8 Moving between groups is slow.

  Per Abrahamsen <abraham@dina.kvl.dk> writes:

  Do you call `define-key` or something like that in one of the summary mode hooks? This would force Emacs to recalculate the keyboard shortcuts. Removing the call should speed up M-x gnus-summary-mode RET by a couple of orders of magnitude. You can use

  ```
  (define-key gnus-summary-mode-map KEY COMMAND)
  ```

  in your `` `.gnus' `` instead.

Reading News

- Q3.1 How do I convert my kill files to score files?

  A kill-to-score translator was written by Ethan Bradford <ethanb@ptolemy.astro.washington.edu>. It is available from `` `http://baugi.ifi.uio.no/~larsi/ding-various/gnus-kill-to-score.el' ``.

- Q3.2 My news server has a lot of groups, and killing groups is painfully slow.

  Don't do that then. The best way to get rid of groups that should be dead is to edit your newsrc directly. This problem will be addressed in the near future.

- Q3.3 How do I use an NNTP server with authentication?

  Put the following into your .gnus:

  ```
  (add-hook 'nntp-server-opened-hook 'nntp-send-authinfo)
  ```

- Q3.4 Not reading the first article.

  How do I avoid reading the first article when a group is selected?

  1. Use RET to select the group instead of SPC.
  2. `(setq gnus-auto-select first nil)`
  3. Luis Fernandes <elf@mailhost.ee.ryerson.ca>writes:
     This is what I use...customize as necessary...

     ```
     ;;; Don't auto-select first article if reading sources, or archives or
     ;;; jobs postings, etc. and just display the summary buffer
     (add-hook 'gnus-select-group-hook
               (function
                (lambda ()
                  (cond ((string-match "sources" gnus-newsgroup-name)
                         (setq gnus-auto-select-first nil))
                               ((string-match "jobs" gnus-newsgroup-name)
                                    (setq gnus-auto-select-first nil))
                        ((string-match "comp\\.archives" gnus-newsgroup-name)
                         (setq gnus-auto-select-first nil))
                        ((string-match "reviews" gnus-newsgroup-name)
                         (setq gnus-auto-select-first nil))
                        ((string-match "announce" gnus-newsgroup-name)
                         (setq gnus-auto-select-first nil))
                        ((string-match "binaries" gnus-newsgroup-name)
                         (setq gnus-auto-select-first nil))
                        (t
                         (setq gnus-auto-select-first t))))))
     ```

4. Per Abrahamsen <abraham@dina.kvl.dk> writes:
   Another possibility is to create an `all.binaries.all.SCORE' file like this:

   ```
   ((local
     (gnus-auto-select-first nil)))
   ```

   and insert

   ```
   (setq gnus-auto-select-first t)
   ```

   in your `.gnus'.

- Q3.5 Why aren't BBDB known posters marked in the summary buffer?

  Brian Edmonds <edmonds@cs.ubc.ca> writes:
  Due to changes in Gnus 5.0, `bbdb-gnus.el' no longer marks known posters in the summary buffer. An updated version, `gnus-bbdb.el' is available at the locations listed below. This package also supports autofiling of incoming mail to folders specified in the BBDB. Extensive instructions are included as comments in the file.

  Send mail to `majordomo@edmonds.home.cs.ubc.ca' with the following line in the body of the message: *get misc gnus-bbdb.el*.

  Or get it from the World Wide Web:
  `http://www.cs.ubc.ca/spider/edmonds/gnus-bbdb.el'.

Reading Mail

- Q4.1 What does the message "Buffer has changed on disk" mean in a mail group?

  Your filter program should not deliver mail directly to your folders, instead it should put the mail into spool files. Gnus will then move the mail safely from the spool files into the folders. This will eliminate the problem. Look it up in the manual, in the section entitled "Mail & Procmail".

- Q4.2 How do you make articles un-expirable?

  I am using nnml to read news and have used `gnus-auto-expirable-newsgroups` to automagically expire articles in some groups (Gnus being one of them). Sometimes there are interesting articles in these groups that I want to keep. Is there any way of explicitly marking an article as un-expirable - that is mark it as read but not expirable?

  Use u, !, d or M-u in the summary buffer. You just remove the E mark by setting some other mark. It's not necessary to tick the articles.

- Q4.3 How do I delete bogus nnml: groups?

  My problem is that I have various mail (nnml) groups generated while experimenting with Gnus. How do I remove them now? Setting the level to 9 does not help. Also `gnus-group-check-bogus-groups` does not recognize them.

  Removing mail groups is tricky at the moment. (It's on the to-do list, though.) You basically have to kill the groups in Gnus, shut down Gnus, edit the active file to exclude these groups, and probably remove the nnml directories that contained these groups as well. Then start Gnus back up again.

- Q4.4 What happened to my new mail groups?

  I got new mail, but I have never seen the groups they should have been placed in.

  They are probably there, but as zombies. Press A z to list zombie groups, and then subscribe to the groups you want with u. This is all documented quite nicely in the user's manual.

- Q4.5 Not scoring mail groups

  How do you *totally* turn off scoring in mail groups?

  Use an nnbabyl:all.SCORE (or nnmh, or nnml, or whatever) file containing:

  ```
  ((adapt ignore)
   (local (gnus-use-scoring nil))
   (exclude-files "all.SCORE"))
  ```

mh-e

The Emacs Interface to MH

by Bill Wohler

Edition 1.2 for mh-e Version 5.0.2

August 1995

Preface

These chapters introduce another interface to MH that is accessible through the GNU Emacs editor, namely, *mh-e*. mh-e is easy to use. I don't assume that you know GNU Emacs or even MH at this point, since I didn't know either of them when I discovered mh-e. However, mh-e was the tip of the iceberg, and I discovered more and more niceties about GNU Emacs and MH. Now I'm fully hooked on both of them.

The mh-e package is distributed with GNU Emacs, (1) so you shouldn't have to do anything special to use it. But it's important to note a brief history of mh-e. Version 3 was prevalent through the Emacs 18 and early Emacs 19 years. Then Version 4 came out (Emacs 19.23), which introduced several new and changed commands. Finally, Version 5.0 was released, which fixed some bugs and incompatibilities. This is the version covered by this manual. section Getting Started will help you decide which version you have.

If you don't already use GNU Emacs but want to learn more, you can read an online tutorial by starting GNU Emacs and typing C-h t (`help-with-tutorial`). (This notation is described in section GNU Emacs Terms and Conventions.) If you want to take the plunge, consult the GNU Emacs Manual, from the Free Software Foundation.

If more information is needed, you can go to the Unix manual pages of the individual MH commands. When the name is not obvious, I'll guide you to a relevant MH manual page that describes the action

more fully.

I hope you enjoy these chapters! If you have any comments, or suggestions for this document, please let me know.

Bill Wohler <*wohler@newt.com*>
8 February 1995

Tour Through mh-e

This chapter introduces some of the terms you'll need to know and then takes you on a tour of mh-e. (2) When you're done, you'll be able to send, read, and file mail, which is all that a lot of people ever do. But if you're the curious type, you'll read section Using mh-e to be able to use all the features of mh-e. If you're the adventurous type, you'll read section Customizing mh-e to make mh-e do what you want. I suggest you read this chapter first to get the big picture, and then you can read the other two as you wish.

GNU Emacs Terms and Conventions

If you're an experienced Emacs user, you can skip the following conventions and definition of terms and go directly to section Getting Started below. The conventions are as follows:

C-x
: Hold down the CTRL (Control) key and press the x key.

M-x
: Hold down the META or ALT key and press the x key.

  Since some keyboards don't have a META key, you can generate M-x, for example, by pressing ESC (Escape), *releasing it*, (3) and then pressing the x key.

RET
: Press the RETURN or ENTER key. This is normally used to complete a command.

SPC
: Press the space bar.

TAB
: Press the TAB key.

DEL
: Press the DELETE key. This may also be a Backspace key, depending on your keyboard or Emacs configuration.

A prefix argument allows you to pass an argument to any Emacs function. To pass an argument, type C-u before the Emacs command or keystroke. Numeric arguments can be passed as well. For example, to insert five f's, use C-u 5 f. There is a default of four when using C-u, and you can use multiple prefix arguments to provide arguments of powers of four. To continue our example, you could insert four f's with C-u f, 16 f's with C-u C-u f, 64 f's with C-u C-u C-u f, and so on. Numeric and valueless negative arguments can also be inserted with the META key. Examples include M-5 to specify an argument of 5, or M-- which specifies a negative argument with no particular value.

NOTE

The prefix C-u or M- is not necessary in mh-e's MH-Folder modes (see section Receiving Mail). In these modes, simply enter the numerical argument before entering the command.

There are several other terms that are used in Emacs that you should know. The point is where the cursor currently is. You can save your current place in the file by setting a mark. This operation is useful in several ways. The mark can be later used when defining a region, which is the text between the point and mark. Many commands operate on regions, such as those for deleting text or filling paragraphs. A mark can be set with C-@ (or C-SPC).

The minibuffer is the bottom line of the Emacs window, where all prompting and multiple-character input is directed. If you are prompted for information in the minibuffer, such as a filename, Emacs can help you complete your answer if you type SPC or TAB. A second SPC or TAB will list all possibilities at that point. The minibuffer is also where you enter Emacs function names after typing M-x. For example, in the first paragraph, I mentioned that you could obtain help with C-h t (`help-with-tutorial`). What this means is that you can get a tutorial by typing either C-h t or M-x help-with-tutorial. In the latter case, you are prompted for `help-with-tutorial' in the minibuffer after typing M-x.

In case of trouble: Emacs can be interrupted at any time with C-g. For example, if you've started a command that requests that you enter something in the minibuffer, but then you change your mind, type C-g and you'll be back where you started. If you want to exit Emacs entirely, use C-x C-c.

Getting Started

Because there are many old versions of mh-e out there, it is important to know which version you have. I'll be talking about Version 5 which is similar to Version 4 and vastly different from Version 3.

First, enter M-x load-library RET mh-e RET. (4) The message, `Loading mh-e...done', should be displayed in the minibuffer. If you get `Cannot open load file: mh-e', then your Emacs is very badly configured, or mh-e is missing. You may wish to have your system administrator install a new Emacs or at least the latest mh-e files.

Having loaded mh-e successfully, enter M-x mh-version RET. The version of mh-e should be displayed. Hopefully it says that you're running Version 5.0.2 which is the latest version as of this printing. If instead Emacs beeps and says `[No match]', then you're running an old version of mh-e.

If these tests reveal a non-existent or old version of mh-e, please consider obtaining a new version. You can have your system administrator upgrade the system-wide version, or you can install your own personal version. It's really quite easy; instructions for getting and installing mh-e are in section Getting mh-e. In the meantime, see section Changes to mh-e, which compares the old and new names of commands, functions, variables, and buffers.

Also, older versions of mh-e assumed that you had already set up your MH environment. Newer versions set up a new MH environment for you by running `install-mh` and notifying you of this fact with the message in a temporary buffer:

```
I'm going to create the standard MH path for you.
```

Therefore, if you've never run MH before and you're using an old version of mh-e, you need to run `install-mh` from the shell before you continue the tour. If you don't, you'll be greeted with the error message: `Can't find MH profile'.

If, during the tour described in this chapter, you see a message like: `Searching for program: no such file or directory, /usr/local/bin/mhpath', it means that the MH programs and files are kept in a nonstandard directory.

In this case, simply add the following to `~/.emacs' and restart emacs.

```
(setq mh-progs "/path/to/MH/binary/directory/")
(setq mh-lib "/path/to/MH/library/directory/")
```

The `~' notation used by `~/.emacs' above represents your home directory. This is used by the bash and csh shells. If your shell does not support this feature, you could use the environment variable `$HOME' (such as `$HOME/.emacs') or the absolute path (as in `/home/wohler/.emacs') instead.

At this point, you should see something like the screen in the figure in section Receiving Mail. We're now ready to move on.

Sending Mail

Let's start our tour by sending ourselves a message which we can later read and process. Enter M-x mh-smail to invoke the mh-e program to send messages. You will be prompted in the minibuffer by `To:'. Enter your login name. The next prompt is `cc:'. Hit RET to indicate that no carbon copies are to be sent. At the `Subject:' prompt, enter Test or anything else that comes to mind.

Once you've specified the recipients and subject, your message appears in an Emacs buffer whose mode (5) is MH-Letter. Enter some text in the body of the message, using normal Emacs commands. You should now have something like this: (6)

```
-----Emacs: *scratch*         (Lisp Interaction)--All--------------------
To: wohler
cc:
Subject: Test
--------
  This is a test message to get the wheels churning...#

--**-{draft}      (MH-Letter)--All-----------------------------------------
```

mh-e message composition window

Note the line of dashes that separates the header and the body of the message. It is essential that these dashes (or a blank line) are present or the body of your message will be considered to be part of the header.

There are several commands specific to MH-Letter mode, but at this time we'll only use C-c C-c to send your message. Type C-c C-c now. That's all there is to it!

Receiving Mail

To read the mail you've just sent yourself, enter M-x mh-rmail. This incorporates the new mail and put the output from `inc` (called scan lines after the MH program `scan` which prints a one-line summary of each message) into a buffer called `+inbox' whose major mode is MH-Folder.

NOTE

> The M-x mh-rmail command will show you only new mail, not old mail. If you were to run this tour again, you would use M-r to pull all your messages into mh-e.

You should see the scan line for your message, and perhaps others. Use n or p to move the cursor to your test message and type RET to read your message. You should see something like:

```
   3  24Aug  root       received fax files on Wed Aug 24 11:00:13 PDT 1994
#  4+ 24Aug  To:wohler  Test<<This is a test message to get the wheels chu

--%%-{+inbox} 4 msgs (1-4)      (MH-Folder Show)--Bot--------------------
To: wohler
Subject: Test
Date: Wed, 24 Aug 1994 13:01:13 -0700
From: Bill Wohler <wohler@newt.com>

  This is a test message to get the wheels churning...

-----{show-+inbox} 4      (MH-Show)--Bot---------------------------------
```

After incorporating new messages

If you typed a long message, you can view subsequent pages with SPC and previous pages with DEL.

Processing Mail

The first thing we want to do is reply to the message that we sent ourselves. Ensure that the cursor is still on the same line as your test message and type r. You are prompted in the minibuffer with `Reply to whom:'. Here mh-e is asking whether you'd like to reply to the original sender only, to the sender and primary recipients, or to the sender and all recipients. If you simply hit RET, you'll reply only to the sender. Hit RET now.

You'll find yourself in an Emacs buffer similar to that when you were sending the original message, like this:

```
To: wohler
Subject: Re: Test
In-reply-to: Bill Wohler's message of Wed, 24 Aug 1994 13:01:13 -0700
```

```
                <199408242001.NAA00505@newt.com>
--------
#

--**-{draft}      (MH-Letter)--All-----------------------------------------
To: wohler
Subject: Test
Date: Wed, 24 Aug 1994 13:01:13 -0700
From: Bill Wohler <wohler@newt.com>

  This is a test message to get the wheels churning...

-----{show-+inbox} 4      (MH-Show)--Bot-------------------------------------
Composing a reply...done
```
Composition window during reply

By default, MH will not add you to the address list of your replies, so if you find that the `To:' header field is missing, don't worry. In this case, type C-c C-f C-t to create and go to the `To:' field, where you can type your login name again. You can move around with the arrow keys or with C-p (`previous-line`), C-n (`next-line`), C-b (`backward-char`), and C-f (`forward-char`) and can delete the previous character with DEL. When you're finished editing your message, send it with C-c C-c as before.

You'll often want to save messages that were sent to you in an organized fashion. This is done with folders. You can use folders to keep messages from your friends, or messages related to a particular topic. With your cursor in the MH-Folder buffer and positioned on the message you sent to yourself, type o to output (`refile` in MH parlance) that message to a folder. Enter test at the `Destination:' prompt and type y (or SPC) when mh-e asks to create the folder `+test'. Note that a `^' (caret) appears next to the message number, which means that the message has been marked for refiling but has not yet been refiled. We'll talk about how the refile is actually carried out in a moment.

Your previous reply is now waiting in the system mailbox. You incorporate this mail into your MH-Folder buffer named `+inbox' with the i command. Do this now. After the mail is incorporated, use n or p to move the cursor to the new message, and read it with RET. Let's delete this message by typing d. Note that a `D' appears next to the message number. This means that the message is marked for deletion but is not yet deleted. To perform the deletion (and the refile we did previously), use the x command.

If you want to send another message you can use m instead of M-x mh-smail. So go ahead, send some mail to your friends!

Leaving mh-e

You may now wish to exit `emacs` entirely. Use C-x C-c to exit `emacs`. If you exited without running x in the `+inbox' buffer, Emacs will offer to save it for you. Type y or SPC to save `+inbox' changes, which means to perform any refiles and deletes that you did there.

If you don't want to leave Emacs, you can type q to bury (hide) the mh-e folder or delete them entirely with C-x k. You can then later recall them with C-x b or M-x mh-rmail.

More About mh-e

These are the basic commands to get you going, but there are plenty more. If you think that mh-e is for you, read section Using mh-e and section Customizing mh-e to find out how you can:

- Print your messages. (section Printing Your Mail and section Printing Your Mail.)
- Edit messages and include your signature. (section Editing a Draft and section Editing a Draft.)
- Forward messages. (section Forwarding Mail and section Forwarding Mail.)
- Read digests. (section Viewing Your Mail.)
- Edit bounced messages. (section Editing Old Drafts and Bounced Messages and section Editing Old Drafts and Bounced Messages.)
- Send multimedia messages. (section Editing Multimedia Messages and section Editing Multimedia Messages.)
- Process mail that was sent with `shar` or `uuencode`. (section Files and Pipes.)
- Use sequences conveniently. (section Using Sequences.)
- Show header fields in different fonts. (section Viewing Your Mail.)
- Find previously refiled messages. (section Searching Through Messages.)
- Place messages in a file. (section Files and Pipes.)

Remember that you can also use MH commands when you're not running mh-e (and when you are!).

Go to the previous, next section.

Go to the previous, next section.

Using mh-e

This chapter leaves the tutorial style and goes into more detail about every mh-e command. The default, or "out of the box," behavior is documented. If this is not to your liking (for instance, you print with something other than `lpr`), see the associated section in section Customizing mh-e which is organized exactly like this chapter.

There are many commands, but don't get intimidated. There are command summaries at the beginning of each section. In case you have or would like to rebind the keys, the command summaries also list the associated Emacs Lisp function. Furthermore, even if you're stranded on a desert island with a laptop and are without your manuals, you can get a summary of all these commands with GNU Emacs online help: use C-h m (`describe-mode`) for a brief summary of commands or C-h i to read this manual via Info. The online help is quite good; try running C-h C-h C-h. This brings up a list of available help topics, one of which displays the documentation for a given key (like C-h k C-n). In addition, review section GNU Emacs Terms and Conventions, if any of the GNU Emacs conventions are strange to you.

Let's get started!

Reading Your Mail

The mh-e entry point for reading mail is M-x mh-rmail. This command incorporates your mail and creates a buffer called `+inbox' in MH-Folder mode. The M-x mh-rmail command shows you only new mail, not old mail. (7) The `+inbox' buffer contains scan lines, which are one-line summaries of each incorporated message. You can perform most MH commands on these messages via one-letter commands discussed in this chapter. See `scan`(1) for a description of the contents of the scan lines, and see the Figure in section Receiving Mail, for an example.

RET
: Display a message (`mh-show`).

SPC
: Go to next page in message (`mh-page-msg`).

DEL
: Go to previous page in message (`mh-previous-page`).

, (comma)
: Display a message with all header fields (`mh-header-display`).

M-SPC
: Go to next message in digest (`mh-page-digest`).

M-DEL
: Go to previous message in digest (`mh-page-digest-backwards`).

M-b
: Break up digest into separate messages (`mh-burst-digest`).

n
: Display next message (`mh-next-undeleted-msg`).

p
: Display previous message (`mh-previous-undeleted-msg`).

g
: Go to a message (`mh-goto-msg`).

M-<
: Go to first message (`mh-first-msg`).

M->
: Go to last message (`mh-last-msg`).

t
: Toggle between MH-Folder and MH-Folder Show modes (`mh-toggle-showing`).

Viewing Your Mail

The RET (`mh-show`) command displays the message that the cursor is on. If the message is already displayed, it scrolls to the beginning of the message. Use SPC (`mh-page-msg`) and DEL (`mh-previous-page`) to move forwards and backwards one page at a time through the message. You can give either of these commands a prefix argument that specifies the number of lines to scroll (such as 10 SPC). mh-e normally hides a lot of the superfluous header fields that mailers add to a message, but if you wish to see all of them, use the , (comma; `mh-header-display`) command.

Reading Digests

A digest is a message that contains other messages. Special mh-e commands let you read digests conveniently. You can use SPC and DEL to page through the digest as if it were a normal message, but if you wish to skip to the next message in the digest, use M-SPC (`mh-page-digest`). To return to a previous message, use M-DEL (`mh-page-digest-backwards`).

Another handy command is M-b (`mh-burst-digest`). This command uses the MH command `burst` to break out each message in the digest into its own message. Using this command, you can quickly delete unwanted messages, like this: Once the digest is split up, toggle out of MH-Folder Show mode with t (see section Moving Around) so that the scan lines fill the screen and messages aren't displayed. Then use d (see section Deleting Your Mail) to quickly delete messages that you don't want to read (based on the `Subject:' header field). You can also burst the digest to reply directly to the people who posted the messages in the digest. One problem you may encounter is that the `From:' header fields are preceded with a `>' so that your reply can't create the `To:' field correctly. In this case, you must correct the `To:' field yourself. This is described later in section Editing Textual Messages.

Reading Multimedia Mail

MH has the ability to read MIME (Multipurpose Internet Mail Extensions) messages. Unfortunately, mh-e does not yet have this ability, so you have to use the MH commands `show` or `mhn` from the shell to read MIME messages. (8)

Moving Around

To move on to the next message, use the n (`mh-next-undeleted-msg`) command; use the p (`mh-previous-undeleted-msg`) command to read the previous message. Both of these commands can be given a prefix argument to specify how many messages to skip (for example, 5 n). You can also move to a specific message with g (`mh-goto-msg`). You can enter the message number either before or after typing g. In the latter case, Emacs prompts you. Finally, you can go to the first or last message with M-< (`mh-first-msg`) and M-> (`mh-last-msg`) respectively.

You can also use the Emacs commands C-p (`previous-line`) and C-n (`next-line`) to move up and down the scan lines in the MH-Folder window. These commands can be used in conjunction with RET to look at deleted or refiled messages.

The command t (`mh-toggle-showing`) switches between MH-Folder mode and MH-Folder Show mode. (9) MH-Folder mode turns off the associated show buffer so that you can perform operations on the messages quickly without reading them. This is an excellent way to prune out your junk mail or to refile a group of messages to another folder for later examination.

Sending Mail

You can send a mail message in several ways. You can call M-x mh-smail directly, or from the command line like this:

```
% emacs -f mh-smail
```

From within mh-e's MH-Folder mode, other methods of sending mail are available as well:

m
: Compose a message (`mh-send`).

r
: Reply to a message (`mh-reply`).

f
: Forward message(s) (`mh-forward`).

M-d
: Redistribute a message (`mh-redistribute`).

M-e
: Edit a message that was bounced by mailer (`mh-extract-rejected-mail`).

M-a
: Edit a message to send it again (`mh-edit-again`).

From within a MH-Folder buffer, you can simply use the command m (`mh-send`). However you invoke `mh-send`, you are prompted for the `To:', `cc:', and `Subject:' header fields. Once you've specified the recipients and subject, your message appears in an Emacs buffer whose mode is MH-Letter (see the Figure in section Sending Mail to see what the buffer looks like). MH-Letter mode allows you to edit your message, to check the validity of the recipients, to insert other messages into your message, and to send the message. We'll go more into depth about editing a draft (10) (a message you're composing) in just a moment.

TOC

`mh-smail` always creates a two-window layout with the current buffer on top and the draft on the bottom. If you would rather preserve the window layout, use M-x mh-smail-other-window.

Replying to Mail

To compose a reply to a message, use the r (`mh-reply`) command. If you supply a prefix argument (as in C-u r), the message you are replying to is inserted in your reply after having first been run through `mhl` with the format file `` `mhl.reply' ``. See `mhl`(1) to see how you can modify the default `` `mhl.reply' `` file.

When you reply to a message, you are first prompted with `Reply to whom?'. You have several choices here.

Response	Reply Goes To
from	The person who sent the message. This is the default, so RET is sufficient.
to	Replies to the sender, plus all recipients in the `To:' header field.
all cc	Forms a reply to the sender, plus all recipients.

Depending on your answer, `repl` is given a different argument to form your reply. Specifically, a choice of from or none at all runs `repl -nocc all`, and a choice of to runs `repl -cc to`. Finally, either cc or all runs `repl -cc all -nocc me`.

Two windows are then created. One window contains the message to which you are replying. Your draft, in MH-Letter mode (described in section Editing a Draft), is in the other window.

If you wish to customize the header or other parts of the reply draft, please see `repl`(1) and `mh-format`(5).

Forwarding Mail

To forward a message, use the f (`mh-forward`) command. You are given a draft to edit that looks like it would if you had run the MH command `forw`. You are given a chance to add some text (see section Editing a Draft).

You can forward several messages by using a prefix argument; in this case, you are prompted for the name of a sequence, a symbolic name that represents a list or range of message numbers (for example, C-u f forbob RET). All of the messages in the sequence are inserted into your draft. By the way, although sequences are often mentioned in this chapter, you don't have to worry about them for now; the full description of sequences in mh-e is at the end in section Using Sequences. To learn more about sequences in general, please see `mh-sequence`(5).

Redistributing Your Mail

The command M-d (`mh-redistribute`) is similar in function to forwarding mail, but it does not allow you to edit the message, nor does it add your name to the `From:' header field. It appears to the recipient as if the message had come from the original sender. For more information on redistributing messages, see `dist`(1). Also investigate the M-a (`mh-edit-again`) command in section Editing Old Drafts and Bounced Messages, for another way to redistribute messages.

Editing Old Drafts and Bounced Messages

If you don't complete a draft for one reason or another, and if the draft buffer is no longer available, you can pick your draft up again with M-a (`mh-edit-again`). If you don't use a draft folder, your last `` `draft' `` file will be used. If you use draft folders, you'll need to visit the draft folder with M-f drafts RET, use n to move to the appropriate message, and then use M-a to prepare the message for editing.

The M-a command can also be used to take messages that were sent to you and to send them to more people.

Don't use M-a to re-edit a message from a *Mailer-Daemon* who complained that your mail wasn't posted for some reason or another. In this case, use M-e (`mh-extract-rejected-mail`) to prepare the message for editing by removing the *Mailer-Daemon* envelope and unneeded header fields. Fix whatever addressing problem you had, and send the message again with C-c C-c.

Editing a Draft

When you edit a message that you want to send (called a draft in this case), the mode used is MH-Letter. This mode provides several commands in addition to the normal Emacs editing commands to help you edit your draft.

C-c C-y
: Insert contents of message to which you're replying (`mh-yank-cur-msg`).

C-c C-i
: Insert a message from a folder (`mh-insert-letter`).

C-c C-f C-t
: Move to `To:' header field (`mh-to-field`).

C-c C-f C-c
: Move to `cc:' header field (`mh-to-field`).

C-c C-f C-s
: Move to `Subject:' header field (`mh-to-field`).

C-c C-f C-f
: Move to `From:' header field (`mh-to-field`).

C-c C-f C-b
: Move to `Bcc:' header field (`mh-to-field`).

C-c C-f C-f
: Move to `Fcc:' header field (`mh-to-fcc`).

C-c C-f C-d
: Move to `Dcc:' header field (`mh-to-field`).

C-c C-w
: Display expanded recipient list (`mh-check-whom`).

C-c C-s
: Insert signature in message (`mh-insert-signature`).

C-c C-m C-f
: Include forwarded message (MIME) (`mh-mhn-compose-forw`).

C-c C-m C-e
: Include anonymous ftp reference (MIME) (`mh-mhn-compose-anon-ftp`).

C-c C-m C-t
: Include anonymous ftp reference to compressed tar file (MIME) (`mh-mhn-compose-external-compressed-tar`).

C-c C-m C-i
: Include binary, image, sound, etc. (MIME) (`mh-mhn-compose-insertion`).

C-c C-e
: Run through `mhn` before sending (`mh-edit-mhn`).

C-c C-m C-u
: Undo effects of `mhn` (`mh-revert-mhn-edit`).

C-c C-c
: Save draft and send message (`mh-send-letter`).

C-c C-q
: Quit editing and delete draft message (`mh-fully-kill-draft`).

Editing Textual Messages

The following sections show you how to edit a draft. The commands described here are also applicable to messages that have multimedia components.

Inserting letter to which you're replying

It is often useful to insert a snippet of text from a letter that someone mailed to provide some context for your reply. The command C-c C-y (`mh-yank-cur-msg`) does this by yanking a portion of text from the message to which you're replying and inserting `> ' before each line.

You can control how much text is included when you run this command. If you run this command right away, without entering the buffer containing the message to you, this command will yank the entire message, as is, into your reply. (11) If you enter the buffer containing the message sent to you and move the cursor to a certain point and return to your reply and run C-c C-y, then the text yanked will range from that point to the end of the message. Finally, the most common action you'll perform is to enter the message sent to you, move the cursor to the beginning of a paragraph or phrase, set the mark with C-SPC or C-@, and move the cursor to the end of the paragraph or phrase. The cursor position is called the point, and the space between the mark and point is called the region. Having done that, C-c C-y will insert the region you selected.

Inserting messages

Messages can be inserted with C-c C-i (`mh-insert-letter`). This command prompts you for the folder and message number and inserts the message, indented by `> '. Certain undesirable header fields are removed before insertion. If given a prefix argument (like C-u C-c C-i), the header is left intact, the message is not indented, and `> ' is not inserted before each line.

Editing the header

Because the header is part of the message, you can edit the header fields as you wish. However, several convenience functions exist to help you create and edit them. For example, the command C-c C-f C-t (`mh-to-field`; alternatively, C-c C-f t) moves the cursor to the `To:' header field, creating it if necessary. The functions to move to the `cc:', `Subject:', `From:', `Bcc:', and `Dcc:' header fields are similar.

One function behaves differently from the others, namely, C-c C-f C-f (`mh-to-fcc`; alternatively, C-c C-f f). This function will prompt you for the folder name in which to file a copy of the draft.

Be sure to leave a row of dashes or a blank line between the header and the body of the message.

Checking recipients

The C-c C-w (`mh-check-whom`) command expands aliases so you can check the actual address(es) in the alias. A new buffer is created with the output of `whom`.

Inserting your signature

You can insert your signature at the current cursor location with the C-c C-s (`mh-insert-signature`) command. The text of your signature is taken from the file `` `~/.signature' ``.

Editing Multimedia Messages

mh-e has the capability to create multimedia messages. It uses the MIME (Multipurpose Internet Mail Extensions) protocol. The MIME protocol allows you to incorporate images, sound, video, binary files, and even commands that fetch a file with `ftp' when your recipient reads the message! If you were to create a multimedia message with plain MH commands, you would use `mhn`. Indeed, the mh-e MIME commands merely insert `mhn` directives which are later expanded by `mhn`.

Each of the mh-e commands for editing multimedia messages or for incorporating multimedia objects is prefixed with C-c C-m .

Several MIME objects are defined. They are called content types. The table in section Editing a Draft contains a list of the content types that mh-e currently knows about. Several of the mh-e commands fill in the content type for you, whereas others require you to enter one. Most of the time, it should be obvious which one to use (e.g., use image/jpeg to include a JPEG image). If not, you can refer to RFC 1521, (12) which defines the MIME protocol, for a list of valid content types.

You are also sometimes asked for a content description. This is simply an optional brief phrase, in your own words, that describes the object. If you don't care to enter a content description, just press return and none will be included; however, a reader may skip over multimedia fields unless the content description is compelling.

Remember: you can always add `mhn` directives by hand.

Forwarding multimedia messages

Mail may be forwarded with MIME using the command C-c C-m C-f (`mh-mhn-compose-forw`). You are prompted for a content description, the name of the folder in which the messages to forward are located, and the messages' numbers.

Including an ftp reference

You can even have your message initiate an `ftp` transfer when the recipient reads the message. To do this, use the C-c C-m C-e (`mh-mhn-compose-anon-ftp`) command. You are prompted for the remote host and pathname, the content type, and the content description.

Including tar files

If the remote file (see section Including an ftp reference) is a compressed tar file, you can use C-c C-m C-t (`mh-mhn-compose-external-compressed-tar`). Then, in addition to retrieving the file via anonymous *ftp*, the file will also be uncompressed and untarred. You are prompted for the remote host and pathname and the content description. The pathname should contain at least one `/' (slash), because the pathname is broken up into directory and name components.

Including other multimedia objects

Images, sound, and video can be inserted in your message with the C-c C-m C-i (`mh-mhn-compose-insertion`) command. You are prompted for the filename containing the object, the content type, and a content description of the object.

Readying multimedia messages for sending

When you are finished editing a MIME message, it might look like this:

```
   3  24Aug  root                 received fax files on Wed Aug 24 11:00:13
   4+ 24Aug  To:wohler            Test<<This is a test message to get the wh

```

```
--**-{draft}      (MH-Letter)--All-----------------------------------
```

TOC

mh-e MIME draft

The lines added by the previous commands are `mhn` directives and need to be converted to MIME directives before sending. This is accomplished by the command C-c C-e (`mh-edit-mhn`), which runs `mhn` on the message. The following screen shows what those commands look like in full MIME format. You can see why mail user agents are usually built to hide these details from the user.

```

mh-e MIME draft ready to send

This action can be undone by running C-c C-m C-u (`mh-revert-mhn-edit`). It does this by reverting to a backup file. You are prompted to confirm this action, but you can avoid the confirmation by adding an argument (for example, C-u C-c C-m C-u).

Sending a Message

When you are all through editing a message, you send it with the C-c C-c (`mh-send-letter`) command. You can give an argument (as in C-u C-c C-c) to monitor the first stage of the delivery.

Killing the Draft

If for some reason you are not happy with the draft, you can kill it instead with C-c C-q (`mh-fully-kill-draft`). Emacs then kills the draft buffer and deletes the draft message.

Moving Your Mail Around

This section covers how messages and folders can be moved about or manipulated. Messages may be incorporated into your `` `+inbox' ``, deleted, and refiled. Messages containing `shar` or `uuencode` output can be stored. Folders can be visited, sorted, packed, or deleted. Here's a list of the available commands to do these things:

i
: Incorporate new mail into folder (`mh-inc-folder`).

d
: Delete message (`mh-delete-msg`).

C-d
: Delete message, don't move to next message (`mh-delete-msg-no-motion`).

M-s
: Find messages that meet search criteria (`mh-search-folder`).

o
: Output (refile) message to folder (`mh-refile-msg`).

c
: Copy message to folder (`mh-copy-msg`).

C-o
: Output (write) message to file (`mh-write-msg-to-file`).

!
: Repeat last output command (`mh-refile-or-write-again`).

l
: Print message with `lpr` (`mh-print-msg`).

|
: Pipe message through shell command (`mh-pipe-msg`).

M-n
: Unpack message created with `uudecode` or `shar` (`mh-store-msg`).

M-l
: List all folders (`mh-list-folders`).

M-f
: Visit folder (`mh-visit-folder`).

M-r
: Regenerate scan lines (`mh-rescan-folder`).

M-x mh-sort-folder

Sort folder.

M-p

Pack folder (`mh-pack-folder`).

M-k

Remove folder (`mh-kill-folder`).

x

Execute pending refiles and deletes (`mh-execute-commands`).

u

Undo pending refile or delete (`mh-undo`).

M-u

Undo all pending refiles and deletes (`mh-undo-folder`).

q

Quit (`mh-quit`).

Incorporating Your Mail

If at any time you receive new mail, incorporate the new mail into your `+inbox' buffer with i (`mh-inc-folder`). Note that i will display the `+inbox' buffer, even if there isn't any new mail. You can incorporate mail from any file into the current folder by specifying a prefix argument; you'll be prompted for the name of the file to use (for example, C-u i ~/mbox RET).

Emacs can notify you when you have new mail by displaying `Mail' in the mode line. To enable this behavior, and to have a clock in the mode line besides, add the following to `~/.emacs':

```
(display-time)
```

Deleting Your Mail

To mark a message for deletion, use the d (`mh-delete-msg`) command. A `D' is placed by the message in the scan window, and the next message is displayed. If the previous command had been p, then the next message displayed is the message previous to the message just deleted. If you specify a prefix argument, you will be prompted for a sequence (see section Using Sequences) to delete (for example, C-u d frombob RET). The x command actually carries out the deletion (see section Finishing Up). C-d (`mh-delete-msg-no-motion`) marks the message for deletion but leaves the cursor at the current message in case you wish to perform other operations on the message.

Organizing Your Mail with Folders

mh-e has analogies for each of the MH `folder` and `refile` commands. To refile a message in another folder, use the o (`mh-refile-msg`) (mnemonic: "output") command. You are prompted for the folder name.

If you are refiling several messages into the same folder, you can use the ! (`mh-refile-or-write-again`) command to repeat the last refile or write (see the description of C-o in

section Files and Pipes). Or, place the messages into a sequence (section Using Sequences) and specify a prefix argument to o, in which case you'll be prompted for the name of the sequence (for example, C-u o search RET).

If you wish to copy a message to another folder, you can use the c (`mh-copy-msg`) command (see the `-link` argument to `refile`(1)). You are prompted for a folder, and you can specify a prefix argument if you want to copy a sequence into another folder. In this case, you are then prompted for the sequence. Note that unlike the o command, the copy takes place immediately. The original copy remains in the current folder.

When you want to read the messages that you have refiled into folders, use the M-f (`mh-visit-folder`) command to visit the folder. You are prompted for the folder name.

Other commands you can perform on folders include: M-l (`mh-list-folders`), to list all the folders in your mail directory; M-k (`mh-kill-folder`), to remove a folder; M-x mh-sort-folder, to sort the messages by date (see `sortm`(1) to see how to sort by other criteria); M-p (`mh-pack-folder`), to pack a folder, removing gaps from the numbering sequence; and M-r (`mh-rescan-folder`), to rescan the folder, which is useful to grab all messages in your `` `+inbox' `` after processing your new mail for the first time. If you don't want to rescan the entire folder, give M-r or M-p a prefix argument and you'll be prompted for a range of messages to display (for instance, C-u M-r last:50 RET).

Printing Your Mail

Printing mail is simple. Enter l (`mh-print-msg`) (for *l*ine printer or *l*pr). The message is formatted with `mhl` and printed with the `lpr` command. You can print all the messages in a sequence by specifying a prefix argument, in which case you are prompted for the name of the sequence (as in C-u l frombob RET).

Files and Pipes

mh-e does offer a couple of commands that are not a part of MH. The first one, C-o (`mh-write-msg-to-file`), writes a message to a file (think of the o as in "output"). You are prompted for the filename. If the file already exists, the message is appended to it. You can also write the message to the file without the header by specifying a prefix argument (such as C-u C-o /tmp/foobar RET). Subsequent writes to the same file can be made with the ! command.

You can also pipe the message through a Unix shell command with the | (`mh-pipe-msg`) command. You are prompted for the Unix command through which you wish to run your message. If you give an argument to this command, the message header is included in the text passed to the command (the contrived example C-u | lpr would be done with the l command instead).

If the message is a shell archive `shar` or has been run through `uuencode` use M-n (`mh-store-msg`) to extract the body of the message. The default directory for extraction is the current directory, and you have a chance to specify a different extraction directory. The next time you use this command, the default directory is the last directory you used.

Finishing Up

If you've deleted a message or refiled it, but changed your mind, you can cancel the action before you've executed it. Use u (`mh-undo`) to undo a refile on or deletion of a single message. You can also undo refiles and deletes for messages that belong to a given sequence by specifying a prefix argument. You'll be prompted

for the name of the sequence (as in C-u u frombob RET). Alternatively, you can use M-u (`mh-undo-folder`) to undo all refiles or deletes in the current folder.

If you've marked messages to be deleted or refiled and you want to go ahead and delete or refile the messages, use x (`mh-execute-commands`). Many mh-e commands that may affect the numbering of the messages (such as M-r or M-p) will ask if you want to process refiles or deletes first and then either run x for you or undo the pending refiles and deletes, which are lost.

When you want to quit using mh-e and go back to editing, you can use the q (`mh-quit`) command. This buries the buffers of the current mh-e folder and restores the buffers that were present when you first ran M-x mh-rmail. You can later restore your mh-e session by selecting the `+inbox' buffer or by running M-x mh-rmail again.

Searching Through Messages

You can search a folder for messages to or from a particular person or about a particular subject. In fact, you can also search for messages containing selected strings in any arbitrary header field or any string found within the messages. Use the M-s (`mh-search-folder`) command. You are first prompted for the name of the folder to search and then placed in the following buffer in MH-Pick mode:

```
From: #
To:
Cc:
Date:
Subject:
--------

--**-Emacs: pick-pattern    (MH-Pick)------All----------------------------
```

Pick window

Edit this template by entering your search criteria in an appropriate header field that is already there, or create a new field yourself. If the string you're looking for could be anywhere in a message, then place the string underneath the row of dashes. The M-s command uses the MH command `pick` to do the real work, so read `pick`(1) to find out more about how to enter the criteria.

There are no semantics associated with the search criteria--they are simply treated as strings. Case is ignored when all lowercase is used, and regular expressions (a la `ed`) are available. It is all right to specify several search criteria. What happens then is that a logical *and* of the various fields is performed. If you prefer a logical *or* operation, run M-s multiple times.

As an example, let's say that we want to find messages from Ginnean about horseback riding in the Kosci National Park (Australia) during January, 1994. Normally we would start with a broad search and narrow down if necessary to produce a manageable amount of data, but we'll cut to the chase and create a fairly restrictive set of criteria as follows:

```
From: ginnean
To:
Cc:
Date: Jan 1994
Subject: horse.*kosciusko
--------
```

As with MH-Letter mode, MH-Pick provides commands like C-c C-f C-t to help you fill in the blanks.

C-c C-f C-t
: Move to `To:' header field (`mh-to-field`).

C-c C-f C-c
: Move to `cc:' header field (`mh-to-field`).

C-c C-f C-s
: Move to `Subject:' header field (`mh-to-field`).

C-c C-f C-f
: Move to `From:' header field (`mh-to-field`).

C-c C-f C-b
: Move to `Bcc:' header field (`mh-to-field`).

C-c C-f C-f
: Move to `Fcc:' header field (`mh-to-field`).

C-c C-f C-d
: Move to `Dcc:' header field (`mh-to-field`).

C-c C-c
: Execute the search (`mh-do-pick-search`).

To perform the search, type C-c C-c (`mh-do-pick-search`). The selected messages are placed in the *search* sequence, which you can use later in forwarding (see section Forwarding Mail), printing (see section Printing Your Mail), or narrowing your field of view (see section Using Sequences). Subsequent searches are appended to the *search* sequence. If, however, you wish to start with a clean slate, first delete the *search* sequence (how to do this is discussed in section Using Sequences).

If you're searching in a folder that is already displayed in a MH-Folder buffer, only those messages contained in the buffer are used for the search. Therefore, if you want to search in all messages, first kill the folder's buffer with C-x k or scan the entire folder with M-r.

Using Sequences

For the whole scoop on MH sequences, refer to `mh-sequence`(5). As you've read, several of the mh-e commands can operate on a sequence, which is a shorthand for a range or group of messages. For example, you might want to forward several messages to a friend or colleague. Here's how to manipulate sequences.

%
: Put message in a sequence (`mh-put-msg-in-seq`).

?
: Display sequences that message belongs to (`mh-msg-is-in-seq`).

M-q
: List all sequences in folder (`mh-list-sequences`).

M-%
: Remove message from sequence (`mh-delete-msg-from-seq`).

M-#
: Delete sequence (`mh-delete-seq`).

C-x n
: Restrict display to messages in sequence (`mh-narrow-to-seq`).

C-x w
: Remove restriction; display all messages (`mh-widen`).

M-x mh-update-sequences
: Push mh-e's state out to MH.

To place a message in a sequence, use % (`mh-put-msg-in-seq`) to do it manually, or use the MH command `pick` or the mh-e version of `pick` (section Searching Through Messages) which create a sequence automatically. Give % a prefix argument and you can add all the messages in one sequence to another sequence (for example, C-u % SourceSequence RET).

Once you've placed some messages in a sequence, you may wish to narrow the field of view to just those messages in the sequence you've created. To do this, use C-x n (`mh-narrow-to-seq`). You are prompted for the name of the sequence. What this does is show only those messages that are in the selected sequence in the MH-Folder buffer. In addition, it limits further mh-e searches to just those messages. When you want to widen the view to all your messages again, use C-x w (`mh-widen`).

You can see which sequences a message is in with the ? (`mh-msg-is-in-seq`) command. Or, you can list all sequences in a selected folder (default is current folder) with M-q (`mh-list-sequences`).

If you want to remove a message from a sequence, use M-% (`mh-delete-msg-from-seq`), and if you want to delete an entire sequence, use M-# (`mh-delete-seq`). In the latter case you are prompted for the sequence to delete. Note that this deletes only the sequence, not the messages in the sequence. If you want to delete the messages, use C-u d (see section Deleting Your Mail above).

Two sequences are maintained internally by mh-e and pushed out to MH when you type either the x or q command. They are the sequence specified by your `Unseen-Sequence:' profile entry and *cur*. However, you can also just update MH's state with the command M-x mh-update-sequences. See section Viewing Your Mail

for an example of how this command might be used.

With the exceptions of C-x n and C-x w, the underlying MH command dealing with sequences is `mark`.

Miscellaneous Commands

One other command worth noting is M-x mh-version. Since there were a few changes in command letters between Versions 3 and 4, use this command to see which version you are running. This command didn't exist before Version 4, so the message `[No match]' indicates that it's time to upgrade (see section Getting mh-e). In the meantime, use the older commands that are listed in section Changes to mh-e. The output of M-x mh-version should also be included with any bug report you send (see section Bug Reports).

Go to the previous, next section.

Go to the previous, next section.

Customizing mh-e

Until now, we've talked about the mh-e commands as they work "out of the box." Of course, it is also possible to reconfigure mh-e beyond recognition. The following sections describe all of the customization variables, show the defaults, and make recommendations for customization. The outline of this chapter is identical to that of section Using mh-e, to make it easier to find the variables you'd need to modify to affect a particular command.

However, when customizing your mail environment, first try to change what you want in MH, and only change mh-e if changing MH is not possible. That way you will get the same behavior inside and outside GNU Emacs. Note that mh-e does not provide hooks for customizations that can be done in MH; this omission is intentional.

Many string or integer variables are easy enough to modify using Emacs Lisp. Any such modifications should be placed in a file called `.emacs' in your home directory (that is, `~/.emacs'). For example, to modify the variable that controls printing, you could add:

```
(setq mh-lpr-command-format "nenscript -G -r -2 -i'%s'")
```

section Printing Your Mail talks more about this variable.

Variables can also hold Boolean values. In Emacs Lisp, the Boolean values are `nil`, which means false, and `t`, which means true. Usually, variables are turned off by setting their value to `nil`, as in

```
(setq mh-bury-show-buffer nil)
```

which keeps the MH-Show buffer at the top of the buffer stack. To turn a variable on, you use

```
(setq mh-bury-show-buffer t)
```

which places the MH-Show buffer at the bottom of the buffer stack. However, the text says to turn on a variable by setting it to a *non-`nil`* value, because sometimes values other than `t` are meaningful (for example, see `mhl-formfile`, described in section Viewing Your Mail). Other variables, such as hooks, involve a little more Emacs Lisp programming expertise.

You can also "preview" the effects of changing variables before committing the changes to `~/.emacs'. Variables can be changed in the current Emacs session by using M-x set-variable.

In general, commands in this text refer to Emacs Lisp functions. Programs outside of Emacs are specifically called MH commands, shell commands, or Unix commands.

I hope I've included enough examples here to get you well on your way. If you want to explore Emacs Lisp further, a programming manual does exist, (13) and you can look at the code itself for examples. Look in the Emacs Lisp directory on your system (such as `/usr/local/lib/emacs/lisp') and find all the `mh-*.el' files there. When calling mh-e and other Emacs Lisp functions directly from Emacs Lisp code, you'll need to know the correct arguments. Use the online help for this. For example, try C-h f mh-execute-commands RET. If you write your own functions, please do not prefix your symbols (variables and functions) with `mh-`. This prefix is reserved for the mh-e package. To avoid conflicts with existing mh-e symbols, use a prefix like `my-` or your initials.

Reading Your Mail

I'll start out by including a function that I use as a front end to mh-e. (14) It toggles between your working window configuration, which may be quite involved--windows filled with source, compilation output, man pages, and other documentation--and your mh-e window configuration. Like the rest of the customization described in this chapter, simply add the following code to `~/.emacs'. Don't be intimidated by the size of this example; most customizations are only one line.

@filbreak

Starting mh-e

```
(defvar my-mh-screen-saved nil
  "Set to non-nil when mh-e window configuration shown.")
(defvar my-normal-screen nil "Normal window configuration.")
(defvar my-mh-screen nil "mh-e window configuration.")

(defun my-mh-rmail (&optional arg)
  "Toggle between mh-e and normal screen configurations.
With non-nil or prefix argument, inc mailbox as well
when going into mail."
  (interactive "P")                ; user callable function, P=prefix arg
  (setq my-mh-screen-saved         ; save state
        (cond
         ;; Bring up mh-e screen if arg or normal window configuration.
         ;; If arg or +inbox buffer doesn't exist, run mh-rmail.
         ((or arg (null my-mh-screen-saved))
          (setq my-normal-screen (current-window-configuration))
          (if (or arg (null (get-buffer "+inbox")))
              (mh-rmail)
            (set-window-configuration my-mh-screen))
          t)                       ; set my-mh-screen-saved to t
         ;; Otherwise, save mh-e screen and restore normal screen.
         (t
          (setq my-mh-screen (current-window-configuration))
          (set-window-configuration my-normal-screen)
          nil))))                  ; set my-mh-screen-saved to nil

(global-set-key "\C-x\r" 'my-mh-rmail)  ; call with C-x RET
```

If you type an argument (C-u) or if `my-mh-screen-saved` is `nil` (meaning a non-mh-e window configuration), the current window configuration is saved, either +inbox is displayed or `mh-rmail` is run, and the mh-e window configuration is shown. Otherwise, the mh-e window configuration is saved and the original configuration is displayed.

Now to configure mh-e. The following table lists general mh-e variables and variables that are used while reading mail.

`mh-progs`

Directory containing MH programs (default: dynamic).

`mh-lib`
: Directory containing MH support files and programs (default: dynamic).

`mh-do-not-confirm`
: Don't confirm on non-reversible commands (default: `nil`).

`mh-summary-height`
: Number of scan lines to show (includes mode line) (default: 4).

`mh-folder-mode-hook`
: Functions to run in MH-Folder mode (default: `nil`).

`mh-clean-message-header`
: Remove extraneous headers (default: `nil`).

`mh-invisible-headers`
: Headers to hide (default: `'"^Received: \\| ^Message-Id: \\| ^Remailed-\\| ^Via: \\| ^Mail-from: \\| ^Return-Path: \\| ^In-Reply-To: \\| ^Resent-'").

`mh-visible-headers`
: Headers to display (default: `nil`).

`mhl-formfile`
: Format file for `mhl` (default: `nil`).

`mh-show-hook`
: Functions to run when showing message (default: `nil`).

`mh-show-mode-hook`
: Functions to run when showing message (default: `nil`).

`mh-bury-show-buffer`
: Leave show buffer at bottom of stack (default: `t`).

`mh-show-buffer-mode-line-buffer-id`
: Name of show buffer in mode line (default: `'"{show-%s} %d"').

The two variables `mh-progs` and `mh-lib` are used to tell mh-e where the MH programs and supporting files are kept, respectively. mh-e does try to figure out where they are kept for itself by looking in common places and in the user's `PATH' environment variable, but if it cannot find the directories, or finds the wrong ones, you should set these variables. The name of the directory should be placed in double quotes, and there should be a trailing slash (`/'). See the example in section Getting Started.

If you never make mistakes, and you do not like confirmations for your actions, you can set `mh-do-not-confirm` to a non-`nil` value to disable confirmation for unrecoverable commands such as M-k (`mh-kill-folder`) and M-u (`mh-undo-folder`). Here's how you set boolean values:

```
(setq mh-do-not-confirm t)
```

The variable `mh-summary-height` controls the number of scan lines displayed in the MH-Folder window, including the mode line. The default value of 4 means that 3 scan lines are displayed. Here's how you set numerical values:

```
(setq mh-summary-height 2)              ; only show the current scan line
```

Normally the buffer for displaying messages is buried at the bottom at the buffer stack. You may wish to disable

this feature by setting `mh-bury-show-buffer` to `nil`. One advantage of not burying the show buffer is that one can delete the show buffer more easily in an electric buffer list because of its proximity to its associated MH-Folder buffer. Try running M-x electric-buffer-list to see what I mean.

The hook `mh-folder-mode-hook` is called when a new folder is created with MH-Folder mode. This could be used to set your own key bindings, for example:

```
Create additional key bindings via mh-folder-mode-hook

(defvar my-mh-init-done nil "Non-nil when one-time mh-e settings made.")

(defun my-mh-folder-mode-hook ()
  "Hook to set key bindings in MH-Folder mode."
  (if (not my-mh-init-done)             ; only need to bind the keys once
      (progn
        (local-set-key "/" 'search-msg)
        (local-set-key "b" 'mh-burst-digest)    ; better use of b
        (setq my-mh-init-done t))))

;;; Emacs 19
(add-hook 'mh-folder-mode-hook 'my-mh-folder-mode-hook)
;;; Emacs 18
;;;   (setq mh-folder-mode-hook (cons 'my-mh-folder-mode-hook
;;;                                   mh-folder-mode-hook))

(defun search-msg ()
  "Search for a regexp in the current message."
  (interactive)                         ; user function
  (save-window-excursion
    (other-window 1)                    ; go to next window
    (isearch-forward-regexp)))          ; string search; hit return (ESC
                                        ;   in Emacs 18) when done
```

Viewing Your Mail

Several variables control what displayed messages look like. Normally messages are delivered with a handful of uninteresting header fields. You can make them go away by setting `mh-clean-message-header` to a non-`nil` value. The header can then be cleaned up in two ways. By default, the header fields in `mh-invisible-headers` are removed. On the other hand, you could set `mh-visible-headers` to the fields that you would like to see. If this variable is set, `mh-invisible-headers` is ignored. I suggest that you not set `mh-visible-headers` since if you use this variable, you might miss a lot of header fields that you'd rather not miss. As an example of how to set a string variable, `mh-visible-headers` can be set to show a minimum set of header fields (see (section 'Syntax of Regular Expressions' in The GNU Emacs Manual, for a description of the special characters in this string):

```
(setq mh-visible-headers "^From: \\|^Subject: \\|^Date: ")
```

Normally mh-e takes care of displaying messages itself (rather than calling an MH program to do the work). If you'd rather have `mhl` display the message (within mh-e), set the variable `mhl-formfile` to a non-`nil` value. You can set this variable either to `t` to use the default format file or to a filename if you have your own format file

(`mhl`(1) tells you how to write one). When writing your own format file, use a nonzero value for `overflowoffset` to ensure the header is RFC 822 compliant and parsable by mh-e. `mhl` is always used for printing and forwarding; in this case, the value of `mhl-formfile` is consulted if it is a filename.

Two hooks can be used to control how messages are displayed. The first hook, `mh-show-mode-hook`, is called early on in the process of displaying of messages. It is used to perform some actions on the contents of messages, such as highlighting the header fields. If you're running Emacs 19 under the X Window System, the following example will highlight the `From:' and `Subject:' header fields. This is a very nice feature indeed.

Emphasize header fields in different fonts via mh-show-mode-hook

```
(defvar my-mh-keywords
   '(("^From: \\(.*\\)" 1 'bold t)
     ("^Subject: \\(.*\\)" 1 'highlight t))
  "mh-e additions for font-lock-keywords.")

(defun my-mh-show-mode-hook ()
  "Hook to turn on and customize fonts."
  (require 'font-lock)                  ; for font-lock-keywords below
  (make-local-variable 'font-lock-mode-hook) ; don't affect other buffers
  (add-hook 'font-lock-mode-hook        ; set a hook with inline function
            (function                   ; modifies font-lock-keywords when
             (lambda ()                 ; font-lock-mode run
               (setq font-lock-keywords
                     (append my-mh-keywords font-lock-keywords)))))
  (font-lock-mode 1))                   ; change the typefaces

(if window-system                       ; can't do this on ASCII terminal
    (add-hook 'mh-show-mode-hook 'my-mh-show-mode-hook))
```

The second hook, `mh-show-hook`, is the last thing called after messages are displayed. It's used to affect the behavior of mh-e in general or when `mh-show-mode-hook` is too early. For example, if you wanted to keep mh-e in sync with MH, you could use `mh-show-hook` as follows:

```
(add-hook 'mh-show-hook 'mh-update-sequences)
```

The function `mh-update-sequences` is documented in section Finishing Up. For those who like to modify their mode lines, use `mh-show-buffer-mode-line-buffer-id` to modify the mode line in the MH-Show buffers. Place the two escape strings `%s' and `%d', which will display the folder name and the message number, respectively, somewhere in the string in that order. The default value of `"{show-%s} %d"' yields a mode line of

```
-----{show-+inbox} 4      (MH-Show)--Bot---------------------------------
```

Moving Around

When you use t (`mh-toggle-showing`) to toggle between show mode and scan mode, the MH-Show buffer is hidden and the MH-Folder buffer is left alone. Setting `mh-recenter-summary-p` to a non-`nil` value causes the toggle to display as many scan lines as possible, with the cursor at the middle. The effect of `mh-recenter-summary-p` is rather useful, but it can be annoying on a slow network connection.

Sending Mail

You may wish to start off by adding the following useful key bindings to your `.emacs' file:

```
(global-set-key "\C-xm" 'mh-smail)
(global-set-key "\C-x4m" 'mh-smail-other-window)
```

In addition, several variables are useful when sending mail or replying to mail. They are summarized in the following table.

`mh-comp-formfile`
: Format file for drafts (default: `"components"').

`mh-repl-formfile`
: Format file for replies (default: `"replcomps"').

`mh-letter-mode-hook`
: Functions to run in MH-Letter mode (default: `nil`).

`mh-compose-letter-function`
: Functions to run when starting a new draft (default: `nil`).

`mh-reply-default-reply-to`
: Whom reply goes to (default: `nil`).

`mh-forward-subject-format`
: Format string for forwarded message subject (default: `"%s: %s"').

`mh-redist-full-contents`
: `send` requires entire message (default: `nil`).

`mh-new-draft-cleaned-headers`
: Remove these header fields from re-edited draft (default: `"^Date:\\| ^Received:\\| ^Message-Id:\\| ^From:\\| ^Sender:\\| ^Delivery-Date:\\| ^Return-Path:"').

Since mh-e does not use `comp` to create the initial draft, you need to set `mh-comp-formfile` to the name of your components file if it isn't `components'. This is the name of the file that contains the form for composing messages. If it does not contain an absolute pathname, mh-e searches for the file first in your MH directory and then in the system MH library directory (such as `/usr/local/lib/mh'). Replies, on the other hand, are built using `repl`. You can change the location of the field file from the default of `replcomps' by modifying `mh-repl-formfile`.

Two hooks are provided to run commands on your freshly created draft. The first hook, `mh-letter-mode-hook`, allows you to do some processing before editing a letter. For example, you may wish to modify the header after `repl` has done its work, or you may have a complicated `components' file and need to tell mh-e where the cursor should go. Here's an example of how you would use this hook--all of the other hooks are set in this fashion as well.

```
Prepare draft for editing via mh-letter-mode-hook

(defvar letter-mode-init-done nil
  "Non-nil when one-time mh-e settings have made.")

(defun my-mh-letter-mode-hook ()
```

```
  "Hook to prepare letter for editing."
  (if (not letter-mode-init-done)    ; only need to bind the keys once
      (progn
        (local-set-key "\C-ctb" 'add-enriched-text)
        (local-set-key "\C-cti" 'add-enriched-text)
        (local-set-key "\C-ctf" 'add-enriched-text)
        (local-set-key "\C-cts" 'add-enriched-text)
        (local-set-key "\C-ctB" 'add-enriched-text)
        (local-set-key "\C-ctu" 'add-enriched-text)
        (local-set-key "\C-ctc" 'add-enriched-text)
        (setq letter-mode-init-done t)))
  (setq fill-prefix "  ")            ; I find indented text easier to read
  (save-excursion
    (goto-char (point-max))          ; go to end of message to
    (mh-insert-signature)))          ;   insert signature

(add-hook 'mh-letter-mode-hook 'my-mh-letter-mode-hook)
```

The function, `add-enriched-text` is defined in the example in section Editing Multimedia Messages.

The second hook, a function really, is `mh-compose-letter-function`. Like `mh-letter-mode-hook`, it is called just before editing a new message; however, it is the last function called before you edit your message. The consequence of this is that you can write a function to write and send the message for you. This function is passed three arguments: the contents of the `To:', `Subject:', and `cc:' header fields.

Replying to Mail

If you find that most of the time that you specify cc when you reply to a message, set `mh-reply-default-reply-to` to `cc'. This variable is normally set to `nil` so that you are prompted for the recipient of a reply. It can be set to one of `from', `to', or `cc'; you are then no longer prompted for the recipient(s) of your reply.

Forwarding Mail

When forwarding a message, the format of the `Subject:' header field can be modified by the variable `mh-forward-subject-format`. This variable is a string which includes two escapes (`%s'). The first `%s' is replaced with the sender of the original message, and the second one is replaced with the original `Subject:'. The default value of `"%s: %s"' takes a message with the header:

```
To: Bill Wohler <wohler@newt.com>
Subject: Re: 49er football
From: Greg DesBrisay <gd@cellnet.com>
```

and creates a subject header field of:

```
Subject: Greg DesBrisay: Re: 49er football
```

TOC

Redistributing Your Mail

The variable `mh-redist-full-contents` must be set to non-`nil` if `dist` requires the whole letter for redistribution, which is the case if `send` is compiled with the BERK (15) option (which many people abhor). If you find that MH will not allow you to redistribute a message that has been redistributed before, this variable should be set to `nil`.

Editing Old Drafts and Bounced Messages

The header fields specified by `mh-new-draft-cleaned-headers` are removed from an old draft that has been recreated with M-e (`mh-extract-rejected-mail`) or M-a (`mh-edit-again`). If when you edit an old draft with these commands you find that there are header fields that you don't want included, you can append them to this variable. For example,

```
(setq mh-new-draft-cleaned-headers
      (concat mh-new-draft-cleaned-headers "\\|^Some-Field:"))
```

This appends the regular expression `\\|^Some-Field:' to the variable (see section 'Syntax of Regular Expressions' in The GNU Emacs Manual). The `\\|' means *or*, and the `^' (caret) matches the beginning of the line. This is done to be very specific about which fields match. The literal `:' is appended for the same reason.

Editing a Draft

There are several variables used during the draft editing phase. Examples include changing the name of the file that holds your signature or telling mh-e about new multimedia types. They are:

`mh-yank-from-start-of-msg`
: How to yank when region not set (default: `t`).

`mh-ins-buf-prefix`
: Indent for yanked messages (default: `"> "').

`mail-citation-hook`
: Functions to run on yanked messages (default: `nil`).

`mh-delete-yanked-msg-window`
: Delete message window on yank (default: `nil`).

`mh-mime-content-types`
: List of valid content types (default: `'(("text/plain")
("text/richtext") ("multipart/mixed") ("multipart/alternative")
("multipart/digest") ("multipart/parallel") ("message/rfc822")
("message/partial") ("message/external-body")
("application/octet-stream") ("application/postscript")
("image/jpeg") ("image/gif") ("audio/basic") ("video/mpeg"))').

`mh-mhn-args`
: Additional arguments for `mhn` (default: `nil`).

`mh-signature-file-name`
: File containing signature (default: `"~/.signature"').

`mh-before-send-letter-hook`

Functions to run before sending draft (default: `nil`).

`mh-send-prog`

MH program used to send messages (default: `"send"').

Editing Textual Messages

The following two sections include variables that customize the way you edit a draft. The discussion here applies to editing multimedia messages as well.

Inserting letter to which you're replying

To control how much of the message to which you are replying is yanked by C-c C-y (`mh-yank-cur-msg`) into your reply, modify `mh-yank-from-start-of-msg`. The default value of `t` means that the entire message is copied. If it is set to `'body` (don't forget the apostrophe), then only the message body is copied. If it is set to `nil`, only the part of the message following point (the current cursor position in the message's buffer) is copied. In any case, this variable is ignored if a region is set in the message you are replying to. The string contained in `mh-ins-buf-prefix` is inserted before each line of a message that is inserted into a draft with C-c C-y (`mh-yank-cur-msg`). I suggest that you not modify this variable. The default value of `"> '" is the default string for many mailers and news readers: messages are far easier to read if several included messages have all been indented by the same string. The variable `mail-citation-hook` is `nil` by default, which means that when a message is inserted into the letter, each line is prefixed by `mh-ins-buf-prefix`. Otherwise, it can be set to a function that modifies an included citation. (16) If you like to yank all the text from the message you're replying to in one go, set `mh-delete-yanked-msg-window` to non-`nil` to delete the window containing the original message after yanking it to make more room on your screen for your reply.

Inserting your signature

You can change the name of the file inserted with C-c C-s (`mh-insert-signature`) by changing `mh-signature-file-name` (default: `"~/.signature"').

Editing Multimedia Messages

The variable `mh-mime-content-types` contains a list of the currently valid content types. They are listed in the table in section Editing a Draft. If you encounter a new content type, you can add it like this:

```
(setq mh-mime-content-types (append mh-mime-content-types
                                    '(("new/type"))))
```

Emacs macros can be used to insert enriched text directives like `<bold>'. The following code will make, for example, C-c t b insert the `<bold>' directive.

```
Emacs macros for entering enriched text

(defvar enriched-text-types '(("b" . "bold") ("i" . "italic") ("f" . "fixed")
                              ("s" . "smaller") ("B" . "bigger")
                              ("u" . "underline") ("c" . "center"))
  "Alist of (final-character . directive) choices for add-enriched-text.
Additional types can be found in RFC 1563.")
```

```
(defun add-enriched-text (begin end)
  "Add enriched text directives around region.
The directive used comes from the list enriched-text-types and is
specified by the last keystroke of the command.  When called from Lisp,
arguments are BEGIN and END."
  (interactive "r")
  ;; Set type to the directive indicated by the last keystroke.
  (let ((type (cdr (assoc (char-to-string (logior last-input-char ?`))
                          enriched-text-types))))
    (save-restriction              ; restores state from narrow-to-region
      (narrow-to-region begin end) ; narrow view to region
      (goto-char (point-min))      ; move to beginning of text
      (insert "<" type ">")        ; insert beginning directive
      (goto-char (point-max))      ; move to end of text
      (insert "</" type ">"))))    ; insert terminating directive
```

To use the function `add-enriched-text`, first create keybindings for it (see section Sending Mail). Then, set the mark with C-@ or C-SPC, type in the text to be highlighted, and type C-c t b. This adds `<bold>' where you set the mark and adds `</bold>' at the location of your cursor, giving you something like: `You should be <bold>very</bold>'. You may also be interested in investigating `sgml-mode`.

Readying multimedia messages for sending

If you wish to pass additional arguments to `mhn` to affect how it builds your message, use the variable `mh-mhn-args`. For example, you can build a consistency check into the message by setting `mh-mhn-args` to `-check`. The recipient of your message can then run `mhn -check` on the message---`mhn` will complain if the message has been corrupted on the way. The C-c C-e (`mh-mhn-edit`) command only consults this variable when given a prefix argument.

Sending a Message

If you want to check your spelling in your message before sending, use `mh-before-send-letter-hook` like this:

Spell-check message via mh-before-send-letter-hook

```
(add-hook 'mh-before-send-letter-hook 'ispell-message)
```

In case the MH `send` program is installed under a different name, use `mh-send-prog` to tell mh-e the name.

Moving Your Mail Around

If you change the name of some of the MH programs or have your own printing programs, the following variables can help you. They are described in detail in the subsequent sections.

`mh-inc-prog`

Program to incorporate mail (default: `'"inc"').

`mh-inc-folder-hook`

Functions to run when incorporating mail (default: `nil`).

`mh-delete-msg-hook`
: Functions to run when deleting messages (default: `nil`).

`mh-print-background`
: Print in foreground or background (default: `nil`).

`mh-lpr-command-format`
: Command used to print (default: `'"lpr -J '%s'"').

`mh-default-folder-for-message-function`
: Function to generate a default folder (default: `nil`).

`mh-auto-folder-collect`
: Collect folder names in background at startup (default: `t`).

`mh-recursive-folders`
: Collect nested folders (default: `nil`).

`mh-refile-msg-hook`
: Functions to run when refiling message (default: `nil`).

`mh-store-default-directory`
: Default directory for storing files created by `uuencode` or `shar` (default: `nil`).

`mh-sortm-args`
: Additional arguments for `sortm` (default: `nil`).

`mh-scan-prog`
: Program to scan messages (default: `'"scan"').

`mh-before-quit-hook`
: Functions to run before quitting (default: `nil`). See also `mh-quit-hook`.

`mh-quit-hook`
: Functions to run after quitting (default: `nil`). See also `mh-before-quit-hook`.

Incorporating Your Mail

The name of the program that incorporates new mail is stored in `mh-inc-prog`; it is `'"inc"' by default. This program generates a one-line summary for each of the new messages. Unless it is an absolute pathname, the file is assumed to be in the `mh-progs` directory. You may also link a file to `inc` that uses a different format (see `mh-profile`(5)). You'll then need to modify several variables appropriately; see `mh-scan-prog` below. You can set the hook `mh-inc-folder-hook`, which is called after new mail is incorporated by the i (`mh-inc-folder`) command. A good use of this hook is to rescan the whole folder either after running M-x mh-rmail the first time or when you've changed the message numbers from outside of mh-e.

Rescan folder after incorporating new mail via mh-inc-folder-hook

```
(defun my-mh-inc-folder-hook ()
  "Hook to rescan folder after incorporating mail."
  (if (buffer-modified-p)            ; if outstanding refiles and deletes,
      (mh-execute-commands))         ;   carry them out
  (mh-rescan-folder)                 ; synchronize with +inbox
  (mh-show))                         ; show the current message
```

```
(add-hook 'mh-inc-folder-hook 'my-mh-inc-folder-hook)
```

Deleting Your Mail

The hook `mh-delete-msg-hook` is called after you mark a message for deletion. For example, the current maintainer of mh-e used this once when he kept statistics on his mail usage.

Organizing Your Mail with Folders

By default, operations on folders work only one level at a time. Set `mh-recursive-folders` to non-`nil` to operate on all folders. This mostly means that you'll be able to see all your folders when you press TAB when prompted for a folder name. The variable `mh-auto-folder-collect` is normally turned on to generate a list of folder names in the background as soon as mh-e is loaded. Otherwise, the list is generated when you need a folder name the first time (as with o (`mh-refile-msg`)). If you have a lot of folders and you have `mh-recursive-folders` set, this could take a while, which is why it's nice to do the folder collection in the background.

The function `mh-default-folder-for-message-function` is used by o (`mh-refile-msg`) and C-c C-f C-f (`mh-to-fcc`) to generate a default folder. The generated folder name should be a string with a `+' before it. For each of my correspondents, I use the same name for both an alias and a folder. So, I wrote a function that takes the address in the `From:' header field, finds it in my alias file, and returns the alias, which is used as a default folder name. This is the most complicated example given here, and it demonstrates several features of Emacs Lisp programming. You should be able to drop this into `~/.emacs', however. If you use this to store messages in a subfolder of your Mail directory, you can modify the line that starts `(format +%s...' and insert your subfolder after the folder symbol `+'.

@filbreak

Creating useful default folder for refiling via mh-default-folder-for-message-function

```
(defun my-mh-folder-from-address ()
  "Determine folder name from address.
Takes the address in the From: header field, and returns its corresponding
alias from the user's personal aliases file. Returns nil if the address
was not found."
  (require 'rfc822)                        ; for the rfc822 functions
  (search-forward-regexp "^From: \\(.*\\)") ; grab header field contents
  (save-excursion                          ; save state
    (let ((addr (car (rfc822-addresses  ; get address
                      (buffer-substring (match-beginning 1)
                                        (match-end 1)))))
          (buffer (get-buffer-create " *temp*")) ; set local variables
          folder)
      (set-buffer buffer)                  ; jump to temporary buffer
      (unwind-protect                      ; run kill-buffer when done
          (progn                           ; function grouping construct
            (insert-file-contents (expand-file-name "aliases"
                                                    mh-user-path))
            (goto-char (point-min))   ; grab aliases file and go to start
```

```
            (setq folder
                  ;; Search for the given address, even commented-out
                  ;; addresses are found!
                  ;; The function search-forward-regexp sets values that are
                  ;; later used by match-beginning and match-end.
                  (if (search-forward-regexp (format "^;*\\(.*\\):.*%s"
                                                     addr) nil t)
                      ;; NOTE WELL: this is what the return value looks like.
                      ;; You can modify the format string to match your own
                      ;; Mail hierarchy.
                      (format "+%s" (buffer-substring (match-beginning 1)
                                                      (match-end 1))))))
              (kill-buffer buffer))          ; get rid of our temporary buffer
            folder)))                        ; function's return value

(setq mh-default-folder-for-message-function 'my-mh-folder-from-address)
```

The hook `mh-refile-msg-hook` is called after a message is marked to be refiled.

The variable `mh-sortm-args` holds extra arguments to pass on to the `sortm` command. Note: this variable is only consulted when a prefix argument is given to M-x mh-sort-folder. It is used to override any arguments given in a `sortm:` entry in your MH profile (`` `~/.mh_profile' ``).

Scan line formatting

The name of the program that generates a listing of one line per message is held in `mh-scan-prog` (default: `"scan"'). Unless this variable contains an absolute pathname, it is assumed to be in the `mh-progs` directory. You may link another program to `scan` (see `mh-profile`(5)) to produce a different type of listing.

If you change the format of the scan lines you'll need to tell mh-e how to parse the new format. As you see, quite a lot of variables are involved to do that. The first variable has to do with pruning out garbage.

`mh-valid-scan-line`

> This regular expression describes a valid scan line. This is used to eliminate error messages that are occasionally produced by `inc` or `scan` (default: `"^ *[0-9]"').

Next, two variables control how the message numbers are parsed.

`mh-msg-number-regexp`

> This regular expression is used to extract the message number from a scan line. Note that the message number must be placed in quoted parentheses, (\\(...\\)), as in the default of `"^ *\\([0-9]+\\)"'.

`mh-msg-search-regexp`

> Given a message number (which is inserted in `%d'), this regular expression will match the scan line that it represents (default: `"^[^0-9]*%d[^0-9]"').

Finally, there are a slew of variables that control how mh-e marks up the scan lines.

`mh-cmd-note`

> Number of characters to skip over before inserting notation (default: 4). Note how it relates to the following regular expressions.

`mh-deleted-msg-regexp`

> This regular expression describes deleted messages (default: `"^....D"'). See also `mh-note-deleted`.

`mh-refiled-msg-regexp`

This regular expression describes refiled messages (default: `'"^....\\^"'). See also `mh-note-refiled`.

`mh-cur-scan-msg-regexp`

This regular expression matches the current message (default: `'"^....\\+"'). See also `mh-note-cur`.

`mh-good-msg-regexp`

This regular expression describes which messages should be shown when mh-e goes to the next or previous message. Normally, deleted or refiled messages are skipped over (default: `'"^....[^D^]"').

`mh-note-deleted`

Messages that have been deleted to are marked by this string (default: `'"D"'). See also `mh-deleted-msg-regexp`.

`mh-note-refiled`

Messages that have been refiled are marked by this string (default: `'"^"'). See also `mh-refiled-msg-regexp`.

`mh-note-copied`

Messages that have been copied are marked by this string (default: `'"C"').

`mh-note-cur`

The current message (in MH, not in mh-e) is marked by this string (default: `'"+"'). See also `mh-cur-scan-msg-regexp`.

`mh-note-repl`

Messages that have been replied to are marked by this string (default: `'"-"').

`mh-note-forw`

Messages that have been forwarded are marked by this string (default: `'"F"').

`mh-note-dist`

Messages that have been redistributed are marked by this string (default: `'"R"').

`mh-note-printed`

Messages that have been printed are marked by this string (default: `'"P"').

`mh-note-seq`

Messages in a sequence are marked by this string (default: `'"%"').

Printing Your Mail

Normally messages are printed in the foreground. If this is slow on your system, you may elect to set `mh-print-background` to non-`nil` to print in the background. If you do this, do not delete the message until it is printed or else the output may be truncated. The variable `mh-lpr-command-format` controls how the printing is actually done. The string can contain one escape, `%s', which is filled with the name of the folder and the message number and is useful for print job names. As an example, the default is `'"lpr -J '%s'"'.

Files and Pipes

The initial directory for the `mh-store-msg` command is held in `mh-store-default-directory`. Since I almost always run `mh-store-msg` on sources, I set it to my personal source directory like this:

```
(setq mh-store-default-directory (expand-file-name "~/src/"))
```

Subsequent incarnations of `mh-store-msg` offer the last directory used as the default. By the way, `mh-store-msg` calls the Emacs Lisp function `mh-store-buffer`. I mention this because you can use it directly if you're editing a buffer that contains a file that has been run through `uuencode` or `shar`. For example, you can extract the contents of the current buffer in your home directory by typing M-x mh-store-buffer RET ~ RET.

Finishing Up

The two variables `mh-before-quit-hook` and `mh-quit-hook` are called by q (`mh-quit`). The former one is called before the quit occurs, so you might use it to perform any mh-e operations; you could perform some query and abort the quit or call `mh-execute-commands`, for example. The latter is not run in an mh-e context, so you might use it to modify the window setup.

Searching Through Messages

If you find that you do the same thing over and over when editing the search template, you may wish to bind some shortcuts to keys. This can be done with the variable `mh-pick-mode-hook`, which is called when M-s (`mh-search-folder`) is run on a new pattern.

The string `mh-partial-folder-mode-line-annotation` is used to annotate the mode line when only a portion of the folder is shown. For example, this will be displayed after running M-s (`mh-search-folder`) to list messages based on some search criteria (see section Searching Through Messages). The default annotation of `"select"' yields a mode line that looks like:

```
--%%-{+inbox/select} 2 msgs (2-3)      (MH-Folder)--All----------------
```

Go to the previous, next section.

Go to the previous, next section.

Odds and Ends

This appendix covers a few topics that don't fit elsewhere. Here I tell you how to report bugs and how to get on the mh-e mailing list. I also point out some additional sources of information.

Bug Reports

The current maintainer of mh-e is Stephen Gildea <*gildea@lcs.mit.edu*>. Please mail bug reports directly to him, as well as any praise or suggestions. Please include the output of M-x mh-version (see section Miscellaneous Commands) in any bug report you send.

mh-e Mailing List

There is a mailing list, *mh-e@x.org*, for discussion of mh-e and announcements of new versions. Send a "subscribe" message to *mh-e-request@x.org* to be added. Do not report bugs on this list; mail them directly to the maintainer (see section Bug Reports).

MH FAQ

An FAQ appears monthly in the newsgroup `comp.mail.mh'. While very little is there that deals with mh-e specifically, there is an incredible wealth of material about MH itself which you will find useful. The subject of the FAQ is MH Frequently Asked Questions (FAQ) with Answers.

The FAQ can be also obtained by anonymous `ftp` or via the World Wide Web (WWW). It is located at:

`ftp://rtfm.mit.edu/pub/usenet/news.answers/mail/mh-faq/part1`
`http://www.cis.ohio-state.edu/hypertext/faq/usenet/mail/mh-faq/part1/faq.html`

Otherwise, you can use mail. Send mail to *mail-server@rtfm.mit.edu* containing the following:

```
send usenet/news.answers/mail/mh-faq/part1
```

Getting mh-e

If you're running a pre-4.0 version of mh-e, please consider upgrading. You can either have your system administrator upgrade your Emacs, or just the files for mh-e.

The MH distribution contains a copy of mh-e in `` `miscellany/mh-e' ``. Make sure it is at least Version 4.0.

The latest version of mh-e can be obtained via anonymous `ftp` from `ftp.x.org'. The file containing mh-e is currently `` `/misc/mh-e/mh-e-5.0.2.tar.Z' `` I suggest that you extract the files from `` `mh-e-5.0.2.tar.Z' `` in the following fashion:

```
% cd                                  # Start in your home directory
% mkdir lib lib/emacs                 # Create directory for mh-e
% cd lib/emacs
% zcat path/to/mh-e-5.0.2.tar.Z | tar xvf -    # Extract files
```

To use these new files, add the following to `~/.emacs':

```
(setq load-path (cons (expand-file-name "~/lib/emacs") load-path))
```

That's it! If you're already running Emacs, please quit that session and start again to load in the new mh-e. Check that you're running the new version with the command M-x mh-version after running any mh-e command. The distribution comes with a file called `MH-E-NEWS' so you can see what's new.

Go to the previous, next section.

Go to the previous, next section.

History of mh-e

mh-e was originally written by Brian Reid in 1983 and has changed hands twice since then. Jim Larus wanted to do something similar for GNU Emacs, and ended up completely rewriting it that same year. In 1989, Stephen Gildea picked it up and is now currently improving and maintaining it.

From Brian Reid

One day in 1983 I got the flu and had to stay home from work for three days with nothing to do. I used that time to write MHE. The fundamental idea behind MHE was that it was a "puppeteer" driving the MH programs underneath it. MH had a model that the editor was supposed to run as a subprocess of the mailer, which seemed to me at the time to be the tail wagging the dog. So I turned it around and made the editor drive the MH programs. I made sure that the UCI people (who were maintaining MH at the time) took in my changes and made them stick.

Today, I still use my own version of MHE because I don't at all like the way that GNU mh-e works and I've never gotten to be good enough at hacking Emacs Lisp to make GNU mh-e do what I want. The Gosling-emacs version of MHE and the GNU Emacs version of mh-e have almost nothing in common except similar names. They work differently, have different conceptual models, and have different key bindings. (17)

Brian Reid, June 1994

From Jim Larus

Brian Reid, while at CMU or shortly after going to Stanford wrote a mail reading program called MHE for Gosling Emacs. It had much the same structure as mh-e (i.e., invoked MH programs), though it was simpler and the commands were slightly different. Unfortunately, I no longer have a copy so the differences are lost in the mists of time.

In '82-83, I was working at BBN and wrote a lot of mlisp code in Gosling Emacs to make it look more like Tennex Emacs. One of the packages that I picked up and improved was Reid's mail system. In '83, I went back to Berkeley. About that time, Stallman's first version of GNU Emacs came out and people started to move to it from Gosling Emacs (as I recall, the transition took a year or two). I decided to port Reid's MHE and used the mlisp to Emacs Lisp translator that came with GNU Emacs. It did a lousy job and the resulting code didn't work, so I bit the bullet and rewrote the code by hand (it was a lot smaller and simpler then, so it took only a day or two).

Soon after that, mh-e became part of the standard Emacs distribution and suggestions kept dribbling in for improvements. mh-e soon reached sufficient functionality to keep me happy, but I kept on improving it because I was a graduate student with plenty of time on my hands and it was more fun than my dissertation. In retrospect, the one thing that I regret is not writing any documentation, which seriously

limited the use and appeal of the package.

In '89, I came to Wisconsin as a professor and decided not to work on mh-e. It was stable, except for minor bugs, and had enough functionality, so I let it be for a few years. Stephen Gildea of BBN began to pester me about the bugs, but I ignored them. In 1990, he went off to the X Consortium, said good bye, and said that he would now be using `xmh`. A few months later, he came back and said that he couldn't stand `xmh` and could I put a few more bug fixes into mh-e. At that point, I had no interest in fixing mh-e, so I gave the responsibility of maintenance to him and he has done a fine job since then.

Jim Larus, June 1994

From Stephen Gildea

In 1987 I went to work for Bolt Beranek and Newman, as Jim had before me. In my previous job, I had been using RMAIL, but as my folders tend to run large, I was frustrated with the speed of RMAIL. However, I stuck with it because I wanted the GNU Emacs interface. I am very familiar and comfortable with the Emacs interface (with just a few modifications of my own) and dislike having to use applications with embedded editors; they never live up to Emacs.

MH is the mail reader of choice at BBN, so I converted to it. Since I didn't want to give up using an Emacs interface, I started using mh-e. As is my wont, I started hacking on it almost immediately. I first used version 3.4m. One of the first features I added was to treat the folder buffer as a file-visiting buffer: you could lock it, save it, and be warned of unsaved changes when killing it. I also worked to bring its functionality a little closer to RMAIL. Jim Larus was very cooperative about merging in my changes, and my efforts first appeared in version 3.6, distributed with Emacs 18.52 in 1988. Next I decided mh-e was too slow and optimized it a lot. Version, 3.7, distributed with Emacs 18.56 in 1990, was noticeably faster.

When I moved to the X Consortium I became the first person there to not use xmh. (There is now one other engineer there using mh-e.) About this point I took over maintenance of mh-e from Jim and was finally able to add some features Jim hadn't accepted, such as the backward searching undo. My first release was 3.8 (Emacs 18.58) in 1992.

Now, in 1994, we see a flurry of releases, with both 4.0 and 5.0. Version 4.0 added many new features, including background folder collection and support for composing MIME messages. (Reading MIME messages remains to be done, alas.) While writing this book, Bill Wohler gave mh-e its closest examination ever, uncovering bugs and inconsistencies that required a new major version to fix, and so version 5 was released.

Stephen Gildea, June 1994

Go to the previous, next section.

Changes to mh-e

mh-e had a fairly major facelift between Versions 3 and 4. The differences between Versions 4 and 5 from the user's viewpoint are relatively minor. The prompting order for the folder and message number in a couple of functions had been switched inadvertently in Version 4. Version 5 switches the order back. The `+inbox' folder is no longer hard-coded, but rather uses the `Inbox' MH Profile entry. See the file `etc/MH-E-NEWS' in the Emacs distribution for more details on the changes.

This section documents the changes between Version 3 and newer versions so that you'll know which commands to use (or which commands you won't have) in case you're stuck with an old version.

The following tables summarize the changes to buffer names, commands and variables.

Buffer Mode Names

Version 3	Version 4
mh-e folder	MH-Folder
mh-e scan	MH-Folder
mh-e show	MH-Folder Show
Fundamental	MH-Show
mh-e letter	MH-Letter
mh-e letter	MH-Pick

Commands

Version 3		Version 4	
Function	**Command**	**Command**	**Function**
mh-first-msg	<	M-<	mh-first-msg
-	-	M->	mh-last-msg
mh-show	.	RET	mh-show
-	-	,	mh-header-display
mh-reply	a	r	mh-reply
mh-redistribute	r	M-d	mh-redistribute
mh-unshar-msg	-	M-n	mh-store-msg
mh-write-msg-to-file	M-o	C-o	mh-write-msg-to-file
mh-delete-msg-from-seq	C-u M-%	M-#	mh-delete-seq
-	-	M-q	mh-list-sequences
mh-quit	b	q	mh-quit
-	-	C-C C-f C-r	mh-to-field (`From:')

- - C-C C-f C-d mh-to-field (`Dcc:'

Variables

Version 3		Version 4	
Variable	**Value**	**Value**	**Variable**
mh-show-buffer-mode-line-buffer-id	"{%%b} %s/%d"	"{show-%s} %d"	mh-show-buffer-mode-line-buffer-id
mh-unshar-default-directory	""	nil	mh-store-default-directory

New Variables

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free

TOC

use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.

2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

   You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

3. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:

   1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
   2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
   3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

These requirements apply to the modified work as a whole. If identifiable sections of that wor not derived from the Program, and can be reasonably considered independent and separate wo in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for noncommercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

    The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

    If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.

5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so

long as such parties remain in full compliance.

6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on it.
7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

   If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

   It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

   This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.
9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number

of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.

11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the

"copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and an idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or
modify it under the terms of the GNU General Public License
as published by the Free Software Foundation; either version 2
of the License, or (at your option) any later version.

This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details
type `show w'.  This is free software, and you are welcome
to redistribute it under certain conditions; type `show c'
for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright
interest in the program `Gnomovision'
(which makes passes at compilers) written
by James Hacker.

signature of Ty Coon, 1 April 1989
Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License

instead of this License.

mh-e

TOC

(1)

Note that mh-e is supported with MH 6 and either Emacs 18 or Emacs 19. Reportedly, large parts of it work with MH 5 and also with Lucid/XEmacs and Epoch, but there are no guarantees. It is also distributed with Lucid/XEmacs, as well as with MH itself.

(2)

The keys mentioned in these chapters refer to the default key bindings. If you've changed the bindings, refer to the command summaries at the beginning of each major section in section Using mh-e, for a mapping between default key bindings and function names.

(3)

This is emphasized because pressing ESC twice or holding it down a second too long so that it repeats gives you an error message.

(4)

You wouldn't ordinarily do this.

(5)

A mode changes Emacs to make it easier to edit a particular type of text.

(6)

If you're running Emacs under the X Window System, then you would also see a menubar. I've left out the menubar in all of the example screens.

(7)

If you want to see your old mail as well, use M-r to pull all your messages into mh-e. Or, give a prefix argument to `mh-rmail` so it will prompt you for folder to visit like M-f (for example, C-u M-x mh-rmail RET bob RET). Both M-r and M-f are described in section Organizing Your Mail with Folders.

(8)

You can call them directly from Emacs if you're running the X Window System: type M-! xterm -e mhn message-number. You can leave out the `xterm -e` if you use `mhn -list` or `mhn -store`.

(9)

For you Emacs wizards, this is implemented as an Emacs minor mode.

(10)

I highly recommend that you use a draft folder so that you can edit several drafts in parallel. To do so, create a folder (e.g. `+drafts'), and add a profile component called `Draft-Folder:' which contains `+drafts' (see mh-profile(5)).

(11)

If you'd rather have the header cleaned up, use C-u r instead of r when replying (see section Replying to Mail).

(12)

This RFC (Request For Comments) is available via the URL `ftp://ds.internic.net/rfc/rfc1521.txt'.

(13)

The GNU Emacs Lisp Reference Manual may be available online in the Info system by typing C-h i m Emacs Lisp RET. If not, you can order a printed manual, which has the desirable side-effect of helping to support the Free Software Foundation which made all this great software available. You can find an order form by running C-h C-d, or you can request an order form from *gnu@prep.ai.mit.edu*.

(14)

Stephen Gildea's favorite binding is (global-set-key "\C-cr" 'mh-rmail).

(15)

To see which options your copy of MH was compiled with, use M-x mh-version (section Miscellaneous Commands).

(16)

Supercite is an example of a full-bodied, full-featured citation package. It is in Emacs versions 19.15 and later, and its URL is `ftp://archive.cis.ohio-state.edu/pub/gnu/emacs/elisp-archive/packages/sc3.1.tar.Z'

(17)

After reading this article, I questioned Brian about his version of MHE, and received some great ideas for improving mh-e such as a dired-like method of selecting folders; and removing the prompting when sending mail, filling in the blanks in the draft buffer instead. I passed them on to Stephen Gildea, the current maintainer, and he was excited about the ideas as well. Perhaps one day, mh-e will again resemble MHE, although none of these ideas are manifest in Version 5.0.

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.
2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

   You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.
3. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:
   1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
   2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
   3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

   These requirements apply to the modified work as a whole. If identifiable sections of that work are not derived from the Program, and can be reasonably considered independent and separate works in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

   Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

In addition, mere aggregation of another work not based on the Program with the Program (or with a w based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for noncommercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

    The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

    If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.
5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.
6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on it.
7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to

refrain entirely from distribution of the Program.

If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.

9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.
11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES,

INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and an idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or
modify it under the terms of the GNU General Public License
as published by the Free Software Foundation; either version 2
of the License, or (at your option) any later version.

This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details
type `show w'.  This is free software, and you are welcome
to redistribute it under certain conditions; type `show c'
for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright
interest in the program `Gnomovision'
(which makes passes at compilers) written
by James Hacker.

signature of Ty Coon, 1 April 1989
Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License instead of this License.

Overview

`gzip` reduces the size of the named files using Lempel-Ziv coding (LZ77). Whenever possible, each file is replaced by one with the extension `.gz', while keeping the same ownership modes, access and modification times. (The default extension is `-gz' for VMS, `z' for MSDOS, OS/2 FAT and Atari.) If no files are specified or if a file name is "-", the standard input is compressed to the standard output. `gzip` will only attempt to compress regular files. In particular, it will ignore symbolic links.

If the new file name is too long for its file system, `gzip` truncates it. `gzip` attempts to truncate only the parts of the file name longer than 3 characters. (A part is delimited by dots.) If the name consists of small parts only, the longest parts are truncated. For example, if file names are limited to 14 characters, gzip.msdos.exe is compressed to gzi.msd.exe.gz. Names are not truncated on systems which do not have a limit on file name length.

By default, `gzip` keeps the original file name and timestamp in the compressed file. These are used when decompressing the file with the `-N' option. This is useful when the compressed file name was truncated or when the time stamp was not preserved after a file transfer.

Compressed files can be restored to their original form using `gzip -d' or `gunzip` or `zcat`. If the original name saved in the compressed file is not suitable for its file system, a new name is constructed from the original one to make it legal.

`gunzip` takes a list of files on its command line and replaces each file whose name ends with `.gz', `.z', `.Z', `-gz', `-z' or `_z' and which begins with the correct magic number with an uncompressed file without the original extension. `gunzip` also recognizes the special extensions `.tgz' and `.taz' as shorthands for `.tar.gz' and `.tar.Z' respectively. When compressing, `gzip` uses the `.tgz' extension if necessary instead of truncating a file with a `.tar' extension.

`gunzip` can currently decompress files created by `gzip`, `zip`, `compress` or `pack`. The detection of the input format is automatic. When using the first two formats, `gunzip` checks a 32 bit CRC (cyclic redundancy check). For `pack`, `gunzip` checks the uncompressed length. The `compress` format was not designed to allow consistency checks. However `gunzip` is sometimes able to detect a bad `.Z' file. If you get an error when uncompressing a `.Z' file, do not assume that the `.Z' file is correct simply because the standard `uncompress` does not complain. This generally means that the standard `uncompress` does not check its input, and happily generates garbage output. The SCO `compress -H' format (`lzh` compression method) does not include a CRC but also allows some consistency checks.

Files created by `zip` can be uncompressed by `gzip` only if they have a single member compressed with the 'deflation' method. This feature is only intended to help conversion of `tar.zip` files to the `tar.gz` format. To extract `zip` files with several members, use `unzip` instead of `gunzip`.

`zcat` is identical to `gunzip -c'. `zcat` uncompresses either a list of files on the command line or its standard input and writes the uncompressed data on standard output. `zcat` will uncompress files that have the correct magic number whether they have a `.gz' suffix or not.

`gzip` uses the Lempel-Ziv algorithm used in `zip` and PKZIP. The amount of compression obtained depends on the size of the input and the distribution of common substrings. Typically, text such as source code or English is reduced by 60-70%. Compression is generally much better than that achieved by LZW (as used in `compress`), Huffman coding (as used in `pack`), or adaptive Huffman coding (`compact`).

Compression is always performed, even if the compressed file is slightly larger than the original. The worst case expansion is a few bytes for the `gzip` file header, plus 5 bytes every 32K block, or an expansion ratio of 0.015% for large files. Note that the actual number of used disk blocks almost never increases. `gzip` preserves the mode, ownership and timestamps of files when compressing or decompressing.

Sample Output

Here are some realistic examples of running `gzip`.

This is the output of the command `gzip -h':

```
gzip 1.2.4 (18 Aug 93)
usage: gzip [-cdfhlLnNrtvV19] [-S suffix] [file ...]
 -c --stdout      write on standard output, keep original files unchanged
 -d --decompress  decompress
 -f --force       force overwrite of output file and compress links
 -h --help        give this help
 -l --list        list compressed file contents
 -L --license     display software license
 -n --no-name     do not save or restore the original name and time stamp
 -N --name        save or restore the original name and time stamp
 -q --quiet       suppress all warnings
 -r --recursive   operate recursively on directories
 -S .suf  --suffix .suf     use suffix .suf on compressed files
 -t --test        test compressed file integrity
 -v --verbose     verbose mode
 -V --version     display version number
 -1 --fast        compress faster
 -9 --best        compress better
 file...          files to (de)compress. If none given, use standard input.
```

This is the output of the command `gzip -v texinfo.tex':

```
texinfo.tex:             71.6% -- replaced with texinfo.tex.gz
```

The following command will find all `gzip` files in the current directory and subdirectories, and extract them in

place without destroying the original:

```
find . -name '*.gz' -print | sed 's/^\(.*\)[.]gz$/gunzip < "&" > "\1"/' | sh
```

Invoking gzip

The format for running the `gzip` program is:

```
gzip option ...
```

`gzip` supports the following options:

`--stdout'

`--to-stdout'

`-c'

Write output on standard output; keep original files unchanged. If there are several input files, the output consists of a sequence of independently compressed members. To obtain better compression, concatenate all input files before compressing them.

`--decompress'

`--uncompress'

`-d'

Decompress.

`--force'

`-f'

Force compression or decompression even if the file has multiple links or the corresponding file already exists, or if the compressed data is read from or written to a terminal. If the input data is not in a format recognized by `gzip`, and if the option --stdout is also given, copy the input data without change to the standard ouput: let `zcat` behave as `cat`. If `-f' is not given, and when not running in the background, `gzip` prompts to verify whether an existing file should be overwritten.

`--help'

`-h'

Print an informative help message describing the options then quit.

`--list'

`-l'

For each compressed file, list the following fields:

```
compressed size: size of the compressed file
uncompressed size: size of the uncompressed file
ratio: compression ratio (0.0% if unknown)
uncompressed_name: name of the uncompressed file
```

The uncompressed size is given as `-1' for files not in `gzip` format, such as compressed `.Z' files. To get the uncompressed size for such a file, you can use:

```
zcat file.Z | wc -c
```

In combination with the --verbose option, the following fields are also displayed:

```
method: compression method (deflate,compress,lzh,pack)
crc: the 32-bit CRC of the uncompressed data
date & time: time stamp for the uncompressed file
```

The crc is given as ffffffff for a file not in gzip format.

With --verbose, the size totals and compression ratio for all files is also displayed, unless some sizes are unknown. With --quiet, the title and totals lines are not displayed.

`--license'

`-L'

Display the `gzip` license then quit.

`--no-name'

`-n'

When compressing, do not save the original file name and time stamp by default. (The original name is always saved if the name had to be truncated.) When decompressing, do not restore the original file name if present (remove only the `gzip` suffix from the compressed file name) and do not restore the original time stamp if present (copy it from the compressed file). This option is the default when decompressing.

`--name'

`-N'

When compressing, always save the original file name and time stamp; this is the default. When decompressing, restore the original file name and time stamp if present. This option is useful on systems which have a limit on file name length or when the time stamp has been lost after a file transfer.

`--quiet'

`-q'

Suppress all warning messages.

`--recursive'

`-r'

Travel the directory structure recursively. If any of the file names specified on the command line are directories, `gzip` will descend into the directory and compress all the files it finds there (or decompress them in the case of `gunzip`).

`--suffix suf'

`-S suf'

Use suffix `suf' instead of `.gz'. Any suffix can be given, but suffixes other than `.z' and `.gz' should be avoided to avoid confusion when files are transferred to other systems. A null suffix forces gunzip to try decompression on all given files regardless of suffix, as in:

```
gunzip -S "" *        (*.* for MSDOS)
```

Previous versions of gzip used the `.z' suffix. This was changed to avoid a conflict with `pack`.

`--test'

`-t'

Test. Check the compressed file integrity.

`--verbose'

`-v'

Verbose. Display the name and percentage reduction for each file compressed.

`--version'

`-V'

Version. Display the version number and compilation options, then quit.

`--fast'

`--best'

`-n'

Regulate the speed of compression using the specified digit n, where `-1' or `--fast' indicates the fastest compression method (less compression) and `--best' or `-9' indicates the slowest compression method (optimal compression). The default compression level is `-6' (that is, biased towards high compression at expense of speed).

Advanced usage

Multiple compressed files can be concatenated. In this case, `gunzip` will extract all members at once. If one member is damaged, other members might still be recovered after removal of the damaged member. Better compression can be usually obtained if all members are decompressed and then recompressed in a single step.

This is an example of concatenating `gzip` files:

```
gzip -c file1  > foo.gz
gzip -c file2 >> foo.gz
```

Then

```
gunzip -c foo
```

is equivalent to

```
cat file1 file2
```

In case of damage to one member of a `.gz' file, other members can still be recovered (if the damaged member is removed). However, you can get better compression by compressing all members at once:

```
cat file1 file2 | gzip > foo.gz
```

compresses better than

```
gzip -c file1 file2 > foo.gz
```

If you want to recompress concatenated files to get better compression, do:

```
zcat old.gz | gzip > new.gz
```

If a compressed file consists of several members, the uncompressed size and CRC reported by the `--list' option applies to the last member only. If you need the uncompressed size for all members, you can use:

```
zcat file.gz | wc -c
```

If you wish to create a single archive file with multiple members so that members can later be extracted independently, use an archiver such as `tar` or `zip`. GNU `tar` supports the `-z' option to invoke `gzip` transparently. `gzip` is designed as a complement to `tar`, not as a replacement.

Environment

The environment variable `GZIP` can hold a set of default options for `gzip`. These options are interpreted first and can be overwritten by explicit command line parameters. For example:

```
for sh:    GZIP="-8v --name"; export GZIP
for csh:   setenv GZIP "-8v --name"
for MSDOS: set GZIP=-8v --name
```

On Vax/VMS, the name of the environment variable is `GZIP_OPT`, to avoid a conflict with the symbol set for invocation of the program.

Using `gzip` on tapes

When writing compressed data to a tape, it is generally necessary to pad the output with zeroes up to a block boundary. When the data is read and the whole block is passed to `gunzip` for decompression, `gunzip` detects that there is extra trailing garbage after the compressed data and emits a warning by default. You have to use the `--quiet' option to suppress the warning. This option can be set in the `GZIP` environment variable, as in:

```
for sh:    GZIP="-q"  tar -xfz --block-compress /dev/rst0
for csh:   (setenv GZIP "-q"; tar -xfz --block-compress /dev/rst0)
```

In the above example, `gzip` is invoked implicitly by the `-z' option of GNU `tar`. Make sure that the same block size (`-b' option of `tar`) is used for reading and writing compressed data on tapes. (This example assumes you are using the GNU version of `tar`.)

Reporting Bugs

If you find a bug in `gzip`, please send electronic mail to `jloup@chorus.fr' or, if this fails, to `bug-gnu-utils@prep.ai.mit.edu'. Include the version number, which you can find by running `gzip -V'. Also include in your message the hardware and operating system, the compiler used to compile `gzip`, a description of the bug behavior, and the input to `gzip` that triggered the bug.

Getting Started

This first part of the Info manual describes how to get around inside of Info. The second part of the manual describes various advanced Info commands, and how to write an Info as distinct from a Texinfo file. The third part is about how to generate Info files from Texinfo files.

This manual is primarily designed for use on a computer, so that you can try Info commands while reading about them. Reading it on paper is less effective, since you must take it on faith that the commands described really do what the manual says. By all means go through this manual now that you have it; but please try going through the on-line version as well.

There are two ways of looking at the online version of this manual:

1. Type `info` at your shell's command line. This approach uses a stand-alone program designed just to read Info files.
2. Type `emacs` at the command line; then type C-h i (Control h, followed by i). This approach uses the Info mode of the Emacs program, an editor with many other capabilities.

In either case, then type mInfo (just the letters), followed by RET---the "Return" or "Enter" key. At this point, you should be ready to follow the instructions in this manual as you read them on the screen.

Starting Info on a Small Screen

(In Info, you only see this section if your terminal has a small number of lines; most readers pass by it without seeing it.)

Since your terminal has an unusually small number of lines on its screen, it is necessary to give you special advice at the beginning.

If you see the text `--All----' at near the bottom right corner of the screen, it means the entire text you are looking at fits on the screen. If you see `--Top----' instead, it means that there is more text below that does not fit. To move forward through the text and see another screen full, press the Space bar, SPC. To move back up, press the key labeled `Delete' or DEL.

How to use Info

You are talking to the program Info, for reading documentation.

Right now you are looking at one Node of Information. A node contains text describing a specific topic at a specific level of detail. This node's topic is "how to use Info".

The top line of a node is its header. This node's header (look at it now) says that it is the node named `Help' in the file `info'. It says that the `Next' node after this one is the node called `Help-P'. An advanced Info command lets you go to any node whose name you know.

Besides a `Next', a node can have a `Previous' or an `Up'. This node has a `Previous' but no `Up', as you can see.

Now it is time to move on to the `Next' node, named `Help-P'.

```
>> Type `n' to move there.  Type just one character;
   do not type the quotes and do not type a RET afterward.
```

`>>' in the margin means it is really time to try a command.

Returning to the Previous node

This node is called `Help-P'. The `Previous' node, as you see, is `Help', which is the one you just came from using the n command. Another n command now would take you to the next node, `Help-^L'.

```
>> But do not do that yet.  First, try the p command, which takes
   you to the `Previous' node.  When you get there, you can do an
   n again to return here.
```

This all probably seems insultingly simple so far, but *do not* be led into skimming. Things will get more complicated soon. Also, do not try a new command until you are told it is time to. Otherwise, you may make Info skip past an important warning that was coming up.

```
>> Now do an n to get to the node `Help-^L' and learn more.
```

The Space, Delete, B and ^L commands.

This node's header tells you that you are now at node `Help-^L', and that p would get you back to `Help-P'. The node's title is underlined; it says what the node is about (most nodes have titles).

This is a big node and it does not all fit on your display screen. You can tell that there is more that is not visible because you can see the string `--Top-----' rather than `--All----' near the bottom right corner of the screen.

The Space, Delete and B commands exist to allow you to "move around" in a node that does not all fit on the screen at once. Space moves forward, to show what was below the bottom of the screen. Delete moves backward, to show what was above the top of the screen (there is not anything above the top until you have typed some spaces).

```
>> Now try typing a Space (afterward, type a Delete to return here).
```

When you type the space, the two lines that were at the bottom of the screen appear at the top, followed by more lines. Delete takes the two lines from the top and moves them to the bottom, *usually*, but if there are not a full screen's worth of lines above them they may not make it all the way to the bottom.

If you type Space when there is no more to see, it rings the bell and otherwise does nothing. The same goes for Delete when the header of the node is visible.

If your screen is ever garbaged, you can tell Info to print it out again by typing C-l (Control-L, that is--hold down "Control" and type an L or l).

```
>> Type C-l now.
```

To move back to the beginning of the node you are on, you can type a lot of Deletes. You can also type simply b for beginning.

```
>> Try that now.  (We have put in enough verbiage to push this past
the first screenful, but screens are so big nowadays that perhaps it
isn't enough.  You may need to shrink your Emacs or Info window.)
Then come back, with Spaces.
```

If your screen is very tall, all of this node might fit at once. In that case, "b" won't do anything. Sorry; what can we do?

You have just learned a considerable number of commands. If you want to use one but have trouble remembering which, you should type a ? which prints out a brief list of commands. When you are finished looking at the list, make it go away by typing a SPC.

```
>> Type a ? now.  After it finishes, type a SPC.
```

(If you are using the standalone Info reader, type `l' to return here.)

From now on, you will encounter large nodes without warning, and will be expected to know how to use Space and Delete to move around in them without being told. Since not all terminals have the same size

screen, it would be impossible to warn you anyway.

```
>> Now type n to see the description of the m command.
```

Menus

Menus and the m command

With only the n and p commands for moving between nodes, nodes are restricted to a linear sequence. Menus allow a branching structure. A menu is a list of other nodes you can move to. It is actually just part of the text of the node formatted specially so that Info can interpret it. The beginning of a menu is always identified by a line which starts with `* Menu:'. A node contains a menu if and only if it has a line in it which starts that way. The only menu you can use at any moment is the one in the node you are in. To use a menu in any other node, you must move to that node first.

After the start of the menu, each line that starts with a `*' identifies one subtopic. The line usually contains a brief name for the subtopic (followed by a `:'), the name of the node that talks about that subtopic, and optionally some further description of the subtopic. Lines in the menu that do not start with a `*' have no special meaning--they are only for the human reader's benefit and do not define additional subtopics. Here is an example:

```
* Foo:  FOO's Node      This tells about FOO
```

The subtopic name is Foo, and the node describing it is `FOO's Node'. The rest of the line is just for the reader's Information. [[ But this line is not a real menu item, simply because there is no line above it which starts with `* Menu:'.]]

When you use a menu to go to another node (in a way that will be described soon), what you specify is the subtopic name, the first thing in the menu line. Info uses it to find the menu line, extracts the node name from it, and goes to that node. The reason that there is both a subtopic name and a node name is that the node name must be meaningful to the computer and may therefore have to be ugly looking. The subtopic name can be chosen just to be convenient for the user to specify. Often the node name is convenient for the user to specify and so both it and the subtopic name are the same. There is an abbreviation for this:

```
* Foo::   This tells about FOO
```

This means that the subtopic name and node name are the same; they are both `Foo'.

```
>> Now use Spaces to find the menu in this node, then come back to
   the front with a b and some Spaces.  As you see, a menu is
   actually visible in its node.  If you cannot find a menu in a node
   by looking at it, then the node does not have a menu and the
   m command is not available.
```

The command to go to one of the subnodes is m---but *do not do it yet!* Before you use m, you must understand the difference between commands and arguments. So far, you have learned several commands that do not need arguments. When you type one, Info processes it and is instantly ready for another command. The m command is different: it is incomplete without the name of the subtopic. Once you have typed m, Info tries to

read the subtopic name.

Now look for the line containing many dashes near the bottom of the screen. There is one more line beneath that one, but usually it is blank. If it is empty, Info is ready for a command, such as n or b or Space or m. If that line contains text ending in a colon, it mean Info is trying to read the argument to a command. At such times, commands do not work, because Info tries to use them as the argument. You must either type the argument and finish the command you started, or type Control-g to cancel the command. When you have done one of those things, the line becomes blank again.

The command to go to a subnode via a menu is m. After you type the m, the line at the bottom of the screen says `Menu item: '. You must then type the name of the subtopic you want, and end it with a RET.

You can abbreviate the subtopic name. If the abbreviation is not unique, the first matching subtopic is chosen. Some menus put the shortest possible abbreviation for each subtopic name in capital letters, so you can see how much you need to type. It does not matter whether you use upper case or lower case when you type the subtopic. You should not put any spaces at the end, or inside of the item name, except for one space where a space appears in the item in the menu.

You can also use the completion feature to help enter the subtopic name. If you type the Tab key after entering part of a name, it will magically fill in more of the name--as much as follows uniquely from what you have entered.

If you move the cursor to one of the menu subtopic lines, then you do not need to type the argument: you just type a Return, and it stands for the subtopic of the line you are on.

Here is a menu to give you a chance to practice.

* Menu: The menu starts here.

This menu gives you three ways of going to one place, Help-FOO.

* Foo: Help-FOO. A node you can visit for fun.
* Bar: Help-FOO. Strange! two ways to get to the same place.
* Help-FOO:: And yet another!

```
>>  Now type just an m and see what happens:
```

Now you are "inside" an m command. Commands cannot be used now; the next thing you will type must be the name of a subtopic.

You can change your mind about doing the m by typing Control-g.

```
>> Try that now;  notice the bottom line clear.

>> Then type another m.

>> Now type `BAR' item name.  Do not type Return yet.
```

While you are typing the item name, you can use the Delete key to cancel one character at a time if you make a mistake.

```
>> Type one to cancel the `R'.  You could type another `R' to
```

replace it. You do not have to, since `BA' is a valid abbreviation.

>> Now you are ready to go. Type a RET.

After visiting Help-FOO, you should return here.

>> Type n to see more commands.

Here is another way to get to Help-FOO, a menu. You can ignore this if you want, or else try it (but then please come back to here).

The u command

Congratulations! This is the node `Help-FOO'. Unlike the other nodes you have seen, this one has an `Up': `Help-M', the node you just came from via the m command. This is the usual convention--the nodes you reach from a menu have `Up' nodes that lead back to the menu. Menus move Down in the tree, and `Up' moves Up. `Previous', on the other hand, is usually used to "stay on the same level but go backwards"

You can go back to the node `Help-M' by typing the command u for "Up". That puts you at the *front* of the node--to get back to where you were reading you have to type some SPCs.

>> Now type u to move back up to `Help-M'.

Some advanced Info commands

The course is almost over, so please stick with it to the end.

If you have been moving around to different nodes and wish to retrace your steps, the l command (l for last) will do that, one node-step at a time. As you move from node to node, Info records the nodes where you have been in a special history list. The l command revisits nodes in the history list; each successive l command moves one step back through the history.

If you have been following directions, ad l command now will get you back to `Help-M'. Another l command would undo the u and get you back to `Help-FOO'. Another l would undo the m and get you back to `Help-M'.

>> Try typing three l's, pausing in between to see what each
    l does.

Then follow directions again and you will end up back here.

Note the difference between l and p: l moves to where *you* last were, whereas p always moves to the node which the header says is the `Previous' node (from this node, to `Help-M').

The `d' command gets you instantly to the Directory node. This node, which is the first one you saw when you entered Info, has a menu which leads (directly, or indirectly through other menus), to all the nodes that exist.

>> Try doing a `d', then do an l to return here (yes,
   do return).

Sometimes, in Info documentation, you will see a cross reference. Cross references look like this: See sec The node reached by the cross reference in Info. That is a real, live cross reference which is named `Cross points at the node named `Help-Cross'.

If you wish to follow a cross reference, you must use the `f' command. The `f' must be followed by the cross reference name (in this case, `Cross'). While you enter the name, you can use the Delete key to edit your input. If you change your mind about following any reference, you can use Control-g to cancel the command.

Completion is available in the `f' command; you can complete among all the cross reference names in the current node by typing a Tab.

```
>> Type `f', followed by `Cross', and a RET.
```

To get a list of all the cross references in the current node, you can type ? after an `f'. The `f' continues to await a cross reference name even after printing the list, so if you don't actually want to follow a reference, you should type a Control-g to cancel the `f'.

```
>> Type "f?" to get a list of the cross references in this node.  Then
   type a Control-g and see how the `f' gives up.

>> Now type n to see the last node of the course.
```

The node reached by the cross reference in Info

This is the node reached by the cross reference named `Cross'.

While this node is specifically intended to be reached by a cross reference, most cross references lead to nodes that "belong" someplace else far away in the structure of Info. So you cannot expect the footnote to have a `Next', `Previous' or `Up' pointing back to where you came from. In general, the l (el) command is the only way to get back there.

```
>> Type l to return to the node where the cross reference was.
```

Quitting Info

To get out of Info, back to what you were doing before, type q for Quit.

This is the end of the course on using Info. There are some other commands that are meant for experienced users; they are useful, and you can find them by looking in the directory node for documentation on Info. Finding them will be a good exercise in using Info in the usual manner.

```
>> Type `d' to go to the Info directory node; then type
   `mInfo' and Return, to get to the node about Info and
   see what other help is available.
```

Info for Experts

This chapter describes various advanced Info commands, and how to write an Info as distinct from a Texinfo file. (However, in most cases, writing a Texinfo file is better, since you can use it *both* to generate an Info file and to make a printed manual. See section 'Overview of Texinfo' in Texinfo: The GNU Documentation Format.)

Advanced Info Commands

g, s, 1, -- 9, and e

If you know a node's name, you can go there by typing g, the name, and RET. Thus, gTopRET would go to the node called `Top' in this file (its directory node). gExpertRET would come back here.

Unlike m, g does not allow the use of abbreviations.

To go to a node in another file, you can include the filename in the node name by putting it at the front, in parentheses. Thus, g(dir)TopRET would go to the Info Directory node, which is node `Top' in the file `dir'.

The node name `*' specifies the whole file. So you can look at all of the current file by typing g*RET or all of any other file with g(FILENAME)RET.

The s command allows you to search a whole file for a string. It switches to the next node if and when that is necessary. You type s followed by the string to search for, terminated by RET. To search for the same string again, just s followed by RET will do. The file's nodes are scanned in the order they are in in the file, which has no necessary relationship to the order that they may be in in the tree structure of menus and `next' pointers. But normally the two orders are not very different. In any case, you can always do a b to find out what node you have reached, if the header is not visible (this can happen, because s puts your cursor at the occurrence of the string, not at the beginning of the node).

If you grudge the system each character of type-in it requires, you might like to use the commands 1, 2, 3, 4, ... 9. They are short for the m command together with an argument. 1 goes through the first item in the current node's menu; 2 goes through the second item, etc.

If you display supports multiple fonts, and you are using Emacs' Info mode to read Info files, the `*' for the fifth menu item is underlines, and so is the `*' for the ninth item; these underlines make it easy to see at a glance which number to use for an item.

On ordinary terminals, you won't have underlining. If you need to actually count items, it is better to use m instead, and specify the name.

The Info command e changes from Info mode to an ordinary Emacs editing mode, so that you can edit the text of the current node. Type C-c C-c to switch back to Info. The e command is allowed only if the variable `Info-enable-edit` is non-`nil`.

Adding a new node to Info

To add a new topic to the list in the Info directory, you must:

1. Create some nodes, in some file, to document that topic.
2. Put that topic in the menu in the directory. See section How to Create Menus.

Usually, the way to create the nodes is with Texinfo see section 'Overview of Texinfo' in Texinfo: The GNU Documentation Format); this has the advantage that you can also make a printed manual from them. However, if hyou want to edit an Info file, here is how.

The new node can live in an existing documentation file, or in a new one. It must have a ^_ character before it (invisible to the user; this node has one but you cannot see it), and it ends with either a ^_, a ^L, or the end of file. Note: If you put in a ^L to end a new node, be sure that there is a ^_ after it to start the next one, since ^L cannot *start* a node. Also, a nicer way to make a node boundary be a page boundary as well is to put a ^L *right after* the ^_.

The ^_ starting a node must be followed by a newline or a ^L newline, after which comes the node's header line. The header line must give the node's name (by which Info finds it), and state the names of the `Next', `Previous', and `Up' nodes (if there are any). As you can see, this node's `Up' node is the node `Top', which points at all the documentation for Info. The `Next' node is `Menus'.

The keywords Node, Previous, Up, and Next, may appear in any order, anywhere in the header line, but the recommended order is the one in this sentence. Each keyword must be followed by a colon, spaces and tabs, and then the appropriate name. The name may be terminated with a tab, a comma, or a newline. A space does not end it; node names may contain spaces. The case of letters in the names is insignificant.

A node name has two forms. A node in the current file is named by what appears after the `Node: ' in that node's first line. For example, this node's name is `Add'. A node in another file is named by `(filename)node-within-file', as in `(info)Add' for this node. If the file name starts with "./", then it is relative to the current directory; otherwise, it is relative starting from the standard Info file directory of your site. The name `(filename)Top' can be abbreviated to just `(filename)'. By convention, the name `Top' is used for the "highest" node in any single file--the node whose `Up' points out of the file. The Directory node is `(dir)'. The `Top' node of a document file listed in the Directory should have an `Up: (dir)' in it.

The node name * is special: it refers to the entire file. Thus, g* shows you the whole current file. The use of the node * is to make it possible to make old-fashioned, unstructured files into nodes of the tree.

The `Node:' name, in which a node states its own name, must not contain a filename, since Info when searching for a node does not expect one to be there. The `Next', `Previous' and `Up' names may contain them. In this node, since the `Up' node is in the same file, it was not necessary to use one.

Note that the nodes in this file have a file name in the header line. The file names are ignored by Info, but they serve as comments to help identify the node for the user.

How to Create Menus

Any node in the Info hierarchy may have a menu---a list of subnodes. The m command searches the current node's menu for the topic which it reads from the terminal.

A menu begins with a line starting with `* Menu:'. The rest of the line is a comment. After the starting lin every line that begins with a `* ' lists a single topic. The name of the topic--the argument that the user mu give to the m command to select this topic--comes right after the star and space, and is followed by a colon, spaces and tabs, and the name of the node which discusses that topic. The node name, like node names following `Next', `Previous' and `Up', may be terminated with a tab, comma, or newline; it may also be terminated with a period.

If the node name and topic name are the same, then rather than giving the name twice, the abbreviation `* NAME::' may be used (and should be used, whenever possible, as it reduces the visual clutter in the menu).

It is considerate to choose the topic names so that they differ from each other very near the beginning--this allows the user to type short abbreviations. In a long menu, it is a good idea to capitalize the beginning of each item name which is the minimum acceptable abbreviation for it (a long menu is more than 5 or so entries).

The nodes listed in a node's menu are called its "subnodes", and it is their "superior". They should each have an `Up:' pointing at the superior. It is often useful to arrange all or most of the subnodes in a sequence of `Next' and `Previous' pointers so that someone who wants to see them all need not keep revisiting the Menu.

The Info Directory is simply the menu of the node `(dir)Top'---that is, node `Top' in file ``../info/dir'`. You can put new entries in that menu just like any other menu. The Info Directory is *not* the same as the file directory called `` `info' ``. It happens that many of Info's files live on that file directory, but they do not have to; and files on that directory are not automatically listed in the Info Directory node.

Also, although the Info node graph is claimed to be a "hierarchy", in fact it can be *any* directed graph. Shared structures and pointer cycles are perfectly possible, and can be used if they are appropriate to the meaning to be expressed. There is no need for all the nodes in a file to form a connected structure. In fact, this file has two connected components. You are in one of them, which is under the node `Top'; the other contains the node `Help' which the h command goes to. In fact, since there is no garbage collector, nothing terrible happens if a substructure is not pointed to, but such a substructure is rather useless since nobody can ever find out that it exists.

Creating Cross References

A cross reference can be placed anywhere in the text, unlike a menu item which must go at the front of a line. A cross reference looks like a menu item except that it has `*note' instead of *. It *cannot* be terminated by a `)', because `)"s are so often part of node names. If you wish to enclose a cross reference in parentheses, terminate it with a period first. Here are two examples of cross references pointers:

```
*Note details: commands.  (See *note 3: Full Proof.)
```

They are just examples. The places they "lead to" do not really exist!

Tag Tables for Info Files

You can speed up the access to nodes of a large Info file by giving it a tag table. Unlike the tag table for a program, the tag table for an Info file lives inside the file itself and is used automatically whenever Info reads in the file.

To make a tag table, go to a node in the file using Emacs Info mode and type M-x Info-tagify. Then you must

use C-x C-s to save the file.

Once the Info file has a tag table, you must make certain it is up to date. If, as a result of deletion of text, any node moves back more than a thousand characters in the file from the position recorded in the tag table, Info will no longer be able to find that node. To update the tag table, use the `Info-tagify` command again.

An Info file tag table appears at the end of the file and looks like this:

```
^_
Tag Table:
File: info, Node: Cross-refs^?21419
File: info,  Node: Tags^?22145
^_
End Tag Table
```

Note that it contains one line per node, and this line contains the beginning of the node's header (ending just after the node name), a Delete character, and the character position in the file of the beginning of the node.

Checking an Info File

When creating an Info file, it is easy to forget the name of a node when you are making a pointer to it from another node. If you put in the wrong name for a node, this is not detected until someone tries to go through the pointer using Info. Verification of the Info file is an automatic process which checks all pointers to nodes and reports any pointers which are invalid. Every `Next', `Previous', and `Up' is checked, as is every menu item and every cross reference. In addition, any `Next' which does not have a `Previous' pointing back is reported. Only pointers within the file are checked, because checking pointers to other files would be terribly slow. But those are usually few.

To check an Info file, do M-x Info-validate while looking at any node of the file with Emacs Info mode.

Emacs Info-mode Variables

The following variables may modify the behaviour of Info-mode in Emacs; you may wish to set one or several of these variables interactively, or in your `` `~/.emacs' `` init file. See section 'Examining and Setting Variables' in The GNU Emacs Manual.

`Info-enable-edit`

Set to `nil`, disables the `e' (`Info-edit`) command. A non-`nil` value enables it. See section Adding a new node to Info.

`Info-enable-active-nodes`

When set to a non-`nil` value, allows Info to execute Lisp code associated with nodes. The Lisp code is executed when the node is selected.

`Info-directory-list`

The list of directories to search for Info files. Each element is a string (directory name) or `nil` (try default directory).

`Info-directory`

The standard directory for Info documentation files. Only used when the function `Info-direct` is called.

Creating an Info File from a Makeinfo file

`makeinfo` is a utility that converts a Texinfo file into an Info file; `texinfo-format-region` and `texinfo-format-buffer` are GNU Emacs functions that do the same.

See section 'Creating an Info File' in the Texinfo Manual, to learn how to create an Info file from a Texinfo file.

See section 'Overview of Texinfo' in Texinfo: The GNU Documentation Format, to learn how to write a Texinfo file.

@nwnode Using Stand-alone Info, Options, , Top

Using the Stand-alone Info Reader

@lowersections @paragraphindent 2

What is Info?

This text documents the use of the GNU Info program, version 2.10.

Info is a program which is used to view info files on an ASCII terminal. info files are the result of processing texinfo files with the program `makeinfo` or with the Emacs command `M-x texinfo-format-buffer`. Finally, texinfo is a documentation language which allows a printed manual and online documentation (an info file) to be produced from a single source file.

Command Line Options

GNU Info accepts several options to control the initial node being viewed, and to specify which directories to search for info files. Here is a template showing an invocation of GNU Info from the shell:

```
info [--option-name option-value] menu-item...
```

The following option-names are available when invoking Info from the shell:

`--directory directory-path`

`-d directory-path`

Adds directory-path to the list of directory paths searched when Info needs to find a file. You may issue `--directory` multiple times; once for each directory which contains info files. Alternatively, you may specify a value for the environment variable `INFOPATH`; if `--directory` is not given, the value of `INFOPATH` is used. The value of `INFOPATH` is a colon separated list of directory names. If you do not supply `INFOPATH` or `--directory-path` a default path is used.

`--file filename`

`-f filename`

Specifies a particular info file to visit. Instead of visiting the file `dir`, Info will start with `(filename)Top` as the first file and node.

`--node nodename`

`-n nodename`

Specifies a particular node to visit in the initial file loaded. This is especially useful in conjunction with `--file`(1). You may specify `--node` multiple times; for an interactive Info, each nodename is visited in its own window, for a non-interactive Info (such as when `--output` is given) each nodename is processed sequentially.

`--output filename`

`-o filename`

Specify filename as the name of a file to output to. Each node that Info visits will be output to filename instead of interactively viewed. A value of `-` for filename specifies the standard output.

`--subnodes`

This option only has meaning when given in conjunction with `--output`. It means to recursively output the nodes appearing in the menus of each node being output. Menu items which resolve to external info files are not output, and neither are menu items which are members of an index. Each node is only output once.

`--help`

`-h`

Produces a relatively brief description of the available Info options.

`--version`

Prints the version information of Info and exits.

`menu-item`

Remaining arguments to Info are treated as the names of menu items. The first argument would be a menu item in the initial node visited, while the second argument would be a menu item in the first argument's node. You can easily move to the node of your choice by specifying the menu names which describe the path to that node. For example,

```
info emacs buffers
```

first selects the menu item `Emacs' in the node `(dir)Top', and then selects the menu item `Buffers' in the node `(emacs)Top'.

Moving the Cursor

Many people find that reading screens of text page by page is made easier when one is able to indicate particular pieces of text with some kind of pointing device. Since this is the case, GNU Info (both the Emacs and standalone versions) have several commands which allow you to move the cursor about the screen. The notation used in this manual to describe keystrokes is identical to the notation used within the Emacs manual, and the GNU Readline manual. See section 'Character Conventions' in the GNU Emacs Manual, if you are unfamilar with the notation.

The following table lists the basic cursor movement commands in Info. Each entry consists of the key sequence you should type to execute the cursor movement, the `M-x`(2) command name (displayed in parentheses), and a short description of what the command does. All of the cursor motion commands can take an numeric argument (see section Miscellaneous Commands}), to find out how to supply them. With a numeric argument, the motion commands are simply executed that many times; for example, a numeric argument of 4 given to `next-line` causes the cursor to move down 4 lines. With a negative numeric argument, the motion is reversed; an argument of -4 given to the `next-line` command would cause the cursor to move *up* 4 lines.

`C-n` (`next-line`)

Moves the cursor down to the next line.

`C-p` (`prev-line`)

Move the cursor up to the previous line.

`C-a` (`beginning-of-line`)

Move the cursor to the start of the current line.

`C-e` (`end-of-line`)

Moves the cursor to the end of the current line.

`C-f` (`forward-char`)

Move the cursor forward a character.

`C-b` (`backward-char`)

Move the cursor backward a character.

`M-f` (`forward-word`)

Moves the cursor forward a word.

`M-b` (`backward-word`)

Moves the cursor backward a word.

`M-<` (`beginning-of-node`)

`b`

Moves the cursor to the start of the current node.

`M->` (`end-of-node`)

Moves the cursor to the end of the current node.

`M-r` (`move-to-window-line`)

Moves the cursor to a specific line of the window. Without a numeric argument, `M-r` moves the cursor to the start of the line in the center of the window. With a numeric argument of n, `M-r` moves the cursor

to the start of the nth line in the window.

Moving Text Within a Window

Sometimes you are looking at a screenful of text, and only part of the current paragraph you are reading is visible on the screen. The commands detailed in this section are used to shift which part of the current node is visible on the screen.

`SPC` (`scroll-forward`)

`C-v`

Shift the text in this window up. That is, show more of the node which is currently below the bottom of the window. With a numeric argument, show that many more lines at the bottom of the window; a numeric argument of 4 would shift all of the text in the window up 4 lines (discarding the top 4 lines), and show you four new lines at the bottom of the window. Without a numeric argument, SPC takes the bottom two lines of the window and places them at the top of the window, redisplaying almost a completely new screenful of lines.

`DEL` (`scroll-backward`)

`M-v`

Shift the text in this window down. The inverse of `scroll-forward`.

The `scroll-forward` and `scroll-backward` commands can also move forward and backward through the node structure of the file. If you press SPC while viewing the end of a node, or DEL while viewing the beginning of a node, what happens is controlled by the variable `scroll-behaviour`. See section Manipulating Variables}, for more information.

`C-l` (`redraw-display`)

Redraw the display from scratch, or shift the line containing the cursor to a specified location. With no numeric argument, `C-l' clears the screen, and then redraws its entire contents. Given a numeric argument of n, the line containing the cursor is shifted so that it is on the nth line of the window.

`C-x w` (`toggle-wrap`)

Toggles the state of line wrapping in the current window. Normally, lines which are longer than the screen width wrap, i.e., they are continued on the next line. Lines which wrap have a `\' appearing in the rightmost column of the screen. You can cause such lines to be terminated at the rightmost column by changing the state of line wrapping in the window with `C-x w`. When a line which needs more space than one screen width to display is displayed, a `$' appears in the rightmost column of the screen, and the remainder of the line is invisible.

Selecting a New Node

This section details the numerous Info commands which select a new node to view in the current window.

The most basic node commands are `n', `p', `u', and `l'.

When you are viewing a node, the top line of the node contains some Info pointers which describe where the next, previous, and up nodes are. Info uses this line to move about the node structure of the file when you use the following commands:

`n` (`next-node`)

Selects the `Next' node.

`p` (`prev-node`)

Selects the `Prev' node.

`u` (`up-node`)

Selects the `Up' node.

You can easily select a node that you have already viewed in this window by using the `l' command -- this name stands for "last", and actually moves through the list of already visited nodes for this window. `l' with a negative numeric argument moves forward through the history of nodes for this window, so you can quickly step between two adjacent (in viewing history) nodes.

`l` (`history-node`)

Selects the most recently selected node in this window.

Two additional commands make it easy to select the most commonly selected nodes; they are `t' and `d'.

`t` (`top-node`)

Selects the node `Top' in the current info file.

`d` (`dir-node`)

Selects the directory node (i.e., the node `(dir)').

Here are some other commands which immediately result in the selection of a different node in the current window:

`<` (`first-node`)

Selects the first node which appears in this file. This node is most often `Top', but it doesn't have to be.

`>` (`last-node`)

Selects the last node which appears in this file.

`]` (`global-next-node`)

Moves forward or down through node structure. If the node that you are currently viewing has a `Next' pointer, that node is selected. Otherwise, if this node has a menu, the first menu item is selected. If there is no `Next' and no menu, the same process is tried with the `Up' node of this node.

`[` (`global-prev-node`)

Moves backward or up through node structure. If the node that you are currently viewing has a `Prev' pointer, that node is selected. Otherwise, if the node has an `Up' pointer, that node is selected, and if it has a menu, the last item in the menu is selected.

TOC

You can get the same behaviour as `global-next-node` and `global-prev-node` while simply scrolling through the file with SPC and DEL; See section Manipulating Variables, for more information.

`g` (`goto-node`)

Reads the name of a node and selects it. No completion is done while reading the node name, since the desired node may reside in a separate file. The node must be typed exactly as it appears in the info file. A file name may be included as with any node specification, for example

```
g(emacs)Buffers
```

finds the node `Buffers' in the info file `` `emacs' ``.

`C-x k` (`kill-node`)

Kills a node. The node name is prompted for in the echo area, with a default of the current node. Killing a node means that Info tries hard to forget about it, removing it from the list of history nodes kept for the window where that node is found. Another node is selected in the window which contained the killed node.

`C-x C-f` (`view-file`)

Reads the name of a file and selects the entire file. The command

```
C-x C-f filename
```

is equivalent to typing

```
g(filename)*
```

`C-x C-b` (`list-visited-nodes`)

Makes a window containing a menu of all of the currently visited nodes. This window becomes the selected window, and you may use the standard Info commands within it.

`C-x b` (`select-visited-node`)

Selects a node which has been previously visited in a visible window. This is similar to `C-x C-b' followed by `m', but no window is created.

Searching an Info File

GNU Info allows you to search for a sequence of characters throughout an entire info file, search through the indices of an info file, or find areas within an info file which discuss a particular topic.

`s` (`search`)

Reads a string in the echo area and searches for it.

`C-s` (`isearch-forward`)

Interactively searches forward through the info file for a string as you type it.

`C-r` (`isearch-backward`)

Interactively searches backward through the info file for a string as you type it.

`i` (`index-search`)

Looks up a string in the indices for this info file, and selects a node where the found index entry points

to.

`,` (`next-index-match`)
Moves to the node containing the next matching index item from the last `i' command.

The most basic searching command is `s' (`search`). The `s' command prompts you for a string in the echo area, and then searches the remainder of the info file for an ocurrence of that string. If the string is found, the node containing it is selected, and the cursor is left positioned at the start of the found string. Subsequent `s' commands show you the default search string within `[' and `]'; pressing RET instead of typing a new string will use the default search string.

Incremental searching is similar to basic searching, but the string is looked up while you are typing it, instead of waiting until the entire search string has been specified.

Selecting Cross References

We have already discussed the `Next', `Prev', and `Up' pointers which appear at the top of a node. In addition to these pointers, a node may contain other pointers which refer you to a different node, perhaps in another info file. Such pointers are called cross references, or xrefs for short.

Parts of an Xref

Cross references have two major parts: the first part is called the label; it is the name that you can use to refer to the cross reference, and the second is the target; it is the full name of the node that the cross reference points to.

The target is separated from the label by a colon `:'; first the label appears, and then the target. For example, in the sample menu cross reference below, the single colon separates the label from the target.

```
* Foo Label: Foo Target.        More information about Foo.
```

Note the `.' which ends the name of the target. The `.' is not part of the target; it serves only to let Info know where the target name ends.

A shorthand way of specifying references allows two adjacent colons to stand for a target name which is the same as the label name:

```
* Foo Commands::                Commands pertaining to Foo.
```

In the above example, the name of the target is the same as the name of the label, in this case `Foo Commands`.

You will normally see two types of cross references while viewing nodes: menu references, and note references. Menu references appear within a node's menu; they begin with a `*' at the beginning of a line, and continue with a label, a target, and a comment which describes what the contents of the node pointed to contains.

Note references appear within the body of the node text; they begin with `*Note`, and continue with a label and a target.

Like `Next', `Prev' and `Up' pointers, cross references can point to any valid node. They are used to refer you to a place where more detailed information can be found on a particular subject. Here is a cross reference which points to a node within the Texinfo documentation: See section 'Writing an Xref' in the Texinfo Manual, for more information on creating your own texinfo cross references.

Selecting Xrefs

The following table lists the Info commands which operate on menu items.

`1` (`menu-digit`)

`2` ... `9`

Within an Info window, pressing a single digit, (such as `1'), selects that menu item, and places its node in the current window. For convenience, there is one exception; pressing `0' selects the *last* item in the node's menu.

`0` (`last-menu-item`)

Select the last item in the current node's menu.

`m` (`menu-item`)

Reads the name of a menu item in the echo area and selects its node. Completion is available while reading the menu label.

`M-x find-menu`

Moves the cursor to the start of this node's menu.

This table lists the Info commands which operate on note cross references.

`f` (`xref-item`)

`r`

Reads the name of a note cross reference in the echo area and selects its node. Completion is available while reading the cross reference label.

Finally, the next few commands operate on menu or note references alike:

`TAB` (`move-to-next-xref`)

Moves the cursor to the start of the next nearest menu item or note reference in this node. You can then use RET (`select-reference-this-line` to select the menu or note reference.

`M-TAB` (`move-to-prev-xref`)

Moves the cursor the start of the nearest previous menu item or note reference in this node.

`RET` (`select-reference-this-line`)

Selects the menu item or note reference appearing on this line.

Manipulating Multiple Windows

A window is a place to show the text of a node. Windows have a view area where the text of the node is displayed, and an associated mode line, which briefly describes the node being viewed.

GNU Info supports multiple windows appearing in a single screen; each window is separated from the next by its modeline. At any time, there is only one active window, that is, the window in which the cursor appears. There are commands available for creating windows, changing the size of windows, selecting which window is active, and for deleting windows.

The Mode Line

A mode line is a line of inverse video which appears at the bottom of an info window. It describes the contents of the window just above it; this information includes the name of the file and node appearing in that window, the number of screen lines it takes to display the node, and the percentage of text that is above the top of the window. It can also tell you if the indirect tags table for this info file needs to be updated, and whether or not the info file was compressed when stored on disk.

Here is a sample mode line for a window containing an uncompressed file named `dir', showing the node `Top'.

```
-----Info: (dir)Top, 40 lines --Top-----------------------------------
           ^^   ^   ^^^         ^^
         (file)Node #lines    where
```

When a node comes from a file which is compressed on disk, this is indicated in the mode line with two small `z"s. In addition, if the info file containing the node has been split into subfiles, the name of the subfile containing the node appears in the modeline as well:

```
--zz-Info: (emacs)Top, 291 lines --Top-- Subfile: emacs-1.Z--------------
```

When Info makes a node internally, such that there is no corresponding info file on disk, the name of the node is surrounded by asterisks (`*'). The name itself tells you what the contents of the window are; the sample mode line below shows an internally constructed node showing possible completions:

```
-----Info: *Completions*, 7 lines --All-------------------------------
```

Window Commands

It can be convenient to view more than one node at a time. To allow this, Info can display more than one window. Each window has its own mode line (see section The Mode Line) and history of nodes viewed in that window (see section Selecting a New Node).

`C-x o` (`next-window`)

Selects the next window on the screen. Note that the echo area can only be selected if it is already in use, and you have left it temporarily. Normally, `C-x o' simply moves the cursor into the next window

TOC

on the screen, or if you are already within the last window, into the first window on the screen. Giv numeric argument, `C-x o' moves over that many windows. A negative argument causes `C-x o' to select the previous window on the screen.

`M-x prev-window`

Selects the previous window on the screen. This is identical to `C-x o' with a negative argument.

`C-x 2` (`split-window`)

Splits the current window into two windows, both showing the same node. Each window is one half the size of the original window, and the cursor remains in the original window. The variable `automatic-tiling` can cause all of the windows on the screen to be resized for you automatically, please see section Manipulating Variables for more information.

`C-x 0` (`delete-window`)

Deletes the current window from the screen. If you have made too many windows and your screen appears cluttered, this is the way to get rid of some of them.

`C-x 1` (`keep-one-window`)

Deletes all of the windows excepting the current one.

`ESC C-v` (`scroll-other-window`)

Scrolls the other window, in the same fashion that `C-v' might scroll the current window. Given a negative argument, the "other" window is scrolled backward.

`C-x ^` (`grow-window`)

Grows (or shrinks) the current window. Given a numeric argument, grows the current window that many lines; with a negative numeric argument, the window is shrunk instead.

`C-x t` (`tile-windows`)

Divides the available screen space among all of the visible windows. Each window is given an equal portion of the screen in which to display its contents. The variable `automatic-tiling` can cause `tile-windows` to be called when a window is created or deleted. See section Manipulating Variables.

The Echo Area

The echo area is a one line window which appears at the bottom of the screen. It is used to display informative or error messages, and to read lines of input from you when that is necessary. Almost all of the commands available in the echo area are identical to their Emacs counterparts, so please refer to that documentation for greater depth of discussion on the concepts of editing a line of text. The following table briefly lists the commands that are available while input is being read in the echo area:

`C-f` (`echo-area-forward`)

Moves forward a character.

`C-b` (`echo-area-backward`)

Moves backward a character.

`C-a` (`echo-area-beg-of-line`)

Moves to the start of the input line.

`C-e` (`echo-area-end-of-line`)

Moves to the end of the input line.

`M-f` (`echo-area-forward-word`)

Moves forward a word.

`M-b` (`echo-area-backward-word`)

Moves backward a word.

`C-d` (`echo-area-delete`)

Deletes the character under the cursor.

`DEL` (`echo-area-rubout`)

Deletes the character behind the cursor.

`C-g` (`echo-area-abort`)

Cancels or quits the current operation. If completion is being read, `C-g' discards the text of the input line which does not match any completion. If the input line is empty, `C-g' aborts the calling function.

`RET` (`echo-area-newline`)

Accepts (or forces completion of) the current input line.

`C-q` (`echo-area-quoted-insert`)

Inserts the next character verbatim. This is how you can insert control characters into a search string, for example.

printing character (`echo-area-insert`)

Inserts the character.

`M-TAB` (`echo-area-tab-insert`)

Inserts a TAB character.

`C-t` (`echo-area-transpose-chars`)

Transposes the characters at the cursor.

The next group of commands deal with killing, and yanking text. For an in depth discussion of killing and yanking, see section 'Killing and Deleting' in the GNU Emacs Manual

`M-d` (`echo-area-kill-word`)

Kills the word following the cursor.

`M-DEL` (`echo-area-backward-kill-word`)

Kills the word preceding the cursor.

`C-k` (`echo-area-kill-line`)

Kills the text from the cursor to the end of the line.

`C-x DEL` (`echo-area-backward-kill-line`)

Kills the text from the cursor to the beginning of the line.

`C-y` (`echo-area-yank`)

Yanks back the contents of the last kill.

`M-y` (`echo-area-yank-pop`)

Yanks back a previous kill, removing the last yanked text first.

Sometimes when reading input in the echo area, the command that needed input will only accept one of a list

of several choices. The choices represent the possible completions, and you must respond with one of them. Since there are a limited number of responses you can make, Info allows you to abbreviate what you type, only typing as much of the response as is necessary to uniquely identify it. In addition, you can request Info to fill in as much of the response as is possible; this is called completion.

The following commands are available when completing in the echo area:

`TAB` (`echo-area-complete`)

`SPC`

Inserts as much of a completion as is possible.

`?` (`echo-area-possible-completions`)

Displays a window containing a list of the possible completions of what you have typed so far. For example, if the available choices are:

```
bar
foliate
food
forget
```

and you have typed an `f', followed by `?', the possible completions would contain:

```
foliate
food
forget
```

i.e., all of the choices which begin with `f'. Pressing SPC or TAB would result in `fo' appearing in the echo area, since all of the choices which begin with `f' continue with `o'. Now, typing `l' followed by `TAB' results in `foliate' appearing in the echo area, since that is the only choice which begins with `fol'.

`ESC C-v` (`echo-area-scroll-completions-window`)

Scrolls the completions window, if that is visible, or the "other" window if not.

Printing Out Nodes

You may wish to print out the contents of a node as a quick reference document for later use. Info provides you with a command for doing this. In general, we recommend that you use TeX to format the document and print sections of it, by running `tex` on the texinfo source file.

`M-x print-node`

Pipes the contents of the current node through the command in the environment variable `INFO_PRINT_COMMAND`. If the variable doesn't exist, the node is simply piped to `lpr`.

Miscellaneous Commands

GNU Info contains several commands which self-document GNU Info:

`M-x describe-command`

Reads the name of an Info command in the echo area and then displays a brief description of what that command does.

`M-x describe-key`

Reads a key sequence in the echo area, and then displays the name and documentation of the Info command that the key sequence invokes.

`M-x describe-variable`

Reads the name of a variable in the echo area and then displays a brief description of what the variable affects.

`M-x where-is`

Reads the name of an Info command in the echo area, and then displays a key sequence which can be typed in order to invoke that command.

`C-h` (`get-help-window`)

`?`

Creates (or moves into) the window displaying `*Help*`, and places a node containing a quick reference card into it. This window displays the most concise information about GNU Info available.

`h` (`get-info-help-node`)

Tries hard to visit the node `(info)Help`. The info file `` `info.texi' `` distributed with GNU Info contains this node. Of course, the file must first be processed with `makeinfo`, and then placed into the location of your info directory.

Here are the commands for creating a numeric argument:

`C-u` (`universal-argument`)

Starts (or multiplies by 4) the current numeric argument. `C-u' is a good way to give a small numeric argument to cursor movement or scrolling commands; `C-u C-v' scrolls the screen 4 lines, while `C-u C-u C-n' moves the cursor down 16 lines.

`M-1` (`add-digit-to-numeric-arg`)

`M-2` ... `M-9`

Adds the digit value of the invoking key to the current numeric argument. Once Info is reading a numeric argument, you may just type the digits of the argument, without the Meta prefix. For example, you might give `C-l' a numeric argument of 32 by typing:

```
C-u 3 2 C-l
```

or

```
M-3 2 C-l
```

`C-g' is used to abort the reading of a multi-character key sequence, to cancel lengthy operations (such as multi-file searches) and to cancel reading input in the echo area.

`C-g` (`abort-key`)

Cancels current operation.

The `q' command of Info simply quits running Info.

`q` (`quit`)

Exits GNU Info.

If the operating system tells GNU Info that the screen is 60 lines tall, and it is actually only 40 lines tall, here is a way to tell Info that the operating system is correct.

`M-x set-screen-height`

Reads a height value in the echo area and sets the height of the displayed screen to that value.

Finally, Info provides a convenient way to display footnotes which might be associated with the current node that you are viewing:

`ESC C-f` (`show-footnotes`)

Shows the footnotes (if any) associated with the current node in another window. You can have Info automatically display the footnotes associated with a node when the node is selected by setting the variable `automatic-footnotes`. See section Manipulating Variables.

Manipulating Variables

GNU Info contains several variables whose values are looked at by various Info commands. You can change the values of these variables, and thus change the behaviour of Info to more closely match your environment and info file reading manner.

`M-x set-variable`

Reads the name of a variable, and the value for it, in the echo area and then sets the variable to that value. Completion is available when reading the variable name; often, completion is available when reading the value to give to the variable, but that depends on the variable itself. If a variable does *not* supply multiple choices to complete over, it expects a numeric value.

`M-x describe-variable`

Reads the name of a variable in the echo area and then displays a brief description of what the variable affects.

Here is a list of the variables that you can set in Info.

`automatic-footnotes`

When set to `On`, footnotes appear and disappear automatically. This variable is `On` by default. When a node is selected, a window containing the footnotes which appear in that node is created, and the footnotes are displayed within the new window. The window that Info creates to contain the footnotes is called `*Footnotes*'. If a node is selected which contains no footnotes, and a `*Footnotes*' window is on the screen, the `*Footnotes*' window is deleted. Footnote windows created in this fashion are not automatically tiled so that they can use as little of the display as is possible.

`automatic-tiling`

When set to `On`, creating or deleting a window resizes other windows. This variable is `Off` by default. Normally, typing `C-x 2' divides the current window into two equal parts. When

`automatic-tiling` is set to `On`, all of the windows are resized automatically, keeping an equal number of lines visible in each window. There are exceptions to the automatic tiling; specifically, windows `*Completions*' and `*Footnotes*' are *not* resized through automatic tiling; they remain the original size.

`visible-bell`

When set to `On`, GNU Info attempts to flash the screen instead of ringing the bell. This variable is `Off` by default. Of course, Info can only flash the screen if the terminal allows it; in the case that the terminal does not allow it, the setting of this variable has no effect. However, you can make Info perform quietly by setting the `errors-ring-bell` variable to `Off`.

`errors-ring-bell`

When set to `On`, errors cause the bell to ring. The default setting of this variable is `On`.

`gc-compressed-files`

When set to `On`, Info garbage collects files which had to be uncompressed. The default value of this variable is `Off`. Whenever a node is visited in Info, the info file containing that node is read into core, and Info reads information about the tags and nodes contained in that file. Once the tags information is read by Info, it is never forgotten. However, the actual text of the nodes does not need to remain in core unless a particular info window needs it. For non-compressed files, the text of the nodes does not remain in core when it is no longer in use. But de-compressing a file can be a time consuming operation, and so Info tries hard not to do it twice. `gc-compressed-files` tells Info it is okay to garbage collect the text of the nodes of a file which was compressed on disk.

`show-index-match`

When set to `On`, the portion of the matched search string is highlighted in the message which explains where the matched search string was found. The default value of this variable is `On`. When Info displays the location where an index match was found, (see section Searching an Info File), the portion of the string that you had typed is highlighted by displaying it in the inverse case from its surrounding characters.

`scroll-behaviour`

Controls what happens when forward scrolling is requested at the end of a node, or when backward scrolling is requested at the beginning of a node. The default value for this variable is `Continuous`. There are three possible values for this variable:

`Continuous`

Tries to get the first item in this node's menu, or failing that, the `Next' node, or failing that, the `Next' of the `Up'. This behaviour is identical to using the `]' (`global-next-node`) and `[' (`global-prev-node`) commands.

`Next Only`

Only tries to get the `Next' node.

`Page Only`

Simply gives up, changing nothing. If `scroll-behaviour` is `Page Only`, no scrolling command can change the node that is being viewed.

- scroll-step The number of lines to scroll when the cursor moves out of the window. Scrolling happens automatically if the cursor has moved out of the visible portion of the node text when it is time to display. Usually the scrolling is done so as to put the cursor on the center line of the current window. However, if the variable `scroll-step` has a nonzero value, Info attempts to scroll the node text by that many lines; if that is

enough to bring the cursor back into the window, that is what is done. The default value of this variable is thus placing the cursor (and the text it is attached to) in the center of the window. Setting this variable to 1 causes a kind of "smooth scrolling" which some people prefer.

- ISO-Latin When set to `On`, Info accepts and displays ISO Latin-1 characters. By default, Info assumes an ASCII character set. `ISO-Latin` tells Info that it is running in an environment where the European standard character set is in use, and allows you to input such characters to Info, as well as display them.

@raisesections

Info 1.0

TOC

(1)

Of course, you can specify both the file and node in a `--node` command; but don't forget to escape the open and close parentheses from the shell as in: `info --node '(emacs)Buffers'`

(2)

`M-x` is also a command; it invokes `execute-extended-command`. See section 'Executing an extended command' in the GNU Emacs Manual, for more detailed information.

ISPELL V3.1

ISPELL V3.1

Using ispell from emacs

Checking a single word

The simplest emacs command for calling ispell is 'M-$' (meta-dollar. On some terminals, you must type ESC-$.) This checks the spelling of the word under the cursor. If the word is found in the dictionary, then a message is printed in the echo area. Otherwise, ISPELL attempts to generate near misses.

If any near misses are found, they are displayed in a separate window, each preceded by a digit or character. If one of these is the word you wanted, just type its digit or character, and it will replace the original word in your buffer.

If no near miss is right, or if none are displayed, you have five choices:

I

Insert the word in your private dictionary. Use this if you know that the word is spelled correctly.

A

Accept the word for the duration of this editing session, but do not put it in your private dictionary. Use this if you are not sure about the spelling of the word, but you do not want to look it up immediately, or for terms that appear in your document but are not truly words. The next time you start ispell, it will have forgotten any accepted words.

SPC

Leave the word alone, and consider it misspelled if it is checked again.

R

Replace the word. This command prompts you for a string in the minibuffer. You may type more than one word, and each word you type is checked again, possibly finding other near misses. This command provides a handy way to close in on a word that you have no idea how to spell. You can keep trying different spellings until you find one that is close enough to get a near miss.

L

Lookup. Display words from the dictionary that contain a specified substring. The substring is a regular expression, which means it can contain special characters to be more selective about which words get displayed. See section 'Regexps' in emacs.

If the only special character in the regular expression is a leading ^, then a very fast binary search will be used, instead of scanning the whole file.

Only a few matching words can be displayed in the ISPELL window. If you want to see more, use the `look` program directly from the shell.

Of course, you can also type ^G to stop the command without changing anything.

If you make a change that you don't like, just use emacs' normal undo feature See section 'undo' in emacs.

Checking a whole buffer

If you want to check the spelling of all the words in a buffer, type the command M-x ispell-buffer. This command scans the file, and makes a list of all the misspelled words. When it is done, it moves the cursor to the first word on the list, and acts like you just typed M-$ See section Checking a single word.

When you finish with one word, the cursor is automatically moved to the next. If you want to stop in the middle of the list type X or ^G.

Checking a region

You may check the words in the region with the command M-x ispell-region. See See section 'mark' in emacs.

The commands available are the same as for checking a whole buffer.

Using Multiple Dictionaries

Your site may have multiple dictionaries installed: a default one (usually `` `english.hash' ``), and several others for different languages (e.g. `` `deutsch.hash' ``) or variations on a language (such as British spelling for English).

`ispell-change-dictionary`

> This is the command to change the dictionary. It prompts for a new dictionary name, with completion on the elements of `ispell-dictionary`.
>
> It changes `ispell-dictionary` and kills the old ispell process, if one was running. A new one will be started as soon as necessary.
>
> By just answering RET you can find out what the current dictionary is.

`ispell-dictionary`

> If non-nil, a dictionary to use instead of the default one. This is passed to the ispell process using the `-d` switch and is used as key in `ispell-dictionary-alist`.
>
> You should set this variable before your first call to ispell (e.g. in your `` `.emacs' ``), or use the M-x ispell-change-dictionary command to change it, as changing this variable only takes effect in a newly started ispell process.

`ispell-dictionary-alist`

> An alist of dictionaries and their associated parameters.
>
> Each element of this list is also a list:
>
> ```
> (dictionary-name
>     casechars not-casechars otherchars many-otherchars-p
>     ispell-args)
> ```
>
> dictionary-name is a possible value of variable `ispell-dictionary`, `nil` means the default dictionary.

casechars is a regular expression of valid characters that comprise a word.

not-casechars is the opposite regexp of casechars.

otherchars is a regular expression of other characters that are valid in word constructs. Otherchars cannot be adjacent to each other in a word, nor can they begin or end a word. This implies we can't check `Stevens" as a correct possessive and other correct formations.

Hint: regexp syntax requires the hyphen to be declared first here.

many-otherchars-p is non-nil if many otherchars are to be allowed in a word instead of only one.

ispell-args is a list of additional arguments passed to the ispell subprocess.

Note that the casechars and otherchars slots of the alist should contain the same character set as casechars and otherchars in the language `.aff' file (e.g., `english.aff').

Old Emacs

Until ispell becomes part of the standard emacs distribution, you will have to explicitly request that it be loaded. Put the following lines in your emacs init file See section 'init file' in emacs.

```
(autoload 'ispell-word "ispell" "Check the spelling of word in buffer." t)
(autoload 'ispell-region "ispell" "Check the spelling of region." t)
(autoload 'ispell-buffer "ispell" "Check the spelling of buffer." t)
(global-set-key "\e$" 'ispell-word)
```

(It will do no harm to have these lines in your init file even after ispell is installed by default.)

Your private dictionary

Whenever ispell is started the file `.ispell_words' is read from your home directory (if it exists). This file contains a list of words, one per line. The order of the words is not important, but the case is. Ispell will consider all of the words good, and will use them as possible near misses.

The I command adds words to `.ispell_words', so normally you don't have to worry about the file. You may want to check it from time to time to make sure you have not accidentally inserted a misspelled word.

All commands in emacs mode

DIGIT

Select a near miss

I

Insert into private dictionary

A

Accept for this session

SPC

Skip this time

R

Replace with one or more words

L

Lookup: search the dictionary using a regular expression

M-$

Check word

M-x ispell-buffer

Check buffer

M-x ispell-region

Check region

M-x ispell-change-dictionary

Select different dictionary.

Definition of a near miss

Two words are near each other if they can be made identical with one of the following changes to one of the words:

```
Insert a blank space
Interchange two adjacent letters.
Change one letter.
Delete one letter.
Add one letter.
```

Someday, perhaps ispell will be extended so that words that sound alike would also be considered near misses. If you would like to implement this, see Knuth, Volume 3, page 392 for a description of the Soundex algorithm which might apply.

Where it came from

Ispell has a long and convoluted history. Originally called SPELL, it was written by Ralph E. Gorin in 1971. That version was written in assembly language for the DEC PDP-10 to run under the WAITS operating system at the Stanford Artificial Intelligence Laboratory. Subsequent versions, also in PDP-10 assembly language, were developed for the BBN TENEX, MIT ITS, and DEC TOPS-10 and TOPS-20 operating systems. It was later revised by W. E. Matson (1974), and W. B. Ackerman (1978), changing its name to ISPELL in the process.

In 1983, Pace Willisson (pace@ai.mit.edu) converted this version to the C language and modified it to work under Unix.

In 1987, Walt Buehring revised and enhanced ispell, and posted it to the Usenet along with a dictionary. In addition, Walt wrote the first version of "ispell.el", the emacs interface.

Geoff Kuenning (geoff@ITcorp.com, that's me, and by the way I pronounce it "Kenning") picked up this version, fixed many bugs, and added further enhancements. In 1988 I got ambitious and rewrote major portions of the code, resulting in the table-driven multi-lingual version. Ken Stevens (stevens@hplabs.hp.com) made overwhelming contributions to the elisp support to produce the version you are using now.

Due to a misunderstanding involving the Free Software Foundation, it later became necessary to rename this version to ispell to avoid confusion on the part of users.

Many other enhancements and bug fixes were provided by other people. Although I omit mention here due to space, many of these people have also made significant contributions to the version of ispell you see here. For a full list of people who have contributed to ispell, refer to the file `Contributors' which is distributed with the ispell sources.

Kpathsearch library

for version 1.6

February 1994

Karl Berry

Kpathsearch library

@defcodeindex cm @defcodeindex fl @defcodeindex op

Introduction

This manual corresponds to version 1.6 of the Kpathsearch library, released in February 1994.

The library's fundamental purpose is to look up a file in a list of directories specified by the user.

The following software, all of which I maintain, uses this library:

- web2c
- Xdvik
- Dvipsk (see section 'Introduction' in Dvips: A DVI driver)
- GNU font utilities (see section 'Introduction' in GNU font utilities)

The library is still under development. I do not promise to keep the interface unchanged. If you have comments or suggestions, please send them to me (see section Reporting bugs for the address).

Currently, I distribute the library under the GNU General Public License (see section GNU GENERAL PUBLIC LICENSE). In summary, this means if you write a program using the library, you must (offer to) distribute the source, and allow anyone to modify the source and distribute their modifications.

If you have a problem with this, please contact me. I would consider putting the library under the GNU Library General Public License, which would permit you to distribute the source only to the library, not the your program using it. But I will only do this if someone actually says they will not use the library under the GPL conditions, and would use it under the LGPL.

This manual contains a few references to the C source for the library; they're there to help programmers reconcile my statements in this documentation with the Awful Truth of the code. If you're not a programmer, just ignore them.

Installation

Here are the basic steps for configuration and installation:

@flindex configure

1. `configure`. This automatically determines most system dependencies.

@flindex Makefile, editing @flindex c-auto.h, editing

2. If necessary, edit the definitions in `` `Makefile' `` or `` `c-auto.h' ``. See section System dependencies, below, for additional definitions you may need to make.
3. `make`.
4. `make install`. This installs the library, header files, and documentation.
5. `make distclean`. This removes all files created by the build.

Since I only distribute Kpathsea as part of another package, you will probably be doing the above in a top-level directory that contains a `Makefile', `kpathsea', and the other package. But you can do the installation in `kpathsea' itself, if you only want to install the library, not the other package.

System dependencies

Although `configure` can reliably determine most aspects of your system, there are a few things it does not do.

Default paths

The directories into which files are installed are defined in the top-level `` `Makefile' ``. The default paths which programs use to search for inputs are defined in `` `kpathsea/paths.h' ``. You will almost certainly want to change either or both of these to match your preferred local directory structure.

Both of these files are automatically created: the `` `Makefile' `` at `configure' time, `` `kpathsea/paths.h' `` at compile time. Thus, to change the default paths, the simplest thing to do is edit the template files `` `Makefile.in' `` and `` `paths.h.in' `` before running `configure'.

The Make definitions are all repeated in several `` `Makefile' ``s; but changing the top-level `` `Makefile' `` should suffice, as it passes down all the variable definitions, thus overriding the submakes. (The definitions are repeated so people can potentially run Make in the subdirectories.)

The file `` `kpathsea/HIER' `` has some explanation of the default setup.

A caveat: If you put `$HOME' or `~' in any of the paths, do not search that component recursively: when you run as root, you might wind up searching (say) `` `/zoneinfo/Brazil/tex/macros' ``. And of course it will take quite some time to look at every directory on the system.

wchar_t

The upshot of all the following is that if you get error messages regarding `wchar_t`, try defining `NO_FOIL_X_WCHAR_T`. This is reported to be necessary on Linux.

`wchar_t` has caused infinite trouble. None of my code ever uses `wchar_t`; all I want to do is include X header files and various system header files, compiling with GCC. This seems an impossible task.

The X11R5 `` `<Xlib.h>' `` and GCC's `` `<stddef.h>' `` have conflicting definitions for wchar_t.

The particulars: `` `<X11/Xlib.h>' `` from MIT X11R5 defines `wchar_t` if `X_WCHAR` is defined, which is defined if `X_NOT_STDC_ENV` is defined, and we define *that* if `STDC_HEADERS` is not defined (`configure' decides if STDC_HEADERS gets defined). But when compiling with gcc on SunOS 4.1.x, `STDC_HEADERS` is not defined (`` `string.h' `` doesn't declare the `mem'* functions), so we do get X's `wchar_t`---and we also get gcc's `wchar_t` from its `` `<stddef.h>' ``. Result: conflicting definitions.

On the other hand, SunOS 4.1.1 with some other X configurations actually needs GCC to define `wchar_t`, and fails otherwise.

My current theory is to define `wchar_t` to a nonsense symbol before the X include files are read; that way its definition (if any) will be ignored by other system include files. Going along with that, define `X_WCHAR` to tell X not to use `` `<stddef.h>' ``, that we've already included, but instead to make its own definition.

But this is not the end of the story. The X11 include files distributed with DG/UX 5.4.2 for the Aviion have been modified to include `` `<_int_wchar_t.h>' `` if `X_WCHAR`, so our `#define` will not have any typedef to change--but the uses of `wchar_t` in the X include files will be changed to reference this undefined symbol. So there's nothing to foil in this case; I don't know how to detect this automatically, so it's up to you to define `NO_FOIL_X_WCHAR_T` yourself.

putenv

If you are on a Net2/BSD or other system which has a `putenv` that knows how to avoid garbage when the same environment variable is set many times, define `SMART_PUTENV`. (And if you can write a test for this that could be incorporated into the `configure` script, please send it to the address given in section Reporting bugs.)

The `configure` script

(This section is largely from the Autoconf manual, by David MacKenzie. See section 'Running `configure` scripts' in Autoconf.)

The `configure` script that comes with this distribution was generated by the Autoconf program. Thus, you can regenerate `configure` by rerunning Autoconf. You might want to do this if a new version of Autoconf is released, for example.

The purpose of `configure` is to adapt the present source to the particulars of your system. For example, the name of the directory header file (`` `dirent.h' `` or `` `sys/dir.h' ``), whether the GNU C compiler `gcc` is available, and so on.

@flindex #! in `configure` script Normally, you do not need to give any options to `configure`; just to the directory with the source code and type `configure'. Exceptions: if `.' is not in your `PATH`, you r type `./configure'; if you are using a non-Bourne compatible shell on systems that do not support `#!', you must type `sh configure'.

@opindex -v option to `configure` @flindex /dev/null Running `configure` takes a minute or two. While it is running, it prints some messages that tell what it is doing. If you don't want to see the messages, run `configure` with its standard output redirected to `/dev/null'; e.g., `configure >/dev/null'. On the other hand, if you want to see even more messages, give `configure` the `-v' option.

To compile the package in a different directory from the one containing the source code, you must use a variant of Make that supports the `VPATH` variable, such as GNU Make. `cd` to the directory where you want the object files and executables to go and run `configure` with the option `--srcdir=dir', where dir is the directory that contains the source code. Using this option is unnecessary if the source code is in the parent directory of the one in which you are compiling; `configure` automatically checks for the source code in `..' if it does not find it in `.'.

@flindex /usr/local default prefix `configure` (in the top-level directory) guesses the default installation prefix (we'll call it `$(prefix)`, which is the corresponding Make variable) by looking for a directory which contains an executable named `tex', and using its parent. In the package subdirectories, such as `kpathsea', `configure` doesn't try to guess the prefix (to avoid a conflict with the guess made at the top level); the default `/usr/local' is left.

@opindex --prefix option to `configure` @opindex --exec-prefix option to `configure` You can override this default guess for the installation prefix by giving `configure` the option `--prefix=path'. You can also specify separate installation prefixes for architecture-specific files and architecture-independent files by giving `configure` the option `--exec-prefix=xpath' (which substitutes for the Make variable `$(exec_prefix)'). Then xpath will be the prefix for installing programs and libraries. Data files and documentation will still use `$(prefix)'.

@flindex config.status @opindex --no-create option to `configure` @opindex --recheck option to `config.status` You can tell `configure` to figure out the configuration for your system, and record it in a file `config.status', without actually configuring the package. To do this, give `configure` the `--no-create' option. Later, you can run `./config.status' to actually configure the package. This option is useful mainly in `Makefile' rules for updating `config.status' and the `Makefile' itself. You can also give `config.status' the `--recheck' option, which makes it rerun `configure` with the same arguments you used before. This is useful if you change `configure`.

`configure` ignores any other arguments that you give it.

On systems that require unusual options for compilation or linking that the package's `configure` script does not know about, you can give `configure` initial values for variables by setting them in the environment. In Bourne-compatible shells, you can do that on the command line like this:

```
CC='gcc -traditional' LIBS=-lposix sh configure
```

The Make variables that you might want to override with environment variables when running `configure` are:

(For these variables, any value given in the environment overrides the value that `configure` would

choose.)

`CC`

The C compiler program. The default is `gcc` if that is in your `PATH`, `cc` otherwise.

`INSTALL`

The program to use to install files. The default is `install` if you have it, `cp` otherwise.

(For these variables, any value given in the environment is added to the value that `configure` chooses.)

`DEFS`

Configuration options, in the form `-Dfoo -Dbar...'.

`LIBS`

Libraries to link with, in the form `-lfoo -lbar...'.

@flindex configure.in Of course, problems requiring manual intervention (e.g., setting these variables) should ideally be fixed by updating either the Autoconf macros or the `` `configure.in' `` file for that package.

Reporting bugs

@flindex tex-k@cs.umb.edu bug address If you encounter problems, report them to `tex-k@cs.umb.edu'. Include the version number of the library, the system you are using, and enough information to reproduce the bug in your report. To get on this mailing list yourself, email `tex-k-request@cs.umb.edu' with a message whose body contains a line

```
subscribe your-preferred-email-address
```

To avoid wasted effort and time (both mine and yours), I strongly advise applying the principles given in the GNU C manual (see section 'Reporting Bugs' in The GNU CC manual) to your bug reports for any software.

Please also report bugs in this documentation--not only factual errors, but unclear explanations, typos, wrong fonts, ...

When compiling with old C compilers, you may get some warnings about "illegal pointer combinations". These are spurious; ignore them. I do not want to clutter up the source with casts to get rid of them. In general, if you have trouble with a system C compiler, I advise trying the GNU C compiler.

Path specifications

This chapter describes the user interface of the path specifications that the Kpathsearch library implements.

Conceptually, there are two distinct stages: generating a list of directories in which to search, and then looking up files using that list. The sections below describe each of these in turn.

In the implementation, however, these stages are interleaved--directory lists are only generated as needed for a particular file lookup, then they are cached for future lookups. (Analogous to lazy evaluation in programming languages.) This implies that directories that are created *during* the run are not seen.

Directory list generation

Kpathsearch constructs a directory list from an environment variable var set by the user, (possibly) a setting from a configuration file, and a default path set at compile time. Each of these are colon-separated lists of directories. If var is set, its value is used; otherwise, if a config file defines a value, that value is used; otherwise, the compilation default is used. In any case, once the path specification to use is determined, its evaluation is independent of its source.

The "colon" and "slash" mentioned below aren't necessarily `:' and `/' on non-Unix systems; the library tries to adapt these characters to other operating systems' conventions.

The following subdirectories explain the various kinds of expansion the path is subjected to. After expansion, nonexistent directories in the path is ignored.

Default expansion

If an environment variable or config file value has a leading or trailing or doubled colon, the default path is inserted at that point.

Putting an extra colon into the default value has unpredictable results, and may cause the program to crash, so installers beware.

Tilde expansion

A leading `~' or `~user' in a path component is replaced by the current or user's home directory, respectively.

If user is invalid, or the home directory cannot be determined, Kpathsea uses `.' instead.

Variable expansion

A construct `$foo' or `${foo}' is replaced by the expansion of the environment variable `foo'. In the first case, the variable name consists of consecutive alphanumeric-or-underscore characters. In the second, the variable name consists of everything between the braces.

Remember to quote the `$"s and braces as necessary for your shell.

Shell variable values cannot be seen by Kpathsea.

Subdirectory expansion

If a component directory d contains `//', all subdirectories of d are included in the path: first those subdirectories directly under d, then the subsubdirectories under those, and so on. At each level, the order in which the directories are searched is unspecified.

If you specify any filename components after the `//', only subdirectories which have those components are included. For example, `/a//b' would expand into directories `/a/1/b', `/a/2/b', `/a/1/1/b', and so on, but not `/a/b/c' or `/a/1'.

Subdirectory problems

Perhaps the first problem is best put as a question-and-answer.

Question: I know all about slow starting TeX `:-)'. How do I organize the directory scheme to avoid the slowness, while at the same time enjoying a structured inputs directory?

(Naturally, this applies to any Kpathsea-using program, not just TeX.)

I will give the false Short Answer first, then the Real Explanation.

The Short Answer: in your equivalent of `/usr/local/lib/tex/macros//' and `.../fonts//', make each subdirectory contain either 1) only directories; or 2) only files.

As long as you do not have (literally) hundreds of subdirectories, this should cure the problem. It has in every case I have been told about.

The Real Explanation: the thing that makes TeX slow is calling `stat` (if you don't know what `stat` (2) is, ignore this explanation) on "too many" pathnames, where "too many" is some nebulous number depending on things like whether the filesystem is NFS-mounted or not, whether it's on a fast disk, whether your Fast File System implementation is really Fast, etc., etc.

(Side note: If you're curious, you can find this number by writing a program that does nothing but read filenames (presumably from a file) and stat them, and see how many pathnames make the execution time noticeable. On the systems I use (Suns with an NFS-mounted directory, ISC 2.2.1 and a local directory), it's several hundred, at least. On an NFS-mounted mounted directory under Solaris 2.1, 150 is quite slow, according to `hammer@kis.uni-freiburg.de'.)
