Whether or not it's directories or files that are being stat-ed is irrelevant (this is why the Short Answer is false). It's sheer numbers that count.

@flindex debug.h If you think your directory structure is ok, and you're still experiencing slowness, I advise running TeX (or whatever program) under a debugger, setting the bit `DEBUG_STAT` in the variable `kpathsea_debug` (see `debug.h') to one and seeing exactly what is getting stat-ed. If only a few things are getting stat-ed, and TeX is still slow, tell me.

I should also mention "the trick", which I stole from GNU find. (Matthew Farwell `<dylan@ibmpcug.co.uk>' suggested it, and David MacKenzie `<djm@gnu.ai.mit.edu>' implemented it, I believe.)

The trick is that in every real Unix implementation (that I know about) (as opposed to the POSIX specification), a directory which contains no subdirectories will have exactly two links (specifically, one each for `.' and `..'). That is to say, the `st_nlink` field in the stat structure will be two. Thus, the path searching code doesn't have to stat every entry in the bottom-level directories--it can check `st_nlink`, and if it's two, it knows there are no subdirectories.

But if you have a directory that contains *one* subdirectory and five hundred files, st_nlink will be 3, and Kpathsea has to stat every one of those 501 entries. Therein lies slowness.

You can disable the trick by undefining UNIX_ST_LINK in `kpathsea/config.h'.

The subdirectory searching has one other known (and irreconciliable) deficiency. If a directory d being

searched for subdirectories contains plain files and symbolic links to other directories, but no true subdirectories, d will be considered a leaf directory, i.e., the symbolic links will not be followed.

The directory immediately followed by the `//', however, is always searched for subdirectories, even if it is a "leaf". We do this since presumably you would not have asked for the directory to be searched for subdirectories if you didn't want it to be.

This is a consequence of the trick explained above. You can work around this problem by simply creating an empty dummy subdirectory in d; then d will no longer be a leaf, and the symlinks will be followed.

Path specification example

For example, the following value for an environment variable says to search the following: the current user's `fonts' directory and alll its subdirectories, then the directory `fonts' in user `karl's home directory, and finally the system default directories specified at compilation time.

```
~/fonts//:~karl/fonts:
```

File lookups

Given the directory list generated from the rules in the previous section, looking up a file presents no problem at all: we just look in each directory in the list in turn, and return the first one found.

The only complication is if the filename is absolute or explicitly relative, i.e., (under Unix-like operating systems) starts with `/' or `./' or `../'. Then the library does not use the directory list at all. Instead, the file is simply searched for in the given directory.

TeX support

Although the basic features in Kpathsea can be used for any type of path searching, I wrote Kpathsea specifically for TeX system programs. I had been struggling with the programs I was using (Dvips, Xdvi, and TeX itself) having slightly different notions of how to specify paths; and debugging was painful, since no code was shared.

Therefore, Kpathsea provides some TeX-specific features. Indeed, many of the supposedly generic path searching features were provided because it seemed useful in conTeXt, particularly for font lookup.

TeX environment variables

Kpathsea defines a sequence of environment variables to search for each type of TeX file. This makes it easy for different programs to check the same environment variables, in the same order.

The following table lists the environment variables searched for each file type in the order they are searched (and a brief description of the file type). That is, only if the first variable is unset is the second variable checked, and so on. If none are set, a default set at compilation time is used.

`.base'

@flindex .base (Metafont memory dump) `MFBASES'

`.bib'

@flindex .bib (BibTeX source) `BIBINPUTS'

`.bst'

@flindex .bst (BibTeX style file) `BSTINPUTS', `TEXINPUTS'

`.fmt'

@flindex .fmt (TeX memory dump) `TEXFORMATS'

`gf'

@flindex .gf (generic font bitmap) `GFFONTS', `GLYPHFONTS', `TEXFONTS'

`.mf'

@flindex .mf (Metafont source) `MFINPUTS'

`mf.pool'

@flindex .pool (Metafont program strings) `MFPOOL'

`pk'

@flindex .pk (packed bitmap font) `PKFONTS', `TEXPKS', `GLYPHFONTS', `TEXFONTS'

`.tex'

@flindex .tex (TeX source) `TEXINPUTS'

`tex.pool'

@flindex .pool (TeX program strings) `TEXPOOL'

`.tfm'

@flindex .tfm (TeX font metrics) `TFMFONTS', `TEXFONTS'

`.vf'

@flindex .vf (virtual font) `VFFONTS', `TEXFONTS'

@flindex kpathsea/filefmt.h These lists are defined in the source file `kpathsea/filefmt.h'.

For the font variables, the intent is that:

1. `TEXFONTS' is the default for everything.
2. `GLYPHFONTS' the default for bitmap (or, more precisely, non-metric) files.
3. Each format has its own variable.
4. Not shown in the table is that each program can and should have its own path as well---`XDVIFONTS' and `DVIPSFONTS' in the case of Xdvik and Dvipsk.

Glyph lookup

@flindex kpathsea/tex-glyph.c Kpathsea provides a routine (`kpse_find_glyph_format` in `kpathsea/tex-glyph.c`) which searches for a bitmap font in GF or PK format (or either) given a font name (e.g., `cmr10') and a resolution (e.g., 300).

The search is based solely on filenames, not file contents--if a PK file is named `cmr10.300gf', it will be found as a GF file.

Here is an outline of the search strategy (details in the sections below) for a file name at resolution dpi. The search stops at the first successful lookup.

1. Look for an existing file name.dpi in the specified formats.
2. If name is an alias for a file a in some "fontmap" file, look for a.dpi.
3. Run an external script (typically named `MakeTeXPK`) to generate the font.
4. Look for fallback.dpi, where fallback is some last-resort font (typically `cmr10').

Basic glyph lookup

When Kpathsea looks for a bitmap font name at resolution dpi in a format format, it first checks if a file `name.dpiformat' exists; for example, `cmr10.300pk'. Kpathsea looks for a PK file first, then a GF file.

If that fails, Kpathsea looks for a font with a close-enough dpi. "Close enough" is defined (by the macro `KPSE_BITMAP_TOLERANCE` in `` `kpathsea/tex-glyph.h' ``) to be `dpi / 500 + 1`, which is slightly more than the 0.2% allowed by the DVI standard.

The filename is not hardwired to `name.dpiformat'; you can change it by setting the environment variable `KPATHSEA_BITMAP_NAME' to a different specification. The default spec is

```
$KPATHSEA_NAME.$KPATHSEA_DPI$KPATHSEA_FORMAT
```

Kpathsea sets these environment variables as it runs, as appropriate for each lookup. You can use any environment variables you like, not just these, in the spec.

Fontmap

If a bitmap font is not found, Kpathsea looks through any fontmap files for an alias for the original font name. I implemented this for two reasons:

1. An alias name is limited in length only by your available memory, not by whatever bizarre limitations your filesystem might impose. Therefore, if you want to ask for `` `Adobe-Lucida-Bold-Sans=Typewriter--10' `` instead of `` `plcbst10' ``, you can.
2. A few fonts have historically had multiple names: specifically, LaTeX's "circle font" has variously been known as `` `circle10' ``, `` `lcircle10' ``, and `` `lcirc10' ``. Aliases can make all the names equivalent, so that it no longer matters what the name of the installed file is; TeX documents will find their favorite name.

The format of fontmap files that implement these ideas is straightforward: the first word on each line is the true filename; the second word is the alias; subsequent words are ignored. A word is just a sequence of non-whitespace characters. Blank lines are ignored; comments start with `%' and continue to end-of-line.

If an alias has an extension, it matches only those files with that extension; otherwise, it matches anything with the same root, regardless of extension. For example, an alias `foo.tfm' matches only when exactly `` `foo.tfm' `` is being searched for; but an alias `foo' matches `` `foo.vf' ``, `` `foo.300pk' ``, or whatever.

As an example, here are the fontmap entries that make the circle fonts equivalent:

```
circle10        lcircle10
circle10        lcirc10
lcircle10       circle10
lcircle10       lcirc10
lcirc10         circle10
lcirc10         lcircle10
```

`MakeTeX'... scripts

If Kpathsea cannot find a bitmap font, by either its original name or a fontmap alias, it can be configured to invoke an external program to create it. The same mechanism can be used for other nonexistent files.

The script is passed the name of the file to create and possibly other arguments, as explained below. It must echo the full pathname of the file it created (and nothing else) to standard output; it can write diagnostics to standard error.

`MakeTeX'... script names

@flindex tex-make.c The following table shows the default name of the script for each possible file types. (The source is the variable `kpse_make_specs` in `kpathsea/tex-make.c'.)

`MakeTeXPK'
: Glyph fonts.

`MakeTeXTeX'
: TeX input files.

`MakeTeXMF'
: Metafont input files.

`MakeTeXTFM'
: TFM files.

These names are overridden by an environment variable specific to the program---`DVIPSMAKEPK' and `XDVIMAKEPK', in the case of Dvipsk and Xdvik.

`MakeTeX'... script arguments

The first argument to a `MakeTeX'... script is always the name of the file to be created. In the case of `MakeTeXPK', there are three or four additional arguments passed, via corresponding environment variables:

1. The dpi to make the font at (`KPATHSEA_DPI').
2. The "base dpi" the program is operating at (`MAKETEX_BASE_DPI').
3. A "magstep" string suitable for assigning to the Metafont `mag` variable (`MAKETEX_MAG').
4. Possibly, a Metafont mode name for assigning to the Metafont `mode` variable (`MAKETEX_MODE').

Kpathsea sets `KPATHSEA_DPI' appropriately for each font. It's up to the program using Kpathsea to set the others.

You can change the specification for the arguments passed to the external script by setting the environment

variable named as the script name, but all capitals---`MAKETEXPK', for example. If you've changed the script name by setting (say) `DVIPSMAKEPK' to `foo', then the spec is taken from the environment variable `FOO'.

The spec can contain any variable references, to the above variables or any others you might have set. As an example, the default spec for `MakeTeXPK' is

```
$KPATHSEA_DPI $MAKETEX_BASE_DPI $MAKETEX_MAG $MAKETEX_MODE
```

The name of the file to be created being passed as the first argument cannot be changed.

Fallback font

If a bitmap font cannot be found or created at the requested size, Kpathsea looks for the font at a set of fallback resolutions. You specify these resolutions as a colon-separated list (like search paths). Kpathsea looks first for a program-specific environment variable (`DVIPSSIZES' and `XDVISIZES', in the case of Dvipsk and Xdvik), then the environment variable `TEXSIZES', then a default specified at compilation time (the Make variable `default_texsizes`). You can set this list to be empty if you prefer to find fonts at their stated size or not at all.

Finally, if the font cannot be found even at the fallback resolutions, Kpathsea looks for a fallback font, typically `cmr10'. Programs must enable this feature by assigning to the global variable `kpse_fallback_font`; the default is no such fallback font.

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

```
Copyright (C) 1989, 1991 Free Software Foundation, Inc.
675 Mass Ave, Cambridge, MA 02139, USA

Everyone is permitted to copy and distribute verbatim copies
of this license document, but changing it is not allowed.
```

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the

software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.
2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

   You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

3. You may modify your copy or copies of the Program or any portion of it, thus forming a work bas on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:
    1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
    2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
    3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

    These requirements apply to the modified work as a whole. If identifiable sections of that work are not derived from the Program, and can be reasonably considered independent and separate works in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

    Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

    In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.
4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for noncommercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

    The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus

any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.

5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.
6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on it.
7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

   If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

   It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

   This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.

9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.
11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

Appendix: How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and a brief idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or modify
it under the terms of the GNU General Public License as published by
the Free Software Foundation; either version 2 of the License, or
(at your option) any later version.

This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details type `show w'.
This is free software, and you are welcome to redistribute it
under certain conditions; type `show c' for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright interest in the program
`Gnomovision' (which makes passes at compilers) written by James Hacker.

signature of Ty Coon, 1 April 1989
```

Ty Coon, President of Vice

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License instead of this License.

Regain your programming freedom

Until a few years ago, programmers in the United States could write any program they wished. This freedom has now been taken away by two developments: software patents, which grant the patent holder an absolute monopoly on some programming technique, and user interface copyright, which forbid compatible implementations of an existing user interface.

In Europe, especially through the GATT treaty, things are rapidly approaching the same pass.

Software patents

The U.S. Patent and Trademark Office has granted numerous software patents on software techniques. Patents are an absolute monopoly--independent reinvention is precluded. This monopoly lasts for seventeen years, i.e., forever (with respect to computer science).

One patent relevant to TeX is patent 4,956,809, issued to the Mark Williams company on September 11, 1990, applied for in 1982, which covers (among other things)

> representing in a standardized order consisting of a standard binary structure file stored on auxiliary memory or transported on a communications means, said standardized order being different from a different order used on at least one of the different computers;
>
> Converting in each of the different computers binary data read from an auxiliary data storage or communications means from the standardized order to the natural order of the respective host computer after said binary data are read from said auxiliary data storage or communications means and before said binary data are used by the respective host computer; and
>
> Converting in each of the different computers binary data written into auxiliary data storage or communications means from the natural order of the respective host computer to the standardized order prior to said writing.

... in other words, storing data on disk in a machine-independent order, as the DVI, TFM, GF, and PK file formats specify. Even though TeX is "prior art" in this respect, the patent was granted (the patent examiners not being computer scientists, even less computer typographers). Since there is a strong presumption in the courts of a patent's validity once it has been granted, there is a good chance that users or implementors of TeX could be successfully sued on the issue.

As another example, the X window system, which was intended to be able to be used freely by everyone, is now being threatened by two patents: 4,197,590 on the use of exclusive-or to redraw cursors, held by Cadtrak, a litigation company (this has been upheld twice in court); and 4,555,775, held by AT&T, on the use of backing store to redraw windows quickly.

Here is one excerpt from a recent mailing by the League for Programming Freedom (see section What to do?) which I feel sums up the situation rather well. It comes from an article in Think magazine, issue #5, 1990. The comments after the quote were written by Richard Stallman.

> "You get value from patents in two ways," says Roger Smith, IBM Assistant General Counsel, intellectual property law. "Through fees, and through licensing negotiations that give IBM access to other patents.
>
> "The IBM patent portfolio gains us the freedom to do what we need to do through cross-licensing--it gives us access to the inventions of others that are the key to rapid innovation. Access is far more valuable to IBM than the fees it receives from its 9,000 active patents. There's no direct calculation of this value, but it's many times larger than the fee income, perhaps an order of magnitude larger."

This information should dispel the belief that the patent system will "protect" a small software developer from competition from IBM. IBM can always find patents in its collection which the small developer is infringing, and thus obtain a cross-license.

However, the patent system does cause trouble for the smaller companies which, like IBM, need access to patented techniques in order to do useful work in software. Unlike IBM, the smaller companies do not have 9,000 patents and cannot usually get a cross-license. No matter how hard they try, they cannot have enough patents to do this.

Only the elimination of patents from the software field can enable most software developers to continue with their work.

The value IBM gets from cross-licensing is a measure of the amount of harm that the patent system would do to IBM if IBM could not avoid it. IBM's estimate is that the trouble could easily be ten times the good one can expect from one's own patents--even for a company with 9,000 of them.

User interface copyright

(This section is copied from the GCC manual, by Richard Stallman.)

> *This section is a political message from the League for Programming Freedom to the users of the GNU font utilities. It is included here as an expression of support for the League on my part.*

Apple, Lotus and Xerox are trying to create a new form of legal monopoly: a copyright on a class of user interfaces. These monopolies would cause serious problems for users and developers of computer software and systems.

Until a few years ago, the law seemed clear: no one could restrict others from using a user interface; programmers were free to implement any interface they chose. Imitating interfaces, sometimes with changes, was standard practice in the computer field. The interfaces we know evolved gradually in this way; for example, the Macintosh user interface drew ideas from the Xerox interface, which in turn drew on work done at Stanford and SRI. 1-2-3 imitated VisiCalc, and dBase imitated a database program from JPL.

Most computer companies, and nearly all computer users, were happy with this state of affairs. The companies that are suing say it does not offer "enough incentive" to develop their products, but they must have considered it "enough" when they made their decision to do so. It seems they are not satisfied with the opportunity to continue to compete in the marketplace--not even with a head start.

If Xerox, Lotus, and Apple are permitted to make law through the courts, the precedent will hobble the software industry:

- Gratuitous incompatibilities will burden users. Imagine if each car manufacturer had to arrange the pedals in a different order.
- Software will become and remain more expensive. Users will be "locked in" to proprietary interfaces, for which there is no real competition.
- Large companies have an unfair advantage wherever lawsuits become commonplace. Since they can easily afford to sue, they can intimidate small companies with threats even when they don't really have a case.
- User interface improvements will come slower, since incremental evolution through creative imitation will no longer be permitted.
- Even Apple, etc., will find it harder to make improvements if they can no longer adapt the good ideas that others introduce, for fear of weakening their own legal positions. Some users suggest that this stagnation may already have started.
- If you use GNU software, you might find it of some concern that user interface copyright will make it hard for the Free Software Foundation to develop programs compatible with the interfaces that you already know.

What to do?

(This section is copied from the GCC manual, by Richard Stallman.)

To protect our freedom from lawsuits like these, a group of programmers and users have formed a new grass-roots political organization, the League for Programming Freedom.

The purpose of the League is to oppose new monopolistic practices such as user-interface copyright and software patents; it calls for a return to the legal policies of the recent past, in which these practices were not allowed. The League is not concerned with free software as an issue, and not affiliated with the Free Software Foundation.

The League's membership rolls include John McCarthy, inventor of Lisp, Marvin Minsky, founder of the Artificial Intelligence lab, Guy L. Steele, Jr., author of well-known books on Lisp and C, as well as Richard Stallman, the developer of GNU CC. Please join and add your name to the list. Membership dues in the League are $42 per year for programmers, managers and professionals; $10.50 for students; $21 for others.

The League needs both activist members and members who only pay their dues.

To join, or for more information, phone (617) 492-0023 or write to:

```
League for Programming Freedom
1 Kendall Square #143
P.O. Box 9171
Cambridge, MA 02139
```

You can also send electronic mail to `league@prep.ai.mit.edu`.

Here are some suggestions from the League for things you can do to protect your freedom to write programs:

- Don't buy from Xerox, Lotus or Apple. Buy from their competitors or from the defendants they ar suing.
- Don't develop software to work with the systems made by these companies.
- Port your existing software to competing systems, so that you encourage users to switch.
- Write letters to company presidents to let them know their conduct is unacceptable.
- Tell your friends and colleagues about this issue and how it threatens to ruin the computer industry.
- Above all, don't work for the look-and-feel plaintiffs, and don't accept contracts from them.
- Write to Congress to explain the importance of this issue.

```
House Subcommittee on Intellectual Property
2137 Rayburn Bldg
Washington, DC 20515

Senate Subcommittee on Patents, Trademarks and Copyrights
United States Senate
Washington, DC 20510
```

(These committees have received lots of mail already; let's give them even more.)

Express your opinion! You can make a difference.

to the GNU C++ Library

last updated April 29, 1992

for version 2.0

Doug Lea (dl@g.oswego.edu)

Go to the next section.

Note: The GNU C++ library is still in test release. You will be performing a valuable service if you report any bugs you encounter.

Contributors to GNU C++ library

Aside from Michael Tiemann, who worked out the front end for GNU C++, and Richard Stallman, who worked out the back end, the following people (not including those who have made their contributions to GNU CC) should not go unmentioned.

- Doug Lea contributed most otherwise unattributed classes.
- Per Bothner contributed the iostream I/O classes.
- Dirk Grunwald contributed the Random number generation classes, and PairingHeaps.
- Kurt Baudendistel contributed Fixed precision reals.
- Doug Schmidt contributed ordered hash tables, a perfect hash function generator, and several other utilities.
- Marc Shapiro contributed the ideas and preliminary code for Plexes.
- Eric Newton contributed the curses window classes.
- Some of the I/O code is derived from BSD 4.4, and was developed by the University of California, Berkeley.
- The code for converting accurately between floating point numbers and their string representations was written by David M. Gay of AT&T.

Go to the previous, next section.

Installing GNU C++ library

1. Read through the README file and the Makefile. Make sure that all paths, system-dependent compile switches, and program names are correct.
2. Check that files `values.h', `stdio.h', and `math.h' declare and define values appropriate for your system.
3. Type `make all' to compile the library, test, and install. Current details about contents of the tests and utilities are in the `README' file.

Go to the previous, next section.

Go to the previous, next section.

Trouble in Installation

Here are some of the things that have caused trouble for people installing GNU C++ library.

1. Make sure that your GNU C++ version number is at least as high as your libg++ version number. For example, libg++ 1.22.0 requires g++ 1.22.0 or later releases.
2. Double-check system constants in the header files mentioned above.

Go to the previous, next section.

Go to the previous, next section.

GNU C++ library aims, objectives, and limitations

The GNU C++ library, libg++ is an attempt to provide a variety of C++ programming tools and other support to GNU C++ programmers.

Differences in distribution policy are only part of the difference between libg++.a and AT&T libC.a. libg++ is not intended to be an exact clone of libC. For one, libg++ contains bits of code that depend on special features of GNU g++ that are either different or lacking in the AT&T version, including slightly different inlining and overloading strategies, dynamic local arrays, etc. All of these differences are minor. For example, while the AT&T and GNU stream classes are implemented in very different ways, the vast majority of C++ programs compile and run under either version with no visible difference. Additionally, all g++-specific constructs are conditionally compiled; The library is designed to be compatible with any 2.0 C++ compiler.

libg++ has also contained workarounds for some limitations in g++: both g++ and libg++ are still undergoing rapid development and testing--a task that is helped tremendously by the feedback of active users. This manual is also still under development; it has some catching up to do to include all the facilities now in the library.

libg++ is not the only freely available source of C++ class libraries. Some notable alternative sources are Interviews and NIHCL. (InterViews has been available on the X-windows X11 tapes and also from interviews.stanford.edu. NIHCL is available by anonymous ftp from GNU archives (such as the pub directory of prep.ai.mit.edu), although it is not supported by the FSF - and needs some work before it will work with g++.)

As every C++ programmer knows, the design (moreso than the implementation) of a C++ class library is something of a challenge. Part of the reason is that C++ supports two, partially incompatible, styles of object-oriented programming -- The "forest" approach, involving a collection of free-standing classes that can be mixed and matched, versus the completely hierarchical (smalltalk style) approach, in which all classes are derived from a common ancestor. Of course, both styles have advantages and disadvantages. So far, libg++ has adopted the "forest" approach. Keith Gorlen's OOPS library adopts the hierarchical approach, and may be an attractive alternative for C++ programmers who prefer this style.

Currently (and/or in the near future) libg++ provides support for a few basic kinds of classes:

The first kind of support provides an interface between C++ programs and C libraries. This includes basic header files (like `` `stdio.h' ``) as well as things like the File and stream classes. Other classes that interface to other aspects of C libraries (like those that maintain environmental information) are in various stages of development; all will undergo implementation modifications when the forthcoming GNU libc library is released.

The second kind of support contains general-purpose basic classes that transparently manage

variable-sized objects on the freestore. This includes Obstacks, multiple-precision Integers and Ratio arbitrary length Strings, BitSets, and BitStrings.

Third, several classes and utilities of common interest (e.g., Complex numbers) are provided.

Fourth, a set of pseudo-generic prototype files are available as a mechanism for generating common container classes. These are described in more detail in the introduction to container prototypes. Currently, only a textual substitution mechanism is available for generic class creation.

Go to the previous, next section.

Go to the previous, next section.

GNU C++ library stylistic conventions

- C++ source files have file extension `.cc'. Both C-compatibility header files and class declaration files have extension `.h'.
- C++ class names begin with capital letters, except for `istream` and `ostream`, for AT&T C++ compatibility. Multi-word class names capitalize each word, with no underscore separation.
- Include files that define C++ classes begin with capital letters (as do the names of the classes themselves). `stream.h' is uncapitalized for AT&T C++ compatibility.
- Include files that supply function prototypes for other C functions (system calls and libraries) are all lower case.
- All include files define a preprocessor variable _X_h, where X is the name of the file, and conditionally compile only if this has not been already defined. The `#pragma once` facility is also used to avoid re-inclusion.
- Structures and objects that must be publicly defined, but are not intended for public use have names beginning with an underscore. (for example, the `_Srep` struct, which is used only by the String and SubString classes.)
- The underscore is used to separate components of long function names, e.g., `set_File_exception_handler()`.
- When a function could be usefully defined either as a member or a friend, it is generally a member if it modifies and/or returns itself, else it is a friend. There are cases where naturalness of expression wins out over this rule.
- Class declaration files are formatted so that it is easy to quickly check them to determine function names, parameters, and so on. Because of the different kinds of things that may appear in class declarations, there is no perfect way to do this. Any suggestions on developing a common class declaration formatting style are welcome.
- All classes use the same simple error (exception) handling strategy. Almost every class has a member function named `error(char* msg)` that invokes an associated error handler function via a pointer to that function, so that the error handling function may be reset by programmers. By default nearly all call `*lib_error_handler`, which prints the message and then aborts execution. This system is subject to change. In general, errors are assumed to be non-recoverable: Library classes do not include code that allows graceful continuation after exceptions.

Go to the previous, next section.

Support for representation invariants

Most GNU C++ library classes possess a method named `OK()`, that is useful in helping to verify correct performance of class operations.

The `OK()` operations checks the "representation invariant" of a class object. This is a test to check whether the object is in a valid state. In effect, it is a (sometimes partial) verification of the library's promise that (1) class operations always leave objects in valid states, and (2) the class protects itself so that client functions cannot corrupt this state.

While no simple validation technique can assure that all operations perform correctly, calls to `OK()` can at least verify that operations do not corrupt representations. For example for `String a, b, c; ... a = b + c;`, a call to `a.OK();` will guarantee that `a` is a valid `String`, but does not guarantee that it contains the concatenation of `b + c`. However, given that `a` is known to be valid, it is possible to further verify its properties, for example via `a.after(b) == c && a.before(c) == b`. In other words, `OK()` generally checks only those internal representation properties that are otherwise inaccessible to users of the class. Other class operations are often useful for further validation.

Failed calls to `OK()` call a class's `error` method if one exists, else directly call `abort`. Failure indicates an implementation error that should be reported.

With only rare exceptions, the internal support functions for a class never themselves call `OK()` (although many of the test files in the distribution call `OK()` extensively).

Verification of representational invariants can sometimes be very time consuming for complicated data structures.

Introduction to container class prototypes

As a temporary mechanism enabling the support of generic classes, the GNU C++ Library distribution contains a directory (`g++-include') of files designed to serve as the basis for generating container classes of specified elements. These files can be used to generate `.h' and `.cc' files in the current directory via a supplied shell script program that performs simple textual substitution to create specific classes.

While these classes are generated independently, and thus share no code, it is possible to create versions that do share code among subclasses. For example, using `typedef void* ent`, and then generating a `entList` class, other derived classes could be created using the `void*` coercion method described in Stroustrup, pp204-210.

This very simple class-generation facility is useful enough to serve current purposes, but will be replaced with a more coherent mechanism for handling C++ generics in a way that minimally disrupts current usage. Without knowing exactly when or how parametric classes might be added to the C++ language, provision of this simplest possible mechanism, textual substitution, appears to be the safest strategy, although it does require certain redundancies and awkward constructions.

Specific classes may be generated via the `genclass' shell script program. This program has arguments specifying the kinds of base types(s) to be used. Specifying base types requires two arguments. The first is the name of the base type, which may be any named type, like `int` or `String`. Only named types are supported; things like `int*` are not accepted. However, pointers like this may be used by supplying the appropriate typedefs (e.g., editing the resulting files to include `typedef int* intp;`). The type name must be followed by one of the words `val` or `ref`, to indicate whether the base elements should be passed to functions by-value or by-reference.

You can specify basic container classes using `genclass base [val,ref] proto`, where `proto` is the name of the class being generated. Container classes like dictionaries and maps that require two types may be specified via `genclass -2 keytype [val, ref], basetype [val, ref] proto`, where the key type is specified first and the contents type second. The resulting classnames and filenames are generated by prepending the specified type names to the prototype names, and separating the filename parts with dots. For example, `genclass int val List` generates class `intList` residing in files `int.List.h' and `int.List.cc'. `genclass -2 String ref int val VHMap` generates (the awkward, but unavoidable) class name `StringintVHMap`. Of course, programmers may use `typedef` or simple editing to create more appropriate names. The existence of dot seperators in file names allows the use of GNU make to help automate configuration and recompilation. An example Makefile exploiting such capabilities may be found in the `libg++/proto-kit' directory.

The `genclass` utility operates via simple text substitution using `sed`. All occurrences of the pseudo-types `<T>` and `<C>` (if there are two types) are replaced with the indicated type, and occurrences

of <T&> and <C&> are replaced by just the types, if `val` is specified, or types followed by "&" if `ref` specified.

Programmers will frequently need to edit the `.h' file in order to insert additional `#include` directives or other modifications. A simple utility, `prepend-header' to prepend other `.h' files to generated files is provided in the distribution.

One dubious virtue of the prototyping mechanism is that, because sources files, not archived library classes, are generated, it is relatively simple for programmers to modify container classes in the common case where slight variations of standard container classes are required.

It is often a good idea for programmers to archive (via `ar`) generated classes into `.a' files so that only those class functions actually used in a given application will be loaded. The test subdirectory of the distribution shows an example of this.

Because of `#pragma interface` directives, the `.cc' files should be compiled with `-O` or `-DUSE_LIBGXX_INLINES` enabled.

Many container classes require specifications over and above the base class type. For example, classes that maintain some kind of ordering of elements require specification of a comparison function upon which to base the ordering. This is accomplished via a prototype file `defs.hP' that contains macros for these functions. While these macros default to perform reasonable actions, they can and should be changed in particular cases. Most prototypes require only one or a few of these. No harm is done if unused macros are defined to perform nonsensical actions. The macros are:

`DEFAULT_INITIAL_CAPACITY`

> The initial capacity for containers (e.g., hash tables) that require an initial capacity argument for constructors. Default: 100

`<T>EQ(a, b)`

> return true if a is considered equal to b for the purposes of locating, etc., an element in a container. Default: (a == b)

`<T>LE(a, b)`

> return true if a is less than or equal to b Default: (a <= b)

`<T>CMP(a, b)`

> return an integer < 0 if a<b, 0 if a==b, or > 0 if a>b. Default: (a <= b)? (a==b)? 0 : -1 : 1

`<T>HASH(a)`

> return an unsigned integer representing the hash of a. Default: hash(a) ; where extern unsigned int hash(<T&>). (note: several useful hash functions are declared in builtin.h and defined in hash.cc)

Nearly all prototypes container classes support container traversal via `Pix` pseudo indices, as described elsewhere.

All object containers must perform either a `X::X(X&)` (or `X::X()` followed by `X::operator =(X&)`) to copy objects into containers. (The latter form is used for containers built from C++ arrays, like `VHSets`). When containers are destroyed, they invoke `X::~X()`. Any objects used in containers must have well behaved constructors and destructors. If you want to create containers that merely reference (point to) objects that reside elsewhere, and are not copied or destroyed inside the container,

you must use containers of pointers, not containers of objects.

All prototypes are designed to generate *HOMOGENOUS* container classes. There is no universally applicable method in C++ to support heterogenous object collections with elements of various subclasses of some specified base class. The only way to get heterogenous structures is to use collections of pointers-to-objects, not collections of objects (which also requires you to take responsibility for managing storage for the objects pointed to yourself).

For example, the following usage illustrates a commonly encountered danger in trying to use container classes for heterogenous structures:

```
class Base { int x; ...}
class Derived : public Base { int y; ... }

BaseVHSet s; // class BaseVHSet generated via something like
             // `genclass Base ref VHSet'

void f()
{
  Base b;
  s.add(b); // OK

  Derived d;
  s.add(d);  // (CHOP!)
}
```

At the line flagged with `(CHOP!)', a `Base::Base(Base&)` is called inside `Set::add(Base&)`---*not* `Derived::Derived(Derived&)`. Actually, in `VHSet`, a `Base::operator =(Base&)`, is used instead to place the element in an array slot, but with the same effect. So only the Base part is copied as a `VHSet` element (a so-called chopped-copy). In this case, it has an `x` part, but no `y` part; and a Base, not Derived, vtable. Objects formed via chopped copies are rarely sensible.

To avoid this, you must resort to pointers:

```
typedef Base* BasePtr;

BasePtrVHSet s; // class BaseVHSet generated via something like
                // `genclass BasePtr val VHSet'

void f()
{
  Base* bp = new Base;
  s.add(b);

  Base* dp = new Derived;
```

```
  s.add(d);  // works fine.

  // Don't forget to delete bp and dp sometime.
  // The VHSet won't do this for you.
}
```

Example

The prototypes can be difficult to use on first attempt. Here is an example that may be helpful. The utilities in the `proto-kit' simplify much of the actions described, but are not used here.

Suppose you create a class `Person`, and want to make an Map that links the social security numbers associated with each person. You start off with a file `Person.h'

```
#include <String.h>

class Person
{
  String nm;
  String addr;
  //...
public:
  const String& name() { return nm; }
  const String& address() { return addr; }
  void          print() { ... }
  //...
}
```

And in file `SSN.h',

```
typedef unsigned int SSN;
```

Your first decision is what storage/usage strategy to use. There are several reasonable alternatives here: You might create an "object collection" of Persons, a "pointer collection" of pointers-to-Persons, or even a simple String map, housing either copies of pointers to the names of Persons, since other fields are unused for purposes of the Map. In an object collection, instances of class Person "live" inside the Map, while in a pointer collection, the instances live elsewhere. Also, as above, if instances of subclasses of Person are to be used inside the Map, you must use pointers. In a String Map, the same difference holds, but now only for the name fields. Any of these choices might make sense in particular applications.

The second choice is the Map implementation strategy. Either a tree or a hash table might make sense. Suppose you want an AVL tree Map. There are two things to now check. First, as an object collection, the AVLMap requires that the elsement class contain an `X(X&)` constructor. In C++, if you don't specify such a constructor, one is constructed for you, but it is a very good idea to always do this yourself, to

avoid surprises. In this example, you'd use something like

```
class Person
{ ...;
    Person(const Person& p) :nm(p.nm), addr(p.addr) {}
};
```

Also, an AVLMap requires a comparison function for elements in order to maintain order. Rather than requiring you to write a particular comparison function, a `defs' file is consulted to determine how to compare items. You must create and edit such a file.

Before creating `Person.defs.h', you must first make one additional decision. Should the Map member functions like `m.contains(p)` take arguments (`p`) by reference (i.e., typed as `int Map::contains(const Person& p)` or by value (i.e., typed as `int Map::contains(const Person p)`. Generally, for user-defined classes, you want to pass by reference, and for builtins and pointers, to pass by value. SO you should pick by-reference.

You can now create `Person.defs.h' via `genclass Person ref defs`. This creates a simple skeleton that you must edit. First, add `#include "Person.h"` to the top. Second, edit the `<T>CMP(a,b)` macro to compare on name, via

```
#define <T>CMP(a, b) ( compare(a.name(), b.name()) )
```

which invokes the `int compare(const String&, const String&)` function from `String.h'. Of course, you could define this in any other way as well. In fact, the default versions in the skeleton turn out to be OK (albeit inefficient) in this particular example.

You may also want to create file `SSN.defs.h'. Here, choosing call-by-value makes sense, and since no other capabilities (like comparison functions) of the SSNs are used (and the defaults are OK anyway), you'd type

```
genclass SSN val defs
```

and then edit to place `#include "SSN.h"` at the top.

Finally, you can generate the classes. First, generate the base class for Maps via

```
genclass -2 Person ref SSN val Map
```

This generates only the abstract class, not the implementation, in file `Person.SSN.Map.h' and `Person.SSN.Map.cc'. To create the AVL implementation, type

```
genclass -2 Person ref SSN val AVLMap
```

This creates the class `PersonSSNAVLMap`, in `Person.SSN.AVLMap.h' and `Person.SSN.AVLMap.cc'.

To use the AVL implementation, compile the two generated `.cc' files, and specify `#include

"Person.SSN.AVLMap.h"' in the application program. All other files are included in the right ways automatically.

One last consideration, peculiar to Maps, is to pick a reasonable default contents when declaring an AVLMap. Zero might be appropriate here, so you might declare a Map,

```
PersonSSNAVLMap m((SSN)0);
```

Suppose you wanted a `VHMap` instead of an `AVLMap` Besides generating different implementations, there are two differences in how you should prepare the `` `defs' `` file. First, because a VHMap uses a C++ array internally, and because C++ array slots are initialized differently than single elements, you must ensure that class Person contains (1) a no-argument constructor, and (2) an assignment operator. You could arrange this via

```
class Person
{ ...;
    Person() {}
  void operator = (const Person& p) { nm = p.nm; addr = p.addr; }
};
```

(The lack of action in the constructor is OK here because `Strings` possess usable no-argument constructors.)

You also need to edit `` `Person.defs.h' `` to indicate a usable hash function and default capacity, via something like

```
#include <builtin.h>
#define <T>HASH(x)  (hashpjw(x.name().chars()))
#define DEFAULT_INITIAL_CAPACITY 1000
```

Since the `hashpjw` function from `` `builtin.h' `` is appropriate here. Changing the default capacity to a value expected to exceed the actual capacity helps to avoid "hidden" inefficiencies when a new VHMap is created without overriding the default, which is all too easy to do.

Otherwise, everything is the same as above, substituting `VHMap` for `AVLMap`.

Go to the previous, next section.

Go to the previous, next section.

Variable-Sized Object Representation

One of the first goals of the GNU C++ library is to enrich the kinds of basic classes that may be considered as (nearly) "built into" C++. A good deal of the inspiration for these efforts is derived from considering features of other type-rich languages, particularly Common Lisp and Scheme. The general characteristics of most class and friend operators and functions supported by these classes has been heavily influenced by such languages.

Four of these types, Strings, Integers, BitSets, and BitStrings (as well as associated and/or derived classes) require representations suitable for managing variable-sized objects on the free-store. The basic technique used for all of these is the same, although various details necessarily differ from class to class.

The general strategy for representing such objects is to create chunks of memory that include both header information (e.g., the size of the object), as well as the variable-size data (an array of some sort) at the end of the chunk. Generally the maximum size of an object is limited to something less than all of addressable memory, as a safeguard. The minimum size is also limited so as not to waste allocations expanding very small chunks. Internally, chunks are allocated in blocks well-tuned to the performance of the `new` operator.

Class elements themselves are merely pointers to these chunks. Most class operations are performed via inline "translation" functions that perform the required operation on the corresponding representation. However, constructors and assignments operate by copying entire representations, not just pointers.

No attempt is made to control temporary creation in expressions and functions involving these classes. Users of previous versions of the classes will note the disappearance of both "Tmp" classes and reference counting. These were dropped because, while they did improve performance in some cases, they obscure class mechanics, lead programmers into the false belief that they need not worry about such things, and occasionally have paradoxical behavior.

These variable-sized object classes are integrated as well as possible into C++. Most such classes possess converters that allow automatic coercion both from and to builtin basic types. (e.g., char* to and from String, long int to and from Integer, etc.). There are pro's and con's to circular converters, since they can sometimes lead to the conversion from a builtin type through to a class function and back to a builtin type without any special attention on the part of the programmer, both for better and worse.

Most of these classes also provide special-case operators and functions mixing basic with class types, as a way to avoid constructors in cases where the operations do not rely on anything special about the representations. For example, there is a special case concatenation operator for a String concatenated with a char, since building the result does not rely on anything about the String header. Again, there are arguments both for and against this approach. Supporting these cases adds a non-trivial degree of (mainly inline) function proliferation, but results in more efficient operations. Efficiency wins out over parsimony here, as part of the goal to produce classes that provide sufficient functionality and efficiency so that programmers are not tempted to try to manipulate or bypass the underlying representations.

Go to the previous, next section.

Go to the previous, next section.

Some guidelines for using expression-oriented classes

The fact that C++ allows operators to be overloaded for user-defined classes can make programming with library classes like `Integer`, `String`, and so on very convenient. However, it is worth becoming familiar with some of the inherent limitations and problems associated with such operators.

Many operators are *constructive*, i.e., create a new object based on some function of some arguments. Sometimes the creation of such objects is wasteful. Most library classes supporting expressions contain facilities that help you avoid such waste.

For example, for `Integer a, b, c; ...; c = a + b + a;`, the plus operator is called to sum a and b, creating a new temporary object as its result. This temporary is then added with a, creating another temporary, which is finally copied into c, and the temporaries are then deleted. In other words, this code might have an effect similar to `Integer a, b, c; ...; Integer t1(a); t1 += b; Integer t2(t1); t2 += a; c = t2;`.

For small objects, simple operators, and/or non-time/space critical programs, creation of temporaries is not a big problem. However, often, when fine-tuning a program, it may be a good idea to rewrite such code in a less pleasant, but more efficient manner.

For builtin types like ints, and floats, C and C++ compilers already know how to optimize such expressions to reduce the need for temporaries. Unfortunately, this is not true for C++ user defined types, for the simple (but very annoying, in this context) reason that nothing at all is guaranteed about the semantics of overloaded operators and their interrelations. For example, if the above expression just involved ints, not Integers, a compiler might internally convert the statement into something like `c = a; c += b; c+= a;` , or perhaps something even more clever. But since C++ does not know that Integer operator += has any relation to Integer operator +, A C++ compiler cannot do this kind of expression optimization itself.

In many cases, you can avoid construction of temporaries simply by using the assignment versions of operators whenever possible, since these versions create no temporaries. However, for maximum flexibility, most classes provide a set of "embedded assembly code" procedures that you can use to fully control time, space, and evaluation strategies. Most of these procedures are "three-address" procedures that take two `const` source arguments, and a destination argument. The procedures perform the appropriate actions, placing the results in the destination (which is may involve overwriting old contents). These procedures are designed to be fast and robust. In particular, aliasing is always handled correctly, so that, for example `add(x, x, x);` is perfectly OK. (The names of these procedures are listed along with the classes.)

For example, suppose you had an Integer expression `a = (b - a) * -(d / c);`

This would be compiled as if it were `Integer t1=b-a; Integer t2=d/c; Integer`

```
t3=-t2; Integer t4=t1*t3; a=t4;
```

But, with some manual cleverness, you might yourself some up with `sub(a, b, a); mul(a, c, a); div(a, c, a);`

A related phenomenon occurs when creating your own constructive functions returning instances of such types. Suppose you wanted to write function `Integer f(const Integer& a) { Integer r = a; r += a; return r; }`

This function, when called (as in `a = f(a);`) demonstrates a similar kind of wasted copy. The returned value r must be copied out of the function before it can be used by the caller. In GNU C++, there is an alternative via the use of named return values. Named return values allow you to manipulate the returned object directly, rather than requiring you to create a local inside a function and then copy it out as the returned value. In this example, this can be done via `Integer f(const Integer& a) return r(a) { r += a; return; }`

A final guideline: The overloaded operators are very convenient, and much clearer to use than procedural code. It is almost always a good idea to make it right, *then* make it fast, by translating expression code into procedural code after it is known to be correct.

TOC

Pseudo-indexes

Many useful classes operate as containers of elements. Techniques for accessing these elements from a container differ from class to class. In the GNU C++ library, access methods have been partially standardized across different classes via the use of pseudo-indexes called `Pixes`. A `Pix` acts in some ways like an index, and in some ways like a pointer. (Their underlying representations are just `void*` pointers). A `Pix` is a kind of "key" that is translated into an element access by the class. In virtually all cases, `Pixes` are pointers to some kind internal storage cells. The containers use these pointers to extract items.

`Pixes` support traversal and inspection of elements in a collection using analogs of array indexing. However, they are pointer-like in that `0` is treated as an invalid `Pix`, and unsafe insofar as programmers can attempt to access nonexistent elements via dangling or otherwise invalid `Pixes` without first checking for their validity.

In general it is a very bad idea to perform traversals in the the midst of destructive modifications to containers.

Typical applications might include code using the idiom

```
for (Pix i = a.first(); i != 0; a.next(i)) use(a(i));
```

for some container `a` and function `use`.

Classes supporting the use of `Pixes` always contain the following methods, assuming a container `a` of element types of `Base`.

`Pix i = a.first()`
: Set i to index the first element of a or 0 if a is empty.

`a.next(i)`
: advance i to the next element of a or 0 if there is no next element;

`Base x = a(i); a(i) = x;`
: a(i) returns a reference to the element indexed by i.

`int present = a.owns(i)`
: returns true if Pix i is a valid Pix in a. This is often a relatively slow operation, since the collection must usually traverse through elements to see if any correspond to the Pix.

Some container classes also support backwards traversal via

`Pix i = a.last()`
: Set i to the last element of a or 0 if a is empty.

`a.prev(i)`
: sets i to the previous element in a, or 0 if there is none.

Collections supporting elements with an equality operation possess

`Pix j = a.seek(x)`

sets j to the index of the first occurrence of x, or 0 if x is not contained in a.

Bag classes possess

`Pix j = a.seek(x, Pix from = 0)`

sets j to the index of the next occurrence of x following i, or 0 if x is not contained in a. If i == 0, the first occurrence is returned.

Set, Bag, and PQ classes possess

`Pix j = a.add(x) (or a.enq(x) for priority queues)`

add x to the collection, returning its Pix. The Pix of an item can change in collections where further additions and deletions involve the actual movement of elements (currently in OXPSet, OXPBag, XPPQ, VOHSet), but in all other cases, an item's Pix may be considered a permanent key to its location.

Header files for interfacing C++ to C

The following files are provided so that C++ programmers may invoke common C library and system calls. The names and contents of these files are subject to change in order to be compatible with the forthcoming GNU C library. Other files, not listed here, are simply C++-compatible interfaces to corresponding C library files.

`values.h'

A collection of constants defining the numbers of bits in builtin types, minimum and maximum values, and the like. Most names are the same as those found in `values.h' found on Sun systems.

`std.h'

A collection of common system calls and `libc.a' functions. Only those functions that can be declared without introducing new type definitions (socket structures, for example) are provided. Common `char*` functions (like `strcmp`) are among the declarations. All functions are declared along with their library names, so that they may be safely overloaded.

`string.h'

This file merely includes `<std.h>', where string function prototypes are declared. This is a workaround for the fact that system `string.h' and `strings.h' files often differ in contents.

`osfcn.h'

This file merely includes `<std.h>', where system function prototypes are declared.

`libc.h'

This file merely includes `<std.h>', where C library function prototypes are declared.

`math.h'

A collection of prototypes for functions usually found in libm.a, plus some `#defined` constants that appear to be consistent with those provided in the AT&T version. The value of `HUGE` should be checked before using. Declarations of all common math functions are preceded with `overload` declarations, since these are commonly overloaded.

`stdio.h'

Declaration of `FILE` (`_iobuf`), common macros (like `getc`), and function prototypes for `libc.a' functions that operate on `FILE*`'s. The value `BUFSIZ` and the declaration of `_iobuf` should be checked before using.

`assert.h'

C++ versions of assert macros.

`generic.h'

String concatenation macros useful in creating generic classes. They are similar in function to the AT&T CC versions.

`new.h'

Declarations of the default global operator new, the two-argument placement version, and associated error handlers.

TOC

Utility functions for built in types

Files `builtin.h' and corresponding `.cc' implementation files contain various convenient inline and non-inline utility functions. These include useful enumeration types, such as TRUE, FALSE ,the type definition for pointers to libg++ error handling functions, and the following functions.

`long abs(long x); double abs(double x);`

inline versions of abs. Note that the standard libc.a version, `int abs(int)` is *not* declared as inline.

`void clearbit(long& x, long b);`

clears the b'th bit of x (inline).

`void setbit(long& x, long b);`

sets the b'th bit of x (inline)

`int testbit(long x, long b);`

returns the b'th bit of x (inline).

`int even(long y);`

returns true if x is even (inline).

`int odd(long y);`

returns true is x is odd (inline).

`int sign(long x); int sign(double x);`

returns -1, 0, or 1, indicating whether x is less than, equal to, or greater than zero (inline).

`long gcd(long x, long y);`

returns the greatest common divisor of x and y.

`long lcm(long x, long y);`

returns the least common multiple of x and y.

`long lg(long x);`

returns the floor of the base 2 log of x.

`long pow(long x, long y); double pow(double x, long y);`

returns x to the integer power y using via the iterative O(log y) "Russian peasant" method.

`long sqr(long x); double sqr(double x);`

returns x squared (inline).

`long sqrt(long y);`

returns the floor of the square root of x.

`unsigned int hashpjw(const char* s);`

a hash function for null-terminated char* strings using the method described in Aho, Sethi, & Ullman, p 436.

`unsigned int multiplicativehash(int x);`

a hash function for integers that returns the lower bits of multiplying x by the golden ratio times pow(2, 32). See Knuth, Vol 3, p 508.

`unsigned int foldhash(double x);`

a hash function for doubles that exclusive-or's the first and second words of x, returning the result as an integer.

`double start_timer()`

Starts a process timer.

`double return_elapsed_time(double last_time)`

Returns the process time since last_time. If last_time == 0 returns the time since the last start_timer. Returns -1 if start_timer was not first called.

File `` `Maxima.h' `` includes versions of `MAX, MIN` for builtin types.

File `` `compare.h' `` includes versions of `compare(x, y)` for builtin types. These return negative if the first argument is less than the second, zero for equal, and positive for greater.

Library dynamic allocation primitives

Libg++ contains versions of `malloc, free, realloc` that were designed to be well-tuned to C++ applications. The source file `` `malloc.c' `` contains some design and implementation details. Here are the major user-visible differences from most system malloc routines:

1. These routines *overwrite* storage of freed space. This means that it is never permissible to use a `delete`'d object in any way. Doing so will either result in trapped fatal errors or random aborts within malloc, free, or realloc.
2. The routines tend to perform well when a large number of objects of the same size are allocated and freed. You may find that it is not worth it to create your own special allocation schemes in such cases.
3. The library sets top-level `operator new()` to call malloc and `operator delete()` to call free. Of course, you may override these definitions in C++ programs by creating your own operators that will take precedence over the library versions. However, if you do so, be sure to define *both* `operator new()` and `operator delete()`.
4. These routines do *not* support the odd convention, maintained by some versions of malloc, that you may call `realloc` with a pointer that has been `free`'d.
5. The routines automatically perform simple checks on `free`'d pointers that can often determine whether users have accidentally written beyond the boundaries of allocated space, resulting in a fatal error.
6. The function `malloc_usable_size(void* p)` returns the number of bytes actually allocated for `p`. For a valid pointer (i.e., one that has been `malloc`'d or `realloc`'d but not yet `free`'d) this will return a number greater than or equal to the requested size, else it will normally return 0. Unfortunately, a non-zero return can not be an absolutely perfect indication of lack of error. If a chunk has been `free`'d but then re-allocated for a different purpose somewhere elsewhere, then `malloc_usable_size` will return non-zero. Despite this, the function can be very valuable for performing run-time consistency checks.
7. `malloc` requires 8 bytes of overhead per allocated chunk, plus a mmaximum alignment adjustment of 8 bytes. The number of bytes of usable space is exactly as requested, rounded to the nearest 8 byte boundary.
8. The routines do *not* contain any synchronization support for multiprocessing. If you perform global allocation on a shared memory multiprocessor, you should disable compilation and use of libg++ malloc in the distribution `` `Makefile' `` and use your system version of malloc.

The new input/output classes

The iostream classes implement most of the features of AT&T version 2.0 iostream library classes, and most of the features of the ANSI X3J16 library draft (which is based on the AT&T design). These classes are available in `libg++` for convenience and for compatibility with older releases; however, since the iostream classes are licensed under less stringent terms than `libg++`, they are now also available in a separate library called `libio`---and documented in a separate manual, corresponding to that library.

See section 'Introduction' in The GNU C++ Iostream Library.

Go to the previous, next section.

Go to the previous, next section.

The old I/O library

WARNING: This chapter describes classes that are *obsolete*. These classes are normally not available when libg++ is installed normally. The sources are currently included in the distribution, and you can configure libg++ to use these classes instead of the new iostream classes. This is only a temporary measure; you should convert your code to use iostreams as soon as possible. The iostream classes provide some compatibility support, but it is very incomplete (there is no longer a `File` class).

File-based classes

The `File` class supports basic IO on Unix files. Operations are based on common C stdio library functions.

`File` serves as the base class for istreams, ostreams, and other derived classes. It contains the interface between the Unix stdio file library and these more structured classes. Most operations are implemented as simple calls to stdio functions. `File` class operations are also fully compatible with raw system file reads and writes (like the system `read` and `lseek` calls) when buffering is disabled (see below). The `FILE*` stdio file pointer is, however maintained as protected. Classes derived from File may only use the IO operations provided by File, which encompass essentially all stdio capabilities.

The class contains four general kinds of functions: methods for binding `File`s to physical Unix files, basic IO methods, file and buffer control methods, and methods for maintaining logical and physical file status.

Binding and related tasks are accomplished via `File` constructors and destructors, and member functions `open, close, remove, filedesc, name, setname`.

If a file name is provided in a constructor or open, it is maintained as class variable `nm` and is accessible via `name`. If no name is provided, then `nm` remains null, except that `File`s bound to the default files stdin, stdout, and stderr are automatically given the names `(stdin), (stdout), (stderr)` respectively. The function `setname` may be used to change the internal name of the `File`. This does not change the name of the physical file bound to the File. The member function `close` closes a file. The `~File` destructor closes a file if it is open, except that stdin, stdout, and stderr are flushed but left open for the system to close on program exit since some systems may require this, and on others it does not matter. `remove` closes the file, and then deletes it if possible by calling the system function to delete the file with the name provided in the `nm` field.

Basic IO

- `read` and `write` perform binary IO via stdio `fread` and `fwrite`.
- `get` and `put` for chars invoke stdio `getc` and `putc` macros.

- `put(const char* s)` outputs a null-terminated string via stdio `fputs`.
- `unget` and `putback` are synonyms. Both call stdio `ungetc`.

File Control

`flush`, `seek`, `tell`, and `tell` call the corresponding stdio functions.

`flush(char)` and `fill()` call stdio `_flsbuf` and `_filbuf` respectively.

`setbuf` is mainly useful to turn off buffering in cases where nonsequential binary IO is being performed. `raw` is a synonym for `setbuf(_IONBF)`. After a `f.raw()`, using the stdio functions instead of the system `read, write`, etc., calls entails very little overhead. Moreover, these become fully compatible with intermixed system calls (e.g., `lseek(f.filedesc(), 0, 0)`). While intermixing `File` and system IO calls is not at all recommended, this technique does allow the `File` class to be used in conjunction with other functions and libraries already set up to operate on file descriptors. `setbuf` should be called at most once after a constructor or open, but before any IO.

File Status

File status is maintained in several ways.

A `File` may be checked for accessibility via `is_open()`, which returns true if the File is bound to a usable physical file, `readable()`, which returns true if the File can be read from (opened for reading, and not in a _fail state), or `writable()`, which returns true if the File can be written to.

`File` operations return their status via two means: failure and success are represented via the logical state. Also, the return values of invoked stdio and system functions that return useful numeric values (not just failure/success flags) are held in a class variable accessible via `iocount`. (This is useful, for example, in determining the number of items actually read by the `read` function.)

Like the AT&T i/o-stream classes, but unlike the description in the Stroustrup book, p238, `rdstate()` returns the bitwise OR of `_eof`, `_fail` and `_bad`, not necessarily distinct values. The functions `eof()`, `fail()`, `bad()`, and `good()` can be used to test for each of these conditions independently.

`_fail` becomes set for any input operation that could not read in the desired data, and for other failed operations. As with all Unix IO, `_eof` becomes true only when an input operations fails because of an end of file. Therefore, `_eof` is not immediately true after the last successful read of a file, but only after one final read attempt. Thus, for input operations, `_fail` and `_eof` almost always become true at the same time. `bad` is set for unbound files, and may also be set by applications in order to communicate input corruption. Conversely, `_good` is defined as 0 and is returned by `rdstate()` if all is well.

The state may be modified via `clear(flag)`, which, despite its name, sets the corresponding state_value flag. `clear()` with no arguments resets the state to `_good`. `failif(int cond)` sets the state to `_fail` only if `cond` is true.

Errors occuring during constructors and file opens also invoke the function `error`. `error` in turn calls a resetable error handling function pointed to by the non-member global variable

`File_error_handler` only if a system error has been generated. Since `error` cannot tell if the current system error is actually responsible for a failure, it may at times print out spurious messages. Three error handlers are provided. The default, `verbose_File_error_handler` calls the system function `perror` to print the corresponding error message on standard error, and then returns to the caller. `quiet_File_error_handler` does nothing, and simply returns. `fatal_File_error_handler` prints the error and then aborts execution. These three handlers, or any other user-defined error handlers can be selected via the non-member function `set_File_error_handler`.

All read and write operations communicate either logical or physical failure by setting the `_fail` flag. All further operations are blocked if the state is in a `_fail` or`_bad` condition. Programmers must explicitly use `clear()` to reset the state in order to continue IO processing after either a logical or physical failure. C programmers who are unfamiliar with these conventions should note that, unlike the stdio library, `File` functions indicate IO success, status, or failure solely through the state, not via return values of the functions. The `void*` operator or `rdstate()` may be used to test success. In particular, according to c++ conversion rules, the `void*` coercion is automatically applied whenever the `File&` return value of any `File` function is tested in an `if` or `while`. Thus, for example, an easy way to copy all of stdin to stdout until eof (at which point `get` fails) or some error is `char c; while(cin.get(c) && cout.put(c));`.

The current version of istreams and ostreams differs significantly from previous versions in order to obtain compatibility with AT&T 1.2 streams. Most code using previous versions should still work. However, the following features of `File` are not incorporated in streams (they are still present in `File`): `scan(const char* fmt...), remove(), read(), write(), setbuf(), raw()`. Additionally, the feature of previous streams that allowed free intermixing of stream and stdio input and output is no longer guaranteed to always behave as desired.

Go to the previous, next section.

Go to the previous, next section.

The Obstack class

The `Obstack` class is a simple rewrite of the C obstack macros and functions provided in the GNU CC compiler source distribution.

Obstacks provide a simple method of creating and maintaining a string table, optimized for the very frequent task of building strings character-by-character, and sometimes keeping them, and sometimes not. They seem especially useful in any parsing application. One of the test files demonstrates usage.

A brief summary:

`grow`
: places something on the obstack without committing to wrap it up as a single entity yet.

`finish`
: wraps up a constructed object as a single entity, and returns the pointer to its start address.

`copy`
: places things on the obstack, and *does* wrap them up. `copy` is always equivalent to first grow, then finish.

`free`
: deletes something, and anything else put on the obstack since its creation.

The other functions are less commonly needed:

`blank`
: is like grow, except it just grows the space by size units without placing anything into this space

`alloc`
: is like `blank`, but it wraps up the object and returns its starting address.

`chunk_size, base, next_free, alignment_mask, size, room`
: returns the appropriate class variables.

`grow_fast`
: places a character on the obstack without checking if there is enough room.

`blank_fast`
: like `blank`, but without checking if there is enough room.

`shrink(int n)`
: shrink the current chunk by n bytes.

`contains(void* addr)`
: returns true if the Obstack holds the address addr.

Here is a lightly edited version of the original C documentation:

These functions operate a stack of objects. Each object starts life small, and may grow to maturity. (Consider building a word syllable by syllable.) An object can move while it is growing. Once it has "finished" it never changes address again. So the "top of the stack" is typically an immature growing object, while the rest of the stack is of mature, fixed size and fixed address objects.

These routines grab large chunks of memory, using the GNU C++ `new` operator. On occasion, they free chunks, via `delete`.

Each independent stack is represented by a Obstack.

One motivation for this package is the problem of growing char strings in symbol tables. Unless you are a "fascist pig with a read-only mind" [Gosper's immortal quote from HAKMEM item 154, out of context] you would not like to put any arbitrary upper limit on the length of your symbols.

In practice this often means you will build many short symbols and a few long symbols. At the time you are reading a symbol you don't know how long it is. One traditional method is to read a symbol into a buffer, `realloc()`ating the buffer every time you try to read a symbol that is longer than the buffer. This is beaut, but you still will want to copy the symbol from the buffer to a more permanent symbol-table entry say about half the time.

With obstacks, you can work differently. Use one obstack for all symbol names. As you read a symbol, grow the name in the obstack gradually. When the name is complete, finalize it. Then, if the symbol exists already, free the newly read name.

The way we do this is to take a large chunk, allocating memory from low addresses. When you want to build a symbol in the chunk you just add chars above the current "high water mark" in the chunk. When you have finished adding chars, because you got to the end of the symbol, you know how long the chars are, and you can create a new object. Mostly the chars will not burst over the highest address of the chunk, because you would typically expect a chunk to be (say) 100 times as long as an average object.

In case that isn't clear, when we have enough chars to make up the object, *they are already contiguous in the chunk* (guaranteed) so we just point to it where it lies. No moving of chars is needed and this is the second win: potentially long strings need never be explicitly shuffled. Once an object is formed, it does not change its address during its lifetime.

When the chars burst over a chunk boundary, we allocate a larger chunk, and then copy the partly formed object from the end of the old chunk to the beginning of the new larger chunk. We then carry on accreting characters to the end of the object as we normally would.

A special version of grow is provided to add a single char at a time to a growing object.

Summary:

- We allocate large chunks.
- We carve out one object at a time from the current chunk.
- Once carved, an object never moves.
- We are free to append data of any size to the currently growing object.
- Exactly one object is growing in an obstack at any one time.
- You can run one obstack per control block.

- You may have as many control blocks as you dare.
- Because of the way we do it, you can `unwind' a obstack back to a previous state. (You may remove objects much as you would with a stack.)

The obstack data structure is used in many places in the GNU C++ compiler.

Differences from the the GNU C version

1. The obvious differences stemming from the use of classes and inline functions instead of structs and macros. The C `init` and `begin` macros are replaced by constructors.
2. Overloaded function names are used for grow (and others), rather than the C `grow`, `grow0`, etc.
3. All dynamic allocation uses the the built-in `new` operator. This restricts flexibility by a little, but maintains compatibility with usual C++ conventions.
4. There are now two versions of finish:
    1. finish() behaves like the C version.
    2. finish(char terminator) adds `terminator`, and then calls `finish()`. This enables the normal invocation of `finish(0)` to wrap up a string being grown character-by-character.
5. There are special versions of grow(const char* s) and copy(const char* s) that add the null-terminated string `s` after computing its length.
6. The shrink and contains functions are provided.

Go to the previous, next section.

The AllocRing class

An AllocRing is a bounded ring (circular list), each of whose elements contains a pointer to some space allocated via `new char[some_size]`. The entries are used cyclicly. The size, n, of the ring is fixed at construction. After that, every nth use of the ring will reuse (or reallocate) the same space. AllocRings are needed in order to temporarily hold chunks of space that are needed transiently, but across constructor-destructor scopes. They mainly useful for storing strings containing formatted characters to print across various functions and coercions. These strings are needed across routines, so may not be deleted in any one of them, but should be recovered at some point. In other words, an AllocRing is an extremely simple minded garbage collection mechanism. The GNU C++ library used to use one AllocRing for such formatting purposes, but it is being phased out, and is now only used by obsolete functions. These days, AllocRings are probably not very useful.

Support includes:

`AllocRing a(int n)`

constructs an Alloc ring with n entries, all null.

`void* mem = a.alloc(sz)`

moves the ring pointer to the next entry, and reuses the space if their is enough, also allocates space via new char[sz].

`int present = a.contains(void* ptr)`

returns true if ptr is held in one of the ring entries.

`a.clear()`

deletes all space pointed to in any entry. This is called automatically upon destruction.

`a.free(void* ptr)`

If ptr is one of the entries, calls delete of the pointer, and resets to entry pointer to null.

Go to the previous, next section.

Go to the previous, next section.

The String class

The `String` class is designed to extend GNU C++ to support string processing capabilities similar to those in languages like Awk. The class provides facilities that ought to be convenient and efficient enough to be useful replacements for `char*` based processing via the C string library (i.e., `strcpy, strcmp,` etc.) in many applications. Many details about String representations are described in the Representation section.

A separate `SubString` class supports substring extraction and modification operations. This is implemented in a way that user programs never directly construct or represent substrings, which are only used indirectly via String operations.

Another separate class, `Regex` is also used indirectly via String operations in support of regular expression searching, matching, and the like. The Regex class is based entirely on the GNU Emacs regex functions. See section 'Syntax of Regular Expressions' in GNU Emacs Manual, for a full explanation of regular expression syntax. (For implementation details, see the internal documentation in files `` `regex.h' `` and `` `regex.c' ``.)

Constructors

Strings are initialized and assigned as in the following examples:

`String x; String y = 0; String z = "";`

Set x, y, and z to the nil string. Note that either 0 or "" may always be used to refer to the nil string.

`String x = "Hello"; String y("Hello");`

Set x and y to a copy of the string "Hello".

`String x = 'A'; String y('A');`

Set x and y to the string value "A"

`String u = x; String v(x);`

Set u and v to the same string as String x

`String u = x.at(1,4); String v(x.at(1,4));`

Set u and v to the length 4 substring of x starting at position 1 (counting indexes from 0).

`String x("abc", 2);`

Sets x to "ab", i.e., the first 2 characters of "abc".

`String x = dec(20);`

Sets x to "20". As here, Strings may be initialized or assigned the results of any `char*` function.

There are no directly accessible forms for declaring SubString variables.

The declaration `Regex r("[a-zA-Z_][a-zA-Z0-9_]*");` creates a compiled regular expression

suitable for use in String operations described below. (In this case, one that matches any C++ identi
The first argument may also be a String. Be careful in distinguishing the role of backslashes in quote
GNU C++ char* constants versus those in Regexes. For example, a Regex that matches either one or
more tabs or all strings beginning with "ba" and ending with any number of occurrences of "na" could be
declared as `Regex r = "\\(\t+\\)\\|\\(ba\\(na\\)*\\)"` Note that only one backslash is
needed to signify the tab, but two are needed for the parenthesization and virgule, since the GNU C++
lexical analyzer decodes and strips backslashes before they are seen by Regex.

There are three additional optional arguments to the Regex constructor that are less commonly useful:

`fast (default 0)`

> `fast` may be set to true (1) if the Regex should be "fast-compiled". This causes an additional compilation step that is generally worthwhile if the Regex will be used many times.

`bufsize (default max(40, length of the string))`

> This is an estimate of the size of the internal compiled expression. Set it to a larger value if you know that the expression will require a lot of space. If you do not know, do not worry: realloc is used if necessary.

`transtable (default none == 0)`

> The address of a byte translation table (a char[256]) that translates each character before matching.

As a convenience, several Regexes are predefined and usable in any program. Here are their declarations from `` `String.h' ``.

```
extern Regex RXwhite;      // = "[ \n\t]+"
extern Regex RXint;        // = "-?[0-9]+"
extern Regex RXdouble;     // = "-?\\(\\([0-9]+\\.[0-9]*\\)\\|
                           //    \\([0-9]+\\)\\|
                           //    \\(\\.[0-9]+\\)\\)
                           //    \\([eE][---+]?[0-9]+\\)?"
extern Regex RXalpha;      // = "[A-Za-z]+"
extern Regex RXlowercase;  // = "[a-z]+"
extern Regex RXuppercase;  // = "[A-Z]+"
extern Regex RXalphanum;   // = "[0-9A-Za-z]+"
extern Regex RXidentifier; // = "[A-Za-z_][A-Za-z0-9_]*"
```

Examples

Most `String` class capabilities are best shown via example. The examples below use the following declarations.

```
String x = "Hello";
String y = "world";
String n = "123";
```

```
String z;
char*  s = ",";
String lft, mid, rgt;
Regex  r = "e[a-z]*o";
Regex  r2("/[a-z]*/");
char   c;
int    i, pos, len;
double f;
String words[10];
words[0] = "a";
words[1] = "b";
words[2] = "c";
```

Comparing, Searching and Matching

The usual lexicographic relational operators (`==, !=, <, <=, >, >=`) are defined. A functional form `compare(String, String)` is also provided, as is `fcompare(String, String)`, which compares Strings without regard for upper vs. lower case.

All other matching and searching operations are based on some form of the (non-public) `match` and `search` functions. `match` and `search` differ in that `match` attempts to match only at the given starting position, while `search` starts at the position, and then proceeds left or right looking for a match. As seen in the following examples, the second optional `startpos` argument to functions using `match` and `search` specifies the starting position of the search: If non-negative, it results in a left-to-right search starting at position `startpos`, and if negative, a right-to-left search starting at position `x.length() + startpos`. In all cases, the index returned is that of the beginning of the match, or -1 if there is no match.

Three String functions serve as front ends to `search` and `match`. `index` performs a search, returning the index, `matches` performs a match, returning nonzero (actually, the length of the match) on success, and `contains` is a boolean function performing either a search or match, depending on whether an index argument is provided:

`x.index("lo")`

> returns the zero-based index of the leftmost occurrence of substring "lo" (3, in this case). The argument may be a String, SubString, char, char*, or Regex.

`x.index("l", 2)`

> returns the index of the first of the leftmost occurrence of "l" found starting the search at position x[2], or 2 in this case.

`x.index("l", -1)`

> returns the index of the rightmost occurrence of "l", or 3 here.

`x.index("l", -3)`

> returns the index of the rightmost occurrence of "l" found by starting the search at the 3rd to the

last position of x, returning 2 in this case.

`pos = r.search("leo", 3, len, 0)`

returns the index of r in the `char*` string of length 3, starting at position 0, also placing the length of the match in reference parameter len.

`x.contains("He")`

returns nonzero if the String x contains the substring "He". The argument may be a String, SubString, char, char*, or Regex.

`x.contains("el", 1)`

returns nonzero if x contains the substring "el" at position 1. As in this example, the second argument to `contains`, if present, means to match the substring only at that position, and not to search elsewhere in the string.

`x.contains(RXwhite);`

returns nonzero if x contains any whitespace (space, tab, or newline). Recall that `RXwhite` is a global whitespace Regex.

`x.matches("lo", 3)`

returns nonzero if x starting at position 3 exactly matches "lo", with no trailing characters (as it does in this example).

`x.matches(r)`

returns nonzero if String x as a whole matches Regex r.

`int f = x.freq("l")`

returns the number of distinct, nonoverlapping matches to the argument (2 in this case).

Substring extraction

Substrings may be extracted via the `at`, `before`, `through`, `from`, and `after` functions. These behave as either lvalues or rvalues.

`z = x.at(2, 3)`

sets String z to be equal to the length 3 substring of String x starting at zero-based position 2, setting z to "llo" in this case. A nil String is returned if the arguments don't make sense.

`x.at(2, 2) = "r"`

Sets what was in positions 2 to 3 of x to "r", setting x to "Hero" in this case. As indicated here, SubString assignments may be of different lengths.

`x.at("He") = "je";`

x("He") is the substring of x that matches the first occurrence of it's argument. The substitution sets x to "jello". If "He" did not occur, the substring would be nil, and the assignment would have no effect.

`x.at("l", -1) = "i";`

replaces the rightmost occurrence of "l" with "i", setting x to "Helio".

`z = x.at(r)`

sets String z to the first match in x of Regex r, or "ello" in this case. A nil String is returned if there is no match.

`z = x.before("o")`

sets z to the part of x to the left of the first occurrence of "o", or "Hell" in this case. The argument may also be a String, SubString, or Regex. (If there is no match, z is set to "".)

`x.before("ll") = "Bri";`

sets the part of x to the left of "ll" to "Bri", setting x to "Brillo".

`z = x.before(2)`

sets z to the part of x to the left of x[2], or "He" in this case.

`z = x.after("Hel")`

sets z to the part of x to the right of "Hel", or "lo" in this case.

`z = x.through("el")`

sets z to the part of x up and including "el", or "Hel" in this case.

`z = x.from("el")`

sets z to the part of x from "el" to the end, or "ello" in this case.

`x.after("Hel") = "p";`

sets x to "Help";

`z = x.after(3)`

sets z to the part of x to the right of x[3] or "o" in this case.

`z = " ab c"; z = z.after(RXwhite)`

sets z to the part of its old string to the right of the first group of whitespace, setting z to "ab c"; Use gsub(below) to strip out multiple occurrences of whitespace or any pattern.

`x[0] = 'J';`

sets the first element of x to 'J'. x[i] returns a reference to the ith element of x, or triggers an error if i is out of range.

`common_prefix(x, "Help")`

returns the String containing the common prefix of the two Strings or "Hel" in this case.

`common_suffix(x, "to")`

returns the String containing the common suffix of the two Strings or "o" in this case.

Concatenation

`z = x + s + ' ' + y.at("w") + y.after("w") + ".";`

sets z to "Hello, world."

`x += y;`

sets x to "Helloworld"

`cat(x, y, z)`

A faster way to say z = x + y.

`cat(z, y, x, x)`

Double concatenation; A faster way to say x = z + y + x.

`y.prepend(x);`

A faster way to say y = x + y.

`z = replicate(x, 3);`

sets z to "HelloHelloHello".

`z = join(words, 3, "/")`

sets z to the concatenation of the first 3 Strings in String array words, each separated by "/", setting z to "a/b/c" in this case. The last argument may be "" or 0, indicating no separation.

Other manipulations

`z = "this string has five words"; i = split(z, words, 10, RXwhite);`

sets up to 10 elements of String array words to the parts of z separated by whitespace, and returns the number of parts actually encountered (5 in this case). Here, words[0] = "this", words[1] = "string", etc. The last argument may be any of the usual. If there is no match, all of z ends up in words[0]. The words array is *not* dynamically created by split.

`int nmatches x.gsub("l","ll")`

substitutes all original occurrences of "l" with "ll", setting x to "Hellllo". The first argument may be any of the usual, including Regex. If the second argument is "" or 0, all occurrences are deleted. gsub returns the number of matches that were replaced.

`z = x + y; z.del("loworl");`

deletes the leftmost occurrence of "loworl" in z, setting z to "Held".

`z = reverse(x)`

sets z to the reverse of x, or "olleH".

`z = upcase(x)`

sets z to x, with all letters set to uppercase, setting z to "HELLO"

`z = downcase(x)`

sets z to x, with all letters set to lowercase, setting z to "hello"

`z = capitalize(x)`

sets z to x, with the first letter of each word set to uppercase, and all others to lowercase, setting z to "Hello"

`x.reverse(), x.upcase(), x.downcase(), x.capitalize()`

in-place, self-modifying versions of the above.

Reading, Writing and Conversion

`cout << x`

writes out x.

`cout << x.at(2, 3)`

writes out the substring "llo".

`cin >> x`

reads a whitespace-bounded string into x.

`x.length()`

returns the length of String x (5, in this case).

`s = (const char*)x`

can be used to extract the `char*` char array. This coercion is useful for sending a String as an argument to any function expecting a `const char*` argument (like `atoi`, and `File::open`). This operator must be used with care, since the conversion returns a pointer to `String` internals without copying the characters: The resulting `(char*)` is only valid until the next String operation, and you must not modify it. (The conversion is defined to return a const value so that GNU C++ will produce warning and/or error messages if changes are attempted.)

Go to the previous, next section.

The Integer class.

The `Integer` class provides multiple precision integer arithmetic facilities. Some representation details are discussed in the Representation section.

`Integers` may be up to `b * ((1 << b) - 1)` bits long, where `b` is the number of bits per short (typically 1048560 bits when `b = 16`). The implementation assumes that a `long` is at least twice as long as a `short`. This assumption hides beneath almost all primitive operations, and would be very difficult to change. It also relies on correct behavior of *unsigned* arithmetic operations.

Some of the arithmetic algorithms are very loosely based on those provided in the MIT Scheme `bignum.c' release, which is Copyright (c) 1987 Massachusetts Institute of Technology. Their use here falls within the provisions described in the Scheme release.

Integers may be constructed in the following ways:

`Integer x;`

Declares an uninitialized Integer.

`Integer x = 2; Integer y(2);`

Set x and y to the Integer value 2;

`Integer u(x); Integer v = x;`

Set u and v to the same value as x.

Method: long **Integer::as_long()** *const*

Used to coerce an `Integer` back into longs via the `long` coercion operator. If the Integer cannot fit into a long, this returns MINLONG or MAXLONG (depending on the sign) where MINLONG is the most negative, and MAXLONG is the most positive representable long.

Method: int **Integer::fits_in_long()** *const*

Returns true iff the `Integer` is `< MAXLONG` and `> MINLONG`.

Method: double **Integer::as_double()** *const*

Coerce the `Integer` to a `double`, with potential loss of precision. `+/-HUGE` is returned if the Integer cannot fit into a double.

Method: int **Integer::fits_in_double()** *const*

Returns true iff the `Integer` can fit into a double.

All of the usual arithmetic operators are provided (`+, -, *, /, %, +=, ++, -=, --, *=, /=, %=, ==, !=, <, <=, >, >=`). All operators support special versions for mixed arguments of Integers and regular C++ longs in order to avoid useless coercions, as well as to allow automatic promotion of shorts and ints to longs, so that they may be applied without additional Integer coercion

operators. The only operators that behave differently than the corresponding int or long operators are `++` and `--`. Because C++ does not distinguish prefix from postfix application, these are declared as `void` operators, so that no confusion can result from applying them as postfix. Thus, for Integers x and y, `++x; y = x;` is correct, but `y = ++x;` and `y = x++;` are not.

Bitwise operators (~, &, |, ^, <<, >>, &=, |=, ^=, <<=, >>=) are also provided. However, these operate on sign-magnitude, rather than two's complement representations. The sign of the result is arbitrarily taken as the sign of the first argument. For example, `Integer(-3) & Integer(5)` returns `Integer(-1)`, not -3, as it would using two's complement. Also, ~, the complement operator, complements only those bits needed for the representation. Bit operators are also provided in the BitSet and BitString classes. One of these classes should be used instead of Integers when the results of bit manipulations are not interpreted numerically.

The following utility functions are also provided. (All arguments are Integers unless otherwise noted).

Function: void **divide(const** *Integer& x, const Integer& y, Integer& q, Integer& r)*

Sets q to the quotient and r to the remainder of x and y. (q and r are returned by reference).

Function: Integer **pow(const** *Integer& x, const Integer& p)*

Returns x raised to the power p.

Function: Integer **lpow(long** *x, long p)*

Returns x raised to the power p.

Function: Integer **gcd(const** *Integer& x, const Integer& p)*

Returns the greatest common divisor of x and y.

Function: Integer **lcm(const** *Integer& x, const Integer& p)*

Returns the least common multiple of x and y.

Function: Integer **abs(const** *Integer& x*

Returns the absolute value of x.

Method: void **Integer::negate()**

Negates `this` in place.

`Integer sqr(x)`

returns x * x;

`Integer sqrt(x)`

returns the floor of the square root of x.

`long lg(x);`

returns the floor of the base 2 logarithm of abs(x)

`int sign(x)`

returns -1 if x is negative, 0 if zero, else +1. Using `if (sign(x) == 0)` is a generally fast method of testing for zero than using relational operators.

`int even(x)`

returns true if x is an even number

`int odd(x)`

returns true if x is an odd number.

`void setbit(Integer& x, long b)`

sets the b'th bit (counting right-to-left from zero) of x to 1.

`void clearbit(Integer& x, long b)`

sets the b'th bit of x to 0.

`int testbit(Integer x, long b)`

returns true if the b'th bit of x is 1.

`Integer atoI(char* asciinumber, int base = 10);`

converts the base base char* string into its Integer form.

`void Integer::printon(ostream& s, int base = 10, int width = 0);`

prints the ascii string value of `(*this)` as a base `base` number, in field width at least `width`.

`ostream << x;`

prints x in base ten format.

`istream >> x;`

reads x as a base ten number.

`int compare(Integer x, Integer y)`

returns a negative number if x<y, zero if x==y, or positive if x>y.

`int ucompare(Integer x, Integer y)`

like compare, but performs unsigned comparison.

`add(x, y, z)`

A faster way to say z = x + y.

`sub(x, y, z)`

A faster way to say z = x - y.

`mul(x, y, z)`

A faster way to say z = x * y.

`div(x, y, z)`

A faster way to say z = x / y.

`mod(x, y, z)`

A faster way to say z = x % y.

`and(x, y, z)`

A faster way to say z = x & y.

`or(x, y, z)`

A faster way to say z = x | y.

`xor(x, y, z)`

A faster way to say z = x ^ y.

`lshift(x, y, z)`

A faster way to say z = x << y.

`rshift(x, y, z)`

A faster way to say z = x >> y.

`pow(x, y, z)`

A faster way to say z = pow(x, y).

`complement(x, z)`

A faster way to say z = ~x.

`negate(x, z)`

A faster way to say z = -x.

Go to the previous, next section.

Go to the previous, next section.

The Rational Class

Class `Rational` provides multiple precision rational number arithmetic. All rationals are maintained in simplest form (i.e., with the numerator and denominator relatively prime, and with the denominator strictly positive). Rational arithmetic and relational operators are provided (`+, -, *, /, +=, -=, *=, /=, ==, !=, <, <=, >, >=`). Operations resulting in a rational number with zero denominator trigger an exception.

Rationals may be constructed and used in the following ways:

`Rational x;`

Declares an uninitialized Rational.

`Rational x = 2; Rational y(2);`

Set x and y to the Rational value 2/1;

`Rational x(2, 3);`

Sets x to the Rational value 2/3;

`Rational x = 1.2;`

Sets x to a Rational value close to 1.2. Any double precision value may be used to construct a Rational. The Rational will possess exactly as much precision as the double. Double values that do not have precise floating point equivalents (like 1.2) produce similarly imprecise rational values.

`Rational x(Integer(123), Integer(4567));`

Sets x to the Rational value 123/4567.

`Rational u(x); Rational v = x;`

Set u and v to the same value as x.

`double(Rational x)`

A Rational may be coerced to a double with potential loss of precision. +/-HUGE is returned if it will not fit.

`Rational abs(x)`

returns the absolute value of x.

`void x.negate()`

negates x.

`void x.invert()`

sets x to 1/x.

`int sign(x)`

returns 0 if x is zero, 1 if positive, and -1 if negative.

`Rational sqr(x)`

returns x * x.

`Rational pow(x, Integer y)`
: returns x to the y power.

`Integer x.numerator()`
: returns the numerator.

`Integer x.denominator()`
: returns the denominator.

`Integer floor(x)`
: returns the greatest Integer less than x.

`Integer ceil(x)`
: returns the least Integer greater than x.

`Integer trunc(x)`
: returns the Integer part of x.

`Integer round(x)`
: returns the nearest Integer to x.

`int compare(x, y)`
: returns a negative, zero, or positive number signifying whether x is less than, equal to, or greater than y.

`ostream << x;`
: prints x in the form num/den, or just num if the denominator is one.

`istream >> x;`
: reads x in the form num/den, or just num in which case the denominator is set to one.

`add(x, y, z)`
: A faster way to say z = x + y.

`sub(x, y, z)`
: A faster way to say z = x - y.

`mul(x, y, z)`
: A faster way to say z = x * y.

`div(x, y, z)`
: A faster way to say z = x / y.

`pow(x, y, z)`
: A faster way to say z = pow(x, y).

`negate(x, z)`
: A faster way to say z = -x.

Go to the previous, next section.

Go to the previous, next section.

The Complex class.

Class `Complex` is implemented in a way similar to that described by Stroustrup. In keeping with libg++ conventions, the class is named `Complex`, not `complex`. Complex arithmetic and relational operators are provided (`+, -, *, /, +=, -=, *=, /=, ==, !=`). Attempted division by (0, 0) triggers an exception.

Complex numbers may be constructed and used in the following ways:

`Complex x;`

Declares an uninitialized Complex.

`Complex x = 2; Complex y(2.0);`

Set x and y to the Complex value (2.0, 0.0);

`Complex x(2, 3);`

Sets x to the Complex value (2, 3);

`Complex u(x); Complex v = x;`

Set u and v to the same value as x.

`double real(Complex& x);`

returns the real part of x.

`double imag(Complex& x);`

returns the imaginary part of x.

`double abs(Complex& x);`

returns the magnitude of x.

`double norm(Complex& x);`

returns the square of the magnitude of x.

`double arg(Complex& x);`

returns the argument (amplitude) of x.

`Complex polar(double r, double t = 0.0);`

returns a Complex with abs of r and arg of t.

`Complex conj(Complex& x);`

returns the complex conjugate of x.

`Complex cos(Complex& x);`

returns the complex cosine of x.

`Complex sin(Complex& x);`

returns the complex sine of x.

`Complex cosh(Complex& x);`

returns the complex hyperbolic cosine of x.

```
Complex sinh(Complex& x);
```

returns the complex hyperbolic sine of x.

```
Complex exp(Complex& x);
```

returns the exponential of x.

```
Complex log(Complex& x);
```

returns the natural log of x.

```
Complex pow(Complex& x, long p);
```

returns x raised to the p power.

```
Complex pow(Complex& x, Complex& p);
```

returns x raised to the p power.

```
Complex sqrt(Complex& x);
```

returns the square root of x.

```
ostream << x;
```

prints x in the form (re, im).

```
istream >> x;
```

reads x in the form (re, im), or just (re) or re in which case the imaginary part is set to zero.

Fixed precision numbers

Classes `Fix16`, `Fix24`, `Fix32`, and `Fix48` support operations on 16, 24, 32, or 48 bit quantities that are considered as real numbers in the range [-1, +1). Such numbers are often encountered in digital signal processing applications. The classes may be be used in isolation or together. Class `Fix32` operations are entirely self-contained. Class `Fix16` operations are self-contained except that the multiplication operation `Fix16 * Fix16` returns a `Fix32`. `Fix24` and `Fix48` are similarly related.

The standard arithmetic and relational operations are supported (`=`, `+`, `-`, `*`, `/`, `<<`, `>>`, `+=`, `-=`, `*=`, `/=`, `<<=`, `>>=`, `==`, `!=`, `<`, `<=`, `>`, `>=`). All operations include provisions for special handling in cases where the result exceeds +/- 1.0. There are two cases that may be handled separately: "overflow" where the results of addition and subtraction operations go out of range, and all other "range errors" in which resulting values go off-scale (as with division operations, and assignment or initialization with off-scale values). In signal processing applications, it is often useful to handle these two cases differently. Handlers take one argument, a reference to the integer mantissa of the offending value, which may then be manipulated. In cases of overflow, this value is the result of the (integer) arithmetic computation on the mantissa; in others it is a fully saturated (i.e., most positive or most negative) value. Handling may be reset to any of several provided functions or any other user-defined function via `set_overflow_handler` and `set_range_error_handler`. The provided functions for `Fix16` are as follows (corresponding functions are also supported for the others).

`Fix16_overflow_saturate`

> The default overflow handler. Results are "saturated": positive results are set to the largest representable value (binary 0.111111...), and negative values to -1.0.

`Fix16_ignore`

> Performs no action. For overflow, this will allow addition and subtraction operations to "wrap around" in the same manner as integer arithmetic, and for saturation, will leave values saturated.

`Fix16_overflow_warning_saturate`

> Prints a warning message on standard error, then saturates the results.

`Fix16_warning`

> The default range_error handler. Prints a warning message on standard error; otherwise leaving the argument unmodified.

`Fix16_abort`

> prints an error message on standard error, then aborts execution.

In addition to arithmetic operations, the following are provided:

`Fix16 a = 0.5;`

> Constructs fixed precision objects from double precision values. Attempting to initialize to a value outside the range invokes the range_error handler, except, as a convenience, initialization to 1.0 sets the variable to the most positive representable value (binary 0.1111111...) without invoking the handler.

`short& mantissa(a); long& mantissa(b);`

return a * pow(2, 15) or b * pow(2, 31) as an integer. These are returned by reference, to enable "manual" data manipulation.

`double value(a); double value(b);`

return a or b as floating point numbers.

Go to the previous, next section.

Go to the previous, next section.

Classes for Bit manipulation

libg++ provides several different classes supporting the use and manipulation of collections of bits in different ways.

- Class `Integer` provides "integer" semantics. It supports manipulation of bits in ways that are often useful when treating bit arrays as numerical (integer) quantities. This class is described elsewhere.
- Class `BitSet` provides "set" semantics. It supports operations useful when treating collections of bits as representing potentially infinite sets of integers.
- Class `BitSet32` supports fixed-length BitSets holding exactly 32 bits.
- Class `BitSet256` supports fixed-length BitSets holding exactly 256 bits.
- Class `BitString` provides "string" (or "vector") semantics. It supports operations useful when treating collections of bits as strings of zeros and ones.

These classes also differ in the following ways:

- BitSets are logically infinite. Their space is dynamically altered to adjust to the smallest number of consecutive bits actually required to represent the sets. Integers also have this property. BitStrings are logically finite, but their sizes are internally dynamically managed to maintain proper length. This means that, for example, BitStrings are concatenatable while BitSets and Integers are not.
- BitSet32 and BitSet256 have precisely the same properties as BitSets, except that they use constant fixed length bit vectors.
- While all classes support basic unary and binary operations `~, &, |, ^, -`, the semantics differ. BitSets perform bit operations that precisely mirror those for infinite sets. For example, complementing an empty BitSet returns one representing an infinite number of set bits. Operations on BitStrings and Integers operate only on those bits actually present in the representation. For BitStrings and Integers, the the & operation returns a BitString with a length equal to the minimum length of the operands, and `|, ^` return one with length of the maximum.
- Only BitStrings support substring extraction and bit pattern matching.

BitSet

BitSets are objects that contain logically infinite sets of nonnegative integers. Representational details are discussed in the Representation chapter. Because they are logically infinite, all BitSets possess a trailing, infinitely replicated 0 or 1 bit, called the "virtual bit", and indicated via 0* or 1*.

BitSet32 and BitSet256 have they same properties, except they are of fixed length, and thus have no virtual bit.

BitSets may be constructed as follows:

```
BitSet a;
```

declares an empty BitSet.

`BitSet a = atoBitSet("001000");`

sets a to the BitSet 0010*, reading left-to-right. The "0*" indicates that the set ends with an infinite number of zero (clear) bits.

`BitSet a = atoBitSet("00101*");`

sets a to the BitSet 00101*, where "1*" means that the set ends with an infinite number of one (set) bits.

`BitSet a = longtoBitSet((long)23);`

sets a to the BitSet 111010*, the binary representation of decimal 23.

`BitSet a = utoBitSet((unsigned)23);`

sets a to the BitSet 111010*, the binary representation of decimal 23.

The following functions and operators are provided (Assume the declaration of BitSets a = 0011010*, b = 101101*, throughout, as examples).

`~a`

returns the complement of a, or 1100101* in this case.

`a.complement()`

sets a to ~a.

`a & b; a &= b;`

returns a intersected with b, or 0011010*.

`a | b; a |= b;`

returns a unioned with b, or 1011111*.

`a - b; a -= b;`

returns the set difference of a and b, or 000010*.

`a ^ b; a ^= b;`

returns the symmetric difference of a and b, or 1000101*.

`a.empty()`

returns true if a is an empty set.

`a == b;`

returns true if a and b contain the same set.

`a <= b;`

returns true if a is a subset of b.

`a < b;`

returns true if a is a proper subset of b;

`a != b; a >= b; a > b;`

are the converses of the above.

`a.set(7)`

sets the 7th (counting from 0) bit of a, setting a to 001111010*

`a.clear(2)`

clears the 2nd bit bit of a, setting a to 00011110*

`a.clear()`

clears all bits of a;

`a.set()`

sets all bits of a;

`a.invert(0)`

complements the 0th bit of a, setting a to 10011110*

`a.set(0,1)`

sets the 0th through 1st bits of a, setting a to 110111110* The two-argument versions of clear and invert are similar.

`a.test(3)`

returns true if the 3rd bit of a is set.

`a.test(3, 5)`

returns true if any of bits 3 through 5 are set.

`int i = a[3]; a[3] = 0;`

The subscript operator allows bits to be inspected and changed via standard subscript semantics, using a friend class BitSetBit. The use of the subscript operator a[i] rather than a.test(i) requires somewhat greater overhead.

`a.first(1) or a.first()`

returns the index of the first set bit of a (2 in this case), or -1 if no bits are set.

`a.first(0)`

returns the index of the first clear bit of a (0 in this case), or -1 if no bits are clear.

`a.next(2, 1) or a.next(2)`

returns the index of the next bit after position 2 that is set (3 in this case) or -1. `first` and `next` may be used as iterators, as in `for (int i = a.first(); i >= 0; i = a.next(i))....`

`a.last(1)`

returns the index of the rightmost set bit, or -1 if there or no set bits or all set bits.

`a.prev(3, 0)`

returns the index of the previous clear bit before position 3.

`a.count(1)`

returns the number of set bits in a, or -1 if there are an infinite number.

`a.virtual_bit()`

returns the trailing (infinitely replicated) bit of a.

`a = atoBitSet("ababX", 'a', 'b', 'X');`

converts the char* string into a bitset, with 'a' denoting false, 'b' denoting true, and 'X' denoting infinite replication.

`a.printon(cout, '-', '.', 0)`

prints `a` to `cout` represented with `'-'` for falses, `'.'` for trues, and no replication marker.

`cout << a`

prints `a` to `cout` (representing lases by `'f'`, trues by `'t'`, and using `'*'` as the replication marker).

`diff(x, y, z)`

A faster way to say z = x - y.

`and(x, y, z)`

A faster way to say z = x & y.

`or(x, y, z)`

A faster way to say z = x | y.

`xor(x, y, z)`

A faster way to say z = x ^ y.

`complement(x, z)`

A faster way to say z = ~x.

BitString

BitStrings are objects that contain arbitrary-length strings of zeroes and ones. BitStrings possess some features that make them behave like sets, and others that behave as strings. They are useful in applications (such as signature-based algorithms) where both capabilities are needed. Representational details are discussed in the Representation chapter. Most capabilities are exact analogs of those supported in the BitSet and String classes. A BitSubString is used with substring operations along the same lines as the String SubString class. A BitPattern class is used for masked bit pattern searching.

Only a default constructor is supported. The declaration `BitString a;` initializes a to be an empty BitString. BitStrings may often be initialized via `atoBitString` and `longtoBitString`.

Set operations (`~, complement, &, &=, |, |=, -, ^, ^=`) behave just as the BitSet versions, except that there is no "virtual bit": complementing complements only those bits in the BitString, and all binary operations across unequal length BitStrings assume a virtual bit of zero. The `&` operation returns a BitString with a length equal to the minimum length of the operands, and `|, ^` return one with length of the maximum.

Set-based relational operations (`==, !=, <=, <, >=, >`) follow the same rules. A string-like lexicographic comparison function, `lcompare`, tests the lexicographic relation between two BitStrings. For example, lcompare(1100, 0101) returns 1, since the first BitString starts with 1 and the second with 0.

Individual bit setting, testing, and iterator operations (`set, clear, invert, test, first, next, last, prev`) are also like those for BitSets. BitStrings are automatically expanded when setting bits at positions greater than their current length.

The string-based capabilities are just as those for class String. BitStrings may be concatenated (`+`, searched (`index, contains, matches`), and extracted into BitSubStrings (`before, at, after`) which may be assigned and otherwise manipulated. Other string-based utility functions (`reverse, common_prefix, common_suffix`) are also provided. These have the same capabilities and descriptions as those for Strings.

String-oriented operations can also be performed with a mask via class BitPattern. BitPatterns consist of two BitStrings, a pattern and a mask. On searching and matching, bits in the pattern that correspond to 0 bits in the mask are ignored. (The mask may be shorter than the pattern, in which case trailing mask bits are assumed to be 0). The pattern and mask are both public variables, and may be individually subjected to other bit operations.

Converting to char* and printing (`(atoBitString, atoBitPattern, printon, ostream <<)`) are also as in BitSets, except that no virtual bit is used, and an 'X' in a BitPattern means that the pattern bit is masked out.

The following features are unique to BitStrings.

Assume declarations of BitString a = atoBitString("01010110") and b = atoBitSTring("1101").

`a = b + c;`

Sets a to the concatenation of b and c;

`a = b + 0; a = b + 1;`

sets a to b, appended with a zero (one).

`a += b;`

appends b to a;

`a += 0; a += 1;`

appends a zero (one) to a.

`a << 2; a <<= 2`

return a with 2 zeros prepended, setting a to 0001010110. (Note the necessary confusion of << and >> operators. For consistency with the integer versions, << shifts low bits to high, even though they are printed low bits first.)

`a >> 3; a >>= 3`

return a with the first 3 bits deleted, setting a to 10110.

`a.left_trim(0)`

deletes all 0 bits on the left of a, setting a to 1010110.

`a.right_trim(0)`

deletes all trailing 0 bits of a, setting a to 0101011.

`cat(x, y, z)`

A faster way to say z = x + y.

`diff(x, y, z)`

A faster way to say z = x - y.

`and(x, y, z)`

A faster way to say z = x & y.

`or(x, y, z)`

A faster way to say z = x | y.

`xor(x, y, z)`

A faster way to say z = x ^ y.

`lshift(x, y, z)`

A faster way to say z = x << y.

`rshift(x, y, z)`

A faster way to say z = x >> y.

`complement(x, z)`

A faster way to say z = ~x.

Go to the previous, next section.

Random Number Generators and related classes

The two classes `RNG` and `Random` are used together to generate a variety of random number distributions. A distinction must be made between *random number generators*, implemented by class `RNG`, and *random number distributions*. A random number generator produces a series of randomly ordered bits. These bits can be used directly, or cast to other representations, such as a floating point value. A random number generator should produce a *uniform* distribution. A random number distribution, on the other hand, uses the randomly generated bits of a generator to produce numbers from a distribution with specific properties. Each instance of `Random` uses an instance of class `RNG` to provide the raw, uniform distribution used to produce the specific distribution. Several instances of `Random` classes can share the same instance of `RNG`, or each instance can use its own copy.

RNG

Random distributions are constructed from members of class `RNG`, the actual random number generators. The `RNG` class contains no data; it only serves to define the interface to random number generators. The `RNG::asLong` member returns an unsigned long (typically 32 bits) of random bits. Applications that require a number of random bits can use this directly. More often, these random bits are transformed to a uniform random number:

```
    //
    // Return random bits converted to either a float or a double
    //
    float asFloat();
    double asDouble();
};
```

using either `asFloat` or `asDouble`. It is intended that `asFloat` and `asDouble` return differing precisions; typically, `asDouble` will draw two random longwords and transform them into a legal `double`, while `asFloat` will draw a single longword and transform it into a legal `float`. These members are used by subclasses of the `Random` class to implement a variety of random number distributions.

ACG

Class `ACG` is a variant of a Linear Congruential Generator (Algorithm M) described in Knuth, *Art of Computer Programming, Vol III*. This result is permuted with a Fibonacci Additive Congruential Generator to get good independence between samples. This is a very high quality random number

generator, although it requires a fair amount of memory for each instance of the generator.

The `ACG::ACG` constructor takes two parameters: the seed and the size. The seed is any number to be used as an initial seed. The performance of the generator depends on having a distribution of bits through the seed. If you choose a number in the range of 0 to 31, a seed with more bits is chosen. Other values are deterministically modified to give a better distribution of bits. This provides a good random number generator while still allowing a sequence to be repeated given the same initial seed.

The `size` parameter determines the size of two tables used in the generator. The first table is used in the Additive Generator; see the algorithm in Knuth for more information. In general, this table is `size` longwords long. The default value, used in the algorithm in Knuth, gives a table of 220 bytes. The table size affects the period of the generators; smaller values give shorter periods and larger tables give longer periods. The smallest table size is 7 longwords, and the longest is 98 longwords. The `size` parameter also determines the size of the table used for the Linear Congruential Generator. This value is chosen implicitly based on the size of the Additive Congruential Generator table. It is two powers of two larger than the power of two that is larger than `size`. For example, if `size` is 7, the ACG table is 7 longwords and the LCG table is 128 longwords. Thus, the default size (55) requires 55 + 256 longwords, or 1244 bytes. The largest table requires 2440 bytes and the smallest table requires 100 bytes. Applications that require a large number of generators or applications that aren't so fussy about the quality of the generator may elect to use the `MLCG` generator.

MLCG

The `MLCG` class implements a *Multiplicative Linear Congruential Generator*. In particular, it is an implementation of the double MLCG described in *"Efficient and Portable Combined Random Number Generators"* by Pierre L'Ecuyer, appearing in *Communications of the ACM, Vol. 31. No. 6*. This generator has a fairly long period, and has been statistically analyzed to show that it gives good inter-sample independence.

The `MLCG::MLCG` constructor has two parameters, both of which are seeds for the generator. As in the `MLCG` generator, both seeds are modified to give a "better" distribution of seed digits. Thus, you can safely use values such as `0' or `1' for the seeds. The `MLCG` generator used much less state than the `ACG` generator; only two longwords (8 bytes) are needed for each generator.

Random

A random number generator may be declared by first declaring a `RNG` and then a `Random`. For example, `ACG gen(10, 20); NegativeExpntl rnd (1.0, &gen);` declares an additive congruential generator with seed 10 and table size 20, that is used to generate exponentially distributed values with mean of 1.0.

The virtual member `Random::operator()` is the common way of extracting a random number from a particular distribution. The base class, `Random` does not implement `operator()`. This is performed by each of the subclasses. Thus, given the above declaration of `rnd`, new random values may be obtained via, for example, `double next_exp_rand = rnd();` Currently, the following

subclasses are provided.

Binomial

The binomial distribution models successfully drawing items from a pool. The first parameter to the constructor, `n`, is the number of items in the pool, and the second parameter, `u`, is the probability of each item being successfully drawn. The member `asDouble` returns the number of samples drawn from the pool. Although it is not checked, it is assumed that `n>0` and `0 <= u <= 1`. The remaining members allow you to read and set the parameters.

Erlang

The `Erlang` class implements an Erlang distribution with mean `mean` and variance `variance`.

Geometric

The `Geometric` class implements a discrete geometric distribution. The first parameter to the constructor, `mean`, is the mean of the distribution. Although it is not checked, it is assumed that `0 <= mean <= 1`. `Geometric()` returns the number of uniform random samples that were drawn before the sample was larger than `mean`. This quantity is always greater than zero.

HyperGeometric

The `HyperGeometric` class implements the hypergeometric distribution. The first parameter to the constructor, `mean`, is the mean and the second, `variance`, is the variance. The remaining members allow you to inspect and change the mean and variance.

NegativeExpntl

The `NegativeExpntl` class implements the negative exponential distribution. The first parameter to the constructor is the mean. The remaining members allow you to inspect and change the mean.

Normal

The `Normal`class implements the normal distribution. The first parameter to the constructor, `mean`, is the mean and the second, `variance`, is the variance. The remaining members allow you to inspect and change the mean and variance. The `LogNormal` class is a subclass of `Normal`.

LogNormal

The `LogNormal`class implements the logarithmic normal distribution. The first parameter to the constructor, `mean`, is the mean and the second, `variance`, is the variance. The remaining members allow you to inspect and change the mean and variance. The `LogNormal` class is a subclass of `Normal`.

Poisson

The `Poisson` class implements the poisson distribution. The first parameter to the constructor is the mean. The remaining members allow you to inspect and change the mean.

DiscreteUniform

The `DiscreteUniform` class implements a uniform random variable over the closed interval ranging from `[low..high]`. The first parameter to the constructor is `low`, and the second is `high`, although the order of these may be reversed. The remaining members allow you to inspect and change `low` and `high`.

Uniform

The `Uniform` class implements a uniform random variable over the open interval ranging from `[low..high)`. The first parameter to the constructor is `low`, and the second is `high`, although the order of these may be reversed. The remaining members allow you to inspect and change `low` and `high`.

Weibull

The `Weibull` class implements a weibull distribution with parameters `alpha` and `beta`. The first parameter to the class constructor is `alpha`, and the second parameter is `beta`. The remaining members allow you to inspect and change `alpha` and `beta`.

RandomInteger

The `RandomInteger` class is *not* a subclass of Random, but a stand-alone integer-oriented class that is dependent on the RNG classes. RandomInteger returns random integers uniformly from the closed interval `[low..high]`. The first parameter to the constructor is `low`, and the second is `high`, although both are optional. The last argument is always a generator. Additional members allow you to inspect and change `low` and `high`. Random integers are generated using `asInt()` or `asLong()`. Operator syntax (`()`) is also available as a shorthand for `asLong()`. Because `RandomInteger` is often used in simulations for which uniform random integers are desired over a variety of ranges,

TOC

`asLong()` and `asInt` have `high` as an optional argument. Using this optional argument produces a single value from the new range, but does not change the default range.

Go to the previous, next section.

Go to the previous, next section.

Data Collection

Libg++ currently provides two classes for *data collection* and analysis of the collected data.

SampleStatistic

Class `SampleStatistic` provides a means of accumulating samples of `double` values and providing common sample statistics.

Assume declaration of `double x`.

`SampleStatistic a;`
: declares and initializes a.

`a.reset();`
: re-initializes a.

`a += x;`
: adds sample x.

`int n = a.samples();`
: returns the number of samples.

`x = a.mean;`
: returns the means of the samples.

`x = a.var()`
: returns the sample variance of the samples.

`x = a.stdDev()`
: returns the sample standard deviation of the samples.

`x = a.min()`
: returns the minimum encountered sample.

`x = a.max()`
: returns the maximum encountered sample.

`x = a.confidence(int p)`
: returns the p-percent (0 <= p < 100) confidence interval.

`x = a.confidence(double p)`
: returns the p-probability (0 <= p < 1) confidence interval.

SampleHistogram

Class `SampleHistogram` is a derived class of `SampleStatistic` that supports collection and display of samples in bucketed intervals. It supports the following in addition to `SampleStatisic` operations.

`SampleHistogram h(double lo, double hi, double width);`

declares and initializes h to have buckets of size width from lo to hi. If the optional argument width is not specified, 10 buckets are created. The first bucket and also holds samples less than lo, and the last one holds samples greater than hi.

`int n = h.similarSamples(x)`

returns the number of samples in the same bucket as x.

`int n = h.inBucket(int i)`

returns the number of samples in bucket i.

`int b = h.buckets()`

returns the number of buckets.

`h.printBuckets(ostream s)`

prints bucket counts on ostream s.

`double bound = h.bucketThreshold(int i)`

returns the upper bound of bucket i.

Go to the previous, next section.

Go to the previous, next section.

Curses-based classes

The `CursesWindow` class is a repackaging of standard curses library features into a class. It relies on `` `curses.h' ``.

The supplied `` `curses.h' `` is a fairly conservative declaration of curses library features, and does not include features like "screen" or X-window support. It is, for the most part, an adaptation, rather than an improvement of C-based `` `curses.h' `` files. The only substantive changes are the declarations of many functions as inline functions rather than macros, which was done solely to allow overloading.

The `CursesWindow` class encapsulates curses window functions within a class. Only those functions that control windows are included: Terminal control functions and macros like `cbreak` are not part of the class. All `CursesWindows` member functions have names identical to the corresponding curses library functions, except that the "w" prefix is generally dropped. Descriptions of these functions may be found in your local curses library documentation.

A `CursesWindow` may be declared via

`CursesWindow w(WINDOW* win)`

attaches w to the existing WINDOW* win. This is constructor is normally used only in the following special case.

`CursesWindow w(stdscr)`

attaches w to the default curses library standard screen window.

`CursesWindow w(int lines, int cols, int begin_y, int begin_x)`

attaches to an allocated curses window with the indicated size and screen position.

`CursesWindow sub(CursesWindow& w,int l,int c,int by,int bx,char ar='a')`

attaches to a subwindow of w created via the curses `subwin' command. If ar is sent as `r', the origin (by, bx) is relative to the parent window, else it is absolute.

The class maintains a static counter that is used in order to automatically call the curses library `initscr` and `endscr` functions at the proper times. These need not, and should not be called "manually".

`CursesWindows` maintain a tree of their subwindows. Upon destruction of a `CursesWindow`, all of their subwindows are also invalidated if they had not previously been destroyed.

It is possible to traverse trees of subwindows via the following member functions

`CursesWindow* w.parent()`

returns a pointer to the parent of the subwindow, or 0 if there is none.

`CursesWindow* w.child()`

returns the first child subwindow of the window, or 0 if there is none.

`CursesWindow* w.sibling()`

returns the next sibling of the subwindow, or 0 if there is none.

For example, to call some function `visit` for all subwindows of a window, you could write

```
void traverse(CursesWindow& w)
{
  visit(w);
  if (w.child() != 0) traverse(*w.child);
  if (w.sibling() != 0) traverse(*w.sibling);
}
```

Go to the previous, next section.

List classes

The files `g++-include/List.hP' and `g++-include/List.ccP' provide pseudo-generic Lisp-type List classes. These lists are homogeneous lists, more similar to lists in statically typed functional languages like ML than Lisp, but support operations very similar to those found in Lisp. Any particular kind of list class may be generated via the `genclass` shell command. However, the implementation assumes that the base class supports an equality operator `==`. All equality tests use the `==` operator, and are thus equivalent to the use of `equal`, not `eq` in Lisp.

All list nodes are created dynamically, and managed via reference counts. `List` variables are actually pointers to these list nodes. Lists may also be traversed via Pixes, as described in the section describing Pixes. See section Pseudo-indexes

Supported operations are mirrored closely after those in Lisp. Generally, operations with functional forms are constructive, functional operations, while member forms (often with the same name) are sometimes procedural, possibly destructive operations.

As with Lisp, destructive operations are supported. Programmers are allowed to change head and tail fields in any fashion, creating circular structures and the like. However, again as with Lisp, some operations implicitly assume that they are operating on pure lists, and may enter infinite loops when presented with improper lists. Also, the reference-counting storage management facility may fail to reclaim unused circularly-linked nodes.

Several Lisp-like higher order functions are supported (e.g., `map`). Typedef declarations for the required functional forms are provided int the `.h' file.

For purposes of illustration, assume the specification of class `intList`. Common Lisp versions of supported operations are shown in brackets for comparison purposes.

Constructors and assignment

`intList a; [ (setq a nil) ]`

Declares a to be a nil intList.

`intList b(2); [ (setq b (cons 2 nil)) ]`

Declares b to be an intList with a head value of 2, and a nil tail.

`intList c(3, b); [ (setq c (cons 3 b)) ]`

Declares c to be an intList with a head value of 3, and b as its tail.

`b = a; [ (setq b a) ]`

Sets b to be the same list as a.

Assume the declarations of intLists a, b, and c in the following. See section Pseudo-indexes.

List status

`a.null(); OR !a; [ (null a) ]`

returns true if a is null.

`a.valid(); [ (listp a) ]`

returns true if a is non-null. Inside a conditional test, the `void*` coercion may also be used as in `if (a) ....`

`intList(); [ nil ]`

intList() may be used to null terminate a list, as in `intList f(int x) {if (x == 0) return intList(); ... }` .

`a.length(); [ (length a) ]`

returns the length of a.

`a.list_length(); [ (list-length a) ]`

returns the length of a, or -1 if a is circular.

heads and tails

`a.get(); OR a.head() [ (car a) ]`

returns a reference to the head field.

`a[2]; [ (elt a 2) ]`

returns a reference to the second (counting from zero) head field.

`a.tail(); [ (cdr a) ]`

returns the intList that is the tail of a.

`a.last(); [ (last a) ]`

returns the intList that is the last node of a.

`a.nth(2); [ (nth a 2) ]`

returns the intList that is the nth node of a.

`a.set_tail(b); [ (rplacd a b) ]`

sets a's tail to b.

`a.push(2); [ (push 2 a) ]`

equivalent to a = intList(2, a);

`int x = a.pop() [ (setq x (car a)) (pop a) ]`

returns the head of a, also setting a to its tail.

Constructive operations

`b = copy(a); [ (setq b (copy-seq a)) ]`
sets b to a copy of a.

`b = reverse(a); [ (setq b (reverse a)) ]`
Sets b to a reversed copy of a.

`c = concat(a, b); [ (setq c (concat a b)) ]`
Sets c to a concatenated copy of a and b.

`c = append(a, b); [ (setq c (append a b)) ]`
Sets c to a concatenated copy of a and b. All nodes of a are copied, with the last node pointing to b.

`b = map(f, a); [ (setq b (mapcar f a)) ]`
Sets b to a new list created by applying function f to each node of a.

`c = combine(f, a, b);`
Sets c to a new list created by applying function f to successive pairs of a and b. The resulting list has length the shorter of a and b.

`b = remove(x, a); [ (setq b (remove x a)) ]`
Sets b to a copy of a, omitting all occurrences of x.

`b = remove(f, a); [ (setq b (remove-if f a)) ]`
Sets b to a copy of a, omitting values causing function f to return true.

`b = select(f, a); [ (setq b (remove-if-not f a)) ]`
Sets b to a copy of a, omitting values causing function f to return false.

`c = merge(a, b, f); [ (setq c (merge a b f)) ]`
Sets c to a list containing the ordered elements (using the comparison function f) of the sorted lists a and b.

Destructive operations

`a.append(b); [ (rplacd (last a) b) ]`
appends b to the end of a. No new nodes are constructed.

`a.prepend(b); [ (setq a (append b a)) ]`
prepends b to the beginning of a.

`a.del(x); [ (delete x a) ]`
deletes all nodes with value x from a.

`a.del(f); [ (delete-if f a) ]`
deletes all nodes causing function f to return true.

`a.select(f); [ (delete-if-not f a) ]`
deletes all nodes causing function f to return false.

`a.reverse(); [ (nreverse a) ]`

reverses a in-place.

`a.sort(f); [ (sort a f) ]`

sorts a in-place using ordering (comparison) function f.

`a.apply(f); [ (mapc f a) ]`

Applies void function f (int x) to each element of a.

`a.subst(int old, int repl); [ (nsubst repl old a) ]`

substitutes repl for each occurrence of old in a. Note the different argument order than the Lisp version.

Other operations

`a.find(int x); [ (find x a) ]`

returns the intList at the first occurrence of x.

`a.find(b); [ (find b a) ]`

returns the intList at the first occurrence of sublist b.

`a.contains(int x); [ (member x a) ]`

returns true if a contains x.

`a.contains(b); [ (member b a) ]`

returns true if a contains sublist b.

`a.position(int x); [ (position x a) ]`

returns the zero-based index of x in a, or -1 if x does not occur.

`int x = a.reduce(f, int base); [ (reduce f a :initial-value base) ]`

Accumulates the result of applying int function f(int, int) to successive elements of a, starting with base.

Go to the previous, next section.

Go to the previous, next section.

Linked Lists

SLLists provide pseudo-generic singly linked lists. DLLists provide doubly linked lists. The lists are designed for the simple maintenance of elements in a linked structure, and do not provide the more extensive operations (or node-sharing) of class `List`. They behave similarly to the `slist` and similar classes described by Stroustrup.

All list nodes are created dynamically. Assignment is performed via copying.

Class `DLList` supports all `SLList` operations, plus additional operations described below.

For purposes of illustration, assume the specification of class `intSLList`. In addition to the operations listed here, SLLists support traversal via Pixes. See section Pseudo-indexes

`intSLList a;`
: Declares a to be an empty list.

`intSLList b = a;`
: Sets b to an element-by-element copy of a.

`a.empty()`
: returns true if a contains no elements

`a.length();`
: returns the number of elements in a.

`a.prepend(x);`
: places x at the front of the list.

`a.append(x);`
: places x at the end of the list.

`a.join(b)`
: places all nodes from b to the end of a, simultaneously destroying b.

`x = a.front()`
: returns a reference to the item stored at the head of the list, or triggers an error if the list is empty.

`a.rear()`
: returns a reference to the rear of the list, or triggers an error if the list is empty.

`x = a.remove_front()`
: deletes and returns the item stored at the head of the list.

`a.del_front()`
: deletes the first element, without returning it.

`a.clear()`
: deletes all items from the list.

`a.ins_after(Pix i, item);`

inserts item after position i. If i is null, insertion is at the front.

`a.del_after(Pix i);`

deletes the element following i. If i is 0, the first item is deleted.

Doubly linked lists

Class `DLList` supports the following additional operations, as well as backward traversal via Pixes.

`x = a.remove_rear();`

deletes and returns the item stored at the rear of the list.

`a.del_rear();`

deletes the last element, without returning it.

`a.ins_before(Pix i, x)`

inserts x before the i.

`a.del(Pix& iint dir = 1)`

deletes the item at the current position, then advances forward if dir is positive, else backward.

Go to the previous, next section.

Go to the previous, next section.

Vector classes

The files `g++-include/Vec.ccP' and `g++-include/AVec.ccP' provide pseudo-generic standard array-based vector operations. The corresponding header files are `g++-include/Vec.hP' and `g++-include/AVec.hP'. Class `Vec` provides operations suitable for any base class that includes an equality operator. Subclass `AVec` provides additional arithmetic operations suitable for base classes that include the full complement of arithmetic operators.

`Vecs` are constructed and assigned by copying. Thus, they should normally be passed by reference in applications programs.

Several mapping functions are provided that allow programmers to specify operations on vectors as a whole.

For illustrative purposes assume that classes `intVec` and `intAVec` have been generated via `genclass`.

Constructors and assignment

`intVec a;`
: declares a to be an empty vector. Its size may be changed via resize.

`intVec a(10);`
: declares a to be an uninitialized vector of ten elements (numbered 0-9).

`intVec b(6, 0);`
: declares b to be a vector of six elements, all initialized to zero. Any value can be used as the initial fill argument.

`a = b;`
: Copies b to a. a is resized to be the same as b.

`a = b.at(2, 4)`
: constructs a from the 4 elements of b starting at b[2].

Assume declarations of `intVec a, b, c` and `int i, x` in the following.

Status and access

`a.capacity();`
: returns the number of elements that can be held in a.

`a.resize(20);`
: sets a's length to 20. All elements are unchanged, except that if the new size is smaller than the

original, than trailing elements are deleted, and if greater, trailing elements are uninitialized.

`a[i];`

returns a reference to the i'th element of a, or produces an error if i is out of range.

`a.elem(i)`

returns a reference to the i'th element of a. Unlike the `[]` operator, i is not checked to ensure that it is within range.

`a == b;`

returns true if a and b contain the same elements in the same order.

`a != b;`

is the converse of a == b.

Constructive operations

`c = concat(a, b);`

sets c to the new vector constructed from all of the elements of a followed by all of b.

`c = map(f, a);`

sets c to the new vector constructed by applying int function f(int) to each element of a.

`c = merge(a, b, f);`

sets c to the new vector constructed by merging the elements of ordered vectors a and b using ordering (comparison) function f.

`c = combine(f, a, b);`

sets c to the new vector constructed by applying int function f(int, int) to successive pairs of a and b. The result has length the shorter of a and b.

`c = reverse(a)`

sets c to a, with elements in reverse order.

Destructive operations

`a.reverse();`

reverses a in-place.

`a.sort(f)`

sorts a in-place using comparison function f. The sorting method is a variation of the quicksort functions supplied with GNU emacs.

`a.fill(0, 4, 2)`

fills the 2 elements starting at a[4] with zero.

Other operations

`a.apply(f)`

applies function f to each element in a.

`x = a.reduce(f, base)`

accumulates the results of applying function f to successive elements of a starting with base.

`a.index(int targ);`

returns the index of the leftmost occurrence of the target, or -1, if it does not occur.

`a.error(char* msg)`

invokes the error handler. The default version prints the error message, then aborts.

AVec operations.

AVecs provide additional arithmetic operations. All vector-by-vector operators generate an error if the vectors are not the same length. The following operations are provided, for `AVecs a, b` and base element (scalar) `s`.

`a = b;`

Copies b to a. a and b must be the same size.

`a = s;`

fills all elements of a with the value s. a is not resized.

`a + s; a - s; a * s; a / s`

adds, subtracts, multiplies, or divides each element of a with the scalar.

`a += s; a -= s; a *= s; a /= s;`

adds, subtracts, multiplies, or divides the scalar into a.

`a + b; a - b; product(a, b), quotient(a, b)`

adds, subtracts, multiplies, or divides corresponding elements of a and b.

`a += b; a -= b; a.product(b); a.quotient(b);`

adds, subtracts, multiplies, or divides corresponding elements of b into a.

`s = a * b;`

returns the inner (dot) product of a and b.

`x = a.sum();`

returns the sum of elements of a.

`x = a.sumsq();`

returns the sum of squared elements of a.

`x = a.min();`

returns the minimum element of a.

`x = a.max();`

returns the maximum element of a.

`i = a.min_index();`

returns the index of the minimum element of a.

`i = a.max_index();`

returns the index of the maximum element of a.

Note that it is possible to apply vector versions other arithmetic operators via the mapping functions. For example, to set vector b to the cosines of doubleVec a, use `b = map(cos, a);`. This is often more efficient than performing the operations in an element-by-element fashion.

Go to the previous, next section.

Go to the previous, next section.

Plex classes

A "Plex" is a kind of array with the following properties:

- Plexes may have arbitrary upper and lower index bounds. For example a Plex may be declared to run from indices -10 .. 10.
- Plexes may be dynamically expanded at both the lower and upper bounds of the array in steps of one element.
- Only elements that have been specifically initialized or added may be accessed.
- Elements may be accessed via indices. Indices are always checked for validity at run time. Plexes may be traversed via simple variations of standard array indexing loops.
- Plex elements may be accessed and traversed via Pixes.
- Plex-to-Plex assignment and related operations on entire Plexes are supported.
- Plex classes contain methods to help programmers check the validity of indexing and pointer operations.
- Plexes form "natural" base classes for many restricted-access data structures relying on logically contiguous indices, such as array-based stacks and queues.
- Plexes are implemented as pseudo-generic classes, and must be generated via the `genclass` utility.

Four subclasses of Plexes are supported: A `FPlex` is a Plex that may only grow or shrink within declared bounds; an `XPlex` may dynamically grow or shrink without bounds; an `RPlex` is the same as an `XPlex` but better supports indexing with poor locality of reference; a `MPlex` may grow or shrink, and additionally allows the logical deletion and restoration of elements. Because these classes are virtual subclasses of the "abstract" class `Plex`, it is possible to write user code such as `void f(Plex& a) ...` that operates on any kind of Plex. However, as with nearly any virtual class, specifying the particular Plex class being used results in more efficient code.

Plexes are implemented as a linked list of `IChunks`. Each chunk contains a part of the array. Chunk sizes may be specified within Plex constructors. Default versions also exist, that use a `#define'd` default. Plexes grow by filling unused space in existing chunks, if possible, else, except for FPlexes, by adding another chunk. Whenever Plexes grow by a new chunk, the default element constructors (i.e., those which take no arguments) for all chunk elements are called at once. When Plexes shrink, destructors for the elements are not called until an entire chunk is freed. For this reason, Plexes (like C++ arrays) should only be used for elements with default constructors and destructors that have no side effects.

Plexes may be indexed and used like arrays, although traversal syntax is slightly different. Even though Plexes maintain elements in lists of chunks, they are implemented so that iteration and other constructs that maintain locality of reference require very little overhead over that for simple array traversal Pix-based traversal is also supported. For example, for a plex, p, of ints, the following traversal methods could be used.

```
for (int i = p.low(); i < p.fence(); p.next(i)) use(p[i]);
for (int i = p.high(); i > p.ecnef(); p.prev(i)) use(p[i]);
for (Pix t = p.first(); t != 0; p.next(t)) use(p(i));
for (Pix t = p.last(); t != 0; p.prev(t)) use(p(i));
```

Except for MPlexes, simply using `++i` and `--i` works just as well as `p.next(i)` and `p.prev(i)` when traversing by index. Index-based traversal is generally a bit faster than Pix-based traversal.

`XPlexes` and `MPlexes` are less than optimal for applications in which widely scattered elements are indexed, as might occur when using Plexes as hash tables or "manually" allocated linked lists. In such applications, `RPlexes` are often preferable. `RPlexes` use a secondary chunk index table that requires slightly greater, but entirely uniform overhead per index operation.

Even though they may grow in either direction, Plexes are normally constructed so that their "natural" growth direction is upwards, in that default chunk construction leaves free space, if present, at the end of the plex. However, if the chunksize arguments to constructors are negative, they leave space at the beginning.

All versions of Plexes support the following basic capabilities. (letting `Plex` stand for the type name constructed via the genclass utility (e.g., `intPlex`, `doublePlex`)). Assume declarations of `Plex p, q`, `int i, j`, base element `x`, and Pix `pix`.

`Plex p;`

Declares p to be an initially zero-sized Plex with low index of zero, and the default chunk size. For FPlexes, chunk sizes represent maximum sizes.

`Plex p(int size);`

Declares p to be an initially zero-sized Plex with low index of zero, and the indicated chunk size. If size is negative, then the Plex is created with free space at the beginning of the Plex, allowing more efficient add_low() operations. Otherwise, it leaves space at the end.

`Plex p(int low, int size);`

Declares p to be an initially zero-sized Plex with low index of low, and the indicated chunk size.

`Plex p(int low, int high, Base initval, int size = 0);`

Declares p to be a Plex with indices from low to high, initially filled with initval, and the indicated chunk size if specified, else the default or (high - low + 1), whichever is greater.

`Plex q(p);`

Declares q to be a copy of p.

`p = q;`

Copies Plex q into p, deleting its previous contents.

`p.length()`

Returns the number of elements in the Plex.

`p.empty()`

Returns true if Plex p contains no elements.

`p.full()`

Returns true if Plex p cannot be expanded. This always returns false for XPlexes and MPlexes.

`p[i]`

Returns a reference to the i'th element of p. An exception (error) occurs if i is not a valid index.

`p.valid(i)`

Returns true if i is a valid index into Plex p.

`p.low(); p.high();`

Return the minimum (maximum) valid index of the Plex, or the high (low) fence if the plex is empty.

`p.ecnef(); p.fence();`

Return the index one position past the minimum (maximum) valid index.

`p.next(i); i = p.prev(i);`

Set i to the next (previous) index. This index may not be within bounds.

`p(pix)`

returns a reference to the item at Pix pix.

`pix = p.first(); pix = p.last();`

Return the minimum (maximum) valid Pix of the Plex, or 0 if the plex is empty.

`p.next(pix); p.prev(pix);`

set pix to the next (previous) Pix, or 0 if there is none.

`p.owns(pix)`

Returns true if the Plex contains the element associated with pix.

`p.Pix_to_index(pix)`

If pix is a valid Pix to an element of the Plex, returns its corresponding index, else raises an exception.

`ptr = p.index_to_Pix(i)`

if i is a valid index, returns a the corresponding Pix.

`p.low_element(); p.high_element();`

Return a reference to the element at the minimum (maximum) valid index. An exception occurs if the Plex is empty.

`p.can_add_low(); p.can_add_high();`

Returns true if the plex can be extended one element downward (upward). These always return true for XPlex and MPlex.

`j = p.add_low(x); j = p.add_high(x);`

Extend the Plex by one element downward (upward). The new minimum (maximum) index is returned.

`j = p.del_low(); j = p.del_high()`

Shrink the Plex by one element on the low (high) end. The new minimum (maximum) element is returned. An exception occurs if the Plex is empty.

`p.append(q);`

Append all of Plex q to the high side of p.

`p.prepend(q);`

Prepend all of q to the low side of p.

`p.clear()`

Delete all elements, resetting p to a zero-sized Plex.

`p.reset_low(i);`

Resets p to be indexed starting at low() = i. For example. if p were initially declared via `Plex p(0, 10, 0)`, and then re-indexed via `p.reset_low(5)`, it could then be indexed from indices 5 .. 14.

`p.fill(x)`

sets all p[i] to x.

`p.fill(x, lo, hi)`

sets all of p[i] from lo to hi, inclusive, to x.

`p.reverse()`

reverses p in-place.

`p.chunk_size()`

returns the chunk size used for the plex.

`p.error(const char * msg)`

calls the resettable error handler.

MPlexes are plexes with bitmaps that allow items to be logically deleted and restored. They behave like other plexes, but also support the following additional and modified capabilities:

`p.del_index(i); p.del_Pix(pix)`

logically deletes p[i] (p(pix)). After deletion, attempts to access p[i] generate a error. Indexing via low(), high(), prev(), and next() skip the element. Deleting an element never changes the logical bounds of the plex.

`p.undel_index(i); p.undel_Pix(pix)`

logically undeletes p[i] (p(pix)).

`p.del_low(); p.del_high()`

Delete the lowest (highest) undeleted element, resetting the logical bounds of the plex to the next lowest (highest) undeleted index. Thus, MPlex del_low() and del_high() may shrink the bounds of the plex by more than one index.

`p.adjust_bounds()`

Resets the low and high bounds of the Plex to the indexes of the lowest and highest actual undeleted elements.

`int i = p.add(x)`

Adds x in an unused index, if possible, else performs add_high.

`p.count()`

returns the number of valid (undeleted) elements.

`p.available()`

returns the number of available (deleted) indices.

`int i = p.unused_index()`

returns the index of some deleted element, if one exists, else triggers an error. An unused element may be reused via undel.

`pix = p.unused_Pix()`

returns the pix of some deleted element, if one exists, else 0. An unused element may be reused via undel.

Go to the previous, next section.

Go to the previous, next section.

Stacks

Stacks are declared as an "abstract" class. They are currently implemented in any of three ways.

`VStack`
: implement fixed sized stacks via arrays.

`XPStack`
: implement dynamically-sized stacks via XPlexes.

`SLStack`
: implement dynamically-size stacks via linked lists.

All possess the same capabilities. They differ only in constructors. VStack constructors require a fixed maximum capacity argument. XPStack constructors optionally take a chunk size argument. SLStack constructors take no argument.

Assume the declaration of a base element `x`.

`Stack s; or Stack s(int capacity)`
: declares a Stack.

`s.empty()`
: returns true if stack s is empty.

`s.full()`
: returns true if stack s is full. XPStacks and SLStacks never become full.

`s.length()`
: returns the current number of elements in the stack.

`s.push(x)`
: pushes x on stack s.

`x = s.pop()`
: pops and returns the top of stack

`s.top()`
: returns a reference to the top of stack.

`s.del_top()`
: pops, but does not return the top of stack. When large items are held on the stack it is often a good idea to use `top()` to inspect and use the top of stack, followed by a `del_top()`

`s.clear()`
: removes all elements from the stack.

Go to the previous, next section.

Go to the previous, next section.

Queues

Queues are declared as an "abstract" class. They are currently implemented in any of three ways.

`VQueue`
: implement fixed sized Queues via arrays.

`XPQueue`
: implement dynamically-sized Queues via XPlexes.

`SLQueue`
: implement dynamically-size Queues via linked lists.

All possess the same capabilities; they differ only in constructors. `VQueue` constructors require a fixed maximum capacity argument. `XPQueue` constructors optionally take a chunk size argument. `SLQueue` constructors take no argument.

Assume the declaration of a base element `x`.

`Queue q; or Queue q(int capacity);`
: declares a queue.

`q.empty()`
: returns true if queue q is empty.

`q.full()`
: returns true if queue q is full. XPQueues and SLQueues are never full.

`q.length()`
: returns the current number of elements in the queue.

`q.enq(x)`
: enqueues x on queue q.

`x = q.deq()`
: dequeues and returns the front of queue

`q.front()`
: returns a reference to the front of queue.

`q.del_front()`
: dequeues, but does not return the front of queue

`q.clear()`
: removes all elements from the queue.

Go to the previous, next section.

Go to the previous, next section.

Double ended Queues

Deques are declared as an "abstract" class. They are currently implemented in two ways.

`XPDeque`
: implement dynamically-sized Deques via XPlexes.

`DLDeque`
: implement dynamically-size Deques via linked lists.

All possess the same capabilities. They differ only in constructors. XPDeque constructors optionally take a chunk size argument. DLDeque constructors take no argument.

Double-ended queues support both stack-like and queue-like capabilities:

Assume the declaration of a base element `x`.

`Deque d; or Deque d(int initial_capacity)`
: declares a deque.

`d.empty()`
: returns true if deque d is empty.

`d.full()`
: returns true if deque d is full. Always returns false in current implementations.

`d.length()`
: returns the current number of elements in the deque.

`d.enq(x)`
: inserts x at the rear of deque d.

`d.push(x)`
: inserts x at the front of deque d.

`x = d.deq()`
: dequeues and returns the front of deque

`d.front()`
: returns a reference to the front of deque.

`d.rear()`
: returns a reference to the rear of the deque.

`d.del_front()`
: deletes, but does not return the front of deque

`d.del_rear()`
: deletes, but does not return the rear of the deque.

`d.clear()`

removes all elements from the deque.

Go to the previous, next section.

Go to the previous, next section.

Priority Queue class prototypes.

Priority queues maintain collections of objects arranged for fast access to the least element.

Several prototype implementations of priority queues are supported.

`XPPQs`

implement 2-ary heaps via XPlexes.

`SplayPQs`

implement PQs via Sleator and Tarjan's (JACM 1985) splay trees. The algorithms use a version of "simple top-down splaying" (described on page 669 of the article). The simple-splay mechanism for priority queue functions is loosely based on the one used by D. Jones in the C splay tree functions available from volume 14 of the uunet.uu.net archives.

`PHPQs`

implement pairing heaps (as described by Fredman and Sedgewick in Algorithmica, Vol 1, p111-129). Storage for heap elements is managed via an internal freelist technique. The constructor allows an initial capacity estimate for freelist space. The storage is automatically expanded if necessary to hold new items. The deletion technique is a fast "lazy deletion" strategy that marks items as deleted, without reclaiming space until the items come to the top of the heap.

All PQ classes support the following operations, for some PQ class `Heap`, instance `h`, `Pix ind`, and base class variable `x`.

`h.empty()`

returns true if there are no elements in the PQ.

`h.length()`

returns the number of elements in h.

`ind = h.enq(x)`

Places x in the PQ, and returns its index.

`x = h.deq()`

Dequeues the minimum element of the PQ into x, or generates an error if the PQ is empty.

`h.front()`

returns a reference to the minimum element.

`h.del_front()`

deletes the minimum element.

`h.clear();`

deletes all elements from h;

`h.contains(x)`

returns true if x is in h.

`h(ind)`

returns a reference to the item indexed by ind.

`ind = h.first()`

returns the Pix of first item in the PQ or 0 if empty. This need not be the Pix of the least element.

`h.next(ind)`

advances ind to the Pix of next element, or 0 if there are no more.

`ind = h.seek(x)`

Sets ind to the Pix of x, or 0 if x is not in h.

`h.del(ind)`

deletes the item with Pix ind.

Go to the previous, next section.

Go to the previous, next section.

Set class prototypes

Set classes maintain unbounded collections of items containing no duplicate elements.

These are currently implemented in several ways, differing in representation strategy, algorithmic efficiency, and appropriateness for various tasks. (Listed next to each are average (followed by worst-case, if different) time complexities for [a] adding, [f] finding (via seek, contains), [d] deleting, elements, and [c] comparing (via ==, <=) and [m] merging (via |=, -=, &=) sets).

`XPSets`
: implement unordered sets via XPlexes. ([a O(n)], [f O(n)], [d O(n)], [c O(n^2)] [m O(n^2)]).

`OXPSets`
: implement ordered sets via XPlexes. ([a O(n)], [f O(log n)], [d O(n)], [c O(n)] [m O(n)]).

`SLSets`
: implement unordered sets via linked lists ([a O(n)], [f O(n)], [d O(n)], [c O(n^2)] [m O(n^2)]).

`OSLSets`
: implement ordered sets via linked lists ([a O(n)], [f O(n)], [d O(n)], [c O(n)] [m O(n)]).

`AVLSets`
: implement ordered sets via threaded AVL trees ([a O(log n)], [f O(log n)], [d O(log n)], [c O(n)] [m O(n)]).

`BSTSets`
: implement ordered sets via binary search trees. The trees may be manually rebalanced via the O(n) `balance()` member function. ([a O(log n)/O(n)], [f O(log n)/O(n)], [d O(log n)/O(n)], [c O(n)] [m O(n)]).

`SplaySets`
: implement ordered sets via Sleator and Tarjan's (JACM 1985) splay trees. The algorithms use a version of "simple top-down splaying" (described on page 669 of the article). (Amortized: [a O(log n)], [f O(log n)], [d O(log n)], [c O(n)] [m O(n log n)]).

`VHSets`
: implement unordered sets via hash tables. The tables are automatically resized when their capacity is exhausted. ([a O(1)/O(n)], [f O(1)/O(n)], [d O(1)/O(n)], [c O(n)/O(n^2)] [m O(n)/O(n^2)]).

`VOHSets`
: implement unordered sets via ordered hash tables The tables are automatically resized when their capacity is exhausted. ([a O(1)/O(n)], [f O(1)/O(n)], [d O(1)/O(n)], [c O(n)/O(n^2)] [m O(n)/O(n^2)]).

`CHSets`
: implement unordered sets via chained hash tables. ([a O(1)/O(n)], [f O(1)/O(n)], [d O(1)/O(n)], [c O(n)/O(n^2)] [m O(n)/O(n^2)]).

The different implementations differ in whether their constructors require an argument specifying the initial capacity. Initial capacities are required for plex and hash table based Sets. If none is given `DEFAULT_INITIAL_CAPACITY` (from `` `<T>defs.h' ``) is used.

Sets support the following operations, for some class `Set`, instances `a` and `b`, `Pix ind`, and base element `x`. Since all implementations are virtual derived classes of the `<T>Set` class, it is possible to mix and match operations across different implementations, although, as usual, operations are generally faster when the particular classes are specified in functions operating on Sets.

Pix-based operations are more fully described in the section on Pixes. See section Pseudo-indexes

`Set a; or Set a(int initial_size);`

Declares a to be an empty Set. The second version is allowed in set classes that require initial capacity or sizing specifications.

`a.empty()`

returns true if a is empty.

`a.length()`

returns the number of elements in a.

`Pix ind = a.add(x)`

inserts x into a, returning its index.

`a.del(x)`

deletes x from a.

`a.clear()`

deletes all elements from a;

`a.contains(x)`

returns true if x is in a.

`a(ind)`

returns a reference to the item indexed by ind.

`ind = a.first()`

returns the Pix of first item in the set or 0 if the Set is empty. For ordered Sets, this is the Pix of the least element.

`a.next(ind)`

advances ind to the Pix of next element, or 0 if there are no more.

`ind = a.seek(x)`

Sets ind to the Pix of x, or 0 if x is not in a.

`a == b`

returns true if a and b contain all the same elements.

`a != b`

returns true if a and b do not contain all the same elements.

`a <= b`

returns true if a is a subset of b.

`a |= b`

Adds all elements of b to a.

`a -= b`

Deletes all elements of b from a.

`a &= b`

Deletes all elements of a not occurring in b.

Go to the previous, next section.

Go to the previous, next section.

Bag class prototypes

Bag classes maintain unbounded collections of items potentially containing duplicate elements.

These are currently implemented in several ways, differing in representation strategy, algorithmic efficiency, and appropriateness for various tasks. (Listed next to each are average (followed by worst-case, if different) time complexities for [a] adding, [f] finding (via seek, contains), [d] deleting elements).

`XPBags`
: implement unordered Bags via XPlexes. ([a O(1)], [f O(n)], [d O(n)]).

`OXPBags`
: implement ordered Bags via XPlexes. ([a O(n)], [f O(log n)], [d O(n)]).

`SLBags`
: implement unordered Bags via linked lists ([a O(1)], [f O(n)], [d O(n)]).

`OSLBags`
: implement ordered Bags via linked lists ([a O(n)], [f O(n)], [d O(n)]).

`SplayBags`
: implement ordered Bags via Sleator and Tarjan's (JACM 1985) splay trees. The algorithms use a version of "simple top-down splaying" (described on page 669 of the article). (Amortized: [a O(log n)], [f O(log n)], [d O(log n)]).

`VHBags`
: implement unordered Bags via hash tables. The tables are automatically resized when their capacity is exhausted. ([a O(1)/O(n)], [f O(1)/O(n)], [d O(1)/O(n)]).

`CHBags`
: implement unordered Bags via chained hash tables. ([a O(1)/O(n)], [f O(1)/O(n)], [d O(1)/O(n)]).

The implementations differ in whether their constructors require an argument to specify their initial capacity. Initial capacities are required for plex and hash table based Bags. If none is given `DEFAULT_INITIAL_CAPACITY` (from `` `<T>defs.h' ``) is used.

Bags support the following operations, for some class `Bag`, instances `a` and `b`, `Pix ind`, and base element `x`. Since all implementations are virtual derived classes of the `<T>Bag` class, it is possible to mix and match operations across different implementations, although, as usual, operations are generally faster when the particular classes are specified in functions operating on Bags.

Pix-based operations are more fully described in the section on Pixes. See section Pseudo-indexes

`Bag a; or Bag a(int initial_size)`
: Declares a to be an empty Bag. The second version is allowed in Bag classes that require initial capacity or sizing specifications.

`a.empty()`
: returns true if a is empty.

`a.length()`
: returns the number of elements in a.

`ind = a.add(x)`
: inserts x into a, returning its index.

`a.del(x)`
: deletes one occurrence of x from a.

`a.remove(x)`
: deletes all occurrences of x from a.

`a.clear()`
: deletes all elements from a;

`a.contains(x)`
: returns true if x is in a.

`a.nof(x)`
: returns the number of occurrences of x in a.

`a(ind)`
: returns a reference to the item indexed by ind.

`int = a.first()`
: returns the Pix of first item in the Bag or 0 if the Bag is empty. For ordered Bags, this is the Pix of the least element.

`a.next(ind)`
: advances ind to the Pix of next element, or 0 if there are no more.

`ind = a.seek(x, Pix from = 0)`
: Sets ind to the Pix of the next occurrence x, or 0 if there are none. If from is 0, the first occurrence is returned, else the following from.

Map Class Prototypes

Maps support associative array operations (insertion, deletion, and membership of records based on an associated key). They require the specification of two types, the key type and the contents type.

These are currently implemented in several ways, differing in representation strategy, algorithmic efficiency, and appropriateness for various tasks. (Listed next to each are average (followed by worst-case, if different) time complexities for [a] accessing (via op [], contains), [d] deleting elements).

`AVLMaps`

implement ordered Maps via threaded AVL trees ([a O(log n)], [d O(log n)]).

`RAVLMaps`

Similar, but also maintain ranking information, used via `ranktoPix(int r)`, that returns the `Pix` of the item at rank r, and `rank(key)` that returns the rank of the corresponding item. ([a O(log n)], [d O(log n)]).

`SplayMaps`

implement ordered Maps via Sleator and Tarjan's (JACM 1985) splay trees. The algorithms use a version of "simple top-down splaying" (described on page 669 of the article). (Amortized: [a O(log n)], [d O(log n)]).

`VHMaps`

implement unordered Maps via hash tables. The tables are automatically resized when their capacity is exhausted. ([a O(1)/O(n)], [d O(1)/O(n)]).

`CHMaps`

implement unordered Maps via chained hash tables. ([a O(1)/O(n)], [d O(1)/O(n)]).

The different implementations differ in whether their constructors require an argument specifying their initial capacity. Initial capacities are required for hash table based Maps. If none is given `DEFAULT_INITIAL_CAPACITY` (from `` `<T>defs.h' ``) is used.

All Map classes share the following operations (for some Map class, `Map` instance `d`, `Pix ind` and key variable `k`, and contents variable `x`).

Pix-based operations are more fully described in the section on Pixes. See section Pseudo-indexes

`Map d(x); Map d(x, int initial_capacity)`

Declare d to be an empty Map. The required argument, x, specifies the default contents, i.e., the contents of an otherwise uninitialized location. The second version, specifying initial capacity is allowed for Maps with an initial capacity argument.

`d.empty()`

returns true if d contains no items.

`d.length()`

returns the number of items in d.

`d[k]`

returns a reference to the contents of item with key k. If no such item exists, it is installed with the default contents. Thus d[k] = x installs x, and x = d[k] retrieves it.

`d.contains(k)`

returns true if an item with key field k exists in d.

`d.del(k)`

deletes the item with key k.

`d.clear()`

deletes all items from the table.

`x = d.dflt()`

returns the default contents.

`k = d.key(ind)`

returns a reference to the key at Pix ind.

`x = d.contents(ind)`

returns a reference to the contents at Pix ind.

`ind = d.first()`

returns the Pix of the first element in d, or 0 if d is empty.

`d.next(ind)`

advances ind to the next element, or 0 if there are no more.

`ind = d.seek(k)`

returns the Pix of element with key k, or 0 if k is not in d.

C++ version of the GNU getopt function

The GetOpt class provides an efficient and structured mechanism for processing command-line options from an application program. The sample program fragment below illustrates a typical use of the GetOpt class for some hypothetical application program:

```
#include <stdio.h>
#include <GetOpt.h>
//...
int debug_flag, compile_flag, size_in_bytes;

int
main (int argc, char **argv)
{
  // Invokes ctor `GetOpt (int argc, char **argv,
  //                       char *optstring);'
  GetOpt getopt (argc, argv, "dcs:");
  int option_char;

  // Invokes member function `int operator ()(void);'
  while ((option_char = getopt ()) != EOF)
    switch (option_char)
      {
         case 'd': debug_flag = 1; break;
         case 'c': compile_flag = 1; break;
         case 's': size_in_bytes = atoi (getopt.optarg); break;
         case '?': fprintf (stderr,
                            "usage: %s [dcs<size>]\n", argv[0]);
      }
}
```

Unlike the C library version, the libg++ GetOpt class uses its constructor to initialize class data members containing the argument count, argument vector, and the option string. This simplifies the interface for each subsequent call to member function `int operator ()(void)`.

The C version, on the other hand, uses hidden static variables to retain the option string and argument list values between calls to `getopt`. This complicates the `getopt` interface since the argument count, argument vector, and option string must be passed as parameters for each invocation. For the C version, the loop in the previous example becomes:

```
  while ((option_char = getopt (argc, argv, "dcs:")) != EOF)
    // ...
```

which requires extra overhead to pass the parameters for every call.

Along with the GetOpt constructor and `int operator ()(void)`, the other relevant elements of class GetOpt are:

`char *optarg`

Used for communication from `operator ()(void)` to the caller. When `operator ()(void)` finds an option that takes an argument, the argument value is stored here.

`int optind`

Index in `argv` of the next element to be scanned. This is used for communication to and from the caller and for communication between successive calls to `operator ()(void)`. When `operator ()(void)` returns EOF, this is the index of the first of the non-option elements that the caller should itself scan. Otherwise, `optind` communicates from one call to the next how much of `argv` has been scanned so far.

The libg++ version of GetOpt acts like standard UNIX `getopt` for the calling routine, but it behaves differently for the user, since it allows the user to intersperse the options with the other arguments. As GetOpt works, it permutes the elements of `argv` so that, when it is done, all the options precede everything else. Thus all application programs are extended to handle flexible argument order.

Setting the environment variable _POSIX_OPTION_ORDER disables permutation. Then the behavior is completely standard.

Go to the previous, next section.

Go to the previous section.

Projects and other things left to do

Coming Attractions

Some things that will probably be available in libg++ in the near future:

- Revamped C-compatibility header files that will be compatible with the forthcoming (ANSI-based) GNU libc.a
- A revision of the File-based classes that will use the GNU stdio library, and also be 100% compatible (even at the streambuf level) with the AT&T 2.0 stream classes.
- Additional container class prototypes.
- generic Matrix class prototypes.
- A task package probably based on Dirk Grunwald's threads package.

Wish List

Some things that people have mentioned that they would like to see in libg++, but for which there have not been any offers:

- A method to automatically convert or incorporate libg++ classes so they can be used directly in Gorlen's OOPS environment.
- A class browser.
- A better general exception-handling strategy.
- Better documentation.

How to contribute

Programmers who have written C++ classes that they believe to be of general interest are encourage to write to dl at rocky.oswego.edu. Contributing code is not difficult. Here are some general guidelines:

- FSF must maintain the right to accept or reject potential contributions. Generally, the only reasons for rejecting contributions are cases where they duplicate existing or nearly-released code, contain unremovable specific machine dependencies, or are somehow incompatible with the rest of the library.
- Acceptance of contributions means that the code is accepted for adaptation into libg++. FSF must reserve the right to make various editorial changes in code. Very often, this merely entails formatting, maintenance of various conventions, etc. Contributors are always given authorship credit and shown the final version for approval.
- Contributors must assign their copyright to FSF via a form sent out upon acceptance. Assigning copyright to FSF ensures that the code may be freely distributed.

- Assistance in providing documentation, test files, and debugging support is strongly encourag

Extensions, comments, and suggested modifications of existing libg++ features are also very welcome.

GNU Libtool

For version 1.2, 10 March 1998

Gordon Matzigkeit

This file documents GNU Libtool, a script that allows package developers to provide generic shared library support. This edition documents version 1.2.

See section Reporting bugs, for information on how to report problems with libtool.

This document was generated on 20 May 1999 using the texi2html translator version 1.51a.

Go to the first, previous, next, last section, table of contents.

Troubleshooting

Libtool is under constant development, changing to remain up-to-date with modern operating systems. If libtool doesn't work the way you think it should on your platform, you should read this chapter to help determine what the problem is, and how to resolve it.

The libtool test suite

Libtool comes with its own set of programs that test its capabilities, and report obvious bugs in the libtool program. These tests, too, are constantly evolving, based on past problems with libtool, and known deficiencies in other operating systems.

As described in the `INSTALL' file, you may run make check after you have built libtool (possibly before you install it) in order to make sure that it meets basic functional requirements.

Description of test suite

Here is a list of the current programs in the test suite, and what they test for:

`demo-conf.test`

`demo-exec.test`

`demo-inst.test`

`demo-make.test`

`demo-unst.test`

These programs check to see that the `demo' subdirectory of the libtool distribution can be configured, built, installed, and uninstalled correctly. The `demo' subdirectory contains a demonstration of a trivial package that uses libtool.

`hardcode.test`

On all systems with shared libraries, the location of the library can be encoded in executables that are linked against it see section Linking executables. This test checks the conditions under which your system linker hardcodes the library location, and guarantees that they correspond to libtool's own notion of how your linker behaves.

`link.test`

This test guarantees that linking directly against a non-libtool static library works properly.

`link-2.test`

This test makes sure that files ending in `.lo' are never linked directly into a program file.

`suffix.test`

When other programming languages are used with libtool (see section Using libtool with other languages), the source files may end in suffixes other than `.c'. This test validates that libtool can handle suffixes for all the file types that it supports, and that it fails when the suffix is invalid.

`test-e.test`

This program checks that the `test -e` construct is *never* used in the libtool scripts. Checking for the existence of a file can only be done in a portable way by using `test -f`.

When tests fail

Each of the above tests are designed to produce no output when they are run via make check. The exit status of each program tells the `Makefile' whether or not the test succeeded.

If a test fails, it means that there is either a programming error in libtool, or in the test program itself.

To investigate a particular test, you may run it directly, as you would a normal program. When the test is invoked in this way, it produces output which may be useful in determining what the problem is.

Another way to have the test programs produce output is to set the VERBOSE environment variable to `yes' before running them. For example, env VERBOSE=yes make check runs all the tests, and has each of them display debugging information.

Reporting bugs

If you think you have discovered a bug in libtool, you should think twice: the libtool maintainer is notorious for passing the buck (or maybe that should be "passing the bug"). Libtool was invented to fix known deficiencies in shared library implementations, so, in a way, most of the bugs in libtool are actually bugs in other operating systems. However, the libtool maintainer would definitely be happy to add support for somebody else's buggy operating system. [I wish there was a good way to do winking smiley-faces in texinfo.]

Genuine bugs in libtool include problems with shell script portability, documentation errors, and failures in the test suite (see section The libtool test suite).

First, check the documentation and help screens to make sure that the behaviour you think is a problem is not already mentioned as a feature.

Then, you should read the Emacs guide to reporting bugs (see section `Reporting Bugs' in The Emacs Manual). Some of the details listed there are specific to Emacs, but the principle behind them is a general one.

Finally, send a bug report to the libtool mailing list `<bug-libtool@gnu.org>` with any appropriate *facts*, such as test suite output (see section When tests fail), all the details needed to reproduce the bug, and a brief description of why you think the behaviour is a bug. Be sure to include the word "libtool" in the subject line, as well as the version number you are using (which can be found by typing ltconfig --version).

Please include the generated `libtool` script with your bug report, so that I can see what values `ltconfig` guessed for your system.

Introduction

In the past, if a source code package developer wanted to take advantage of the power of shared libraries, he needed to write custom support code for each platform on which his package ran. He also had to design a configuration interface so that the package installer could choose what sort of libraries were built.

GNU Libtool simplifies the developer's job by encapsulating both the platform-specific dependencies, and the user interface, in a single script. GNU Libtool is designed so that the complete functionality of each host type is available via a generic interface, but nasty quirks are hidden from the programmer.

GNU Libtool's consistent interface is reassuring... users don't need to read obscure documentation in order to have their favorite source package build shared libraries. They just run your package `configure` script (or equivalent), and libtool does all the dirty work.

There are several examples throughout this document. All assume the same environment: we want to build a library, `` `libhello' ``, in a generic way.

`` `libhello' `` could be a shared library, a static library, or both... whatever is available on the host system, as long as libtool has been ported to it.

This chapter explains the original design philosophy of libtool. Feel free to skip to the next chapter, unless you are interested in history, or want to write code to extend libtool in a consistent way.

Motivation for writing libtool

Since early 1995, several different GNU developers have recognized the importance of having shared library support for their packages. The primary motivation for such a change is to encourage modularity and reuse of code (both conceptually and physically) in GNU programs.

Such a demand means that the way libraries are built in GNU packages needs to be general, to allow for any library type the package installer might want. The problem is compounded by the absence of a standard procedure for creating shared libraries on different platforms.

The following sections outline the major issues facing shared library support in GNU, and how I propose that shared library support could be standardized with libtool.

The following specifications were used in developing and evaluating this system:

1. The system must be as elegant as possible.
2. The system must be fully integrated with the GNU Autoconf and Automake utilities, so that it will be easy for GNU maintainers to use. However, the system must not require these tools, so that it can be used by non-GNU packages.

3. Portability to other (non-GNU) architectures and tools is desirable.

Implementation issues

The following issues need to be addressed in any reusable shared library system, specifically libtool:

1. The package installer should be able to control what sort of libraries are built.
2. It can be tricky to run dynamically linked programs whose libraries have not yet been installed. LD_LIBRARY_PATH must be set properly (if it is supported), or programs fail to run.
3. The system must operate consistently even on hosts which don't support shared libraries.
4. The commands required to build shared libraries may differ wildly from host to host. These need to be determined at configure time in a consistent way.
5. It is not always obvious with which suffix a shared library should be installed. This makes it difficult for `Makefile' rules, since they generally assume that file names are the same from host to host.
6. The system needs a simple library version number abstraction, so that shared libraries can be upgraded in place. The programmer should be informed how to design the interfaces to the library to maximize binary compatibility.
7. The install `Makefile' target should warn the package installer to set the proper environment variables (LD_LIBRARY_PATH or equivalent), or run `ldconfig(8)`.

Other implementations

I have investigated several different implementations of systems that build shared libraries as part of a free software package. At first, I made notes on the features of each of these packages for comparison purposes.

Now it is clear that none of these packages have documented the details of shared library systems that libtool requires. So, other packages have been more or less abandoned as influences.

A postmortem analysis of other implementations

In all fairness, each of the implementations that I examined do the job that they were intended to do, for a number of different host systems. However, none of these solutions seem to function well as a generalized, reusable component.

Most were too complex for me to use (much less modify) without understanding exactly what the implementation does, and they were generally not documented.

I think the main problem is that different vendors have different views of what libraries are, and none of the packages I examined seemed to be confident enough to settle on a single paradigm that just *works*.

Ideally, libtool would be a standard that would be implemented as series of extensions and modifications to existing library systems to make them work consistently. However, I don't have the time or power to

convince operating system developers to mend their evil ways, and I want to build shared libraries r now, even on buggy, broken, confused operating systems.

For this reason, I have designed libtool as an independent shell script. It isolates the problems and inconsistencies in library building that plague `Makefile' writers by wrapping the compiler suite on different platforms with a consistent, powerful interface.

I hope that libtool will be useful to and used by the GNU community, and that the lessons I've learned in writing it will be taken up and implemented by designers of library systems.

Go to the first, previous, next, last section, table of contents.

TOC

The libtool paradigm

At first, libtool was designed to support an arbitrary number of library object types. After porting libtool to more platforms, I discovered a new paradigm for describing the relationship between libraries and programs.

In summary, "libraries are programs with multiple entry points, and more formally defined interfaces."

Version 0.7 of libtool was a complete redesign and rewrite of libtool to reflect this new paradigm. So far, it has proved to be successful: libtool is simpler and more useful than before.

The best way to introduce the libtool paradigm is to contrast it with the paradigm of existing library systems, with examples from each. It is a new way of thinking, so it may take a little time to absorb, but when you understand it, the world becomes simpler.

Go to the first, previous, next, last section, table of contents.

TOC

Using libtool

It makes little sense to talk about using libtool in your own packages until you have seen how it makes your life simpler. The examples in this chapter introduce the main features of libtool by comparing the standard library building procedure to libtool's operation on two different platforms:

`a23'
: An Ultrix 4.2 platform with only static libraries.

`burger'
: A NetBSD/i386 1.2 platform with shared libraries.

You can follow these examples on your own platform, using the preconfigured libtool script that was installed with libtool (see section Configuring libtool).

Source files for the following examples are taken from the `demo' subdirectory of the libtool distribution. Assume that we are building a library, `libhello', out of the files `foo.c' and `hello.c'.

Note that the `foo.c' source file uses the `cos(3)` math library function, which is usually found in the standalone math library, and not the C library. So, we need to add -lm to the end of the link line whenever we link `foo.o' or `foo.lo' into an executable or a library (see section Inter-library dependencies).

The same rule applies whenever you use functions that don't appear in the standard C library... you need to add the appropriate -lname flag to the end of the link line when you link against those objects.

After we have built that library, we want to create a program by linking `main.o' against `libhello'.

Creating object files

To create an object file from a source file, the compiler is invoked with the `-c' flag (and any other desired flags):

```
burger$ gcc -g -O -c main.c
burger$
```

The above compiler command produces an object file, `main.o', from the source file `main.c'.

For most library systems, creating object files that become part of a static library is as simple as creating object files that are linked to form an executable:

```
burger$ gcc -g -O -c foo.c
burger$ gcc -g -O -c hello.c
burger$
```

Shared libraries, however, may only be built from **position-independent code** (PIC). So, special flags must be passed to the compiler to tell it to generate PIC rather than the standard position-dependent code.

Since this is a library implementation detail, libtool hides the complexity of PIC compiler flags by using separate library object files (which end in `.lo' instead of `.o'). On systems without shared libraries (or without special PIC compiler flags), these library object files are identical to "standard" object files.

To create library object files for `foo.c' and `hello.c', simply invoke libtool with the standard compilation command as arguments (see section Compile mode):

```
a23$ libtool gcc -g -O -c foo.c
gcc -g -O -c foo.c
ln -s foo.o foo.lo
a23$ libtool gcc -g -O -c hello.c
gcc -g -O -c hello.c
ln -s hello.o hello.lo
a23$
```

Note that libtool creates two object files for each invocation. The `.lo' file is a library object, and the `.o' file is a standard object file. On `a23', these files are identical, because only static libraries are supported.

On shared library systems, libtool automatically inserts the PIC generation flags into the compilation command, so that the library object and the standard object differ:

```
burger$ libtool gcc -g -O -c foo.c
gcc -g -O -c -fPIC -DPIC foo.c
mv -f foo.o foo.lo
gcc -g -O -c foo.c
burger$ libtool gcc -g -O -c hello.c
gcc -g -O -c -fPIC -DPIC hello.c
mv -f hello.o hello.lo
gcc -g -O -c hello.c
burger$
```

Linking libraries

Without libtool, the programmer would invoke the `ar` command to create a static library:

```
burger$ ar cru libhello.a hello.o foo.o
burger$
```

But of course, that would be too simple, so many systems require that you run the `ranlib` command on the resulting library (to give it better karma, or something):

```
burger$ ranlib libhello.a
burger$
```

It seems more natural to use the C compiler for this task, given libtool's "libraries are programs" approach. So, on platforms without shared libraries, libtool simply acts as a wrapper for the system `ar` (and possibly `ranlib`) commands.

Again, the libtool library name differs from the standard name (it has a `.la' suffix instead of a `.a' suffix). The arguments to libtool are the same ones you would use to produce an executable named `libhello.la' with your compiler (see section Link mode):

```
burger$ libtool gcc -g -O -o libhello.la foo.o hello.o
libtool: cannot build libtool library `libhello.la' from non-libtool \
                objects
```

```
burger$
```

Aha! Libtool caught a common error... trying to build a library from standard objects instead of library objects. This doesn't matter for static libraries, but on shared library systems, it is of great importance.

So, let's try again, this time with the library object files:(1)

```
a23$ libtool gcc -g -O -o libhello.la foo.lo hello.lo -lm
libtool: you must specify an installation directory with `-rpath'
a23$
```

Argh. Another complication in building shared libraries is that we need to specify the path to the directory in which they (eventually) will be installed. So, we try again, with an `rpath` setting of `` `/usr/local/lib' ``:

```
a23$ libtool gcc -g -O -o libhello.la foo.lo hello.lo \
                -rpath /usr/local/lib -lm
mkdir .libs
ar cru .libs/libhello.a foo.o hello.o
ranlib .libs/libhello.a
creating libhello.la
a23$
```

Now, let's try the same trick on the shared library platform:

```
burger$ libtool gcc -g -O -o libhello.la foo.lo hello.lo \
                -rpath /usr/local/lib -lm
mkdir .libs
ld -Bshareable -o .libs/libhello.so.0.0 foo.lo hello.lo -lm
ar cru .libs/libhello.a foo.o hello.o
ranlib .libs/libhello.a
creating libhello.la
burger$
```

Now that's significantly cooler... libtool just ran an obscure `ld` command to create a shared library, as well as the static library.

Note how libtool creates extra files in the `` `.libs' `` subdirectory, rather than the current directory. This feature is to make it easier to clean up the build directory, and to help ensure that other programs fail horribly if you accidentally forget to use libtool when you should.

Linking executables

If you choose at this point to **install** the library (put it in a permanent location) before linking executables against it, then you don't need to use libtool to do the linking. Simply use the appropriate `-L' and `-l' flags to specify the library's location.

Some system linkers insist on encoding the full directory name of each shared library in the resulting executable. Libtool has to work around this misfeature by special magic to ensure that only permanent directory names are put into installed executables.

The importance of this bug must not be overlooked: it won't cause programs to crash in obvious ways. It creates a security hole, and possibly even worse, if you are modifying the library source code after you have installed the

package, you will change the behaviour of the installed programs!

So, if you want to link programs against the library before you install it, you must use libtool to do the linking.

Here's the old way of linking against an uninstalled library:

```
burger$ gcc -g -O -o hell.old main.o libhello.a -lm
burger$
```

Libtool's way is almost the same(2) (see section Link mode):

```
a23$ libtool gcc -g -O -o hell main.o libhello.la -lm
gcc -g -O -o hell main.o ./.libs/libhello.a -lm
a23$
```

That looks too simple to be true. All libtool did was transform `libhello.la' to `./.libs/libhello.a', but remember that `a23' has no shared libraries.

On `burger' the situation is different:

```
burger$ libtool gcc -g -O -o hell main.o libhello.la -lm
gcc -g -O -o .libs/hell main.o -L./.libs -R/usr/local/lib -lhello -lm
creating hell
burger$
```

Notice that the executable, `hell`, was actually created in the `.libs' subdirectory. Then, a wrapper script was created in the current directory.

On NetBSD 1.2, libtool encodes the installation directory of `libhello', by using the `-R/usr/local/lib' compiler flag. Then, the wrapper script guarantees that the executable finds the correct shared library (the one in `./.libs') until it is properly installed.

Let's compare the two different programs:

```
burger$ time ./hell.old
Welcome to GNU Hell!
** This is not GNU Hello.  There is no built-in mail reader. **
        0.21 real         0.02 user         0.08 sys
burger$ time ./hell
Welcome to GNU Hell!
** This is not GNU Hello.  There is no built-in mail reader. **
        0.63 real         0.09 user         0.59 sys
burger$
```

The wrapper script takes significantly longer to execute, but at least the results are correct, even though the shared library hasn't been installed yet.

So, what about all the space savings that shared libraries are supposed to yield?

```
burger$ ls -l hell.old libhello.a
-rwxr-xr-x  1 gord  gord  15481 Nov 14 12:11 hell.old
-rw-r--r--  1 gord  gord   4274 Nov 13 18:02 libhello.a
burger$ ls -l .libs/hell .libs/libhello.*
```

```
-rwxr-xr-x  1 gord  gord  11647 Nov 14 12:10 .libs/hell
-rw-r--r--  1 gord  gord   4274 Nov 13 18:44 .libs/libhello.a
-rwxr-xr-x  1 gord  gord  12205 Nov 13 18:44 .libs/libhello.so.0.0
burger$
```

Well, that sucks. Maybe I should just scrap this project and take up basket weaving.

Actually, it just proves an important point: shared libraries incur overhead because of their (relative) complexity. In this situation, the price of being dynamic is eight kilobytes, and the payoff is about four kilobytes. So, having a shared `libhello' won't be an advantage until we link it against at least a few more programs.

Debugging executables

If `hell' was a complicated program, you would certainly want to test and debug it before installing it on your system. In the above section, you saw how it the libtool wrapper script makes it possible to run the program directly, but unfortunately, it interferes with the debugger:

```
burger$ gdb hell
GDB is free software and you are welcome to distribute copies of it
 under certain conditions; type "show copying" to see the conditions.
There is absolutely no warranty for GDB; type "show warranty" for details.
GDB 4.16 (i386-unknown-netbsd), Copyright 1996 Free Software Foundation, Inc...

"hell": not in executable format: File format not recognized

(gdb) quit
burger$
```

Sad. It doesn't work because GDB isn't doesn't know where the executable lives. So, let's try again, by invoking GDB directly on the executable:

```
burger$ gdb .libs/hell
trick:/home/src/libtool/demo$ gdb .libs/hell
GDB is free software and you are welcome to distribute copies of it
 under certain conditions; type "show copying" to see the conditions.
There is absolutely no warranty for GDB; type "show warranty" for details.
GDB 4.16 (i386-unknown-netbsd), Copyright 1996 Free Software Foundation, Inc...
(gdb) break main
Breakpoint 1 at 0x8048547: file main.c, line 29.
(gdb) run
Starting program: /home/src/libtool/demo/.libs/hell
/home/src/libtool/demo/.libs/hell: can't load library 'libhello.so.2'

Program exited with code 020.
(gdb) quit
burger$
```

Argh. Now GDB complains because it cannot find the shared library that `hell' is linked against. So, we must use libtool in order to properly set the library path and run the debugger. Fortunately, we can forget all about the `.libs' directory, and just run it on the executable wrapper (see section Execute mode):

```
burger$ libtool gdb hell
GDB is free software and you are welcome to distribute copies of it
 under certain conditions; type "show copying" to see the conditions.
There is absolutely no warranty for GDB; type "show warranty" for details.
GDB 4.16 (i386-unknown-netbsd), Copyright 1996 Free Software Foundation, Inc...
(gdb) break main
Breakpoint 1 at 0x8048547: file main.c, line 29.
(gdb) run
Starting program: /home/src/libtool/demo/.libs/hell

Breakpoint 1, main (argc=1, argv=0xbffffc40) at main.c:29
29        printf ("Welcome to GNU Hell!\n");
(gdb) quit
The program is running.  Quit anyway (and kill it)? (y or n) y
burger$
```

Installing libraries

Installing libraries on a non-libtool system is quite straightforward... just copy them into place:(3)

```
burger$ su
Password: ********
burger# cp libhello.a /usr/local/lib/libhello.a
burger#
```

Oops, don't forget the `ranlib` command:

```
burger# ranlib /usr/local/lib/libhello.a
burger#
```

Libtool installation is quite simple, as well. Just use the `install` or `cp` command that you normally would (see section Install mode):

```
a23# libtool cp libhello.la /usr/local/lib/libhello.la
cp libhello.la /usr/local/lib/libhello.la
cp .libs/libhello.a /usr/local/lib/libhello.a
ranlib /usr/local/lib/libhello.a
a23#
```

Note that the libtool library `` `libhello.la' `` is also installed, for informational purposes, and to help libtool with uninstallation (see section Uninstall mode).

Here is the shared library example:

```
burger# libtool install -c libhello.la /usr/local/lib/libhello.la
install -c .libs/libhello.so.0.0 /usr/local/lib/libhello.so.0.0
install -c libhello.la /usr/local/lib/libhello.la
install -c .libs/libhello.a /usr/local/lib/libhello.a
ranlib /usr/local/lib/libhello.a
burger#
```

TOC

It is safe to specify the `-s' (strip symbols) flag if you use a BSD-compatible install program when installing libraries. Libtool will either ignore the `-s' flag, or will run a program that will strip only debugging and compiler symbols from the library.

Once the libraries have been put in place, there may be some additional configuration that you need to do before using them. First, you must make sure that where the library is installed actually agrees with the `-rpath' flag you used to build it.

Then, running `libtool -n --finish libdir' can give you further hints on what to do (see section Finish mode):

```
burger# libtool -n --finish /usr/local/lib
ldconfig -m /usr/local/lib
To link against installed libraries in LIBDIR, users may have to:
   - add LIBDIR to their `LD_LIBRARY_PATH' environment variable
   - use the `-LLIBDIR' linker flag
burger#
```

After you have completed these steps, you can go on to begin using the installed libraries. You may also install any executables that depend on libraries you created.

Installing executables

If you used libtool to link any executables against uninstalled libtool libraries (see section Linking executables), you need to use libtool to install the executables after the libraries have been installed (see section Installing libraries).

So, for our Ultrix example, we would run:

```
a23# libtool install -c hell /usr/local/bin/hell
install -c hell /usr/local/bin/hell
a23#
```

On shared library systems, libtool just ignores the wrapper script and installs the correct binary:

```
burger# libtool install -c hell /usr/local/bin/hell
install -c .libs/hell /usr/local/bin/hell
burger#
```

Linking static libraries

Why return to `ar` and `ranlib` silliness when you've had a taste of libtool? Well, sometimes it is desirable to create a static archive that can never be shared. The most frequent case is when you have a "convenience library" that is a collection of related object files without a really nice interface.

To do this, you should ignore libtool entirely, and just use the old `ar` and `ranlib` commands to create a static library.

If you want to install the library (but you probably don't), then you may use libtool if you want:

```
burger$ libtool ./install-sh -c libhello.a /local/lib/libhello.a
./install-sh -c libhello.a /local/lib/libhello.a
ranlib /local/lib/libhello.a
```

```
burger$
```

Using libtool for static library installation protects your library from being accidentally stripped (if the installer used the `-s' flag), as well as automatically running the correct `ranlib` command.

Another common situation where static linking is desirable is in creating a standalone binary. Use libtool to do the linking and add the `-all-static' flag.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Invoking `libtool`

The `libtool` program has the following synopsis:

```
libtool [option]... [mode-arg]...
```

and accepts the following options:

`-n'

`--dry-run'

Don't create, modify, or delete any files, just show what commands would be executed by libtool.

`--features'

Display libtool configuration information and exit. This provides a way for packages to determine whether shared or static libraries will be built.

`--finish'

Same as `--mode=finish'.

`--help'

Display a help message and exit. If `--mode=mode' is specified, then detailed help for mode is displayed.

`--mode=mode'

Use mode as the operation mode. By default, the operation mode is inferred from the contents of mode-args. If mode is specified, it must be one of the following:

`compile'

Compile a source file into a libtool object.

`execute'

Automatically set the library path so that another program can use uninstalled libtool-generated programs or libraries.

`finish'

Complete the installation of libtool libraries on the system.

`install'

Install libraries or executables.

`link'

Create a library or an executable.

`uninstall'

Delete libraries or executables.

`--version'

Print libtool version information and exit.

Compile mode

For `compile' mode, mode-args is a compiler command to be used in creating a `standard' object file. These arguments should begin with the name of the C compiler, and contain the `-c' compiler flag so that only an object file is created.

Libtool determines the name of the output file by removing the directory component from the source file name, then substituting the C source code suffix `.c' with the library object suffix, `.lo'.

If shared libraries are being built, any necessary PIC generation flags are substituted into the compilation command.

Note that the `-o' option is not supported for compile mode, because it cannot be implemented properly for all platforms. It is far easier just to change your Makefiles to create all the output files in the current working directory.

Link mode

`link' mode links together object files (including library objects) to form another library or to create an executable program.

mode-args consist of a command using the C compiler to create an output file (with the `-o' flag) from several object files.

The following components of mode-args are treated specially:

`-all-static'

If output-file is a program, then do not link it against any shared libraries at all. If output-file is a library, then only create a static library.

`-dlopen file'

Same as `-dlpreopen file', if native dlopening is not supported on the host platform (see section Dlopened modules). Otherwise, no effect.

`-dlpreopen file'

Link file into the output program, and add its symbols to dld_preloaded_symbols (see section Dlpreopening).

`-export-dynamic'

Allow symbols from output-file to be resolved with `dlsym(3)` (see section Dlopened modules).

`-Llibdir'

Search libdir for required libraries that have already been installed.

`-lname'

output-file requires the installed library `libname'. This option is required even when

output-file is not an executable.

`-no-undefined'

Declare that output-file does not depend on any other libraries. Some platforms cannot create shared libraries that depend on other libraries (see section Inter-library dependencies).

`-o output-file'

Create output-file from the specified objects and libraries.

`-release release'

Specify that the library was generated by release release of your package, so that users can easily tell which versions are newer than others. Be warned that no two releases of your package will be binary compatible if you use this flag. If you want binary compatibility, use the `-version-info' flag (see section Library interface versions).

`-rpath libdir'

If output-file is a library, it will eventually be installed in libdir.

`-static'

If output-file is a program, then do not link it against any uninstalled shared libtool libraries. If output-file is a library, then only create a static library.

`-version-info current[:revision[:age]]'

If output-file is a libtool library, use interface version information current, revision, and age to build it (see section Library interface versions). Do **not** use this flag to specify package release information, rather see the `-release' flag.

If the output-file ends in `.la', then a libtool library is created, which must be built only from library objects (`.lo' files). The `-rpath' option is required. In the current implementation, libtool libraries may not depend on other uninstalled libtool libraries (see section Inter-library dependencies).

If the output-file ends in `.a', then a standard library is created using `ar` and possibly `ranlib`.

If output-file ends in `.o' or `.lo', then a reloadable object file is created from the input files (generally using `ld -r'). This method is often called **partial linking**.

Otherwise, an executable program is created.

Execute mode

For `execute' mode, the library path is automatically set, then a program is executed.

The first of the mode-args is treated as a program name, with the rest as arguments to that program.

The following components of mode-args are treated specially:

`-dlopen file'

Add the directory containing file to the library path.

This mode sets the library path environment variable according to any `-dlopen' flags.

If any of the args are libtool executable wrappers, then they are translated into the name of their corresponding uninstalled binary, and any of their required library directories are added to the library path.

Install mode

In `install' mode, libtool interprets mode-args as an installation command beginning with `cp`, or a BSD-compatible `install` program.

The rest of the mode-args are interpreted as arguments to that command.

The command is run, and any necessary unprivileged post-installation commands are also completed.

Finish mode

`finish' mode helps system administrators install libtool libraries so that they can be located and linked into user programs.

Each mode-arg is interpreted as the name of a library directory. Running this command may require superuser privileges, so the `--dry-run' option may be useful.

Uninstall mode

This mode deletes installed libraries (and other files).

The first mode-arg is the name of the program to use to delete files (typically `` `/bin/rm' ``).

The remaining mode-args are either flags for the deletion program (beginning with a `-'), or the names of files to delete.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Integrating libtool with your own packages

This chapter describes how to integrate libtool with your packages so that your users can install hassle-free shared libraries.

Writing `Makefile' rules for libtool

Libtool is fully integrated with Automake (see section `Introduction' in The Automake Manual), starting with Automake version 1.2.

If you want to use libtool in a regular `Makefile' (or `Makefile.in'), you are on your own. If you're not using Automake 1.2, and you don't know how to incorporate libtool into your package you need to do one of the following:

1. Download Automake (version 1.2 or later) from your nearest GNU mirror, install it, and start using it.
2. Learn how to write `Makefile' rules by hand. They're sometimes complex, but if you're clever enough to write rules for compiling your old libraries, then you should be able to figure out new rules for libtool libraries (hint: examine the `Makefile.in' in the `demo' subdirectory of the libtool distribution... note especially that it was automatically generated from the `Makefile.am' by Automake).

Using Automake with libtool

Libtool library support is implemented under the `LTLIBRARIES' primary.

Here are some samples from the Automake `Makefile.am' in the libtool distribution's `demo' subdirectory.

First, to link a program against a libtool library, just use the `program_LDADD' variable:

```
bin_PROGRAMS = hell hell.debug

# Build hell from main.c and libhello.la
hell_SOURCES = main.c
hell_LDADD = libhello.la

# Create an easier-to-debug version of hell.
```

```
hell_debug_SOURCES = main.c
hell_debug_LDADD = libhello.la
hell_debug_LDFLAGS = -static
```

You may use the `program_LDFLAGS' variable to stuff in any flags you want to pass to libtool while linking `program' (such as `-static' to avoid linking uninstalled shared libtool libraries).

Building a libtool library is almost as trivial... note the use of `libhello_la_LDFLAGS' to pass the `-version-info' (see section Library interface versions) option to libtool:

```
# Build a libtool library, libhello.la for installation in libdir.
lib_LTLIBRARIES = libhello.la
libhello_la_SOURCES = hello.c foo.c
libhello_la_LDFLAGS = -version-info 3:12:1
```

The `-rpath' option is passed automatically by Automake, so you should not specify it.

See section `The Automake Manual' in The Automake Manual, for more information.

Configuring libtool

Libtool requires intimate knowledge of your compiler suite and operating system in order to be able to create shared libraries and link against them properly. When you install the libtool distribution, a system-specific libtool script is installed into your binary directory.

However, when you distribute libtool with your own packages (see section Including libtool with your package), you do not always know which compiler suite and operating system are used to compile your package.

For this reason, libtool must be **configured** before it can be used. This idea should be familiar to anybody who has used a GNU `configure` script. `configure` runs a number of tests for system features, then generates the `Makefiles' (and possibly a `config.h' header file), after which you can run `make` and build the package.

Libtool has its own equivalent to the `configure` script, `ltconfig`.

Invoking `ltconfig`

`ltconfig` runs a series of configuration tests, then creates a system-specific `libtool` in the current directory. The `ltconfig` program has the following synopsis:

```
ltconfig [option]... ltmain [host]
```

and accepts the following options:

`--disable-shared'

Create a `libtool` that only builds static libraries.

`--disable-static'

Create a `libtool` that builds only shared libraries if they are available. If only static libraries can be built, then this flag has no effect.

`--help'

Display a help message and exit.

`--no-verify'

Do not use `config.sub` to verify that host is a valid canonical host system name.

`--quiet'

`--silent'

Do not print informational messages when running configuration tests.

`--srcdir=dir'

Look for `config.guess` and `config.sub` in dir.

`--version'

Print `ltconfig` version information and exit.

`--with-gcc'

Assume that the GNU C compiler will be used when invoking the created `libtool` to compile and link object files.

ltmain is the `ltmain.sh` shell script fragment that provides the basic libtool functionality (see section Including libtool with your package).

host is the canonical host system name, which by default is guessed by running `config.guess`.

`ltconfig` also recognizes the following environment variables:

Variable: **CC**

The C compiler that will be used by the generated `libtool`.

Variable: **CFLAGS**

Compiler flags used to generate standard object files.

Variable: **CPPFLAGS**

C preprocessor flags.

Variable: **LD**

The system linker to use (if the generated `libtool` requires one).

Variable: **RANLIB**

Program to use rather than checking for `ranlib`.

Using `ltconfig`

Here is a simple example of using `ltconfig` to configure libtool on my NetBSD/i386 1.2 system:

```
burger$ ./ltconfig ltmain.sh
```

```
checking host system type... i386-unknown-netbsd1.2
checking for ranlib... ranlib
checking for gcc... gcc
checking whether we are using GNU C... yes
checking for gcc option to produce PIC... -fPIC -DPIC
checking for gcc option to statically link programs... -static
checking if ld is GNU ld... no
checking if ld supports shared libraries... yes
checking dynamic linker characteristics... netbsd1.2 ld.so
checking if libtool supports shared libraries... yes
checking whether to build shared libraries... yes
creating libtool
burger$
```

This example shows how to configure `libtool` for cross-compiling to a i486 GNU/Hurd 0.1 system (assuming compiler tools reside in `` `/local/i486-gnu/bin' ``):

```
burger$ export PATH=/local/i486-gnu/bin:$PATH
burger$ ./ltconfig ltmain.sh i486-gnu0.1
checking host system type... i486-unknown-gnu0.1
checking for ranlib... ranlib
checking for gcc... gcc
checking whether we are using GNU C... yes
checking for gcc option to produce PIC... -fPIC -DPIC
checking for gcc option to statically link programs... -static
checking if ld is GNU ld... yes
checking if GNU ld supports shared libraries... yes
checking dynamic linker characteristics... gnu0.1 ld.so
checking if libtool supports shared libraries... yes
checking whether to build shared libraries... yes
creating libtool
burger$
```

The `AM_PROG_LIBTOOL` macro

If you are using GNU Autoconf (or Automake), you should add a call to `AM_PROG_LIBTOOL` to your `` `configure.in' `` file. This macro offers seamless integration between the `configure` script and `ltconfig`:

Macro: **AM_PROG_LIBTOOL**

> Add support for the `--enable-shared' and `--disable-shared' `configure` flags. Invoke `ltconfig` with the correct arguments to configure the package (see section Invoking `ltconfig`).(4)

By default, this macro turns on shared libraries if they are available, and also enables static libraries if they don't conflict with the shared libraries. You can modify these defaults by setting calling either the

AM_DISABLE_SHARED or AM_DISABLE_STATIC macros:

```
# Turn off shared libraries during beta-testing, since they make the
# build process take too long.
AM_DISABLE_SHARED
AM_PROG_LIBTOOL
```

The user may specify a modified form of `--enable-shared' and `--enable-static' to choose whether shared or static libraries are built based on the name of the package. For example, to have shared `bfd' and `gdb' libraries built, but not shared `libg++', you can run all three `configure` scripts as follows:

```
trick$ ./configure --enable-shared=bfd,gdb
```

In general, specifying `--enable-shared=pkgs' is the same as specifying `--enable-shared' to every package named in the pkgs list, and `--disable-shared' to every other package. The `--enable-static=pkgs' flag behaves similarly, except it translates into `--enable-static' and `--disable-static'.

The package name `default' matches any packages which have not set their name in the PACKAGE environment variable.

Macro: **AM_DISABLE_SHARED**

Change the default behaviour for AM_PROG_LIBTOOL to disable shared libraries. The user may still override this default by specifying `--enable-shared'.

Macro: **AM_DISABLE_STATIC**

Change the default behaviour for AM_PROG_LIBTOOL to disable static libraries. The user may still override this default by specifying `--enable-static'.

When you invoke the `libtoolize` program (see section Invoking `libtoolize`), it will tell you where to find a definition of AM_PROG_LIBTOOL. If you use Automake, the `aclocal` program will automatically add AM_PROG_LIBTOOL support to your `configure` script.

Including libtool with your package

In order to use libtool, you need to include the following files with your package:

`config.guess'

Attempt to guess a canonical system name.

`config.sub'

Canonical system name validation subroutine script.

`ltconfig'

Generate a libtool script for a given system.

`ltmain.sh'

A generic script implementing basic libtool functionality.

Note that the libtool script itself should *not* be included with your package. See section Configuring

libtool.

You should use the `libtoolize` program, rather than manually copying these files into your package.

Invoking `libtoolize`

The `libtoolize` program provides a standard way to add libtool support to your package. In the future, it may implement better usage checking, or other features to make libtool even easier to use.

The `libtoolize` program has the following synopsis:

```
libtoolize [option]...
```

and accepts the following options:

`--automake'

Work silently, and assume that Automake libtool support is used. `libtoolize --automake' is used by Automake to add libtool files to your package, when `AM_PROG_LIBTOOL` appears in your `` `configure.in' ``.

`--copy'

`-c'

Copy files from the libtool data directory rather than creating symlinks.

`--dry-run'

`-n'

Don't run any commands that modify the file system, just print them out.

`--force'

`-f'

Replace existing libtool files. By default, `libtoolize` won't overwrite existing files.

`--help'

Display a help message and exit.

`--version'

Print `libtoolize` version information and exit.

If `libtoolize` detects an explicit call to `AC_CONFIG_AUX_DIR` (see section `The Autoconf Manual' in The Autoconf Manual) in your `` `configure.in' ``, it will put the files in the specified directory.

`libtoolize` displays hints for adding libtool support to your package, as well.

Autoconf `.o' macros

The Autoconf package comes with a few macros that run tests, then set a variable corresponding to the name of an object file. Sometimes it is necessary to use corresponding names for libtool objects.

Here are the names of variables that list libtool objects:

Variable: **LTALLOCA**

Substituted by `AC_FUNC_ALLOCA` (see section `The Autoconf Manual' in The Autoconf Manual). Is either empty, or contains `alloca.lo'.

Variable: **LTLIBOBJS**

Substituted by `AC_REPLACE_FUNCS` (see section `The Autoconf Manual' in The Autoconf Manual), and a few other functions.

Unfortunately, the most recent version of Autoconf (2.12, at the time of this writing) does not have any way for libtool to provide support for these variables. So, if you depend on them, use the following code immediately before the call to `AC_OUTPUT` in your `` `configure.in' ``:

```
LTLIBOBJS=`echo "$LIBOBJS" | sed 's/\.o/.lo/g'`
AC_SUBST(LTLIBOBJS)
LTALLOCA=`echo "$ALLOCA" | sed 's/\.o/.lo/g'`
AC_SUBST(LTALLOCA)
AC_OUTPUT(...)
```

Static-only libraries

When you are developing a package, it is often worthwhile to configure your package with the `--disable-shared' flag, or to override the defaults for `AM_PROG_LIBTOOL` by using the `AM_DISABLE_SHARED` Autoconf macro (see section The `AM_PROG_LIBTOOL` macro). This prevents libtool from building shared libraries, which has several advantages:

- compilation is twice as fast, which can speed up your development cycle
- debugging is easier because you don't need to deal with any complexities added by shared libraries
- you can see how libtool behaves on static-only platforms

You may want to put a small note in your package `` `README' `` to let other developers know that `--disable-shared' can save them time. The following example note is taken from the GIMP(5) distribution `` `README' ``:

```
The GIMP uses GNU Libtool in order to build shared libraries on a
variety of systems. While this is very nice for making usable
binaries, it can be a pain when trying to debug a program. For that
reason, compilation of shared libraries can be turned off by
specifying the `--disable-shared' option to `configure'.
```

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Library interface versions

The most difficult issue introduced by shared libraries is that of creating and resolving runtime dependencies. Dependencies on programs and libraries are often described in terms of a single name, such as `sed`. So, I may say "libtool depends on sed," and that is good enough for most purposes.

However, when an interface changes regularly, we need to be more specific: "Gnus 5.1 requires Emacs 19.28 or above." Here, the description of an interface consists of a name, and a "version number."

Even that sort of description is not accurate enough for some purposes. What if Emacs 20 changes enough to break Gnus 5.1?

The same problem exists in shared libraries: we require a formal version system to describe the sorts of dependencies that programs have on shared libraries, so that the dynamic linker can guarantee that programs are linked only against libraries that provide the interface they require.

What are library interfaces?

Interfaces for libraries may be any of the following (and more):

- global variables: both names and types
- global functions: argument types and number, return types, and function names
- standard input, standard output, standard error, and file formats
- sockets, pipes, and other inter-process communication protocol formats

Note that static functions do not count as interfaces, because they are not directly available to the user of the library.

Libtool's versioning system

Libtool has its own formal versioning system. It is not as flexible as some, but it is definitely the simplest of the more powerful versioning systems.

Think of a library as exporting several sets of interfaces, arbitrarily represented by integers. When a program is linked against a library, it may use any subset of those interfaces.

Libtool's description of the interfaces that a program uses is simple: it encodes the least and the greatest interface numbers in the resulting binary (first-interface, last-interface).

The dynamic linker is guaranteed that if a library supports *every* interface number between first-interface and last-interface, then the program can be relinked against that library.

Note that this can cause problems because libtool's compatibility requirements are actually stricter th necessary.

Say `libhello' supports interfaces 5, 16, 17, 18, and 19, and that libtool is used to link `test' against `libhello'.

Libtool encodes the numbers 5 and 19 in `test', and the dynamic linker will only link `test' against libraries that support *every* interface between 5 and 19. So, the dynamic linker refuses to link `test' against `libhello'!

In order to eliminate this problem, libtool only allows libraries to declare consecutive interface numbers. So, `libhello' can declare at most that it supports interfaces 16 through 19. Then, the dynamic linker will link `test' against `libhello'.

So, libtool library versions are described by three integers:

current
: The most recent interface number that this library implements.

revision
: The implementation number of the current interface.

age
: The difference between the newest and oldest interfaces that this library implements. In other words, the library implements all the interface numbers in the range from number `current - age` to `current`.

If two libraries have identical current and age numbers, then the dynamic linker chooses the library with the greater revision number.

Updating library version information

If you want to use libtool's versioning system, then you must specify the version information to libtool using the `-version-info' flag during link mode (see section Link mode).

This flag accepts an argument of the form `current[:revision[:age]]'. So, passing `-version-info 3:12:1' sets current to 3, revision to 12, and age to 1.

If either revision or age are omitted, they default to 0. Also note that age must be less than or equal to the current interface number.

Here are a set of rules to help you update your library version information:

1. Start with version information of `0:0:0' for each libtool library.
2. Update the version information only immediately before a public release of your software. More frequent updates are unnecessary, and only guarantee that the current interface number gets larger faster.
3. If the library source code has changed at all since the last update, then increment revision (`c:r:a' becomes `c:r+1:a').

4. If any interfaces have been added, removed, or changed since the last update, increment current, and set revision to 0.
5. If any interfaces have been added since the last public release, then increment age.
6. If any interfaces have been removed since the last public release, then set age to 0.

Never try to set the interface numbers so that they correspond to the release number of your package. This is an abuse that only fosters misunderstanding of the purpose of library versions. Instead, use the `-release' flag (see section Managing release information), but be warned that every release of your package will not be binary compatibility with any other release.

Managing release information

Often, people want to encode the name of the package release into the shared library so that it is obvious to the user which package their programs are linked against. This convention is used especially on Linux:

```
trick$ ls /usr/lib/libbfd*
/usr/lib/libbfd.a           /usr/lib/libbfd.so.2.7.0.2
/usr/lib/libbfd.so
trick$
```

On `trick', `/usr/lib/libbfd.so' is just a symbolic link to `/usr/lib/libbfd.so.2.7.0.2', which was distributed as a part of `binutils-2.7.0.2'.

Unfortunately, this convention conflicts directly with libtool's idea of library interface versions, because the library interface rarely changes at the same time that the release number does, and the library suffix is never the same across all platforms.

So, in order to accomodate both views, you can use the `-release' flag in order to set release information for libraries which you do not want to use `-version-info'. For the `libbfd' example, the next release which uses libtool should be built with `-release 2.9.0', which will produce the following files on Linux:

```
trick$ ls /usr/lib/libbfd*
/usr/lib/libbfd-2.9.0.so.0          /usr/lib/libbfd.so
/usr/lib/libbfd-2.9.0.so.0.0.0      /usr/lib/libbfd.a
trick$
```

In this case, `/usr/lib/libbfd.so' is a symbolic link to `/usr/lib/libbfd-2.9.0.so.0.0.0'. This makes it obvious that the user is dealing with `binutils-2.9.0', without compromising libtool's idea of interface versions.

Note that this option actually causes a modification of the library name, so do not use it if unless you want to break binary compatibility with any past library releases. In general, you should only use `-release' for libraries whose interfaces change very frequently.

Go to the first, previous, next, last section, table of contents.

Tips for interface design

Writing a good library interface takes a lot of practice and thorough understanding of the problem that the library is intended to solve.

If you design a good interface, it won't have to change often, you won't have to keep updating documentation, and users won't have to keep relearning how to use the library.

Here is a brief list of tips for library interface design, which may help you in your exploits:

Plan ahead

> Try to make every interface truly minimal, so that you won't need to delete entry points very often.

Avoid interface changes

> Some people love redesigning and changing entry points just for the heck of it (note: *renaming* a function is considered changing an entry point). Don't be one of those people. If you must redesign an interface, then try to leave compatibility functions behind so that users don't need to rewrite their existing code.

Use opaque data types

> The fewer data type definitions a library user has access to, the better. If possible, design your functions to accept a generic pointer (which you can cast to an internal data type), and provide access functions rather than allowing the library user to directly manipulate the data. That way, you have the freedom to change the data structures without changing the interface. This is essentially the same thing as using abstract data types and inheritance in an object-oriented system.

Use header files

> If you are careful to document each of your library's global functions and variables in header files, and include them in your library source files, then the compiler will let you know if you make any interface changes by accident (see section Writing C header files).

Use the `static` keyword (or equivalent) whenever possible

> The fewer global functions your library has, the more flexibility you'll have in changing them. Static functions and variables may change forms as often as you like... your users cannot access them, so they aren't interface changes.

Writing C header files

Writing portable C header files can be difficult, since they may be read by different types of compilers:

C++ compilers

> C++ compilers require that functions be declared with full prototypes, since C++ is more strongly typed than C. C functions and variables also need to be declared with the `extern "C"` directive,

so that the names aren't mangled. See section Writing libraries for C++, for other issues relevant to using C++ with libtool.

ANSI C compilers

ANSI C compilers are not as strict as C++ compilers, but functions should be prototyped to avoid unnecessary warnings when the header file is `#included`.

non-ANSI C compilers

Non-ANSI compilers will report errors if functions are prototyped.

These complications mean that your library interface headers must use some C preprocessor magic in order to be usable by each of the above compilers.

`foo.h' in the `demo' subdirectory of the libtool distribution serves as an example for how to write a header file that can be safely installed in a system directory.

Here are the relevant portions of that file:

```
/* __BEGIN_DECLS should be used at the beginning of your declarations,
   so that C++ compilers don't mangle their names.  Use __END_DECLS at
   the end of C declarations. */
#undef __BEGIN_DECLS
#undef __END_DECLS
#ifdef __cplusplus
# define __BEGIN_DECLS extern "C" {
# define __END_DECLS }
#else
# define __BEGIN_DECLS /* empty */
# define __END_DECLS /* empty */
#endif

/* __P is a macro used to wrap function prototypes, so that compilers
   that don't understand ANSI C prototypes still work, and ANSI C
   compilers can issue warnings about type mismatches. */
#undef __P
#if defined (__STDC__) || defined (_AIX) \
        || (defined (__mips) && defined (_SYSTYPE_SVR4)) \
        || defined(WIN32) || defined(__cplusplus)
# define __P(protos) protos
#else
# define __P(protos) ()
#endif
```

These macros are used in `foo.h' as follows:

```
#ifndef _FOO_H_
#define _FOO_H_ 1
```

```
/* The above macro definitions. */
...

__BEGIN_DECLS
int foo __P((void));
int hello __P((void));
__END_DECLS

#endif /* !_FOO_H_ */
```

Note that the `#ifndef _FOO_H_' prevents the body of `foo.h' from being read more than once in a given compilation.

Feel free to copy the definitions of __P, __BEGIN_DECLS, and __END_DECLS into your own headers. Then, you may use them to create header files that are valid for C++, ANSI, and non-ANSI compilers.

Do not be naive about writing portable code. Following the tips given above will help you miss the most obvious problems, but there are definitely other subtle portability issues. You may need to cope with some of the following issues:

- Pre-ANSI compilers do not always support the `void *` generic pointer type, and so need to use `char *` in its place.
- The `const` and `signed` keywords are not supported by some compilers, especially pre-ANSI compilers.
- The `long double` type is not supported by many compilers.

TOC

Inter-library dependencies

By definition, every shared library system provides a way for executables to depend on libraries, so that symbol resolution is deferred until runtime.

An **inter-library dependency** is one in which a library depends on other libraries. For example, if the libtool library `libhello' uses the `cos(3)` function, then it has an inter-library dependency on `libm', the math library that implements `cos(3)`.

Some shared library systems provide this feature in an internally-consistent way: these systems allow chains of dependencies of potentially infinite length.

However, most shared library systems are restricted in that they only allow a single level of dependencies. In these systems, programs may depend on shared libraries, but shared libraries may not depend on other shared libraries.

In any event, libtool provides a simple mechanism for you to declare inter-library dependencies: for every library `libname' that your own library depends on, simply add a corresponding `-lname` option to the link line when you create your library.(6) To make an example of our `libhello' that depends on `libm':

```
burger$ libtool gcc -g -O -o libhello.la foo.lo hello.lo \
                -rpath /usr/local/lib -lm
burger$
```

In order to link a program against `libhello', you need to specify the same `-l' options, in order to guarantee that all the required libraries are found. This restriction is only necessary to preserve compatibility with static library systems and simple dynamic library systems.

Some platforms, such as AIX, do not even allow you this flexibility. In order to build a shared library, it must be entirely self-contained (that is, have no references to external symbols), and you need to specify the -no-undefined flag to allow a shared library to be built. By default, libtool builds only static libraries on these kinds of platforms.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Dlopened modules

It can sometimes be confusing to discuss **dynamic linking**, because the term is used to refer to two different concepts:

1. Compiling and linking a program against a shared library, which is resolved automatically at run time by the dynamic linker. In this process, dynamic linking is transparent to the application.
2. The application calling functions such as `dlopen(3)`,(7) which load arbitrary, user-specified modules at runtime. This type of dynamic linking is explicitly controlled by the application.

To mitigate confusion, this manual refers to the second type of dynamic linking as **dlopening** a module.

The main benefit to dlopening object modules is the ability to access compiled object code to extend your program, rather than using an interpreted language. In fact, dlopen calls are frequently used in language interpreters to provide an efficient way to extend the language.

As of version 1.2, libtool provides experimental support for dlopened modules, which does not radically simplify the development of dlopening applications. However, this support is designed to be a portable foundation for generic, higher-level dlopen functions.

This chapter discusses the preliminary support that libtool offers, and how you as a dlopen application developer might use libtool to generate dlopen-accessible modules. It is important to remember that these are experimental features, and not to rely on them for easy answers to the problems associated with dlopened modules.

Building modules to dlopen

On some operating systems, a program symbol must be specially declared in order to be dynamically resolved with the `dlsym(3)` (or equivalent) function.

Libtool provides the `-export-dynamic' link flag (see section Link mode), which does this declaration. You need to use this flag if you are linking an application program that dlopens other modules or a libtool library that will also be dlopened.

For example, if we wanted to build a shared library, `libhello', that would later be dlopened by an application, we would add `-export-dynamic' to the other link flags:

```
burger$ libtool gcc -export-dynamic -o libhello.la foo.lo \
                hello.lo -rpath /usr/local/lib -lm
burger$
```

Another situation where you would use `-export-dynamic' is if symbols from your *executable* are needed to satisfy unresolved references in a library you want to dlopen. In this case, you should use

`-export-dynamic' while linking the executable that calls dlopen:

```
burger$ libtool gcc -export-dynamic -o hell-dlopener main.o
burger$
```

Dlpreopening

Libtool provides special support for dlopening libtool object and libtool library files, so that their symbols can be resolved *even on platforms without any* `dlopen(3)` *and* `dlsym(3)` *functions.*.

Consider the following alternative ways of loading code into your program, in order of increasing "laziness":

1. Linking against object files that become part of the program executable, whether or not they are referenced. If an object file cannot be found, then the linker refuses to create the executable.
2. Declaring a static library to the linker, so that it is searched at link time in order to satisfy any undefined references in the above object files. If the static library cannot be found, then the linker refuses to link the executable.
3. Declaring a shared library to the runtime linker, so that it is searched at runtime in order to satisfy any undefined references in the above files. If the shared library cannot be found, then the dynamic linker aborts the program before it runs.
4. Dlopening a module, so that the application can resolve its own, dynamically-computed references. If there is an error opening the module, or the module is not found, then the application can recover without crashing.

Libtool emulates `-export-dynamic' on static platforms by linking objects into the program at compile time, and creating data structures that represent the program's symbol table.

In order to use this feature, you must declare the objects you want your application to dlopen by using the `-dlopen' or `-dlpreopen' flags when you link your program (see section Link mode).

Structure: **dld_symbol** *name address*

The name attribute is a 0-terminated character string of the symbol name, such as `"fprintf"`. The address attribute is a generic pointer to the appropriate object, which is `&fprintf` in this example.

Variable: dld_symbol * **dld_preloaded_symbols**

An array of dld_symbol structures, representing all the preloaded symbols linked into the program. The last element has a name of `0`.

Variable: int **dld_preloaded_symbol_count**

The number of elements in dld_preloaded_symbols, if it is sorted in ascending order by name. Otherwise, `-1`, to indicate that the application needs to sort and count dld_preloaded_symbols itself, or search it linearly.

Some compilers may allow identifiers which are not valid in ANSI C, such as dollar signs. Libtool only recognizes valid ANSI C symbols (an initial ASCII letter or underscore, followed by zero or more ASCII

letters, digits, and underscores), so non-ANSI symbols will not appear in dld_preloaded_symbols.

Finding the correct name to dlopen

After a library has been linked with `-export-dynamic', it can be dlopened. Unfortunately, because of the variation in library names, your package needs to determine the correct file to dlopen.

The most straightforward and flexible implementation is to determine the name at runtime, by finding the installed `.la' file, and searching it for the following lines:

```
# The name that we can dlopen(3).
dlname='dlname'
```

If dlname is empty, then the library cannot be dlopened. Otherwise, it gives the dlname of the library. So, if the library was installed as `/usr/local/lib/libhello.la', and the dlname was `libhello.so.3', then `/usr/local/lib/libhello.so.3' should be dlopened.

If your program uses this approach, then it should search the directories listed in the LD_LIBRARY_PATH(8) environment variable, as well as the directory where libraries will eventually be installed. Searching this variable (or equivalent) will guarantee that your program can find its dlopened modules, even before installation, provided you have linked them using libtool.

Unresolved dlopen issues

The following problems are not solved by using libtool's dlopen support:

- Dlopen functions are generally only available on shared library platforms. If you want your package to be portable to static platforms, you have to develop your own alternatives to dlopening dynamic code. Most reasonable solutions involve writing wrapper functions for the `dlopen(3)` family, which do package-specific tricks when dlopening is unsupported or not available on a given platform.
- There are major differences in implementations of the `dlopen(3)` family of functions. Some platforms do not even use the same function names (notably HP-UX, with its `shl_load(3)' family).
- The application developer must write a custom search function in order to discover the correct module filename to supply to `dlopen(3)`.

Each of these limitations will be addressed in GNU DLD 4.(9)

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Using libtool with other languages

Libtool was first implemented in order to add support for writing shared libraries in the C language. However, over time, libtool is being integrated with other languages, so that programmers are free to reap the benefits of shared libraries in their favorite programming language.

This chapter describes how libtool interacts with other languages, and what special considerations you need to make if you do not use C.

Writing libraries for C++

Creating libraries of C++ code is a fairly straightforward process, and differs from C code in only two ways:

1. Because of name mangling, C++ libraries are only usable by the C++ compiler that created them. This decision was made by the designers of C++ in order to protect users from conflicting implementations of features such as constructors, exception handling, and RTTI.
2. On some systems, notably SunOS 4, the dynamic linker does not call non-constant initializers. This can lead to hard-to-pinpoint bugs in your library. GCC 2.7 and later versions work around this problem, but previous versions and other compilers do not.

This second issue is complex. Basically, you should avoid any global or static variable initializations that would cause an "initializer element is not constant" error if you compiled them with a standard C compiler.

There are other ways of working around this problem, but they are beyond the scope of this manual.

Go to the first, previous, next, last section, table of contents.

Maintenance notes for libtool

This chapter contains information that the libtool maintainer finds important. It will be of no use to you unless you are considering porting libtool to new systems, or writing your own libtool.

Porting libtool to new systems

To port libtool to a new system, you'll generally need the following information:

man pages for `ld(1)` and `cc(1)`

: These generally describe what flags are used to generate PIC, to create shared libraries, and to link against only static libraries. You may need to follow some cross references to find the information that is required.

man pages for `ld.so(8)`, `rtld(8)`, or equivalent

: These are a valuable resource for understanding how shared libraries are loaded on the system.

man page for `ldconfig(8)`, or equivalent

: This page usually describes how to install shared libraries.

output from ls -l /lib /usr/lib

: This shows the naming convention for shared libraries on the system, including which names should be symbolic links.

any additional documentation

: Some systems have special documentation on how to build and install shared libraries.

Tested platforms

This table describes when libtool was last known to be tested on platforms where it claims to support shared libraries:

canonical host name	compiler	libtool release	results
alpha-dec-osf3.2	cc	0.8	ok
alpha-dec-osf3.2	gcc	0.8	ok
alpha-dec-osf4.0	cc	1.0f	ok
alpha-dec-osf4.0	gcc	1.0f	ok
alpha-unknown-linux-gnu	gcc	0.9h	ok
hppa1.1-hp-hpux9.07	cc	1.0f	ok

```

rs6000-ibm-aix3.2.5           xlc       1.0i      ok
rs6000-ibm-aix3.2.5           gcc       1.0i      ok*
sparc-sun-linux-gnu2.1.23     gcc       0.9h      ok
sparc-sun-sunos4.1.3          gcc       1.0i      ok
sparc-sun-sunos4.1.4          cc        1.0f      ok
sparc-sun-sunos4.1.4          gcc       1.0f      ok
sparc-sun-solaris2.4          cc        1.0a      ok
sparc-sun-solaris2.4          gcc       1.0a      ok
sparc-sun-solaris2.5          cc        1.0f      ok
sparc-sun-solaris2.5          gcc       1.0i      ok
sparc-sun-solaris2.6          gcc       1.0i      ok
-------------------------------------------------------

* Some versions of GCC's collect2 linker program cannot link trivial
static binaries on AIX 3.  For these configurations, libtool's `-static'
flag has no effect.
```

Platform quirks

This section is dedicated to the sanity of the libtool maintainer. It describes the programs that libtool uses, how they vary from system to system, and how to test for them.

Because libtool is a shell script, it is difficult to understand just by reading it from top to bottom. This section helps show why libtool does things a certain way. After reading it, then reading the scripts themselves, you should have a better sense of how to improve libtool, or write your own.

References

The following is a list of valuable documentation references:

- SGI's IRIX Manual Pages, `http://techpubs.sgi.com/cgi-bin/infosrch.cgi?cmd=browse&db=man`.
- Sun's free service area (`http://www.sun.com/service/online/free.html`) and documentation server (`http://docs.sun.com/`).

Compilers

The only compiler characteristics that affect libtool are the flags needed (if any) to generate PIC objects. In general, if a C compiler supports certain PIC flags, then any derivative compilers support the same flags. Until there are some noteworthy exceptions to this rule, this section will document only C compilers.

The following C compilers have standard command line options, regardless of the platform:

`gcc`

This is the GNU C compiler, which is also the system compiler for many free operating systems (FreeBSD, GNU/Hurd, Linux/GNU, Lites, NetBSD, and OpenBSD, to name a few). The `-fpic' or `-fPIC' flags can be used to generate position-independent code. `-fPIC' is guaranteed to generate working code, but the code is slower on m68k, m88k, and Sparc chips. However, using `-fpic' on those chips imposes arbitrary size limits on the shared libraries.

The rest of this subsection lists compilers by the operating system that they are bundled with:

`aix3*`

`aix4*`

AIX compilers have no PIC flags, since AIX has been ported only to PowerPC and RS/6000 chips. (10)

`hpux10*`

Use `+Z' to generate PIC.

`osf3*`

Digital/UNIX 3.x does not have PIC flags, at least not on the PowerPC platform.

`solaris2*`

Use `-KPIC' to generate PIC.

`sunos4*`

Use `-PIC' to generate PIC.

Reloadable objects

On all known systems, a reloadable object can be created by running ld -r -o output.o input1.o input2.o. This reloadable object may be treated as exactly equivalent to other objects.

Archivers

On all known systems, building a static library can be accomplished by running ar cru libname.a obj1.o obj2.o ..., where the `.a' file is the output library, and each `.o' file is an object file.

On all known systems, if there is a program named `ranlib`, then it must be used to "bless" the created library before linking against it, with the ranlib libname.a command.

`libtool` script contents

The `libtool` script is generated by `ltconfig` (see section Configuring libtool). Ever since libtool version 0.7, this script simply sets shell variables, then sources the libtool backend, `ltmain.sh`.

Here is a listing of each of these variables, and how they are used within `ltmain.sh`:

Variable: **AR**

The name of the system library archiver.

Variable: **CC**

The name of the C compiler used to configure libtool.

Variable: **LD**

The name of the linker that libtool should use internally for reloadable linking and possibly shared libraries.

Variable: **LTCONFIG_VERSION**

This is set to the version number of the `ltconfig` script, to prevent mismatches between the configuration information in `libtool`, and how that information is used in `ltmain.sh`.

Variable: **NM**

The name of a BSD-compatible `nm` program, which produces listings of global symbols in one the following formats:

```
address C global-variable-name
address D global-variable-name
address T global-function-name
```

Variable: **RANLIB**

Set to the name of the ranlib program, if any.

Variable: **allow_undefined_flag**

The flag that is used by `archive_cmds' in order to declare that there will be unresolved symbols in the resulting shared library. Empty, if no such flag is required. Set to `unsupported' if there is no way to generate a shared library with references to symbols that aren't defined in that library.

Variable: **archive_cmds**

Variable: **old_archive_cmds**

Commands used to create shared and static libraries, respectively.

Variable: **build_libtool_libs**

Whether libtool should build shared libraries on this system. Set to `yes' or `no'.

Variable: **build_old_libs**

Whether libtool should build static libraries on this system. Set to `yes' or `no'.

Variable: **echo**

An `echo(1)` program which does not interpret backslashes as an escape character.

Variable: **export_dynamic_flag_spec**

Compiler link flag that allows a dlopened shared library to reference symbols that are defined in the program.

Variable: **finish_cmds**

Commands to tell the dynamic linker how to find shared libraries in a specific directory.

Variable: **finish_eval**

Same as finish_cmds, except the commands are not displayed.

Variable: **global_symbol_pipe**

A pipeline that takes the output of NM, and produces a listing of raw symbols followed by their C names. For example:

```
$ $NM | $global_symbol_pipe
symbol1 C-symbol1
symbol2 C-symbol2
symbol3 C-symbol3
...
$
```

Variable: **hardcode_action**

Either `immediate' or `relink', depending on whether shared library paths can be hardcoded into executables before they are installed, or if they need to be relinked.

Variable: **hardcode_direct**

Set to `yes' or `no', depending on whether the linker hardcodes directories if a library is directly specified on the command line (such as `dir/libname.a').

Variable: **hardcode_libdir_flag_spec**

Flag to hardcode a libdir variable into a binary, so that the dynamic linker searches libdir for shared libraries at runtime.

Variable: **hardcode_libdir_separator**

If the compiler only accepts a single hardcode_libdir_flag, then this variable contains the string that should separate multiple arguments to that flag.

Variable: **hardcode_minus_L**

Set to `yes' or `no', depending on whether the linker hardcodes directories specified by `-L' flags into the resulting executable.

Variable: **hardcode_shlibpath_var**

Set to `yes' or `no', depending on whether the linker hardcodes directories by writing the contents of `$shlibpath_var' into the resulting executable. Set to `unsupported' if directories specified by

`$shlibpath_var' are searched at run time, but not at link time.

Variable: **host**

Variable: **host_alias**

For information purposes, set to the specified and canonical names of the system that libtool was configured for.

Variable: **libname_spec**

The format of a library name prefix. On all Unix systems, static libraries are called `libname.a', but on some systems (such as OS/2 or MS-DOS), the library is just called `name.a'.

Variable: **library_names_spec**

A list of shared library names. The first is the name of the file, the rest are symbolic links to the file. The name in the list is the file name that the linker finds when given `-lname'.

Variable: **link_static_flag**

Linker flag (passed through the C compiler) used to prevent dynamic linking.

Variable: **no_builtin_flag**

Compiler flag to disable builtin functions that conflict with declaring external global symbols as `char`.

Variable: **no_undefined_flag**

The flag that is used by `archive_cmds' in order to declare that there will be no unresolved symbols in the resulting shared library. Empty, if no such flag is required.

Variable: **pic_flag**

Any additional compiler flags for building library object files.

Variable: **postinstall_cmds**

Variable: **old_postinstall_cmds**

Commands run after installing a shared or static library, respectively.

Variable: **reload_cmds**

Variable: **reload_flag**

Commands to create a reloadable object.

Variable: **runpath_var**

The environment variable that tells the linker which directories to hardcode in the resulting executable.

Variable: **shlibpath_var**

The environment variable that tells the dynamic linker where to find shared libraries.

Variable: **soname_spec**

The name coded into shared libraries, if different from the real name of the file.

Variable: **version_type**

The library version numbering type. One of `libtool', `linux', `osf', `sunos', or `none'.

Variable: **wl**

The C compiler flag that allows libtool to pass a flag directly to the linker. Used as: `${wl}some-flag'.

Variables ending in `_cmds' or `_eval' contain a semicolon-separated list of commands that are `eval'ed one after another. If any of the commands return a nonzero exit status, libtool generally exits with an error message.

Variables ending in `_spec' are `eval'ed before being used by libtool.

GNU Libtool

For version 1.2, 10 March 1998

Gordon Matzigkeit

---

(1)

Remember that we need to add -lm to the link command line because `foo.c' uses the cos(3) math library function. See section Using libtool.

(2)

However, you should never use `-L' or `-l' flags to link against an uninstalled libtool library. Just specify the relative path to the `.la' file, such as `../intl/libintl.la'. This is a design decision to eliminate any ambiguity when linking against uninstalled shared libraries.

(3)

Don't accidentally strip the libraries, though, or they will be unusable.

(4)

AM_PROG_LIBTOOL requires that you define the `Makefile' variable top_builddir in your `Makefile.in'. Automake does this automatically, but Autoconf users should set it to the relative path to the top of your build directory (`../..', for example).

(5)

GNU Image Manipulation Program, for those who haven't taken the plunge. See http://www.gimp.org/.

(6)

Unfortunately, as of libtool version 1.2, there is no way to specify inter-library dependencies on libtool libraries that have not yet been installed.

(7)

HP-UX, to be different, uses a function named shl_load(3).

(8)

LIBPATH on AIX, and SHLIB_PATH on HP-UX.

(9)

Unfortunately, the DLD maintainer is also the libtool maintainer, so time spent on one of these projects takes time away from the other. When libtool is reasonably stable, DLD 4 development will proceed.

(10)

All code compiled for the PowerPC and RS/6000 chips (`powerpc-*-*`, `powerpcle-*-*`, and `rs6000-*-*`) is position-independent, regardless of the operating system or compiler suite. So, "regular objects" can be used to build shared libraries on these systems and no special PIC compiler flags are required.

This document was generated on 20 May 1999 using the texi2html translator version 1.51a.

NAME

perl - Practical Extraction and Report Language

SYNOPSIS

For ease of access, the Perl manual has been split up into a number of sections:

- perl Perl overview (this section)
- perldata Perl data structures
- perlsyn Perl syntax
- perlop Perl operators and precedence
- perlre Perl regular expressions
- perlrun Perl execution and options
- perlfunc Perl builtin functions
- perlvar Perl predefined variables
- perlsub Perl subroutines
- perlmod Perl modules
- perlref Perl references and nested data structures
- perlobj Perl objects
- perlbot Perl OO tricks and examples
- perldebug Perl debugging
- perldiag Perl diagnostic messages
- perlform Perl formats
- perlipc Perl interprocess communication
- perlsec Perl security
- perltrap Perl traps for the unwary
- perlstyle Perl style guide
- perlapi Perl application programming interface
- perlguts Perl internal functions for those doing extensions
- perlcall Perl calling conventions from C
- perlovl Perl overloading semantics

- perlbook Perl book information

(If you're intending to read these straight through for the first time, the suggested order will tend to reduce the number of forward references.)

If something strange has gone wrong with your program and you're not sure where you should look for help, try the **-w** switch first. It will often point out exactly where the trouble is.

DESCRIPTION

Perl is an interpreted language optimized for scanning arbitrary text files, extracting information from those text files, and printing reports based on that information. It's also a good language for many system management tasks. The language is intended to be practical (easy to use, efficient, complete) rather than beautiful (tiny, elegant, minimal). It combines (in the author's opinion, anyway) some of the best features of C, **sed** , **awk** , and **sh** , so people familiar with those languages should have little difficulty with it. (Language historians will also note some vestiges of **csh** , Pascal, and even BASIC-PLUS.) Expression syntax corresponds quite closely to C expression syntax. Unlike most Unix utilities, Perl does not arbitrarily limit the size of your data--if you've got the memory, Perl can slurp in your whole file as a single string. Recursion is of unlimited depth. And the hash tables used by associative arrays grow as necessary to prevent degraded performance. Perl uses sophisticated pattern matching techniques to scan large amounts of data very quickly. Although optimized for scanning text, Perl can also deal with binary data, and can make dbm files look like associative arrays (where dbm is available). Setuid Perl scripts are safer than C programs through a dataflow tracing mechanism which prevents many stupid security holes. If you have a problem that would ordinarily use **sed** or **awk** or **sh** , but it exceeds their capabilities or must run a little faster, and you don't want to write the silly thing in C, then Perl may be for you. There are also translators to turn your **sed** and **awk** scripts into Perl scripts.

But wait, there's more...

Perl version 5 is nearly a complete rewrite, and provides the following additional benefits:

*** Many usability enhancements**

It is now possible to write much more readable Perl code (even within regular expressions). Formerly cryptic variable names can be replaced by mnemonic identifiers. Error messages are more informative, and the optional warnings will catch many of the mistakes a novice might make. This cannot be stressed enough. Whenever you get mysterious behavior, try the **-w** switch!!! Whenever you don't get mysterious behavior, try using **-w** anyway.

*** Simplified grammar**

The new yacc grammar is one half the size of the old one. Many of the arbitrary grammar rules have been regularized. The number of reserved words has been cut by 2/3. Despite this, nearly all old Perl scripts will continue to work unchanged.

*** Lexical scoping**

Perl variables may now be declared within a lexical scope, like "auto" variables in C. Not only is this more efficient, but it contributes to better privacy for "programming in the large".

*** Arbitrarily nested data structures**

Any scalar value, including any array element, may now contain a reference to any other variable or subroutine. You can easily create anonymous variables and subroutines. Perl manages your reference counts for you.

*** Modularity and reusability**

The Perl library is now defined in terms of modules which can be easily shared among various packages. A package may choose to import all or a portion of a module's published interface. Pragmas (that is, compiler directives) are defined and used by the same mechanism.

**** Object-oriented programming***

A package can function as a class. Dynamic multiple inheritance and virtual methods are supported in a straightforward manner and with very little new syntax. Filehandles may now be treated as objects.

*** Embeddible and Extensible**

Perl may now be embedded easily in your C or C++ application, and can either call or be called by your routines through a documented interface. The XS preprocessor is provided to make it easy to glue your C or C++ routines into Perl. Dynamic loading of modules is supported.

*** POSIX compliant**

A major new module is the POSIX module, which provides access to all available POSIX routines and definitions, via object classes where appropriate.

*** Package constructors and destructors**

The new BEGIN and END blocks provide means to capture control as a package is being compiled, and after the program exits. As a degenerate case they work just like awk's BEGIN and END when you use the **-p** or **-n** switches.

*** Multiple simultaneous DBM implementations**

A Perl program may now access DBM, NDBM, SDBM, GDBM, and Berkeley DB files from the same script simultaneously. In fact, the old dbmopen interface has been generalized to allow any variable to be tied to an object class which defines its access methods.

*** Subroutine definitions may now be autoloaded**

In fact, the AUTOLOAD mechanism also allows you to define any arbitrary semantics for undefined subroutine calls. It's not just for autoloading.

*** Regular expression enhancements**

You can now specify non-greedy quantifiers. You can now do grouping without creating a backreference. You can now write regular expressions with embedded whitespace and comments for readability. A consistent extensibility mechanism has been added that is upwardly compatible with all old regular expressions.

Ok, that's *definitely* enough hype..

ENVIRONMENT

HOME

Used if chdir has no argument.

LOGDIR

Used if chdir has no argument and HOME is not set.

PATH

Used in executing subprocesses, and in finding the script if **-S** is used.

PERL5LIB

A colon-separated list of directories in which to look for Perl library files before looking in the standard library and the current directory. If PERL5LIB is not defined, PERLLIB is used.

PERL5DB

The command used to get the debugger code. If unset, uses

BEGIN { require 'perl5db.pl' }

PERLLIB

A colon-separated list of directories in which to look for Perl library files before looking in the standard library and the current directory. If PERL5LIB is defined, PERLLIB is not used.

Apart from these, Perl uses no other environment variables, except.to make them available to the script being executed, and to child processes. However, scripts running setuid would do well to execute the following lines before doing anything else, just to keep people honest:

$ENV{'PATH'} = '/bin:/usr/bin'; # or whatever you need $ENV{'SHELL'} = '/bin/sh' if defined $ENV{'SHELL'}; $ENV{'IFS'} = '' if defined $ENV{'IFS'};

DIAGNOSTICS

The **-w** switch produces some lovely diagnostics.

See the *perldiag* manpage for explanations of all Perl's diagnostics.

Compilation errors will tell you the line number of the error, with an indication of the next token or token type that was to be examined. (In the case of a script passed to Perl via **-e** switches, each **-e** is counted as one line.)

Setuid scripts have additional constraints that can produce error messages such as "Insecure dependency". See the *perlsec* manpage .

Did we mention that you should definitely consider using the **-w** switch?

BUGS

The **-w** switch is not mandatory.

Perl is at the mercy of your machine's definitions of various operations such as type casting, *atof()* and *sprintf()* .

If your stdio requires a seek or eof between reads and writes on a particular stream, so does Perl. (This doesn't apply to *sysread()* and *syswrite()* .)

While none of the built-in data types have any arbitrary size limits (apart from memory size), there are still a few arbitrary limits: a given identifier may not be longer than 255 characters, and no component of your PATH may be longer than 255 if you use **-S** . A regular expression may not compile to more than 32767 bytes internally.

Perl actually stands for Pathologically Eclectic Rubbish Lister, but don't tell anyone I said that.

NOTES

TOC

The Perl motto is "There's more than one way to do it." Divining how many more is left as an exercise to the reader.

The three principle virtues of a programmer are Laziness, Impatience, and Hubris. See the Camel Book for why.

NAME

perldata - Perl data structures

DESCRIPTION

Variable names

Perl has three data structures: scalars, arrays of scalars, and associative arrays of scalars, known as "hashes". Normal arrays are indexed by number, starting with 0. (Negative subscripts count from the end.) Hash arrays are indexed by string.

Scalar values are always named with '$', even when referring to a scalar that is part of an array. It works like the English word "the". Thus we have:

$days # the simple scalar value "days" $days[28] # the 29th element of array @days $days{'Feb'} # the 'Feb' value from hash %days $#days # the last index of array @days

but entire arrays or array slices are denoted by '@', which works much like the word "these" or "those":

@days # ($days[0], $days[1],... $days[n]) @days[3,4,5] # same as @days[3..5] @days{'a','c'} # same as ($days{'a'},$days{'c'})

and entire hashes are denoted by '%':

%days # (key1, val1, key2, val2 ...)

In addition, subroutines are named with an initial '&', though this is optional when it's otherwise unambiguous (just as "do" is often redundant in English). Symbol table entries can be named with an initial '*', but you don't really care about that yet.

Every variable type has its own namespace. You can, without fear of conflict, use the same name for a scalar variable, an array, or a hash (or, for that matter, a filehandle, a subroutine name, or a label). This means that **$foo** and **@foo** are two different variables. It also means that **$foo [1]** is a part of **@foo** , not a part of **$foo** . This may seem a bit weird, but that's okay, because it is weird.

Since variable and array references always start with '$', '@', or '%', the "reserved" words aren't in fact reserved with respect to variable names. (They ARE reserved with respect to labels and filehandles, however, which don't have an initial special character. You can't have a filehandle named "log", for instance. Hint: you could say **open(LOG,'logfile')** rather than **open(log,'logfile')** . Using uppercase filehandles also improves readability and protects you from conflict with future reserved words.) Case *IS* significant--"FOO", "Foo" and "foo" are all different names. Names that start with a letter or underscore may also contain digits and underscores.

It is possible to replace such an alphanumeric name with an expression that returns a reference to an object of that type. For a description of this, see the *perlref* manpage .

Names that start with a digit may only contain more digits. Names which do not start with a letter, underscore, or digit are limited to one character, e.g. "$%" or "$$". (Most of these one character names have a predefined significance to Perl. For instance, $ **$** is the current process id.)

Context

The interpretation of operations and values in Perl sometimes depends on the requirements of the context around the operation or value. There are two major contexts: scalar and list. Certain operations return list values in contexts wanting a list, and scalar values otherwise. (If this is true of an operation it will be mentioned in the documentation for that operation.) In other words, Perl overloads certain operations based on whether the expected return value is singular or plural. (Some words in English work this way, like "fish" and "sheep".)

In a reciprocal fashion, an operation provides either a scalar or a list context to each of its arguments. For example, if you say

int(<STDIN>)

the integer operation provides a scalar context for the<STDIN> operator, which responds by reading one line from STDIN and passing it back to the integer operation, which will then find the integer value of that line and return that. If, on the other hand, you say

sort(<STDIN>)

then the sort operation provides a list context for<STDIN>, which will proceed to read every line available up to the end of file, and pass that list of lines back to the sort routine, which will then sort those lines and return them as a list to whatever the context of the sort was.

Assignment is a little bit special in that it uses its left argument to determine the context for the right argument. Assignment to a scalar evaluates the righthand side in a scalar context, while assignment to an array or array slice evaluates the righthand side in a list context. Assignment to a list also evaluates the righthand side in a list context.

User defined subroutines may choose to care whether they are being called in a scalar or list context, but most subroutines do not need to care, because scalars are automatically interpolated into lists. See *wantarray* .

Scalar values

Scalar variables may contain various kinds of singular data, such as numbers, strings and references. In general, conversion from one form to another is transparent. (A scalar may not contain multiple values, but may contain a reference to an array or hash containing multiple values.) Because of the automatic conversion of scalars, operations and functions that return scalars don't need to care (and, in fact, can't care) whether the context is looking for a string or a number.

A scalar value is interpreted as TRUE in the Boolean sense if it is not the null string or the number 0 (or its string equivalent, "0"). The Boolean context is just a special kind of scalar context.

There are actually two varieties of null scalars: defined and undefined. Undefined null scalars are returned when there is no real value for something, such as when there was an error, or at end of file, or when you refer to an uninitialized variable or element of an array. An undefined null scalar may become defined the first time you use it as if it were defined, but prior to that you can use the *defined()* operator to determine whether the value is defined or not.

The length of an array is a scalar value. You may find the length of array **@days** by evaluating **$# days** , as in **csh** . (Actually, it's not the length of the array, it's the subscript of the last element, since there is (ordinarily) a 0th element.) Assigning to **$# days** changes the length of the array. Shortening an array by this method destroys intervening values. Lengthening an array that was previously shortened *NO LONGER* recovers the values that were in those elements. (It used to in Perl 4, but we had to break this make to make sure destructors were called when expected.) You can also gain some measure of efficiency by preextending an array that is going to get big. (You can also extend an array by assigning to an element that is off the end of the array.) You can truncate an array down to nothing by assigning the null list () to it. The following are equivalent:

@whatever = (); $#whatever = $[- 1;

If you evaluate a named array in a scalar context, it returns the length of the array. (Note that this is not true of lists, which return the last value, like the C comma operator.) The following is always true:

scalar(@whatever) == $#whatever - $[+ 1;

Version 5 of Perl changed the semantics of $[: files that don't set the value of $[no longer need to worry about whether another file changed its value. (In other words, use of $[is deprecated.) So in general you can just assume that

scalar(@whatever) == $#whatever + 1;

If you evaluate a hash in a scalar context, it returns a value which is true if and only if the hash contains any key/value pairs. (If there are any key/value pairs, the value returned is a string consisting of the number of used buckets and the number of allocated buckets, separated by a slash. This is pretty much only useful to find out whether Perl's (compiled in) hashing algorithm is performing poorly on your data set. For example, you stick 10,000 things in a hash, but evaluating **%HASH** in scalar context reveals "1/16", which means only one out of sixteen buckets has been touched, and presumably contains all 10,000 of your items. This isn't supposed to happen.)

Scalar value constructors

Numeric literals are specified in any of the customary floating point or integer formats:

12345 12345.67 .23E-10 0xffff # hex 0377 # octal 4_294_967_296 # underline for legibility

String literals are delimited by either single or double quotes. They work much like shell quotes: double-quoted string literals are subject to backslash and variable substitution; single-quoted strings are

not (except for " \' " and " \\ "). The usual Unix backslash rules apply for making characters such as newline, tab, etc., as well as some more exotic forms. See *qq* for a list.

You can also embed newlines directly in your strings, i.e. they can end on a different line than they begin. This is nice, but if you forget your trailing quote, the error will not be reported until Perl finds another line containing the quote character, which may be much further on in the script. Variable substitution inside strings is limited to scalar variables, arrays, and array slices. (In other words, identifiers beginning with **$** or @, followed by an optional bracketed expression as a subscript.) The following code segment prints out "The price is **$100** ."

$Price = '$100'; # not interpreted print "The price is $Price.\n"; # interpreted

As in some shells, you can put curly brackets around the identifier to delimit it from following alphanumerics. In fact, an identifier within such curlies is forced to be a string, as is any single identifier within a hash subscript. Our earlier example,

$days{'Feb'}

can be written as

$days{Feb}

and the quotes will be assumed automatically. But anything more complicated in the subscript will be interpreted as an expression.

Note that a single-quoted string must be separated from a preceding word by a space, since single quote is a valid (though deprecated) character in an identifier (see *Packages*).

Two special literals are __LINE__ and __FILE__, which represent the current line number and filename at that point in your program. They may only be used as separate tokens; they will not be interpolated into strings. In addition, the token __END__ may be used to indicate the logical end of the script before the actual end of file. Any following text is ignored, but may be read via the DATA filehandle. (The DATA filehandle may read data only from the main script, but not from any required file or evaluated string.) The two control characters ^D and ^Z are synonyms for __END__.

A word that has no other interpretation in the grammar will be treated as if it were a quoted string. These are known as "barewords". As with filehandles and labels, a bareword that consists entirely of lowercase letters risks conflict with future reserved words, and if you use the **-w** switch, Perl will warn you about any such words. Some people may wish to outlaw barewords entirely. If you say

use strict 'subs';

then any bareword that would NOT be interpreted as a subroutine call produces a compile-time error instead. The restriction lasts to the end of the enclosing block. An inner block may countermand this by saying **no strict 'subs'** .

Array variables are interpolated into double-quoted strings by joining all the elements of the array with the delimiter specified in the **$"** variable, space by default. The following are equivalent:

$temp = join($",@ARGV); system "echo $temp"; system "echo @ARGV";

Within search patterns (which also undergo double-quotish substitution) there is a bad ambiguity: Is /**$foo [bar]**/ to be interpreted as /**${ foo}[bar]**/ (where **[bar]** is a character class for the regular expression) or as /**${ foo[bar]}**/ (where **[bar]** is the subscript to array **@foo**)? If **@foo** doesn't otherwise exist, then it's obviously a character class. If **@foo** exists, Perl takes a good guess about **[bar]** , and is almost always right. If it does guess wrong, or if you're just plain paranoid, you can force the correct interpretation with curly brackets as above.

A line-oriented form of quoting is based on the shell "here-doc" syntax. Following a << you specify a string to terminate the quoted material, and all lines following the current line down to the terminating string are the value of the item. The terminating string may be either an identifier (a word), or some quoted text. If quoted, the type of quotes you use determines the treatment of the text, just as in regular quoting. An unquoted identifier works like double quotes. There must be no space between the << and the identifier. (If you put a space it will be treated as a null identifier, which is valid, and matches the first blank line--see the Merry Christmas example below.) The terminating string must appear by itself (unquoted and with no surrounding whitespace) on the terminating line.

```
    print <<EOF;      # same as above
The price is  $Price .
EOF
    print <<"EOF";    # same as above
The price is  $Price .
EOF
    print << x 10;    # Legal but discouraged.  Use <<"".
Merry Christmas!
    print <<`EOC`;    # execute commands
echo hi there
echo lo there
EOC
    print <<"foo", <<"bar";     # you can stack them
I said foo.
foo
I said bar.
bar
    myfunc(<<"THIS", 23, <<'THAT');
Here's a line
or two.
THIS
and here another.
THAT
```

Just don't forget that you have to put a semicolon on the end to finish the statement, as Perl doesn't know you're not going to try to do this:

```
    print <<ABC
179231
```

```
    ABC
        + 20;
```

List value constructors

List values are denoted by separating individual values by commas (and enclosing the list in parentheses where precedence requires it):

(LIST)

In a context not requiring a list value, the value of the list literal is the value of the final element, as with the C comma operator. For example,

@foo = ('cc', '-E', $bar);

assigns the entire list value to array foo, but

$foo = ('cc', '-E', $bar);

assigns the value of variable bar to variable foo. Note that the value of an actual array in a scalar context is the length of the array; the following assigns to **$foo** the value 3:

@foo = ('cc', '-E', $bar); $foo = @foo; # $foo gets 3

You may have an optional comma before the closing parenthesis of an list literal, so that you can say:

@foo = (1, 2, 3,);

LISTs do automatic interpolation of sublists. That is, when a LIST is evaluated, each element of the list is evaluated in a list context, and the resulting list value is interpolated into LIST just as if each individual element were a member of LIST. Thus arrays lose their identity in a LIST--the list

(@foo,@bar,&SomeSub)

contains all the elements of **@foo** followed by all the elements of **@bar** , followed by all the elements returned by the subroutine named SomeSub. To make a list reference that does *NOT* interpolate, see the *perlref* manpage .

The null list is represented by (). Interpolating it in a list has no effect. Thus ((),(),()) is equivalent to (). Similarly, interpolating an array with no elements is the same as if no array had been interpolated at that point.

A list value may also be subscripted like a normal array. You must put the list in parentheses to avoid ambiguity. Examples:

Stat returns list value. $time = (stat($file))[8]; # Find a hex digit. $hexdigit = ('a','b','c','d','e','f')[$digit-10]; # A "reverse comma operator". return (pop(@foo),pop(@foo))[0];

Lists may be assigned to if and only if each element of the list is legal to assign to:

TOC

($a, $b, $c) = (1, 2, 3); ($map{'red'}, $map{'blue'}, $map{'green'}) = (0x00f, 0x0f0, 0xf00);

The final element may be an array or a hash:

($a, $b, @rest) = split; local($a, $b, %rest) = @_;

You can actually put an array anywhere in the list, but the first array in the list will soak up all the values, and anything after it will get a null value. This may be useful in a *local()* or *my()* .

A hash literal contains pairs of values to be interpreted as a key and a value:

same as map assignment above %map = ('red',0x00f,'blue',0x0f0,'green',0xf00);

It is often more readable to use the => operator between key/value pairs (the => operator is actually nothing more than a more visually distinctive synonym for a comma):

%map = ('red' => 0x00f, 'blue' => 0x0f0, 'green' => 0xf00,);

Array assignment in a scalar context returns the number of elements produced by the expression on the right side of the assignment:

$x = (($foo,$bar) = (3,2,1)); # set $x to 3, not 2

This is very handy when you want to do a list assignment in a Boolean context, since most list functions return a null list when finished, which when assigned produces a 0, which is interpreted as FALSE.

TOC

NAME

perlsyn - Perl syntax

DESCRIPTION

A Perl script consists of a sequence of declarations and statements. The only things that need to be declared in Perl are report formats and subroutines. See the sections below for more information on those declarations. All uninitialized user-created objects are assumed to start with a null or 0 value until they are defined by some explicit operation such as assignment. (Though you can get warnings about the use of undefined values if you like.) The sequence of statements is executed just once, unlike in **sed** and **awk** scripts, where the sequence of statements is executed for each input line. While this means that you must explicitly loop over the lines of your input file (or files), it also means you have much more control over which files and which lines you look at. (Actually, I'm lying--it is possible to do an implicit loop with either the **-n** or **-p** switch. It's just not the mandatory default like it is in **sed** and **awk** .)

Perl is, for the most part, a free-form language. (The only exception to this is format declarations, for obvious reasons.) Comments are indicated by the "#" character, and extend to the end of the line. If you attempt to use **/* */** C-style comments, it will be interpreted either as division or pattern matching, depending on the context, and C++ // comments just look like a null regular expression, So don't do that.

A declaration can be put anywhere a statement can, but has no effect on the execution of the primary sequence of statements--declarations all take effect at compile time. Typically all the declarations are put at the beginning or the end of the script.

As of Perl 5, declaring a subroutine allows a subroutine name to be used as if it were a list operator from that point forward in the program. You can declare a subroutine without defining it by saying just

sub myname; $me = myname $0 or die "can't get myname";

Note that it functions as a list operator though, not a unary operator, so be careful to use **or** instead of **||** there.

Subroutines declarations can also be imported by a **use** statement.

Also as of Perl 5, a statement sequence may contain declarations of lexically scoped variables, but apart from declaring a variable name, the declaration acts like an ordinary statement, and is elaborated within the sequence of statements as if it were an ordinary statement.

Simple statements

The only kind of simple statement is an expression evaluated for its side effects. Every simple statement must be terminated with a semicolon, unless it is the final statement in a block, in which case the semicolon is optional. (A semicolon is still encouraged there if the block takes up more than one line, since you may eventually add another line.) Note that there are some operators like **eval {}** and **do {}** that look like compound statements, but aren't (they're just TERMs in an expression), and thus need an explicit termination if used as the last item in a statement.

Any simple statement may optionally be followed by a *SINGLE* modifier, just before the terminating semicolon (or block ending). The possible modifiers are:

if EXPR unless EXPR while EXPR until EXPR

The **if** and **unless** modifiers have the expected semantics, presuming you're a speaker of English. The **while** and **until** modifiers also have the usual "while loop" semantics (conditional evaluated first), except when applied to a do-BLOCK (or to the now-deprecated do-SUBROUTINE statement), in which case the block executes once before the conditional is evaluated. This is so that you can write loops like:

do { $_ = <STDIN>; ... } until $_ eq ".\n";

See *do* . Note also that the loop control statements described later will *NOT* work in this construct, since modifiers don't take loop labels. Sorry. You can always wrap another block around it to do that sort of thing.)

Compound statements

In Perl, a sequence of statements that defines a scope is called a block. Sometimes a block is delimited by the file containing it (in the case of a required file, or the program as a whole), and sometimes a block is delimited by the extent of a string (in the case of an eval).

But generally, a block is delimited by curly brackets, also known as braces. We will call this syntactic construct a BLOCK.

The following compound statements may be used to control flow:

if (EXPR) BLOCK if (EXPR) BLOCK else BLOCK if (EXPR) BLOCK elsif (EXPR) BLOCK ... else BLOCK LABEL while (EXPR) BLOCK LABEL while (EXPR) BLOCK continue BLOCK LABEL for (EXPR; EXPR; EXPR) BLOCK LABEL foreach VAR (LIST) BLOCK LABEL BLOCK continue BLOCK

Note that, unlike C and Pascal, these are defined in terms of BLOCKs, not statements. This means that the curly brackets are *required* --no dangling statements allowed. If you want to write conditionals without curly brackets there are several other ways to do it. The following all do the same thing:

if (!open(FOO)) { die "Can't open $FOO: $!"; } die "Can't open $FOO: $!" unless open(FOO); open(FOO) or die "Can't open $FOO: $!"; # FOO or bust! open(FOO) ? 'hi mom' : die "Can't open $FOO: $!"; # a bit exotic, that last one

The **if** statement is straightforward. Since BLOCKs are always bounded by curly brackets, there is never any ambiguity about which **if** an **else** goes with. If you use **unless** in place of **if** , the sense of the test is reversed.

The **while** statement executes the block as long as the expression is true (does not evaluate to the null string or 0 or "0"). The LABEL is optional, and if present, consists of an identifier followed by a colon. The LABEL identifies the loop for the loop control statements **next** , **last** , and **redo** (see below). If there is a **continue** BLOCK, it is always executed just before the conditional is about to be evaluated again, just like the third part of a **for** loop in C. Thus it can be used to increment a loop variable, even when the loop has been continued via the **next** statement (which is similar to the C **continue** statement).

If the word **while** is replaced by the word **until** , the sense of the test is reversed, but the conditional is still tested before the first iteration.

In either the **if** or the **while** statement, you may replace "(EXPR)" with a BLOCK, and the conditional is true if the value of the last statement in that block is true. (This feature continues to work in Perl 5 but is deprecated. Please change any occurrences of "if BLOCK" to "if (do BLOCK)".)

The C-style **for** loop works exactly like the corresponding **while** loop:

for ($i = 1; $i < 10; $i++) { ... }

is the same as

$i = 1; while ($i < 10) { ... } continue { $i++; }

The foreach loop iterates over a normal list value and sets the variable VAR to be each element of the list in turn. The variable is implicitly local to the loop and regains its former value upon exiting the loop. (If the variable was previously declared with **my** , it uses that variable instead of the global one, but it's still localized to the loop.) The **foreach** keyword is actually a synonym for the **for** keyword, so you can use **foreach** for readability or **for** for brevity. If VAR is omitted, **$_** is set to each value. If LIST is an actual array (as opposed to an expression returning a list value), you can modify each element of the array by modifying VAR inside the loop. Examples:

for (@ary) { s/foo/bar/; } foreach $elem (@elements) { $elem *= 2; } for ((10,9,8,7,6,5,4,3,2,1,'BOOM')) { print $_, "\n"; sleep(1); } for (1..15) { print "Merry Christmas\n"; } foreach $item (split(/:[\\\n:]*/, $ENV{'TERMCAP'})) { print "Item: $item\n"; }

A BLOCK by itself (labeled or not) is semantically equivalent to a loop that executes once. Thus you can use any of the loop control statements in it to leave or restart the block. The **continue** block is optional. This construct is particularly nice for doing case structures.

SWITCH: { if (/^abc/) { $abc = 1; last SWITCH; } if (/^def/) { $def = 1; last SWITCH; } if (/^xyz/) { $xyz = 1; last SWITCH; } $nothing = 1; }

There is no official switch statement in Perl, because there are already several ways to write the equivalent. In addition to the above, you could write

SWITCH: { $abc = 1, last SWITCH if /^abc/; $def = 1, last SWITCH if /^def/; $xyz = 1, last SWITCH if /^xyz/; $nothing = 1; }

(That's actually not as strange as it looks one you realize that you can use loop control "operators" wi an expression, That's just the normal C comma operator.)

or

SWITCH: { /^abc/ && do { $abc = 1; last SWITCH; }; /^def/ && do { $def = 1; last SWITCH; }; /^xyz/ && do { $xyz = 1; last SWITCH; }; $nothing = 1; }

or formatted so it stands out more as a "proper" switch statement:

SWITCH: { /^abc/ && do { $abc = 1; last SWITCH; }; /^def/ && do { $def = 1; last SWITCH; }; /^xyz/ && do { $xyz = 1; last SWITCH; }; $nothing = 1; }

or

SWITCH: { /^abc/ and $abc = 1, last SWITCH; /^def/ and $def = 1, last SWITCH; /^xyz/ and $xyz = 1, last SWITCH; $nothing = 1; }

or even, horrors,

if (/^abc/) { $abc = 1 } elsif (/^def/) { $def = 1 } elsif (/^xyz/) { $xyz = 1 } else { $nothing = 1 }

NAME

perlop - Perl operators and precedence

SYNOPSIS

Perl operators have the following associativity and precedence, listed from highest precedence to lowest. Note that all operators borrowed from C keep the same precedence relationship with each other, even where C's precedence is slightly screwy. (This makes learning Perl easier for C folks.)

- left terms and list operators (leftward)
- left ->
- nonassoc ++ --
- right **
- right ! ~ \ and unary + and -
- left =~ !~
- left * / % x
- left + - .
- left << >>
- nonassoc named unary operators
- nonassoc < > <= >= lt gt le ge
- nonassoc == != <=> eq ne cmp
- left &
- left | ^
- left &&
- left ||
- nonassoc ..
- right ?:
- right = += -= *= etc.
- left , =>
- nonassoc list operators (rightward)
- left not
- left and
- left or xor

In the following sections, these operators are covered in precedence order.

DESCRIPTIONS

Terms and List Operators (Leftward)

Any TERM is of highest precedence of Perl. These includes variables, quote and quotelike operators, any expression in parentheses, and any function whose arguments are parenthesized. Actually, there aren't really functions in this sense, just list operators and unary operators behaving as functions because you put parentheses around the arguments. These are all documented in the *perlfunc* manpage .

If any list operator (*print()* , etc.) or any unary operator (*chdir()* , etc.) is followed by a left parenthesis as the next token, the operator and arguments within parentheses are taken to be of highest precedence, just like a normal function call.

In the absence of parentheses, the precedence of list operators such as **print** , **sort** , or **chmod** is either very high or very low depending on whether you look at the left side of operator or the right side of it. For example, in

@ary = (1, 3, sort 4, 2); print @ary; # prints 1324

the commas on the right of the sort are evaluated before the sort, but the commas on the left are evaluated after. In other words, list operators tend to gobble up all the arguments that follow them, and then act like a simple TERM with regard to the preceding expression. Note that you have to be careful with parens:

These evaluate exit before doing the print: print($foo, exit); # Obviously not what you want. print $foo, exit; # Nor is this. # These do the print before evaluating exit: (print $foo), exit; # This is what you want. print($foo), exit; # Or this. print ($foo), exit; # Or even this.

Also note that

print ($foo & 255) + 1, "\n";

probably doesn't do what you expect at first glance. See *Named Unary Operators* for more discussion of this.

Also parsed as terms are the **do {}** and **eval {}** constructs, as well as subroutine and method calls, and the anonymous constructors **[]** and **{}** .

See also *Quote and Quotelike Operators* toward the end of this section, as well as *I/O Operators* .

The Arrow Operator

Just as in C and C++, " **->** " is an infix dereference operator. If the right side is either a **[...]** or **{...}** subscript, then the left side must be either a hard or symbolic reference to an array or hash (or a location capable of holding a hard reference, if it's an lvalue (assignable)). See the *perlref* manpage .

Otherwise, the right side is a method name or a simple scalar variable containing the method name, a the left side must either be an object (a blessed reference) or a class name (that is, a package name). the *perlobj* manpage .

Autoincrement and Autodecrement

"++" and "--" work as in C. That is, if placed before a variable, they increment or decrement the variable before returning the value, and if placed after, increment or decrement the variable after returning the value.

The autoincrement operator has a little extra built-in magic to it. If you increment a variable that is numeric, or that has ever been used in a numeric context, you get a normal increment. If, however, the variable has only been used in string contexts since it was set, and has a value that is not null and matches the pattern /^**[a-zA-Z]*[0-9]*$/** , the increment is done as a string, preserving each character within its range, with carry:

print ++($foo = '99'); # prints '100' print ++($foo = 'a0'); # prints 'a1' print ++($foo = 'Az'); # prints 'Ba' print ++($foo = 'zz'); # prints 'aaa'

The autodecrement operator is not magical.

Exponentiation

Binary "**" is the exponentiation operator. Note that it binds even more tightly than unary minus, so -2**4 is -(2**4), not (-2)**4.

Symbolic Unary Operators

Unary "!" performs logical negation, i.e. "not". See also **not** for a lower precedence version of this.

Unary "-" performs arithmetic negation if the operand is numeric. If the operand is an identifier, a string consisting of a minus sign concatenated with the identifier is returned. Otherwise, if the string starts with a plus or minus, a string starting with the opposite sign is returned. One effect of these rules is that **-bareword** is equivalent to **"-bareword"** .

Unary "~" performs bitwise negation, i.e. 1's complement.

Unary "+" has no effect whatsoever, even on strings. It is useful syntactically for separating a function name from a parenthesized expression that would otherwise be interpreted as the complete list of function arguments. (See examples above under *List Operators* .)

Unary "\" creates a reference to whatever follows it. See the *perlref* manpage . Do not confuse this behavior with the behavior of backslash within a string, although both forms do convey the notion of protecting the next thing from interpretation.

Binding Operators

Binary "=~" binds an expression to a pattern match. Certain operations search or modify the string **$_** by default. This operator makes that kind of operation work on some other string. The right argument is a search pattern, substitution, or translation. The left argument is what is supposed to be searched, substituted, or translated instead of the default **$_** . The return value indicates the success of the operation. (If the right argument is an expression rather than a search pattern, substitution, or translation, it is interpreted as a search pattern at run time. This is less efficient than an explicit search, since the pattern must be compiled every time the expression is evaluated--unless you've used **/o** .)

Binary "!~" is just like "=~" except the return value is negated in the logical sense.

Multiplicative Operators

Binary "*" multiplies two numbers.

Binary "/" divides two numbers.

Binary "%" computes the modulus of the two numbers.

Binary "x" is the repetition operator. In a scalar context, it returns a string consisting of the left operand repeated the number of times specified by the right operand. In a list context, if the left operand is a list in parens, it repeats the list.

print '-' x 80; # print row of dashes print "\t" x ($tab/8), ' ' x ($tab%8); # tab over @ones = (1) x 80; # a list of 80 1's @ones = (5) x @ones; # set all elements to 5

Additive Operators

Binary "+" returns the sum of two numbers.

Binary "-" returns the difference of two numbers.

Binary "." concatenates two strings.

Shift Operators

Binary "<<" returns the value of its left argument shifted left by the number of bits specified by the right argument. Arguments should be integers.

Binary >>" returns the value of its left argument shifted right by the number of bits specified by the right argument. Arguments should be integers.

TOC

Named Unary Operators

The various named unary operators are treated as functions with one argument, with optional parentheses. These include the filetest operators, like **-f** , **-M** , etc. See the *perlfunc* manpage .

If any list operator (*print()* , etc.) or any unary operator (*chdir()* , etc.) is followed by a left parenthesis as the next token, the operator and arguments within parentheses are taken to be of highest precedence, just like a normal function call. Examples:

chdir $foo || die; # (chdir $foo) || die chdir($foo) || die; # (chdir $foo) || die chdir ($foo) || die; # (chdir $foo) || die chdir +($foo) || die; # (chdir $foo) || die

but, because * is higher precedence than ||:

chdir $foo * 20; # chdir ($foo * 20) chdir($foo) * 20; # (chdir $foo) * 20 chdir ($foo) * 20; # (chdir $foo) * 20 chdir +($foo) * 20; # chdir ($foo * 20) rand 10 * 20; # rand (10 * 20) rand(10) * 20; # (rand 10) * 20 rand (10) * 20; # (rand 10) * 20 rand +(10) * 20; # rand (10 * 20)

See also *List Operators* .

Relational Operators

Binary <" returns true if the left argument is numerically less than the right argument.

Binary ">" returns true if the left argument is numerically greater than the right argument.

Binary <=" returns true if the left argument is numerically less than or equal to the right argument.

Binary ">=" returns true if the left argument is numerically greater than or equal to the right argument.

Binary "lt" returns true if the left argument is stringwise less than the right argument.

Binary "gt" returns true if the left argument is stringwise greater than the right argument.

Binary "le" returns true if the left argument is stringwise less than or equal to the right argument.

Binary "ge" returns true if the left argument is stringwise greater than or equal to the right argument.

Equality Operators

Binary "==" returns true if the left argument is numerically equal to the right argument.

Binary "!=" returns true if the left argument is numerically not equal to the right argument.

Binary <=>" returns -1, 0, or 1 depending on whether the left argument is numerically less than, equal to, or greater than the right argument.

Binary "eq" returns true if the left argument is stringwise equal to the right argument.

Binary "ne" returns true if the left argument is stringwise not equal to the right argument.

Binary "cmp" returns -1, 0, or 1 depending on whether the left argument is stringwise less than, equa or greater than the right argument.

Bitwise And

Binary "&" returns its operators ANDed together bit by bit.

Bitwise Or and Exclusive Or

Binary "|" returns its operators ORed together bit by bit.

Binary "^" returns its operators XORed together bit by bit.

C-style Logical And

Binary "&&" performs a short-circuit logical AND operation. That is, if the left operand is false, the right operand is not even evaluated. Scalar or list context propagates down to the right operand if it is evaluated.

C-style Logical Or

Binary "||" performs a short-circuit logical OR operation. That is, if the left operand is true, the right operand is not even evaluated. Scalar or list context propagates down to the right operand if it is evaluated.

The || and **&&** operators differ from C's in that, rather than returning 0 or 1, they return the last value evaluated. Thus, a reasonably portable way to find out the home directory (assuming it's not "0") might be:

$home = $ENV{'HOME'} || $ENV{'LOGDIR'} || (getpwuid($<))[7] || die "You're homeless!\n";

As more readable alternatives to **&&** and || , Perl provides "and" and "or" operators (see below). The short-circuit behavior is identical. The precedence of "and" and "or" is much lower, however, so that you can safely use them after a list operator without the need for parentheses:

unlink "alpha", "beta", "gamma" or gripe(), next LINE;

With the C-style operators that would have been written like this:

unlink("alpha", "beta", "gamma") || (gripe(), next LINE);

Range Operator

Binary ".." is the range operator, which is really two different operators depending on the context. In a list context, it returns an array of values counting (by ones) from the left value to the right value. This is useful for writing **for (1..10)** loops and for doing slice operations on arrays. Be aware that under the current implementation, a temporary array is created, so you'll burn a lot of memory if you write something like this:

for (1 .. 1_000_000) { # code }

In a scalar context, ".." returns a boolean value. The operator is bistable, like a flip-flop, and emulates the line-range (comma) operator of **sed** , **awk** , and various editors. Each ".." operator maintains its own boolean state. It is false as long as its left operand is false. Once the left operand is true, the range operator stays true until the right operand is true, *AFTER* which the range operator becomes false again. (It doesn't become false till the next time the range operator is evaluated. It can test the right operand and become false on the same evaluation it became true (as in **awk**), but it still returns true once. If you don't want it to test the right operand till the next evaluation (as in **sed**), use three dots ("...") instead of two.) The right operand is not evaluated while the operator is in the "false" state, and the left operand is not evaluated while the operator is in the "true" state. The precedence is a little lower than || and &&. The value returned is either the null string for false, or a sequence number (beginning with 1) for true. The sequence number is reset for each range encountered. The final sequence number in a range has the string "E0" appended to it, which doesn't affect its numeric value, but gives you something to search for if you want to exclude the endpoint. You can exclude the beginning point by waiting for the sequence number to be greater than 1. If either operand of scalar ".." is a numeric literal, that operand is implicitly compared to the **$.** variable, the current line number. Examples:

As a scalar operator:

if (101 .. 200) { print; } # print 2nd hundred lines next line if (1 .. /^$/); # skip header lines s/^/> / if (/^$/ .. eof()); # quote body

As a list operator:

for (101 .. 200) { print; } # print $_ 100 times @foo = @foo[$[.. $#foo]; # an expensive no-op @foo = @foo[$#foo-4 .. $#foo]; # slice last 5 items

The range operator (in a list context) makes use of the magical autoincrement algorithm if the operaands are strings. You can say

@alphabet = ('A' .. 'Z');

to get all the letters of the alphabet, or

$hexdigit = (0 .. 9, 'a' .. 'f')[$num & 15];

to get a hexadecimal digit, or

@z2 = ('01' .. '31'); print $z2[$mday];

to get dates with leading zeros. If the final value specified is not in the sequence that the magical

increment would produce, the sequence goes until the next value would be longer than the final value specified.

Conditional Operator

Ternary "?:" is the conditional operator, just as in C. It works much like an if-then-else. If the argument before the ? is true, the argument before the : is returned, otherwise the argument after the : is returned. Scalar or list context propagates downward into the 2nd or 3rd argument, whichever is selected. The operator may be assigned to if both the 2nd and 3rd arguments are legal lvalues (meaning that you can assign to them):

($a_or_b ? $a : $b) = $c;

Note that this is not guaranteed to contribute to the readability of your program.

Assigment Operators

"=" is the ordinary assignment operator.

Assignment operators work as in C. That is,

$a += 2;

is equivalent to

$a = $a + 2;

although without duplicating any side effects that dereferencing the lvalue might trigger, such as from *tie()* . Other assignment operators work similarly. The following are recognized:

```
**=     +=      *=      &=      <<=     &&=
        -=      /=      |=     >>=      ||=
        .=      %=      ^=
                x=
```

Note that while these are grouped by family, they all have the precedence of assignment.

Unlike in C, the assignment operator produces a valid lvalue. Modifying an assignment is equivalent to doing the assignment and then modifying the variable that was assigned to. This is useful for modifying a copy of something, like this:

($tmp = $global) =~ tr [A-Z] [a-z];

Likewise,

($a += 2) *= 3;

is equivalent to

$a += 2; $a *= 3;

Comma Operator

Binary "," is the comma operator. In a scalar context it evaluates its left argument, throws that value away, then evaluates its right argument and returns that value. This is just like C's comma operator.

In a list context, it's just the list argument separator, and inserts both its arguments into the list.

The => digraph is simply a synonym for the comma operator. It's useful for documenting arguments that come in pairs.

List Operators (Rightward)

On the right side of a list operator, it has very low precedence, such that it controls all comma-separated expressions found there. The only operators with lower precedence are the logical operators "and", "or", and "not", which may be used to evaluate calls to list operators without the need for extra parentheses:

open HANDLE, "filename" or die "Can't open: $!\n";

See also discussion of list operators in *List Operators (Leftward)* .

Logical Not

Unary "not" returns the logical negation of the expression to its right. It's the equivalent of "!" except for the very low precedence.

Logical And

Binary "and" returns the logical conjunction of the two surrounding expressions. It's equivalent to && except for the very low precedence. This means that it short-circuits: i.e. the right expression is evaluated only if the left expression is true.

Logical or and Exclusive Or

Binary "or" returns the logical disjunction of the two surrounding expressions. It's equivalent to || except for the very low precedence. This means that it short-circuits: i.e. the right expression is evaluated only if the left expression is false.

Binary "xor" returns the exclusive-OR of the two surrounding expressions. It cannot short circuit, of course.

C Operators Missing From Perl

Here is what C has that Perl doesn't:

unary &

Address-of operator. (But see the "\" operator for taking a reference.)

unary *

Dereference-address operator. (Perl's prefix dereferencing operators are typed: $, @, %, and &.)

(TYPE)

Type casting operator.

.

Quote and Quotelike Operators

While we usually think of quotes as literal values, in Perl they function as operators, providing various kinds of interpolating and pattern matching capabilities. Perl provides customary quote characters for these behaviors, but also provides a way for you to choose your quote character for any of them. In the following table, a **{}** represents any pair of delimiters you choose. Non-bracketing delimiters use the same character fore and aft, but the 4 sorts of brackets (round, angle, square, curly) will all nest.

Customary Generic Meaning Interpolates " q{} Literal no "" qq{} Literal yes `` qx{} Command yes qw{} Word list no // m{} Pattern match yes s{}{} Substitution yes tr{}{} Translation no

For constructs that do interpolation, variables beginning with " **$** or " **@** " are interpolated, as are the following sequences:

\t tab \n newline \r return \f form feed \v vertical tab, whatever that is \b backspace \a alarm (bell) \e escape \033 octal char \x1b hex char \c[control char \l lowercase next char \u uppercase next char \L lowercase till \E \U uppercase till \E \E end case modification \Q quote regexp metacharacters till \E

Patterns are subject to an additional level of interpretation as a regular expression. This is done as a second pass, after variables are interpolated, so that regular expressions may be incorporated into the pattern from the variables. If this is not what you want, use **\Q** to interpolate a variable literally.

Apart from the above, there are no multiple levels of interpolation. In particular, contrary to the expectations of shell programmers, backquotes do *NOT* interpolate within double quotes, nor do single quotes impede evaluation of variables when used within double quotes.

?PATTERN?

This is just like the **/pattern/** search, except that it matches only once between calls to the *reset()* operator. This is a useful optimization when you only want to see the first occurrence of something in each file of a set of files, for instance. Only **??** patterns local to the current package are reset.

This usage is vaguely deprecated, and may be removed in some future version of Perl.

m/PATTERN/gimosx

/PATTERN/gimosx

Searches a string for a pattern match, and in a scalar context returns true (1) or false ('). If no string is specified via the =~ or !~ operator, the **$_** string is searched. (The string specified with need not be an lvalue--it may be the result of an expression evaluation, but remember the =~ binds rather tightly.) See also the *perlre* manpage .

Options are:

- g Match globally, i.e. find all occurrences.
- i Do case-insensitive pattern matching.
- m Treat string as multiple lines.
- o Only compile pattern once.
- s Treat string as single line.
- x Use extended regular expressions.

If "/" is the delimiter then the initial **m** is optional. With the **m** you can use any pair of non-alphanumeric, non-whitespace characters as delimiters. This is particularly useful for matching Unix path names that contain "/", to avoid LTS (leaning toothpick syndrome).

PATTERN may contain variables, which will be interpolated (and the pattern recompiled) every time the pattern search is evaluated. (Note that **$)** and **$|** might not be interpolated because they look like end-of-string tests.) If you want such a pattern to be compiled only once, add a **/o** after the trailing delimiter. This avoids expensive run-time recompilations, and is useful when the value you are interpolating won't change over the life of the script. However, mentioning **/o** constitutes a promise that you won't change the variables in the pattern. If you change them, Perl won't even notice.

If the PATTERN evaluates to a null string, the most recently executed (and successfully compiled) regular expression is used instead.

If used in a context that requires a list value, a pattern match returns a list consisting of the subexpressions matched by the parentheses in the pattern, i.e. (**$1** , **$2** , **$3** ...). (Note that here **$1** etc. are also set, and that this differs from Perl 4's behavior.) If the match fails, a null array is returned. If the match succeeds, but there were no parentheses, a list value of (1) is returned.

Examples:

open(TTY, '/dev/tty'); <TTY> =~ /^y/i && foo(); # do foo if desired if (/Version: *([0-9.]*)/) { $version = $1; } next if m#^/usr/spool/uucp#; # poor man's grep $arg = shift; while (<>) { print if /$arg/o; # compile only once } if (($F1, $F2, $Etc) = ($foo =~ /^(\S+)\s+(\S+)\s*(.*)/))

This last example splits **$foo** into the first two words and the remainder of the line, and assigns those three fields to **$F1** , **$F2** and **$Etc** . The conditional is true if any variables were assigned, i.e. if the pattern matched.

The **/g** modifier specifies global pattern matching--that is, matching as many times as possible within the string. How it behaves depends on the context. In a list context, it returns a list of all the substrings matched by all the parentheses in the regular expression. If there are no parentheses, it returns a list of all the matched strings, as if there were parentheses around the whole pattern.

In a scalar context, **m//g** iterates through the string, returning TRUE each time it matches, and FALSE when it eventually runs out of matches. (In other words, it remembers where it left off last time and restarts the search at that point. You can actually find the current match position of a string using the *pos()* function--see the *perlfunc* manpage .) If you modify the string in any way, the match position is reset to the beginning. Examples:

list context ($one,$five,$fifteen) = (`uptime` =~ /(\d+\.\d+)/g); # scalar context $/ = ""; $* = 1; # $* deprecated in Perl 5 while ($paragraph = <>) { while ($paragraph =~ /[a-z]['")]*[.!?]+['")]*\s/g) { $sentences++; } } print "$sentences\n";

q/STRING/

'STRING'

A single-quoted, literal string. Backslashes are ignored, unless followed by the delimiter or another backslash, in which case the delimiter or backslash is interpolated.

$foo = q!I said, "You said, 'She said it.'"!; $bar = q('This is it.');

qq/STRING/

"STRING"

A double-quoted, interpolated string.

$_ .= qq (*** The previous line contains the naughty word "$1".\n) if /(tcl|rexx|python)/; # :-)

qx/STRING/

`STRING`

A string which is interpolated and then executed as a system command. The collected standard output of the command is returned. In scalar context, it comes back as a single (potentially multi-line) string. In list context, returns a list of lines (however you've defined lines with $/ or **$INPUT_RECORD_SEPARATOR**).

$today = qx{ date };

See *I/O Operators* for more discussion.

qw/STRING/

Returns a list of the words extracted out of STRING, using embedded whitespace as the word delimiters. It is exactly equivalent to

split(' ', q/STRING/);

Some frequently seen examples:

use POSIX qw(setlocale localeconv) @EXPORT = qw(foo bar baz);

s/PATTERN/REPLACEMENT/egimosx

Searches a string for a pattern, and if found, replaces that pattern with the replacement text and returns the number of substitutions made. Otherwise it returns false (0).

If no string is specified via the **=~** or **!~** operator, the **$_** variable is searched and modified. (The string specified with **=~** must be a scalar variable, an array element, a hash element, or an assignment to one of those, i.e. an lvalue.)

If the delimiter chosen is single quote, no variable interpolation is done on either the PATTERN or the REPLACEMENT. Otherwise, if the PATTERN contains a **$** that looks like a variable rather than an end-of-string test, the variable will be interpolated into the pattern at run-time. If you only want the pattern compiled once the first time the variable is interpolated, use the **/o** option. If the pattern evaluates to a null string, the most recently executed (and successfully compiled) regular expression is used instead. See the *perlre* manpage for further explanation on these.

Options are:

- e Evaluate the right side as an expression.
- g Replace globally, i.e. all occurrences.
- i Do case-insensitive pattern matching.
- m Treat string as multiple lines.
- o Only compile pattern once.
- s Treat string as single line.
- x Use extended regular expressions.

Any non-alphanumeric, non-whitespace delimiter may replace the slashes. If single quotes are used, no interpretation is done on the replacement string (the **/e** modifier overrides this, however). If backquotes are used, the replacement string is a command to execute whose output will be used as the actual replacement text. If the PATTERN is delimited by bracketing quotes, the REPLACEMENT has its own pair of quotes, which may or may not be bracketing quotes, e.g. **s(foo)(bar)** or **s<foo>/bar/** . A **/e** will cause the replacement portion to be interpreter as a full-fledged Perl expression and *eval()* ed right then and there. It is, however, syntax checked at compile-time.

Examples:

s/\bgreen\b/mauve/g; # don't change wintergreen $path =~ s|/usr/bin|/usr/local/bin|; s/Login: $foo/Login: $bar/; # run-time pattern ($foo = $bar) =~ s/this/that/; $count = ($paragraph =~ s/Mister\b/Mr./g); $_ = 'abc123xyz'; s/\d+/$&*2/e; # yields 'abc246xyz' s/\d+/sprintf("%5d",$&)/e; # yields 'abc 246xyz' s/\w/$& x 2/eg; # yields 'aabbcc 224466xxyyzz' s/%(.)/$percent{$1}/g; # change percent escapes; no /e s/%(.)/$percent{$1} || $&/ge; # expr now, so /e s/^=(\w+)/&pod($1)/ge; # use function call # /e's can even nest; this will expand # simple embedded variables in $_ s/(\$\w+)/$1/eeg; # Delete C comments. $program =~ s { /* (?# Match the opening delimiter.) .*? (?# Match a minimal number of characters.) */ (?# Match the closing delimiter.) } []gsx; s/^\s*(.*?)\s*$/$1/; # trim white space s/([^]*) *([^]*)/$2 $1/; # reverse 1st two fields

Note the use of **$** instead of \ in the last example. Unlike **sed** , we only use the < *digit* > form in the left hand side. Anywhere else it's < *digit* >.

Occasionally, you can't just use a **/g** to get all the changes to occur. Here are two common cases:

put commas in the right places in an integer 1 while s/(.*\d)(\d\d\d)/$1,$2/g; # perl4 1 while s/(\d)(\d\d\d)(?!\d)/$1,$2/g; # perl5 # expand tabs to 8-column spacing 1 while s/\t+/' ' x (length($&)*8 - length($`)%8)/e;

tr/SEARCHLIST/REPLACEMENTLIST/cds

y/SEARCHLIST/REPLACEMENTLIST/cds

Translates all occurrences of the characters found in the search list with the corresponding character in the replacement list. It returns the number of characters replaced or deleted. If no string is specified via the =~ or !~ operator, the **$_** string is translated. (The string specified with =~ must be a scalar variable, an array element, or an assignment to one of those, i.e. an lvalue.) For **sed** devotees, **y** is provided as a synonym for **tr** . If the SEARCHLIST is delimited by bracketing quotes, the REPLACEMENTLIST has its own pair of quotes, which may or may not be bracketing quotes, e.g. **tr[A-Z][a-z]** or **tr(+-*/)/ABCD/** .

Options:

- c Complement the SEARCHLIST.
- d Delete found but unreplaced characters.
- s Squash duplicate replaced characters.

If the **/c** modifier is specified, the SEARCHLIST character set is complemented. If the **/d** modifier is specified, any characters specified by SEARCHLIST not found in REPLACEMENTLIST are deleted. (Note that this is slightly more flexible than the behavior of some **tr** programs, which delete anything they find in the SEARCHLIST, period.) If the **/s** modifier is specified, sequences of characters that were translated to the same character are squashed down to a single instance of the character.

If the **/d** modifier is used, the REPLACEMENTLIST is always interpreted exactly as specified. Otherwise, if the REPLACEMENTLIST is shorter than the SEARCHLIST, the final character is replicated till it is long enough. If the REPLACEMENTLIST is null, the SEARCHLIST is replicated. This latter is useful for counting characters in a class or for squashing character sequences in a class.

Examples:

$ARGV[1] =~ tr/A-Z/a-z/; # canonicalize to lower case $cnt = tr/*/*/; # count the stars in $_ $cnt = $sky =~ tr/*/*/; # count the stars in $sky $cnt = tr/0-9//; # count the digits in $_ tr/a-zA-Z//s; # bookkeeper -> bokeper ($HOST = $host) =~ tr/a-z/A-Z/; tr/a-zA-Z/ /cs; # change non-alphas to single space tr [\200-\377] [\000-\177]; # delete 8th bit

If multiple translations are given for a character, only the first one is used:

tr/AAA/XYZ/

will translate any A to X.

Note that because the translation table is built at compile time, neither the SEARCHLIST nor the REPLACEMENTLIST are subjected to double quote interpolation. That means that if you want to use variables, you must use an *eval()* :

eval "tr/$oldlist/$newlist/"; die $@ if $@; eval "tr/$oldlist/$newlist/, 1" or die $@;

.

I/O Operators

There are several I/O operators you should know about. A string is enclosed by backticks (grave accents) first undergoes variable substitution just like a double quoted string. It is then interpreted as a command, and the output of that command is the value of the pseudo-literal, like in a shell. In a scalar context, a single string consisting of all the output is returned. In a list context, a list of values is returned, one for each line of output. (You can set **$/** to use a different line terminator.) The command is executed each time the pseudo-literal is evaluated. The status value of the command is returned in **$?** (see the *perlvar* manpage for the interpretation of **$?**). Unlike in **csh** , no translation is done on the return data--newlines remain newlines. Unlike in any of the shells, single quotes do not hide variable names in the command from interpretation. To pass a **$** through to the shell you need to hide it with a backslash. The generalized form of backticks is qx// .

Evaluating a filehandle in angle brackets yields the next line from that file (newline included, so it's never false until end of file, at which time an undefined value is returned). Ordinarily you must assign that value to a variable, but there is one situation where an automatic assignment happens. *If and ONLY if* the input symbol is the only thing inside the conditional of a **while** loop, the value is automatically assigned to the variable **$_** . The assigned value is then tested to see if it is defined. (This may seem like an odd thing to you, but you'll use the construct in almost every Perl script you write.) Anyway, the following lines are equivalent to each other:

while (defined($_ = <STDIN>)) { print; } while (<STDIN>) { print; } for (;<STDIN>;) { print; } print while defined($_ = <STDIN>); print while <STDIN>;

The filehandles STDIN, STDOUT and STDERR are predefined. (The filehandles **stdin** , **stdout** and **stderr** will also work except in packages, where they would be interpreted as local identifiers rather than global.) Additional filehandles may be created with the *open()* function.

If a<FILEHANDLE> is used in a context that is looking for a list, a list consisting of all the input lines is returned, one line per list element. It's easy to make a *LARGE* data space this way, so use with care.

The null filehandle<> is special and can be used to emulate the behavior of **sed** and **awk** . Input from<> comes either from standard input, or from each file listed on the command line. Here's how it works: the first time<> is evaluated, the **@ARGV** array is checked, and if it is null, **$ARGV [0]** is set to "-", which when opened gives you standard input. The **@ARGV** array is then processed as a list of filenames. The loop

while (<>) { ... # code for each line }

is equivalent to the following Perl-like pseudo code:

unshift(@ARGV, '-') if $#ARGV < $[; while ($ARGV = shift) { open(ARGV, $ARGV); while (<ARGV>) { ... # code for each line } }

except that it isn't so cumbersome to say, and will actually work. It really does shift array **@ARGV** and put the current filename into variable **$ARGV** . It also uses filehandle *ARGV* internally-<> is just a synonym for<ARGV>, which is magical. (The pseudo code above doesn't work because it treats<ARGV> as non-magical.)

You can modify **@ARGV** before the first<> as long as the array ends up containing the list of filena you really want. Line numbers (**$.**) continue as if the input were one big happy file. (But see examp under *eof()* for how to reset line numbers on each file.)

If you want to set **@ARGV** to your own list of files, go right ahead. If you want to pass switches into your script, you can use one of the Getopts modules or put a loop on the front like this:

while ($_ = $ARGV[0], /^-/) { shift; last if /^--$/; if (/^-D(.*)/) { $debug = $1 } if (/^-v/) { $verbose++ } ... # other switches } while (<>) { ... # code for each line }

The<> symbol will return FALSE only once. If you call it again after this it will assume you are processing another **@ARGV** list, and if you haven't set **@ARGV** , will input from STDIN.

If the string inside the angle brackets is a reference to a scalar variable (e.g.< **$foo** >), then that variable contains the name of the filehandle to input from.

If the string inside angle brackets is not a filehandle, it is interpreted as a filename pattern to be globbed, and either a list of filenames or the next filename in the list is returned, depending on context. One level of **$** interpretation is done first, but you can't say **< $foo >** because that's an indirect filehandle as explained in the previous paragraph. You could insert curly brackets to force interpretation as a filename glob: **< ${ foo}>** . (Alternately, you can call the internal function directly as **glob($foo)** , which is probably the right way to have done it in the first place.) Example:

while (<*.c>) { chmod 0644, $_; }

is equivalent to

open(FOO, "echo *.c | tr -s ' \t\r\f' '\\012\\012\\012\\012'|"); while (<FOO>) { chop; chmod 0644, $_; }

In fact, it's currently implemented that way. (Which means it will not work on filenames with spaces in them unless you have csh(1) on your machine.) Of course, the shortest way to do the above is:

chmod 0644, <*.c>;

Because globbing invokes a shell, it's often faster to call *readdir()* yourself and just do your own *grep()* on the filenames. Furthermore, due to its current implementation of using a shell, the *glob()* routine may get "Arg list too long" errors (unless you've installed tcsh(1L) as */bin/csh*).

Constant Folding

Like C, Perl does a certain amount of expression evaluation at compile time, whenever it determines that all of the arguments to an operator are static and have no side effects. In particular, string concatenation happens at compile time between literals that don't do variable substitution. Backslash interpretation also happens at compile time. You can say

'Now is the time for all' . "\n" . 'good men to come to.'

and this all reduces to one string internally. Likewise, if you say

foreach $file (@filenames) { if (-s $file > 5 + 100 * 2**16) { ... } }

the compiler will pre-compute the number that expression represents so that the interpreter won't hav

Integer arithmetic

By default Perl assumes that it must do most of its arithmetic in floating point. But by saying

use integer;

you may tell the compiler that it's okay to use integer operations from here to the end of the enclosing BLOCK. An inner BLOCK may countermand this by saying

no integer;

which lasts until the end of that BLOCK.

NAME

perlre - Perl regular expressions

DESCRIPTION

For a description of how to use regular expressions in matching operations, see **m//** and **s///** in the *perlop* manpage . The matching operations can have various modifiers, some of which relate to the interpretation of the regular expression inside. These are:

i Do case-insensitive pattern matching. m Treat string as multiple lines. s Treat string as single line. x Use extended regular expressions.

These are usually written as "the **/x** modifier", even though the delimiter in question might not actually be a slash. In fact, any of these modifiers may also be embedded within the regular expression itself using the new **(?...)** construct. See below.

The **/x** modifier itself needs a little more explanation. It tells the regular expression parser to ignore whitespace that is not backslashed or within a character class. You can use this to break up your regular expression into (slightly) more readable parts. Together with the capability of embedding comments described later, this goes a long way towards making Perl 5 a readable language. See the C comment deletion code in the *perlop* manpage .

Regular Expressions

The patterns used in pattern matching are regular expressions such as those supplied in the Version 8 regexp routines. (In fact, the routines are derived (distantly) from Henry Spencer's freely redistributable reimplementation of the V8 routines.) See *Version 8 Regular Expressions* for details.

In particular the following metacharacters have their standard *egrep* -ish meanings:

\ Quote the next metacharacter ^ Match the beginning of the line . Match any character (except newline) $ Match the end of the line | Alternation () Grouping [] Character class

By default, the "^" character is guaranteed to match only at the beginning of the string, the "$" character only at the end (or before the newline at the end) and Perl does certain optimizations with the assumption that the string contains only one line. Embedded newlines will not be matched by "^" or "$". You may, however, wish to treat a string as a multi-line buffer, such that the "^" will match after any newline within the string, and "$" will match before any newline. At the cost of a little more overhead, you can do this by using the /m modifier on the pattern match operator. (Older programs did this by setting **$*** , but this practice is deprecated in Perl 5.)

To facilitate multi-line substitutions, the "." character never matches a newline unless you use the **/s** modifier, which tells Perl to pretend the string is a single line--even if it isn't. The **/s** modifier also overrides the setting of **$*** , in case you have some (badly behaved) older code that sets it in another module.

The following standard quantifiers are recognized:

* Match 0 or more times + Match 1 or more times ? Match 1 or 0 times {n} Match exactly n times {n,} Match at least n times {n,m} Match at least n but not more than m times

(If a curly bracket occurs in any other context, it is treated as a regular character.) The "*" modifier is equivalent to **{0,}** , the "+" modifier to **{1,}** , and the "?" modifier to **{0,1}** . There is no limit to the size of n or m, but large numbers will chew up more memory.

By default, a quantified subpattern is "greedy", that is, it will match as many times as possible without causing the rest pattern not to match. The standard quantifiers are all "greedy", in that they match as many occurrences as possible (given a particular starting location) without causing the pattern to fail. If you want it to match the minimum number of times possible, follow the quantifier with a "?" after any of them. Note that the meanings don't change, just the "gravity":

*? Match 0 or more times +? Match 1 or more times ?? Match 0 or 1 time {n}? Match exactly n times {n,}? Match at least n times {n,m}? Match at least n but not more than m times

Since patterns are processed as double quoted strings, the following also work:

\t tab \n newline \r return \f form feed \v vertical tab, whatever that is \a alarm (bell) \e escape \033 octal char \x1b hex char \c[control char \l lowercase next char \u uppercase next char \L lowercase till \E \U uppercase till \E \E end case modification \Q quote regexp metacharacters till \E

In addition, Perl defines the following:

\w Match a "word" character (alphanumeric plus "_") \W Match a non-word character \s Match a whitespace character \S Match a non-whitespace character \d Match a digit character \D Match a non-digit character

Note that **\w** matches a single alphanumeric character, not a whole word. To match a word you'd need to say **\w+** . You may use **\w** , **\W** , **\s** , **\S** , **\d** and **\D** within character classes (though not as either end of a range).

Perl defines the following zero-width assertions:

\b Match a word boundary \B Match a non-(word boundary) \A Match only at beginning of string \Z Match only at end of string \G Match only where previous m//g left off

A word boundary (**\b**) is defined as a spot between two characters that has a **\w** on one side of it and and a **\W** on the other side of it (in either order), counting the imaginary characters off the beginning and end of the string as matching a **\W** . (Within character classes **\b** represents backspace rather than a word boundary.) The **\A** and **\Z** are just like "^" and "$" except that they won't match multiple times when the **/m** modifier is used, while "^" and "$" will match at every internal line boundary.

When the bracketing construct **(...)** is used, <digit> matches the digit'th substring. (Outside of the

pattern, always use "$" instead of "\" in front of the digit. The scope of <digit> (and **$`** , **$&** , and **$'**) extends to the end of the enclosing BLOCK or eval string, or to the next pattern match with subexpressions. If you want to use parentheses to delimit subpattern (e.g. a set of alternatives) without saving it as a subpattern, follow the (with a ?. The <digit> notation sometimes works outside the current pattern, but should not be relied upon.) You may have as many parentheses as you wish. If you have more than 9 substrings, the variables **$10** , **$11** , ... refer to the corresponding substring. Within the pattern, \10, \11, etc. refer back to substrings if there have been at least that many left parens before the backreference. Otherwise (for backward compatibilty) \10 is the same as \010, a backspace, and \11 the same as \011, a tab. And so on. (\1 through \9 are always backreferences.)

$+** returns whatever the last bracket match matched. **$& returns the entire matched string. (**$0** used to return the same thing, but not any more.) **$`** returns everything before the matched string. **$'** returns everything after the matched string. Examples:

s/^([^]*) *([^]*)/$2 $1/; # swap first two words if (/Time: (..):(..):(..)/) { $hours = $1; $minutes = $2; $seconds = $3; }

You will note that all backslashed metacharacters in Perl are alphanumeric, such as **\b** , **\w** , **\n** . Unlike some other regular expression languages, there are no backslashed symbols that aren't alphanumeric. So anything that looks like \\, \(, \), <, \>, \{, or \} is always interpreted as a literal character, not a metacharacter. This makes it simple to quote a string that you want to use for a pattern but that you are afraid might contain metacharacters. Simply quote all the non-alphanumeric characters:

$pattern =~ s/(\W)/\\$1/g;

You can also use the built-in *quotemeta()* function to do this. An even easier way to quote metacharacters right in the match operator is to say

/$unquoted\Q$quoted\E$unquoted/

Perl 5 defines a consistent extension syntax for regular expressions. The syntax is a pair of parens with a question mark as the first thing within the parens (this was a syntax error in Perl 4). The character after the question mark gives the function of the extension. Several extensions are already supported:

(?#text)

A comment. The text is ignored.

(?:regexp)

This groups things like "()" but doesn't make backrefences like "()" does. So

split(/\b(?:a|b|c)\b/)

is like

split(/\b(a|b|c)\b/)

but doesn't spit out extra fields.

(?=regexp)

A zero-width positive lookahead assertion. For example, **/\w+(?=\t)/** matches a word followed by a tab, without including the tab in **$&** .

(?!regexp)

A zero-width negative lookahead assertion. For example **/foo(?!bar)/** matches any occurrence of "foo" that isn't followed by "bar". Note however that lookahead and lookbehind are NOT the same thing. You cannot use this for lookbehind: **/(?!foo)bar/** will not find an occurrence of "bar" that is preceded by something which is not "foo". That's because the **(?!foo)** is just saying that the next thing cannot be "foo"--and it's not, it's a "bar", so "foobar" will match. You would have to do something like **/(?foo)...bar/** for that. We say "like" because there's the case of your "bar" not having three characters before it. You could cover that this way: **/(?:(?!foo)...|^..?)bar/** . Sometimes it's still easier just to say:

if (/foo/ && $` =~ /bar$/)

(?imsx)

One or more embedded pattern-match modifiers. This is particularly useful for patterns that are specified in a table somewhere, some of which want to be case sensitive, and some of which don't. The case insensitive ones merely need to include **(?i)** at the front of the pattern. For example:

$pattern = "foobar"; if (/$pattern/i) # more flexible: $pattern = "(?i)foobar"; if (/$pattern/)

The specific choice of question mark for this and the new minimal.matching construct was because 1) question mark is pretty rare in older regular expressions, and 2) whenever you see one, you should stop and "question" exactly what is going on. That's psychology...

Version 8 Regular Expressions

In case you're not familiar with the "regular" Version 8 regexp routines, here are the pattern-matching rules not described above.

Any single character matches itself, unless it is a *metacharacter* with a special meaning described here or above. You can cause characters which normally function as metacharacters to be interpreted literally by prefixing them with a "\" (e.g. "\." matches a ".", not any character; "\\" matches a "\"). A series of characters matches that series of characters in the target string, so the pattern **blurfl** would match "blurfl" in the target string.

You can specify a character class, by enclosing a list of characters in **[]** , which will match any one of the characters in the list. If the first character after the "[" is "^", the class matches any character not in the list. Within a list, the "-" character is used to specify a range, so that **a-z** represents all the characters between "a" and "z", inclusive.

Characters may be specified using a metacharacter syntax much like that used in C: "\n" matches a newline, "\t" a tab, "\r" a carriage return, "\f" a form feed, etc. More generally, \ *nnn* , where *nnn* is a string of octal digits, matches the character whose ASCII value is *nnn* . Similarly, \x *nn* , where *nn* are hexidecimal digits, matches the character whose ASCII value is *nn* . The expression \c *x* matches the ASCII character control- *x* . Finally, the "." metacharacter matches any character except "\n" (unless you use **/s**).

You can specify a series of alternatives for a pattern using "|" to separate them, so that **fee|fie|foe** will match any of "fee", "fie", or "foe" in the target string (as would **f(e|i|o)e**). Note that the first alternative

includes everything from the last pattern delimiter ("(", "[", or the beginning of the pattern) up to the first "|", and the last alternative contains everything from the last "|" to the next pattern delimiter. For this reason, it's common practice to include alternatives in parentheses, to minimize confusion about where they start and end. Note however that "|" is interpreted as a literal with square brackets, so if you write **[fee|fie|foe]** you're really only matching **[feio|]** .

Within a pattern, you may designate subpatterns for later reference by enclosing them in parentheses, and you may refer back to the *n* th subpattern later in the pattern using the metacharacter \ *n* . Subpatterns are numbered based on the left to right order of their opening parenthesis. Note that a backreference matches whatever actually matched the subpattern in the string being examined, not the rules for that subpattern. Therefore, **(0|0x)\d*\s\1\d*** will match "0x1234 0x4321",but not "0x1234 01234", since subpattern 1 actually matched "0x", even though the rule **0|0x** could potentially match the leading 0 in the second number.

NAME

perlrun - how to execute the Perl interpreter

SYNOPSIS

perl [switches] filename args

DESCRIPTION

Upon startup, Perl looks for your script in one of the following places:

1. Specified line by line via -e switches on the command line.
2. Contained in the file specified by the first filename on the command line. (Note that systems supporting the #! notation invoke interpreters this way.)
3. Passed in implicitly via standard input. This only works if there are no filename arguments--to pass arguments to a STDIN script you must explicitly specify a "-" for the script name.

With methods 2 and 3, Perl starts parsing the input file from the.beginning, unless you've specified a -x switch, in which case it scans for the first line starting with #! and containing the word "perl", and starts there instead. This is useful for running a script embedded in a larger message. (In this case you would indicate the end of the script using the __END__ token.)

As of Perl 5, the #! line is always examined for switches as the line is being parsed. Thus, if you're on a machine that only allows one argument with the #! line, or worse, doesn't even recognize the #! line, you still can get consistent switch behavior regardless of how Perl was invoked, even if -x was used to find the beginning of the script.

Because many operating systems silently chop off kernel interpretation of the #! line after 32 characters, some switches may be passed in on the command line, and some may not; you could even get a "-" without its letter, if you're not careful. You probably want to make sure that all your switches fall either before or after that 32 character boundary. Most switches don't actually care if they're processed redundantly, but getting a - instead of a complete switch could cause Perl to try to execute standard input instead of your script. And a partial -I switch could also cause odd results.

Parsing of the #! switches starts wherever "perl" is mentioned in the line. The sequences "-*" and "- " are specifically ignored so that you could, if you were so inclined, say

#!/bin/sh -- # -*- perl -*- -p eval 'exec perl $0 -S ${1+"$@"}' if 0;

to let Perl see the -p switch.

If the #! line does not contain the word "perl", the program named after the #! is executed instead of the Perl interpreter. This is slightly bizarre, but it helps people on machines that don't do #!, because they can tell a program that their SHELL is /usr/bin/perl, and Perl will then dispatch the program to the correct interpreter for them.

After locating your script, Perl compiles the entire script to an internal form. If there are any compilation errors, execution of the script is not attempted. (This is unlike the typical shell script, which might run partway through before finding a syntax error.)

If the script is syntactically correct, it is executed. If the script runs off the end without hitting an *exit()* or *die()* operator, an implicit **exit(0)** is provided to indicate successful completion.

Switches

A single-character switch may be combined with the following switch, if any.

#!/usr/bin/perl -spi.bak # same as -s -p -i.bak

Switches include:

-0 *digits*

specifies the record separator (**$/**) as an octal number. If there are no digits, the null character is the separator. Other switches may precede or follow the digits. For example, if you have a version of **find** which can print filenames terminated by the null character, you can say this:

find . -name '*.bak' -print0 | perl -n0e unlink

The special value 00 will cause Perl to slurp files in paragraph mode. The value 0777 will cause Perl to slurp files whole since there is no legal character with that value.

-a

turns on autosplit mode when used with a -n or -p . An implicit split command to the **@F** array is done as the first thing inside the implicit while loop produced by the -n or -p .

perl -ane 'print pop(@F), "\n";'

is equivalent to

while (<>) { @F = split(' '); print pop(@F), "\n"; }

An alternate delimiter may be specified using -F .

-c

causes Perl to check the syntax of the script and then exit without executing it. Actually, it will execute **BEGIN** and **use** blocks, since these are considered part of the compilation.

-d

runs the script under the Perl debugger. See the *perldebug* manpage .

-D *number*

-D *list*

sets debugging flags. To watch how it executes your script, use **-D14** . (This only works if debugging is compiled into your Perl.) Another nice value is **-D1024** , which lists your compiled syntax tree. And **-D512** displays compiled regular expressions. As an alternative specify a list of letters instead of numbers (e.g. **-D14** is equivalent to **-Dtls**):

1 p Tokenizing and Parsing 2 s Stack Snapshots 4 l Label Stack Processing 8 t Trace Execution 16 o Operator Node Construction 32 c String/Numeric Conversions 64 P Print Preprocessor Command for -P 128 m Memory Allocation 256 f Format Processing 512 r Regular Expression Parsing 1024 x Syntax Tree Dump 2048 u Tainting Checks 4096 L Memory Leaks (not supported anymore) 8192 H Hash Dump -- usurps values() 16384 X Scratchpad Allocation 32768 D Cleaning Up

-e *commandline*

may be used to enter one line of script. If -e is given, Perl will not look for a script filename in the argument list. Multiple -e commands may be given to build up a multi-line script. Make sure to use semicolons where you would in a normal program.

-F *regexp*

specifies a regular expression to split on if -a is also in effect. If regexp has // around it, the slashes will be ignored.

-i *extension*

specifies that files processed by the <> construct are to be edited in-place. It does this by renaming the input file, opening the output file by the original name, and selecting that output file as the default for *print()* statements. The extension, if supplied, is added to the name of the old file to make a backup copy. If no extension is supplied, no backup is made. From the shell, saying

$ perl -p -i.bak -e "s/foo/bar/; ... "

is the same as using the script:

#!/usr/bin/perl -pi.bak s/foo/bar/;

which is equivalent to

#!/usr/bin/perl while (<>) { if ($ARGV ne $oldargv) { rename($ARGV, $ARGV . '.bak'); open(ARGVOUT, ">$ARGV"); select(ARGVOUT); $oldargv = $ARGV; } s/foo/bar/; } continue { print; # this prints to original filename } select(STDOUT);

except that the -i form doesn't need to compare **$ARGV** to **$oldargv** to know when the filename has changed. It does, however, use ARGVOUT for the selected filehandle. Note that STDOUT is restored as the default output filehandle after the loop.

You can use **eof** without parenthesis to locate the end of each input file, in case you want to append to each file, or reset line numbering (see example in *eof*).

-I *directory*

may be used in conjunction with -P to tell the C preprocessor where to look for include files. By default /usr/include and /usr/lib/perl are searched.

-l ***octnum***

enables automatic line-ending processing. It has two effects: first, it automatically chomps the line terminator when used with -n or -p , and second, it assigns " **$** " to have the value of *octnum* so that any print statements will have that line terminator added back on. If *octnum* is omitted, sets " **$** " to the current value of " **$/** ". For instance, to trim lines to 80 columns:

perl -lpe 'substr($_, 80) = """

Note that the assignment **$\ = $/** is done when the switch is processed, so the input record separator can be different than the output record separator if the -l switch is followed by a **-0** switch:

gnufind / -print0 | perl -ln0e 'print "found $_" if -p'

This sets $\ to newline and then sets $/ to the null character.

-n

causes Perl to assume the following loop around your script, which makes it iterate over filename arguments somewhat like **sed -n** or **awk** :

while (<>) { ... # your script goes here }

Note that the lines are not printed by default. See -p to have lines printed. Here is an efficient way to delete all files older than a week:

find . -mtime +7 -print | perl -nle 'unlink;'

This is faster than using the **-exec** switch of **find** because you don't have to start a process on every filename found.

BEGIN and **END** blocks may be used to capture control before or after the implicit loop, just as in **awk** .

-p

causes Perl to assume the following loop around your script, which makes it iterate over filename arguments somewhat like **sed** :

while (<>) { ... # your script goes here } continue { print; }

Note that the lines are printed automatically. To suppress printing use the -n switch. A -p overrides a -n switch.

BEGIN and **END** blocks may be used to capture control before or after the implicit loop, just as in awk.

-P

causes your script to be run through the C preprocessor before compilation by Perl. (Since both comments and cpp directives begin with the # character, you should avoid starting comments with any words recognized by the C preprocessor such as "if", "else" or "define".)

-s

enables some rudimentary switch parsing for switches on the command line after the script name but before any filename arguments (or before a **--**). Any switch found there is removed from **@ARGV** and sets the corresponding variable in the Perl script. The following script prints "true" if and only if the script is invoked with a **-xyz** switch.

#!/usr/bin/perl -s if ($xyz) { print "true\n"; }

-S

makes Perl use the PATH environment variable to search for the script (unless the name of the script starts with a slash). Typically this is used to emulate #! startup on machines that don't support #!, in the following manner:

#!/usr/bin/perl eval "exec /usr/bin/perl -S $0 $*" if $running_under_some_shell;

The system ignores the first line and feeds the script to /bin/sh, which proceeds to try to execute the Perl script as a shell script. The shell executes the second line as a normal shell command, and thus starts up the Perl interpreter. On some systems **$0** doesn't always contain the full pathname, so the -S tells Perl to search for the script if necessary. After Perl locates the script, it parses the lines and ignores them because the variable **$running_under_some_shell** is never true. A better construct than **$*** would be **${ 1+"$@"}** , which handles embedded spaces and such in the filenames, but doesn't work if the script is being interpreted by csh. In order to start up sh rather than csh, some systems may have to replace the #! line with a line containing just a colon, which will be politely ignored by Perl. Other systems can't control that, and need a totally devious construct that will work under any of csh, sh or Perl, such as the following:

eval '(exit $?0)' && eval 'exec /usr/bin/perl -S $0 ${1+"$@"}' & eval 'exec /usr/bin/perl -S $0 $argv:q' if 0;

-T

forces "taint" checks to be turned on. Ordinarily these checks are done only when running setuid or setgid. See the *perlsec* manpage .

-u

causes Perl to dump core after compiling your script. You can then take this core dump and turn it into an executable file by using the **undump** program (not supplied). This speeds startup at the expense of some disk space (which you can minimize by stripping the executable). (Still, a "hello world" executable comes out to about 200K on my machine.) If you want to execute a portion of your script before dumping, use the *dump()* operator instead. Note: availability of **undump** is platform specific and may not be available for a specific port of Perl.

-U

allows Perl to do unsafe operations. Currently the only "unsafe" operations are the unlinking of directories while running as superuser, and running setuid programs with fatal taint checks turned into warnings.

-v

prints the version and patchlevel of your Perl executable.

-w

prints warnings about identifiers that are mentioned only once, and scalar variables that are us before being set. Also warns about redefined subroutines, and references to undefined filehand or filehandles opened readonly that you are attempting to write on. Also warns you if you use values as a number that doesn't look like numbers, using an array as though it were a scalar, if your subroutines recurse more than 100 deep, and innumerable other things. See the *perldiag* manpage and the *perltrap* manpage .

-x *directory*

tells Perl that the script is embedded in a message. Leading garbage will be discarded until the first line that starts with #! and contains the string "perl". Any meaningful switches on that line will be applied (but only one group of switches, as with normal #! processing). If a directory name is specified, Perl will switch to that directory before running the script. The -x switch only controls the the disposal of leading garbage. The script must be terminated with **__END__** if there is trailing garbage to be ignored (the script can process any or all of the trailing garbage via the DATA filehandle if desired).

.

TOC

NAME

perlfunc - Perl builtin functions

DESCRIPTION

The functions in this section can serve as terms in an expression. They fall into two major categories: list operators and named unary operators. These differ in their precedence relationship with a following comma. (See the precedence table in the *perlop* manpage .) List operators take more than one argument, while unary operators can never take more than one argument. Thus, a comma terminates the argument of a unary operator, but merely separates the arguments of a list operator. A unary operator generally provides a scalar context to its argument, while a list operator may provide either scalar and list contexts for its arguments. If it does both, the scalar arguments will be first, and the list argument will follow. (Note that there can only ever be one list argument.) For instance, splice() has three scalar arguments followed by a list.

In the syntax descriptions that follow, list operators that expect a list (and provide list context for the elements of the list) are shown with LIST as an argument. Such a list may consist of any combination of scalar arguments or list values; the list values will be included in the list as if each individual element were interpolated at that point in the list, forming a longer single-dimensional list value. Elements of the LIST should be separated by commas.

Any function in the list below may be used either with or without parentheses around its arguments. (The syntax descriptions omit the parens.) If you use the parens, the simple (but occasionally surprising) rule is this: It *LOOKS* like a function, therefore it *IS* a function, and precedence doesn't matter. Otherwise it's a list operator or unary operator, and precedence does matter. And whitespace between the function and left parenthesis doesn't count--so you need to be careful sometimes:

print 1+2+3; # Prints 6. print(1+2) + 3; # Prints 3. print (1+2)+3; # Also prints 3! print +(1+2)+3; # Prints 6. print ((1+2)+3); # Prints 6.

If you run Perl with the **-w** switch it can warn you about this. For example, the third line above produces:

print (...) interpreted as function at - line 1. Useless use of integer addition in void context at - line 1.

For functions that can be used in either a scalar or list context, non-abortive failure is generally indicated in a scalar context by returning the undefined value, and in a list context by returning the null list.

Remember the following rule:

- * *THERE IS NO GENERAL RULE FOR CONVERTING A LIST INTO A SCALAR!*

Each operator and function decides which sort of value it would be most.appropriate to return in a scalar context. Some operators return the length of the list that would have been returned in a list context. Some

operators return the first value in the list. Some operators return the last value in the list. Some operators return a count of successful operations. In general, they do what you want, unless you want consistency.

-X FILEHANDLE

-X EXPR

-X

A file test, where X is one of the letters listed below. This unary operator takes one argument, either a filename or a filehandle, and tests the associated file to see if something is true about it. If the argument is omitted, tests **$_** , except for **-t** , which tests STDIN. Unless otherwise documented, it returns **1** for TRUE and '' for FALSE, or the undefined value if the file doesn't exist. Despite the funny names, precedence is the same as any other named unary operator, and the argument may be parenthesized like any other unary operator. The operator may be any of:

-r File is readable by effective uid/gid. -w File is writable by effective uid/gid. -x File is executable by effective uid/gid. -o File is owned by effective uid. -R File is readable by real uid/gid. -W File is writable by real uid/gid. -X File is executable by real uid/gid. -O File is owned by real uid. -e File exists. -z File has zero size. -s File has non-zero size (returns size). -f File is a plain file. -d File is a directory. -l File is a symbolic link. -p File is a named pipe (FIFO). -S File is a socket. -b File is a block special file. -c File is a character special file. -t Filehandle is opened to a tty. -u File has setuid bit set. -g File has setgid bit set. -k File has sticky bit set. -T File is a text file. -B File is a binary file (opposite of -T). -M Age of file in days when script started. -A Same for access time. -C Same for inode change time.

The interpretation of the file permission operators **-r** , **-R** , **-w** , **-W** , **-x** and -X is based solely on the mode of the file and the uids and gids of the user. There may be other reasons you can't actually read, write or execute the file. Also note that, for the superuser, **-r** , **-R** , **-w** and **-W** always return 1, and **-x** and -X return 1 if any execute bit is set in the mode. Scripts run by the superuser may thus need to do a stat() in order to determine the actual mode of the file, or temporarily set the uid to something else.

Example:

while (<>) { chop; next unless -f $_; # ignore specials ... }

Note that **-s/a/b/** does not do a negated substitution. Saying **-exp($foo)** still works as expected, however--only single letters following a minus are interpreted as file tests.

The **-T** and **-B** switches work as follows. The first block or so of the file is examined for odd characters such as strange control codes or characters with the high bit set. If too many odd characters (>30%) are found, it's a **-B** file, otherwise it's a **-T** file. Also, any file containing null in the first block is considered a binary file. If **-T** or **-B** is used on a filehandle, the current stdio buffer is examined rather than the first block. Both **-T** and **-B** return TRUE on a null file, or a file at EOF when testing a filehandle.

If any of the file tests (or either the stat() or lstat() operators) are given the special filehandle consisting of a solitary underline, then the stat structure of the previous file test (or stat operator) is used, saving a system call. (This doesn't work with **-t** , and you need to remember that lstat() and **-l** will leave values in the stat structure for the symbolic link, not the real file.) Example:

print "Can do.\n" if -r $a || -w _ || -x _; stat($filename); print "Readable\n" if -r _; print "Writable\n" if -w _; print "Executable\n" if -x _; print "Setuid\n" if -u _; print "Setgid\n" if -g _; print "Sticky\n" if -k _; print "Text\n" if -T _; print "Binary\n" if -B _;

abs VALUE

Returns the absolute value of its argument.

accept NEWSOCKET,GENERICSOCKET

Accepts an incoming socket connect, just as the accept(2) system call does. Returns the packed address if it succeeded, FALSE otherwise. See example in the *perlipc* manpage .

alarm SECONDS

Arranges to have a SIGALRM delivered to this process after the specified number of seconds have elapsed. (On some machines, unfortunately, the elapsed time may be up to one second less than you specified because of how seconds are counted.) Only one timer may be counting at once. Each call disables the previous timer, and an argument of 0 may be supplied to cancel the previous timer without starting a new one. The returned value is the amount of time remaining on the previous timer.

For sleeps of finer granularity than one second, you may use Perl's syscall() interface to access setitimer(2) if your system supports it, or else see *select* below.

atan2 Y,X

Returns the arctangent of Y/X in the range -PI to PI.

bind SOCKET,NAME

Binds a network address to a socket, just as the bind system call does. Returns TRUE if it succeeded, FALSE otherwise. NAME should be a packed address of the appropriate type for the socket. See example in the *perlipc* manpage .

binmode FILEHANDLE

Arranges for the file to be read or written in "binary" mode in operating systems that distinguish between binary and text files. Files that are not in binary mode have CR LF sequences translated to LF on input and LF translated to CR LF on output. Binmode has no effect under Unix; in DOS, it may be imperative. If FILEHANDLE is an expression, the value is taken as the name of the filehandle.

bless REF,PACKAGE

bless REF

This function tells the referenced object (passed as REF) that it is now an object in PACKAGE--or the current package if no PACKAGE is specified, which is the usual case. It returns the reference for convenience, since a bless() is often the last thing in a constructor. See the *perlobj* manpage for more about the blessing (and blessings) of objects.

caller EXPR

caller

Returns the context of the current subroutine call. In a scalar context, returns TRUE if there is a caller, that is, if we're in a subroutine or eval() or require() , and FALSE otherwise. In a list context, returns

($package, $filename, $line) = caller;

With EXPR, it returns some extra information that the debugger uses to print a stack trace. The value of EXPR indicates how many call frames to go back before the current one.

($package, $filename, $line, $subroutine, $hasargs, $wantargs) = caller($i);

Furthermore, when called from within the DB package, caller returns more detailed information: it sets sets the list variable **@DB:args** to be the arguments with which that subroutine was invoked.

chdir EXPR

Changes the working directory to EXPR, if possible. If EXPR is omitted, changes to home directory. Returns TRUE upon success, FALSE otherwise. See example under die() .

chmod LIST

Changes the permissions of a list of files. The first element of the list must be the numerical mode. Returns the number of files successfully changed.

$cnt = chmod 0755, 'foo', 'bar'; chmod 0755, @executables;

chomp VARIABLE

chomp LIST

chomp

This is a slightly safer version of chop (see below). It removes any line ending that corresponds to the current value of **$/** (also known as **$INPUT_RECORD_SEPARATOR** in the **English** module). It returns the number of characters removed. It's often used to remove the newline from the end of an input record when you're worried that the final record may be missing its newline. When in paragraph mode (**$/ = ""**), it removes all trailing newlines from the string. If VARIABLE is omitted, it chomps **$_** . Example:

while (<>) { chomp; # avoid \n on last field @array = split(/:/); ... }

You can actually chomp anything that's an lvalue, including an assignment:

chomp($cwd = `pwd`); chomp($answer = <STDIN>);

If you chomp a list, each element is chomped, and the total number of characters removed is returned.

chop VARIABLE

chop LIST

chop

Chops off the last character of a string and returns the character chopped. It's used primarily to remove the newline from the end of an input record, but is much more efficient than **s/\n//** because it neither scans nor copies the string. If VARIABLE is omitted, chops **$_** . Example:

while (<>) { chop; # avoid \n on last field @array = split(/:/); ... }

You can actually chop anything that's an lvalue, including an assignment:

chop($cwd = `pwd`); chop($answer = <STDIN>);

If you chop a list, each element is chopped. Only the value of the last chop is returned.

Note that chop returns the last character. To return all but the last character, use substr(**$string** , 0, -1) .

chown LIST

Changes the owner (and group) of a list of files. The first two elements of the list must be the *NUMERICAL* uid and gid, in that order. Returns the number of files successfully changed.

$cnt = chown $uid, $gid, 'foo', 'bar'; chown $uid, $gid, @filenames;

Here's an example that looks up non-numeric uids in the passwd file:

print "User: "; chop($user = <STDIN>); print "Files: " chop($pattern = <STDIN>); ($login,$pass,$uid,$gid) = getpwnam($user) or die "$user not in passwd file"; @ary = <${pattern}>; # expand filenames chown $uid, $gid, @ary;

chr NUMBER

Returns the character represented by that NUMBER in the character set. For example, chr(65) is "A" in ASCII.

chroot FILENAME

Does the same as the system call of that name. If you don't know what it does, don't worry about it. If FILENAME is omitted, does chroot to **$_** .

close FILEHANDLE

Closes the file or pipe associated with the file handle, returning TRUE only if stdio successfully flushes buffers and closes the system file descriptor. You don't have to close FILEHANDLE if you are immediately going to do another open on it, since open will close it for you. (See open() .) However, an explicit close on an input file resets the line counter ($.), while the implicit close done by open() does not. Also, closing a pipe will wait for the process executing on the pipe to complete, in case you want to look at the output of the pipe afterwards. Closing a pipe explicitly also puts the status value of the command into **$?** . Example:

open(OUTPUT, '|sort >foo'); # pipe to sort ... # print stuff to output close OUTPUT; # wait for sort to finish open(INPUT, 'foo'); # get sort's results

FILEHANDLE may be an expression whose value gives the real filehandle name.

closedir DIRHANDLE

Closes a directory opened by opendir() .

connect SOCKET,NAME

Attempts to connect to a remote socket, just as the connect system call does. Returns TRUE if it succeeded, FALSE otherwise. NAME should be a packed address of the appropriate type for the socket. See example in the *perlipc* manpage .

cos EXPR

Returns the cosine of EXPR (expressed in radians). If EXPR is omitted takes cosine of **$_** .

crypt PLAINTEXT,SALT

Encrypts a string exactly like the crypt(3) function in the C library. Useful for checking the password file for lousy passwords, amongst other things. Only the guys wearing white hats should do this.

Here's an example that makes sure that whoever runs this program knows their own password:

$pwd = (getpwuid($<))[1]; $salt = substr($pwd, 0, 2); system "stty -echo"; print "Password: "; chop($word = <STDIN>); print "\n"; system "stty echo"; if (crypt($word, $salt) ne $pwd) { die "Sorry...\n"; } else { print "ok\n"; }

Of course, typing in your own password to whoever asks you for it is unwise.

dbmclose ASSOC_ARRAY

[This function has been superseded by the untie() function.]

Breaks the binding between a DBM file and an associative array.

dbmopen ASSOC,DBNAME,MODE

[This function has been superseded by the tie() function.]

This binds a dbm(3) or ndbm(3) file to an associative array. ASSOC is the name of the associative array. (Unlike normal open, the first argument is *NOT* a filehandle, even though it looks like one). DBNAME is the name of the database (without the *.dir* or *.pag* extension). If the database does not exist, it is created with protection specified by MODE (as modified by the umask()). If your system only supports the older DBM functions, you may perform only one dbmopen() in your program. If your system has neither DBM nor ndbm, calling dbmopen() produces a fatal error.

If you don't have write access to the DBM file, you can only read associative array variables, not set them. If you want to test whether you can write, either use file tests or try setting a dummy array entry inside an eval() , which will trap the error.

Note that functions such as keys() and values() may return huge array values when used on large DBM files. You may prefer to use the each() function to iterate over large DBM files. Example:

print out history file offsets dbmopen(%HIST,'/usr/lib/news/history',0666); while (($key,$val) = each %HIST) { print $key, ' = ', unpack('L',$val), "\n"; } dbmclose(%HIST);

defined EXPR

Returns a boolean value saying whether the lvalue EXPR has a real value or not. Many operations return the undefined value under exceptional conditions, such as end of file, uninitialized variable, system error and such. This function allows you to distinguish between an undefined null scalar and a defined null scalar with operations that might return a real null string, such as referencing elements of an array. You may also check to see if arrays or subroutines exist. Use of defined on predefined variables is not guaranteed to produce intuitive results.

When used on a hash array element, it tells you whether the value is defined, not whether the key exists in the hash. Use exists() for that.

Examples:

print if defined $switch{'D'}; print "$val\n" while defined($val = pop(@ary)); die "Can't readlink $sym: $!" unless defined($value = readlink $sym); eval '@foo = ()' if defined(@foo); die "No XYZ package defined" unless defined %_XYZ; sub foo { defined &$bar ? &$bar(@_) : die "No bar"; }

See also undef() .

delete EXPR

Deletes the specified value from its hash array. Returns the deleted value, or the undefined value if nothing was deleted. Deleting from **$ENV {}** modifies the environment. Deleting from an array tied to a DBM file deletes the entry from the DBM file. (But deleting from a tie() d hash doesn't necessarily return anything.)

The following deletes all the values of an associative array:

foreach $key (keys %ARRAY) { delete $ARRAY{$key}; }

(But it would be faster to use the undef() command.) Note that the EXPR can be arbitrarily complicated as long as the final operation is a hash key lookup:

delete $ref->[$x][$y]{$key};

die LIST

Outside of an eval() , prints the value of LIST to **STDERR** and exits with the current value of $! (errno). If $! is 0, exits with the value of **($? >> 8)** (backtick `command` status). If **($? >> 8)** is 0, exits with 255. Inside an eval() , the error message is stuffed into **$@** , and the eval() is terminated with the undefined value.

Equivalent examples:

die "Can't cd to spool: $!\n" unless chdir '/usr/spool/news'; chdir '/usr/spool/news' or die "Can't cd to spool: $!\n"

If the value of EXPR does not end in a newline, the current script line number and input line number (if any) are also printed, and a newline is supplied. Hint: sometimes appending ", stopped" to your message will cause it to make better sense when the string "at foo line 123" is appended. Suppose you are running script "canasta".

die "/etc/games is no good"; die "/etc/games is no good, stopped";

produce, respectively

/etc/games is no good at canasta line 123. /etc/games is no good, stopped at canasta line 123.

See also exit() and warn() .

do BLOCK

Not really a function. Returns the value of the last command in the sequence of commands indicated by BLOCK. When modified by a loop modifier, executes the BLOCK once before

testing the loop condition. (On other statements the loop modifiers test the conditional first.)

do SUBROUTINE(LIST)

A deprecated form of subroutine call. See the *perlsub* manpage .

do EXPR

Uses the value of EXPR as a filename and executes the contents of the file as a Perl script. Its primary use is to include subroutines from a Perl subroutine library.

do 'stat.pl';

is just like

eval `cat stat.pl`;

except that it's more efficient, more concise, keeps track of the current filename for error messages, and searches all the **-I** libraries if the file isn't in the current directory (see also the **@INC** array in *Predefined Names*). It's the same, however, in that it does reparse the file every time you call it, so you probably don't want to do this inside a loop.

Note that inclusion of library modules is better done with the use() and require() operators.

dump LABEL

This causes an immediate core dump. Primarily this is so that you can use the **undump** program to turn your core dump into an executable binary after having initialized all your variables at the beginning of the program. When the new binary is executed it will begin by executing a goto LABEL (with all the restrictions that goto suffers). Think of it as a goto with an intervening core dump and reincarnation. If LABEL is omitted, restarts the program from the top. WARNING: any files opened at the time of the dump will NOT be open any more when the program is reincarnated, with possible resulting confusion on the part of Perl. See also **-u** option in the *perlrun* manpage .

Example:

#!/usr/bin/perl require 'getopt.pl'; require 'stat.pl'; %days = ('Sun' => 1, 'Mon' => 2, 'Tue' => 3, 'Wed' => 4, 'Thu' => 5, 'Fri' => 6, 'Sat' => 7,); dump QUICKSTART if $ARGV[0] eq '-d'; QUICKSTART: Getopt('f');

each ASSOC_ARRAY

Returns a 2 element array consisting of the key and value for the next value of an associative array, so that you can iterate over it. Entries are returned in an apparently random order. When the array is entirely read, a null array is returned (which when assigned produces a FALSE (0) value). The next call to each() after that will start iterating again. The iterator can be reset only by reading all the elements from the array. You should not add elements to an array while you're iterating over it. There is a single iterator for each associative array, shared by all each() , keys() and values() function calls in the program. The following prints out your environment like the printenv(1) program, only in a different order:

while (($key,$value) = each %ENV) { print "$key=$value\n"; }

See also keys() and values() .

eof FILEHANDLE

eof

Returns 1 if the next read on FILEHANDLE will return end of file, or if FILEHANDLE is not open. FILEHANDLE may be an expression whose value gives the real filehandle name. (Note that this function actually reads a character and then *ungetc()* s it, so it is not very useful in an interactive context.) Do not read from a terminal file (or call eof(FILEHANDLE) on it) after end-of-file is reached. Filetypes such as terminals may lose the end-of-file condition if you do.

An eof without an argument uses the last file read as argument. Empty parentheses () may be used to indicate the pseudo file formed of the files listed on the command line, i.e. eof() is reasonable to use inside a while <>) loop to detect the end of only the last file. Use eof(ARGV) or eof without the parentheses to test *EACH* file in a while <>) loop. Examples:

reset line numbering on each input file while (<>) { print "$.\t$_"; close(ARGV) if (eof); # Not eof(). } # insert dashes just before last line of last file while (<>) { if (eof()) { print "----------\n"; close(ARGV); # close or break; is needed if we # are reading from the terminal } print; }

Practical hint: you almost never need to use eof in Perl, because the input operators return undef when they run out of data.

eval EXPR

eval BLOCK

EXPR is parsed and executed as if it were a little Perl program. It is executed in the context of the current Perl program, so that any variable settings, subroutine or format definitions remain afterwards. The value returned is the value of the last expression evaluated, or a return statement may be used, just as with subroutines.

If there is a syntax error or runtime error, or a die() statement is executed, an undefined value is returned by eval() , and **$@** is set to the error message. If there was no error, **$@** is guaranteed to be a null string. If EXPR is omitted, evaluates **$_** . The final semicolon, if any, may be omitted from the expression.

Note that, since eval() traps otherwise-fatal errors, it is useful for determining whether a particular feature (such as dbmopen() or symlink()) is implemented. It is also Perl's exception trapping mechanism, where the die operator is used to raise exceptions.

If the code to be executed doesn't vary, you may use the eval-BLOCK form to trap run-time errors without incurring the penalty of recompiling each time. The error, if any, is still returned in **$@** . Examples:

make divide-by-zero non-fatal eval { $answer = $a / $b; }; warn $@ if $@; # same thing, but less efficient eval '$answer = $a / $b'; warn $@ if $@; # a compile-time error eval { $answer = }; # a run-time error eval '$answer ='; # sets $@

With an eval() , you should be especially careful to remember what's being looked at when:

eval $x; # CASE 1 eval "$x"; # CASE 2 eval '$x'; # CASE 3 eval { $x }; # CASE 4 eval "\$$x # CASE 5 $$x++; # CASE 6

Cases 1 and 2 above behave identically: they run the code contained in the variable **$x** . (Although case 2 has misleading double quotes making the reader wonder what else might be happening (nothing is).) Cases 3 and 4 likewise behave in the same way: they run the code< **$x** >, which does nothing at all. (Case 4 is preferred for purely visual reasons.) Case 5 is a place where normally you *WOULD* like to use double quotes, except in that particular situation, you can just use symbolic references instead, as in case 6.

exec LIST

The exec() function executes a system command *AND NEVER RETURNS* . Use the system() function if you want it to return.

If there is more than one argument in LIST, or if LIST is an array with more than one value, calls execvp(3) with the arguments in LIST. If there is only one scalar argument, the argument is checked for shell metacharacters. If there are any, the entire argument is passed to **/bin/sh -c** for parsing. If there are none, the argument is split into words and passed directly to *execvp()* , which is more efficient. Note: exec() (and system(0) do not flush your output buffer, so you may need to set **$|** to avoid lost output. Examples:

exec '/bin/echo', 'Your arguments are: ', @ARGV; exec "sort $outfile | uniq";

If you don't really want to execute the first argument, but want to lie to the program you are executing about its own name, you can specify the program you actually want to run as an "indirect object" (without a comma) in front of the LIST. (This always forces interpretation of the LIST as a multi-valued list, even if there is only a single scalar in the list.) Example:

$shell = '/bin/csh'; exec $shell '-sh'; # pretend it's a login shell

or, more directly,

exec {'/bin/csh'} '-sh'; # pretend it's a login shell

exists EXPR

Returns TRUE if the specified hash key exists in its hash array, even if the corresponding value is undefined.

print "Exists\n" if exists $array{$key}; print "Defined\n" if defined $array{$key}; print "True\n" if $array{$key};

A hash element can only be TRUE if it's defined, and defined if it exists, but the reverse doesn't necessarily hold true.

Note that the EXPR can be arbitrarily complicated as long as the final operation is a hash key lookup:

if (exists $ref->[$x][$y]{$key}) { ... }

exit EXPR

Evaluates EXPR and exits immediately with that value. (Actually, it calls any defined **END**

routines first, but the **END** routines may not abort the exit. Likewise any object destructors that need to be called are called before exit.) Example:

$ans = <STDIN>; exit 0 if $ans =~ /^[Xx]/;

See also die() . If EXPR is omitted, exits with 0 status.

exp EXPR

Returns *e* (the natural logarithm base) to the power of EXPR. If EXPR is omitted, gives exp(**$_**) .

fcntl FILEHANDLE,FUNCTION,SCALAR

Implements the fcntl(2) function. You'll probably have to say

use Fcntl;

first to get the correct function definitions. Argument processing and value return works just like ioctl() below. Note that fcntl() will produce a fatal error if used on a machine that doesn't implement fcntl(2). For example:

use Fcntl; fcntl($filehandle, F_GETLK, $packed_return_buffer);

fileno FILEHANDLE

Returns the file descriptor for a filehandle. This is useful for constructing bitmaps for select() . If FILEHANDLE is an expression, the value is taken as the name of the filehandle.

flock FILEHANDLE,OPERATION

Calls flock(2) on FILEHANDLE. See the flock (2) manpage for definition of OPERATION. Returns TRUE for success, FALSE on failure. Will produce a fatal error if used on a machine that doesn't implement flock(2). Here's a mailbox appender for BSD systems.

$LOCK_SH = 1; $LOCK_EX = 2; $LOCK_NB = 4; $LOCK_UN = 8; sub lock { flock(MBOX,$LOCK_EX); # and, in case someone appended # while we were waiting... seek(MBOX, 0, 2); } sub unlock { flock(MBOX,$LOCK_UN); }

```
open(MBOX, >>/usr/spool/mail/ $ENV {'USER'}")
        or die "Can't open mailbox: $!";
lock();
print MBOX $msg,"\n\n";
unlock();
```

Note that flock() can't lock things over the network. You need to do locking with fcntl() for that.

fork

Does a fork(2) system call. Returns the child pid to the parent process and 0 to the child process, or undef if the fork is unsuccessful. Note: unflushed buffers remain unflushed in both processes, which means you may need to set **$|** (**$AUTOFLUSH** in English) or call the *autoflush()* FileHandle method to avoid duplicate output.

If you fork() without ever waiting on your children, you will accumulate zombies:

$SIG{'CHLD'} = sub { wait };

There's also the double-fork trick (error checking on fork() returns omitted);

unless ($pid = fork) { unless (fork) { exec "what you really wanna do"; die "no exec"; # ... or ... some_perl_code_here; exit 0; } exit 0; } waitpid($pid,0);

formline PICTURE, LIST

This is an internal function used by formats, though you may call it too. It formats (see the *perlform* manpage) a list of values according to the contents of PICTURE, placing the output into the format output accumulator, **$^ A** . Eventually, when a write() is done, the contents of **$^ A** are written to some filehandle, but you could also read **$^ A** yourself and then set **$^ A** back to "". Note that a format typically does one formline() per line of form, but the formline() function itself doesn't care how many newlines are embedded in the PICTURE. This means that the ~ and ~~ tokens will treat the entire PICTURE as a single line. You may therefore need to use multiple formlines to implement a single record format, just like the format compiler.

Be careful if you put double quotes around the picture, since an " **@** " character may be taken to mean the beginning of an array name. formline() always returns TRUE.

getc FILEHANDLE

getc

Returns the next character from the input file attached to FILEHANDLE, or a null string at end of file. If FILEHANDLE is omitted, reads from STDIN.

getlogin

Returns the current login from */etc/utmp* , if any. If null, use getpwuid() .

$login = getlogin || (getpwuid($<))[0] || "Kilroy";

getpeername SOCKET

Returns the packed sockaddr address of other end of the SOCKET connection.

An internet sockaddr $sockaddr = 'S n a4 x8'; $hersockaddr = getpeername(S); ($family, $port, $heraddr) = unpack($sockaddr,$hersockaddr);

getpgrp PID

Returns the current process group for the specified PID, 0 for the current process. Will produce a fatal error if used on a machine that doesn't implement getpgrp(2). If PID is omitted, returns process group of current process.

getppid

Returns the process id of the parent process.

getpriority WHICH,WHO

Returns the current priority for a process, a process group, or a user. (See the getpriority (2) manpage.) Will produce a fatal error if used on a machine that doesn't implement getpriority(2).

getpwnam NAME

getgrnam NAME

gethostbyname NAME
getnetbyname NAME
getprotobyname NAME
getpwuid UID
getgrgid GID
getservbyname NAME,PROTO
gethostbyaddr ADDR,ADDRTYPE
getnetbyaddr ADDR,ADDRTYPE
getprotobynumber NUMBER
getservbyport PORT,PROTO
getpwent
getgrent
gethostent
getnetent
getprotoent
getservent
setpwent
setgrent
sethostent STAYOPEN
setnetent STAYOPEN
setprotoent STAYOPEN
setservent STAYOPEN
endpwent
endgrent
endhostent
endnetent
endprotoent
endservent

These routines perform the same functions as their counterparts in the system library. Within a list context, the return values from the various get routines are as follows:

($name,$passwd,$uid,$gid, $quota,$comment,$gcos,$dir,$shell) = getpw*
($name,$passwd,$gid,$members) = getgr* ($name,$aliases,$addrtype,$length,@addrs) = gethost*
($name,$aliases,$addrtype,$net) = getnet* ($name,$aliases,$proto) = getproto*
($name,$aliases,$port,$proto) = getserv*

(If the entry doesn't exist you get a null list.)

Within a scalar context, you get the name, unless the function was a lookup by name, in which case you get the other thing, whatever it is. (If the entry doesn't exist you get the undefined value.)

For example:

$uid = getpwnam $name = getpwuid $name = getpwent $gid = getgrnam $name = getgrgid $name = getgrent etc.

The **$members** value returned by *getgr*()* is a space separated list of the login names of the members of the group.

For the *gethost*()* functions, if the **h_errno** variable is supported in C, it will be returned to you via **$?** if the function call fails. The **@addrs** value returned by a successful call is a list of the raw addresses returned by the corresponding system library call. In the Internet domain, each address is four bytes long and you can unpack it by saying something like:

($a,$b,$c,$d) = unpack('C4',$addr[0]);

getsockname SOCKET

Returns the packed sockaddr address of this end of the SOCKET connection.

An internet sockaddr $sockaddr = 'S n a4 x8'; $mysockaddr = getsockname(S); ($family, $port, $myaddr) = unpack($sockaddr,$mysockaddr);

getsockopt SOCKET,LEVEL,OPTNAME

Returns the socket option requested, or undefined if there is an error.

glob EXPR

Returns the value of EXPR with filename expansions such as a shell would do. This is the internal function implementing the<*.*> operator.

gmtime EXPR

Converts a time as returned by the time function to a 9-element array with the time localized for the Greenwich timezone. Typically used as follows:

($sec,$min,$hour,$mday,$mon,$year,$wday,$yday,$isdst) = gmtime(time);

All array elements are numeric, and come straight out of a struct tm. In particular this means that **$mon** has the range 0..11 and **$wday** has the range 0..6. If EXPR is omitted, does gmtime(time()) .

goto LABEL

goto EXPR

goto &NAME

The goto-LABEL form finds the statement labeled with LABEL and resumes execution there. It may not be used to go into any construct that requires initialization, such as a subroutine or a foreach loop. It also can't be used to go into a construct that is optimized away. It can be used to go almost anywhere else within the dynamic scope, including out of subroutines, but it's usually better to use some other construct such as last or die. The author of Perl has never felt the need to use this form of goto (in Perl, that is--C is another matter).

The goto-EXPR form expects a label name, whose scope will be resolved dynamically. This allows for computed gotos per FORTRAN, but isn't necessarily recommended if you're optimizing

for maintainability:

goto ("FOO", "BAR", "GLARCH")[$i];

The goto-&NAME form is highly magical, and substitutes a call to the named subroutine for the currently running subroutine. This is used by AUTOLOAD subroutines that wish to load another subroutine and then pretend that the other subroutine had been called in the first place (except that any modifications to **@_** in the current subroutine are propagated to the other subroutine.) After the goto, not even caller() will be able to tell that this routine was called first.

grep BLOCK LIST

grep EXPR,LIST

Evaluates the BLOCK or EXPR for each element of LIST (locally setting **$_** to each element) and returns the list value consisting of those elements for which the expression evaluated to TRUE. In a scalar context, returns the number of times the expression was TRUE.

@foo = grep(!/^#/, @bar); # weed out comments

or equivalently,

@foo = grep {!/^#/} @bar; # weed out comments

Note that, since **$_** is a reference into the list value, it can be used to modify the elements of the array. While this is useful and supported, it can cause bizarre results if the LIST is not a named array.

hex EXPR

Returns the decimal value of EXPR interpreted as an hex string. (To interpret strings that might start with 0 or 0x see oct() .) If EXPR is omitted, uses **$_** .

import

There is no built-in import() function. It is merely an ordinary method subroutine defined (or inherited) by modules that wish to export names to another module. The use() function calls the import() method for the package used. See also *use* and the *perlmod* manpage .

index STR,SUBSTR,POSITION

index STR,SUBSTR

Returns the position of the first occurrence of SUBSTR in STR at or after POSITION. If POSITION is omitted, starts searching from the beginning of the string. The return value is based at 0, or whatever you've set the $[variable to. If the substring is not found, returns one less than the base, ordinarily -1.

int EXPR

Returns the integer portion of EXPR. If EXPR is omitted, uses **$_** .

ioctl FILEHANDLE,FUNCTION,SCALAR

Implements the ioctl(2) function. You'll probably have to say

require "ioctl.ph"; # probably /usr/local/lib/perl/ioctl.ph

first to get the correct function definitions. If ioctl.ph doesn't exist or doesn't have the correct definitions you'll have to roll your own, based on your C header files such as<sys/ioctl.h>. (There is a Perl script called **h2ph** that comes with the Perl kit which may help you in this.) SCALAR will be read and/or written depending on the FUNCTION--a pointer to the string value of SCALAR will be passed as the third argument of the actual ioctl call. (If SCALAR has no string value but does have a numeric value, that value will be passed rather than a pointer to the string value. To guarantee this to be TRUE, add a 0 to the scalar before using it.) The pack() and unpack() functions are useful for manipulating the values of structures used by ioctl() . The following example sets the erase character to DEL.

require 'ioctl.ph'; $sgttyb_t = "ccccs"; # 4 chars and a short if (ioctl(STDIN,$TIOCGETP,$sgttyb)) { @ary = unpack($sgttyb_t,$sgttyb); $ary[2] = 127; $sgttyb = pack($sgttyb_t,@ary); ioctl(STDIN,$TIOCSETP,$sgttyb) || die "Can't ioctl: $!"; }

The return value of ioctl (and fcntl) is as follows:

if OS returns: then Perl returns: -1 undefined value 0 string "0 but true" anything else that number

Thus Perl returns TRUE on success and FALSE on failure, yet you can still easily determine the actual value returned by the operating system:

($retval = ioctl(...)) || ($retval = -1); printf "System returned %d\n", $retval;

join EXPR,LIST

Joins the separate strings of LIST or ARRAY into a single string with fields separated by the value of EXPR, and returns the string. Example:

$_ = join(':', $login,$passwd,$uid,$gid,$gcos,$home,$shell);

See *split* .

keys ASSOC_ARRAY

Returns a normal array consisting of all the keys of the named associative array. (In a scalar context, returns the number of keys.) The keys are returned in an apparently random order, but it is the same order as either the values() or each() function produces (given that the associative array has not been modified). Here is yet another way to print your environment:

@keys = keys %ENV; @values = values %ENV; while ($#keys >= 0) { print pop(@keys), '=', pop(@values), "\n"; }

or how about sorted by key:

foreach $key (sort(keys %ENV)) { print $key, '=', $ENV{$key}, "\n"; }

kill LIST

Sends a signal to a list of processes. The first element of the list must be the signal to send. Returns the number of processes successfully signaled.

$cnt = kill 1, $child1, $child2; kill 9, @goners;

Unlike in the shell, in Perl if the *SIGNAL* is negative, it kills process groups instead of processes.

(On System V, a negative *PROCESS* number will also kill process groups, but that's not portal That means you usually want to use positive not negative signals. You may also use a signal n in quotes.

last LABEL

last

The last command is like the **break** statement in C (as used in loops); it immediately exits the loop in question. If the LABEL is omitted, the command refers to the innermost enclosing loop. The **continue** block, if any, is not executed:

line: while (<STDIN>) { last line if /^$/; # exit when done with header ... }

lc EXPR

Returns an lowercased version of EXPR. This is the internal function implementing the \L escape in double-quoted strings.

lcfirst EXPR

Returns the value of EXPR with the first character lowercased. This is the internal function implementing the \l escape in double-quoted strings.

length EXPR

Returns the length in characters of the value of EXPR. If EXPR is omitted, returns length of **$_** .

link OLDFILE,NEWFILE

Creates a new filename linked to the old filename. Returns 1 for success, 0 otherwise.

listen SOCKET,QUEUESIZE

Does the same thing that the listen system call does. Returns TRUE if it succeeded, FALSE otherwise. See example in the *perlipc* manpage .

local EXPR

In general, you should be using "my" instead of "local", because it's faster and safer. Format variables often use "local" though, as do other variables whose current value must be visible to called subroutines. This is known as dynamic scoping. Lexical scoping is done with "my", which works more like C's auto declarations.

A local modifies the listed variables to be local to the enclosing block, subroutine, eval or "do". If more than one value is listed, the list must be placed in parens. All the listed elements must be legal lvalues. This operator works by saving the current values of those variables in LIST on a hidden stack and restoring them upon exiting the block, subroutine or eval. This means that called subroutines can also reference the local variable, but not the global one. The LIST may be assigned to if desired, which allows you to initialize your local variables. (If no initializer is given for a particular variable, it is created with an undefined value.) Commonly this is used to name the parameters to a subroutine. Examples:

sub RANGEVAL { local($min, $max, $thunk) = @_; local $result = ''; local $i; # Presumably $thunk makes reference to $i for ($i = $min; $i < $max; $i++) { $result .= eval $thunk; } $result; } if ($sw eq '-v') { # init local array with global array local @ARGV = @ARGV; unshift(@ARGV,'echo'); system @ARGV; } # @ARGV restored # temporarily add to digits associative array if ($base12) { # (NOTE: not claiming this is efficient!) local(%digits) =

(%digits,'t',10,'e',11); parse_num(); }

Note that local() is a run-time command, and so gets executed every time through a loop. In Perl 4 it used more stack storage each time until the loop was exited. Perl 5 reclaims the space each time through, but it's still more efficient to declare your variables outside the loop.

A local is simply a modifier on an lvalue expression. When you assign to a localized EXPR, the local doesn't change whether EXPR is viewed as a scalar or an array. So

local($foo) = <STDIN>; local @FOO = <STDIN>;

both supply a list context to the righthand side, while

local $foo = <STDIN>;

supplies a scalar context.

localtime EXPR

Converts a time as returned by the time function to a 9-element array with the time analyzed for the local timezone. Typically used as follows:

($sec,$min,$hour,$mday,$mon,$year,$wday,$yday,$isdst) = localtime(time);

All array elements are numeric, and come straight out of a struct tm. In particular this means that **$mon** has the range 0..11 and **$wday** has the range 0..6. If EXPR is omitted, does localtime(time).

In a scalar context, prints out the ctime(3) value:

$now_string = localtime; # e.g. "Thu Oct 13 04:54:34 1994"

See also *timelocal* and the strftime(3) function available via the POSIX modulie.

log EXPR

Returns logarithm (base *e*) of EXPR. If EXPR is omitted, returns log of **$_** .

lstat FILEHANDLE

lstat EXPR

Does the same thing as the stat() function, but stats a symbolic link instead of the file the symbolic link points to. If symbolic links are unimplemented on your system, a normal stat() is done.

m//

The match operator. See the *perlop* manpage .

map BLOCK LIST

map EXPR,LIST

Evaluates the BLOCK or EXPR for each element of LIST (locally setting **$_** to each element) and returns the list value composed of the results of each such evaluation. Evaluates BLOCK or EXPR in a list context, so each element of LIST may produce zero, one, or more elements in the returned value.

@chars = map(chr, @nums);

translates a list of numbers to the corresponding characters. And

%hash = map {&key($_), $_} @array;

is just a funny way to write

%hash = (); foreach $_ (@array) { $hash{&key($_)} = $_; }

mkdir FILENAME,MODE

Creates the directory specified by FILENAME, with permissions specified by MODE (as modified by umask). If it succeeds it returns 1, otherwise it returns 0 and sets $! (errno).

msgctl ID,CMD,ARG

Calls the System V IPC function msgctl. If CMD is &IPC_STAT, then ARG must be a variable which will hold the returned msqid_ds structure. Returns like ioctl: the undefined value for error, "0 but true" for zero, or the actual return value otherwise.

msgget KEY,FLAGS

Calls the System V IPC function msgget. Returns the message queue id, or the undefined value if there is an error.

msgsnd ID,MSG,FLAGS

Calls the System V IPC function msgsnd to send the message MSG to the message queue ID. MSG must begin with the long integer message type, which may be created with pack("L", **$type**) . Returns TRUE if successful, or FALSE if there is an error.

msgrcv ID,VAR,SIZE,TYPE,FLAGS

Calls the System V IPC function msgrcv to receive a message from message queue ID into variable VAR with a maximum message size of SIZE. Note that if a message is received, the message type will be the first thing in VAR, and the maximum length of VAR is SIZE plus the size of the message type. Returns TRUE if successful, or FALSE if there is an error.

my EXPR

A "my" declares the listed variables to be local (lexically) to the enclosing block, subroutine, eval or "do". If more than one value is listed, the list must be placed in parens. All the listed elements must be legal lvalues. Only alphanumeric identifiers may be lexically scoped--magical builtins like $/ must be localized with "local" instead. In particular, you're not allowed to say

my $_; # Illegal.

Unlike the "local" declaration, variables declared with "my" are totally hidden from the outside world, including any called subroutines (even if it's the same subroutine--every call gets its own copy).

(An eval() , however, can see the lexical variables of the scope it is being evaluated in so long as the names aren't hidden by declarations within the eval() itself. See the *perlref* manpage .)

The EXPR may be assigned to if desired, which allows you to initialize your variables. (If no initializer is given for a particular variable, it is created with an undefined value.) Commonly this is used to name the parameters to a subroutine. Examples:

sub RANGEVAL { my($min, $max, $thunk) = @_; my $result = ''; my $i; # Presumably $thu
makes reference to $i for ($i = $min; $i < $max; $i++) { $result .= eval $thunk; } $result; } if
eq '-v') { # init my array with global array my @ARGV = @ARGV; unshift(@ARGV,'echo');
system @ARGV; } # Outer @ARGV again visible

The "my" is simply a modifier on something you might assign to. So when you do assign to the EXPR, the "my" doesn't change whether EXPR is viewed as a scalar or an array. So

my ($foo) = <STDIN>; my @FOO = <STDIN>;

both supply a list context to the righthand side, while

my $foo = <STDIN>;

supplies a scalar context. But the following only declares one variable:

my $foo, $bar = 1;

That has the same effect as

my $foo; $bar = 1;

The declared variable is not introduced (is not visible) until after the current statement. Thus,

my $x = $x;

can be used to initialize the new **$x** with the value of the old **$x** , and the expression

my $x = 123 and $x == 123

is false unless the old **$x** happened to have the value 123.

Some users may wish to encourage the use of lexically scoped variables. As an aid to catching implicit references to package variables, if you say

use strict 'vars';

then any variable reference from there to the end of the enclosing block must either refer to a lexical variable, or must be fully qualified with the package name. A compilation error results otherwise. An inner block may countermand this with S<"no strict 'vars'">.

next LABEL

next

The next command is like the **continue** statement in C; it starts the next iteration of the loop:

line: while (<STDIN>) { next line if /^#/; # discard comments ... }

Note that if there were a **continue** block on the above, it would get executed even on discarded lines. If the LABEL is omitted, the command refers to the innermost enclosing loop.

no Module LIST

See the "use" function, which "no" is the opposite of.

oct EXPR

Returns the decimal value of EXPR interpreted as an octal string. (If EXPR happens to start off with 0x, interprets it as a hex string instead.) The following will handle decimal, octal, and hex in the standard Perl or C notation:

$val = oct($val) if $val =~ /^0/;

If EXPR is omitted, uses **$_** .

open FILEHANDLE,EXPR

open FILEHANDLE

Opens the file whose filename is given by EXPR, and associates it with FILEHANDLE. If FILEHANDLE is an expression, its value is used as the name of the real filehandle wanted. If EXPR is omitted, the scalar variable of the same name as the FILEHANDLE contains the filename. If the filename begins with <" or nothing, the file is opened for input. If the filename begins with ">", the file is opened for output. If the filename begins with >>", the file is opened for appending. (You can put a '+' in front of the '>' or <' to indicate that you want both read and write access to the file.) If the filename begins with "|", the filename is interpreted as a command to which output is to be piped, and if the filename ends with a "|", the filename is interpreted as command which pipes input to us. (You may not have a command that pipes both in and out.) Opening '-' opens STDIN and opening '>-' opens STDOUT. Open returns non-zero upon success, the undefined value otherwise. If the open involved a pipe, the return value happens to be the pid of the subprocess. Examples:

$ARTICLE = 100; open ARTICLE or die "Can't find article $ARTICLE: $!\n"; while (<ARTICLE>) {...

```
open(LOG, >>/usr/spool/news/twitlog'); # (log is reserved)
open(article, "caesar <$article |");    # decrypt article
open(extract, "|sort >/tmp/Tmp$$");     # $$ is our process id
# process argument list of files along with any includes
foreach $file (@ARGV) {
    process($file, 'fh00');
}
sub process {
    local($filename, $input) = @_;
    $input++;               # this is a string increment
    unless (open($input, $filename)) {
        print STDERR "Can't open $filename: $!\n";
        return;
    }
    while (<$input>) {              # note use of indirection
        if (/^#include "(.*)"/) {
            process($1, $input);
            next;
        }
        ...         # whatever
    }
```

```
    }
```

You may also, in the Bourne shell tradition, specify an EXPR beginning with ">&", in which case the rest of the string is interpreted as the name of a filehandle (or file descriptor, if numeric) which is to be duped and opened. You may use & after >,>>,<, +>, >> and <. The mode you specify should match the mode of the original filehandle. Here is a script that saves, redirects, and restores STDOUT and STDERR:

#!/usr/bin/perl open(SAVEOUT, ">&STDOUT"); open(SAVEERR, ">&STDERR"); open(STDOUT, ">foo.out") || die "Can't redirect stdout"; open(STDERR, ">&STDOUT") || die "Can't dup stdout"; select(STDERR); $| = 1; # make unbuffered select(STDOUT); $| = 1; # make unbuffered print STDOUT "stdout 1\n"; # this works for print STDERR "stderr 1\n"; # subprocesses too close(STDOUT); close(STDERR); open(STDOUT, ">&SAVEOUT"); open(STDERR, ">&SAVEERR"); print STDOUT "stdout 2\n"; print STDERR "stderr 2\n";

If you specify <&=N", where N is a number, then Perl will do an equivalent of C's *fdopen()* of that file descriptor. For example:

open(FILEHANDLE, "<&=$fd")

If you open a pipe on the command "-", i.e. either "|-" or "-|", then there is an implicit fork done, and the return value of open is the pid of the child within the parent process, and 0 within the child process. (Use defined(**$pid**) to determine whether the open was successful.) The filehandle behaves normally for the parent, but i/o to that filehandle is piped from/to the STDOUT/STDIN of the child process. In the child process the filehandle isn't opened--i/o happens from/to the new STDOUT or STDIN. Typically this is used like the normal piped open when you want to exercise more control over just how the pipe command gets executed, such as when you are running setuid, and don't want to have to scan shell commands for metacharacters. The following pairs are more or less equivalent:

open(FOO, "|tr '[a-z]' '[A-Z]'"); open(FOO, "|-") || exec 'tr', '[a-z]', '[A-Z]'; open(FOO, "cat -n '$file'|"); open(FOO, "-|") || exec 'cat', '-n', $file;

Explicitly closing any piped filehandle causes the parent process to wait for the child to finish, and returns the status value in $?. Note: on any operation which may do a fork, unflushed buffers remain unflushed in both processes, which means you may need to set $| to avoid duplicate output.

The filename that is passed to open will have leading and trailing whitespace deleted. In order to open a file with arbitrary weird characters in it, it's necessary to protect any leading and trailing whitespace thusly:

$file =~ s#^(\s)#./$1#; open(FOO, "< $file\0");

opendir DIRHANDLE,EXPR

Opens a directory named EXPR for processing by readdir() , telldir() , seekdir() , rewinddir() and closedir() . Returns TRUE if successful. DIRHANDLEs have their own namespace separate from FILEHANDLEs.

ord EXPR

Returns the numeric ascii value of the first character of EXPR. If EXPR is omitted, uses **$_** .

pack TEMPLATE,LIST

Takes an array or list of values and packs it into a binary structure, returning the string containing the structure. The TEMPLATE is a sequence of characters that give the order and type of values, as follows:

- A An ascii string, will be space padded.
- a An ascii string, will be null padded.
- b A bit string (ascending bit order, like vec()).
- B A bit string (descending bit order).
- h A hex string (low nybble first).
- H A hex string (high nybble first).
- c A signed char value.
- C An unsigned char value.
- s A signed short value.
- S An unsigned short value.
- i A signed integer value.
- I An unsigned integer value.
- l A signed long value.
- L An unsigned long value.
- n A short in "network" order.
- N A long in "network" order.
- v A short in "VAX" (little-endian) order.
- V A long in "VAX" (little-endian) order.
- f A single-precision float in the native format.
- d A double-precision float in the native format.
- p A pointer to a null-terminated string.
- P A pointer to a structure (fixed-length string).
- u A uuencoded string.
- x A null byte.
- X Back up a byte.
- @ Null fill to absolute position.

Each letter may optionally be followed by a number which gives a repeat count. With all types except "a", "A", "b", "B", "h" and "H", and "P" the pack function will gobble up that many values from the LIST. A * for the repeat count means to use however many items are left. The "a" and "A" types gobble just one value, but pack it as a string of length count, padding with nulls or spaces as necessary. (When unpacking, "A" strips trailing spaces and nulls, but "a" does not.) Likewise, the "b" and "B" fields pack a string that many bits long. The "h" and "H" fields pack a string that many nybbles long. The "P" packs a pointer to a structure of the size indicated by the

length. Real numbers (floats and doubles) are in the native machine format only; due to the multiplicity of floating formats around, and the lack of a standard "network" representation, no facility for interchange has been made. This means that packed floating point data written on one machine may not be readable on another - even if both use IEEE floating point arithmetic (as the endian-ness of the memory representation is not part of the IEEE spec). Note that Perl uses doubles internally for all numeric calculation, and converting from double into float and thence back to double again will lose precision (i.e. unpack("f", pack("f", **$foo**)) will not in general equal **$foo**).

Examples:

$foo = pack("cccc",65,66,67,68); # foo eq "ABCD" $foo = pack("c4",65,66,67,68); # same thing $foo = pack("ccxxcc",65,66,67,68); # foo eq "AB\0\0CD" $foo = pack("s2",1,2); # "\1\0\2\0" on little-endian # "\0\1\0\2" on big-endian $foo = pack("a4","abcd","x","y","z"); # "abcd" $foo = pack("aaaa","abcd","x","y","z"); # "axyz" $foo = pack("a14","abcdefg"); # "abcdefg\0\0\0\0\0\0\0" $foo = pack("i9pl", gmtime); # a real struct tm (on my system anyway) sub bintodec { unpack("N", pack("B32", substr("0" x 32 . shift, -32))); }

The same template may generally also be used in the unpack function.

pipe READHANDLE,WRITEHANDLE

Opens a pair of connected pipes like the corresponding system call. Note that if you set up a loop of piped processes, deadlock can occur unless you are very careful. In addition, note that Perl's pipes use stdio buffering, so you may need to set $| to flush your WRITEHANDLE after each command, depending on the application.

pop ARRAY

Pops and returns the last value of the array, shortening the array by 1. Has a similar effect to

$tmp = $ARRAY[$#ARRAY--];

If there are no elements in the array, returns the undefined value.

pos SCALAR

Returns the offset of where the last m//g search left off for the variable in question. May be modified to change that offset.

print FILEHANDLE LIST

print LIST

print

Prints a string or a comma-separated list of strings. Returns non-zero if successful. FILEHANDLE may be a scalar variable name, in which case the variable contains the name of the filehandle, thus introducing one level of indirection. (NOTE: If FILEHANDLE is a variable and the next token is a term, it may be misinterpreted as an operator unless you interpose a + or put parens around the arguments.) If FILEHANDLE is omitted, prints by default to standard output (or to the last selected output channel--see select()). If LIST is also omitted, prints **$_** to STDOUT. To set the default output channel to something other than STDOUT use the select operation. Note that, because print takes a LIST, anything in the LIST is evaluated in a list context, and any subroutine that you call will have one or more of its expressions evaluated in a list context. Also be careful

not to follow the print keyword with a left parenthesis unless you want the corresponding right parenthesis to terminate the arguments to the print--interpose a + or put parens around all the arguments.

printf FILEHANDLE LIST

printf LIST

Equivalent to a "print FILEHANDLE sprintf(LIST)". The first argument of the list will be interpreted as the printf format.

push ARRAY,LIST

Treats ARRAY as a stack, and pushes the values of LIST onto the end of ARRAY. The length of ARRAY increases by the length of LIST. Has the same effect as

for $value (LIST) { $ARRAY[++$#ARRAY] = $value; }

but is more efficient. Returns the new number of elements in the array.

q/STRING/

qq/STRING/

qx/STRING/

qw/STRING/

Generalized quotes. See the *perlop* manpage .

quotemeta EXPR

Returns the value of EXPR with with all regular expression metacharacters backslashed. This is the internal function implementing the \Q escape in double-quoted strings.

rand EXPR

rand

Returns a random fractional number between 0 and the value of EXPR. (EXPR should be positive.) If EXPR is omitted, returns a value between 0 and 1. This function produces repeatable sequences unless srand() is invoked. See also srand() .

(Note: if your rand function consistently returns numbers that are too large or too small, then your version of Perl was probably compiled with the wrong number of RANDBITS. As a workaround, you can usually multiply EXPR by the correct power of 2 to get the range you want. This will make your script unportable, however. It's better to recompile if you can.)

read FILEHANDLE,SCALAR,LENGTH,OFFSET

read FILEHANDLE,SCALAR,LENGTH

Attempts to read LENGTH bytes of data into variable SCALAR from the specified FILEHANDLE. Returns the number of bytes actually read, or undef if there was an error. SCALAR will be grown or shrunk to the length actually read. An OFFSET may be specified to place the read data at some other place than the beginning of the string. This call is actually implemented in terms of stdio's fread call. To get a true read system call, see sysread() .

readdir DIRHANDLE

Returns the next directory entry for a directory opened by opendir() . If used in a list context,

returns all the rest of the entries in the directory. If there are no more entries, returns an undefi value in a scalar context or a null list in a list context.

readlink EXPR

Returns the value of a symbolic link, if symbolic links are implemented. If not, gives a fatal error. If there is some system error, returns the undefined value and sets $! (errno). If EXPR is omitted, uses **$_** .

recv SOCKET,SCALAR,LEN,FLAGS

Receives a message on a socket. Attempts to receive LENGTH bytes of data into variable SCALAR from the specified SOCKET filehandle. Actually does a C *recvfrom()* , so that it can returns the address of the sender. Returns the undefined value if there's an error. SCALAR will be grown or shrunk to the length actually read. Takes the same flags as the system call of the same name.

redo LABEL

redo

The redo command restarts the loop block without evaluating the conditional again. The **continue** block, if any, is not executed. If the LABEL is omitted, the command refers to the innermost enclosing loop. This command is normally used by programs that want to lie to themselves about what was just input:

a simpleminded Pascal comment stripper # (warning: assumes no { or } in strings) line: while (<STDIN>) { while (s|({.*}.*){.*}|$1 |) {} s|{.*}| |; if (s|{.*| |) { $front = $_; while (<STDIN>) { if (/}/) { # end of comment? s|^|$front{|; redo line; } } } print; }

ref EXPR

Returns a TRUE value if EXPR is a reference, FALSE otherwise. The value returned depends on the type of thing the reference is a reference to. Builtin types include:

REF SCALAR ARRAY HASH CODE GLOB

If the referenced object has been blessed into a package, then that package name is returned instead. You can think of ref() as a *typeof()* operator.

if (ref($r) eq "HASH") { print "r is a reference to an associative array.\n"; } if (!ref ($r) { print "r is not a reference at all.\n"; }

See also the *perlref* manpage .

rename OLDNAME,NEWNAME

Changes the name of a file. Returns 1 for success, 0 otherwise. Will not work across filesystem boundaries.

require EXPR

require

Demands some semantics specified by EXPR, or by **$_** if EXPR is not supplied. If EXPR is numeric, demands that the current version of Perl ($] or **$PERL_VERSION**) be equal or greater than EXPR.

Otherwise, demands that a library file be included if it hasn't already been included. The file is included via the do-FILE mechanism, which is essentially just a variety of eval() . Has semant similar to the following subroutine:

sub require { local($filename) = @_; return 1 if $INC{$filename}; local($realfilename,$result); ITER: { foreach $prefix (@INC) { $realfilename = "$prefix/$filename"; if (-f $realfilename) { $result = do $realfilename; last ITER; } } die "Can't find $filename in \@INC"; } die $@ if $@; die "$filename did not return true value" unless $result; $INC{$filename} = $realfilename; $result; }

Note that the file will not be included twice under the same specified name. The file must return TRUE as the last statement to indicate successful execution of any initialization code, so it's customary to end such a file with "1;" unless you're sure it'll return TRUE otherwise. But it's better just to put the " **1;** ", in case you add more statements.

If EXPR is a bare word, the require assumes a " *.pm* " extension for you, to make it easy to load standard modules. This form of loading of modules does not risk altering your namespace.

For a yet-more-powerful import facility, see the *use* and the *perlmod* manpage .

reset EXPR

reset

Generally used in a **continue** block at the end of a loop to clear variables and reset ?? searches so that they work again. The expression is interpreted as a list of single characters (hyphens allowed for ranges). All variables and arrays beginning with one of those letters are reset to their pristine state. If the expression is omitted, one-match searches (?pattern?) are reset to match again. Only resets variables or searches in the current package. Always returns 1. Examples:

reset 'X'; # reset all X variables reset 'a-z'; # reset lower case variables reset; # just reset ?? searches

Resetting "A-Z" is not recommended since you'll wipe out your ARGV and ENV arrays. Only resets package variables--lexical variables are unaffected, but they clean themselves up on scope exit anyway, so anymore you probably want to use them instead. See *my* .

return LIST

Returns from a subroutine or eval with the value specified. (Note that in the absence of a return a subroutine or eval will automatically return the value of the last expression evaluated.)

reverse LIST

In a list context, returns a list value consisting of the elements of LIST in the opposite order. In a scalar context, returns a string value consisting of the bytes of the first element of LIST in the opposite order.

rewinddir DIRHANDLE

Sets the current position to the beginning of the directory for the readdir() routine on DIRHANDLE.

rindex STR,SUBSTR,POSITION

rindex STR,SUBSTR

Works just like index except that it returns the position of the LAST occurrence of SUBSTR in STR. If POSITION is specified, returns the last occurrence at or before that position.

rmdir FILENAME

Deletes the directory specified by FILENAME if it is empty. If it succeeds it returns 1, otherwise it returns 0 and sets $! (errno). If FILENAME is omitted, uses **$_** .

s///

The substitution operator. See the *perlop* manpage .

scalar EXPR

Forces EXPR to be interpreted in a scalar context and returns the value of EXPR.

seek FILEHANDLE,POSITION,WHENCE

Randomly positions the file pointer for FILEHANDLE, just like the *fseek()* call of stdio. FILEHANDLE may be an expression whose value gives the name of the filehandle. The values for WHENCE are 0 to set the file pointer to POSITION, 1 to set the it to current plus POSITION, and 2 to set it to EOF plus offset. You may use the values SEEK_SET, SEEK_CUR, and SEEK_END for this is using the POSIX module. Returns 1 upon success, 0 otherwise.

seekdir DIRHANDLE,POS

Sets the current position for the readdir() routine on DIRHANDLE. POS must be a value returned by telldir() . Has the same caveats about possible directory compaction as the corresponding system library routine.

select FILEHANDLE

select

Returns the currently selected filehandle. Sets the current default filehandle for output, if FILEHANDLE is supplied. This has two effects: first, a write or a print without a filehandle will default to this FILEHANDLE. Second, references to variables related to output will refer to this output channel. For example, if you have to set the top of form format for more than one output channel, you might do the following:

select(REPORT1); $^ = 'report1_top'; select(REPORT2); $^ = 'report2_top';

FILEHANDLE may be an expression whose value gives the name of the actual filehandle. Thus:

$oldfh = select(STDERR); $| = 1; select($oldfh);

With Perl 5, filehandles are objects with methods, and the last example is preferably written

use FileHandle; STDERR->autoflush(1);

select RBITS,WBITS,EBITS,TIMEOUT

This calls the select system(2) call with the bitmasks specified, which can be constructed using fileno() and vec() , along these lines:

$rin = $win = $ein = ''; vec($rin,fileno(STDIN),1) = 1; vec($win,fileno(STDOUT),1) = 1; $ein = $rin | $win;

If you want to select on many filehandles you might wish to write a subroutine:

sub fhbits { local(@fhlist) = split(' ',$_[0]); local($bits); for (@fhlist) { vec($bits,fileno($_),1) } $bits; } $rin = &fhbits('STDIN TTY SOCK');

The usual idiom is:

($nfound,$timeleft) = select($rout=$rin, $wout=$win, $eout=$ein, $timeout);

or to block until something becomes ready:

$nfound = select($rout=$rin, $wout=$win, $eout=$ein, undef);

Any of the bitmasks can also be undef. The timeout, if specified, is in seconds, which may be fractional. Note: not all implementations are capable of returning the **$timeleft** . If not, they always return **$timeleft** equal to the supplied **$timeout** .

You can effect a 250 microsecond sleep this way:

select(undef, undef, undef, 0.25);

semctl ID,SEMNUM,CMD,ARG

Calls the System V IPC function semctl. If CMD is &IPC_STAT or &GETALL, then ARG must be a variable which will hold the returned semid_ds structure or semaphore value array. Returns like ioctl: the undefined value for error, "0 but true" for zero, or the actual return value otherwise.

semget KEY,NSEMS,FLAGS

Calls the System V IPC function semget. Returns the semaphore id, or the undefined value if there is an error.

semop KEY,OPSTRING

Calls the System V IPC function semop to perform semaphore operations such as signaling and waiting. OPSTRING must be a packed array of semop structures. Each semop structure can be generated with pack("sss", **$semnum** , **$semop** , **$semflag**) . The number of semaphore operations is implied by the length of OPSTRING. Returns TRUE if successful, or FALSE if there is an error. As an example, the following code waits on semaphore **$semnum** of semaphore id **$semid:**

$semop = pack("sss", $semnum, -1, 0); die "Semaphore trouble: $!\n" unless semop($semid, $semop);

To signal the semaphore, replace "-1" with "1".

send SOCKET,MSG,FLAGS,TO

send SOCKET,MSG,FLAGS

Sends a message on a socket. Takes the same flags as the system call of the same name. On unconnected sockets you must specify a destination to send TO, in which case it does a C *sendto()* . Returns the number of characters sent, or the undefined value if there is an error.

setpgrp PID,PGRP

Sets the current process group for the specified PID, 0 for the current process. Will produce a fatal error if used on a machine that doesn't implement setpgrp(2).

setpriority WHICH,WHO,PRIORITY

Sets the current priority for a process, a process group, or a user. (See setpriority(2).) Will produce a fatal error if used on a machine that doesn't implement setpriority(2).

setsockopt SOCKET,LEVEL,OPTNAME,OPTVAL

Sets the socket option requested. Returns undefined if there is an error. OPTVAL may be specified as undef if you don't want to pass an argument.

shift ARRAY

shift

Shifts the first value of the array off and returns it, shortening the array by 1 and moving everything down. If there are no elements in the array, returns the undefined value. If ARRAY is omitted, shifts the **@ARGV** array in the main program, and the **@_** array in subroutines. (This is determined lexically.) See also unshift() , push() , and pop() . *Shift()* and unshift() do the same thing to the left end of an array that push() and pop() do to the right end.

shmctl ID,CMD,ARG

Calls the System V IPC function shmctl. If CMD is &IPC_STAT, then ARG must be a variable which will hold the returned shmid_ds structure. Returns like ioctl: the undefined value for error, "0 but true" for zero, or the actual return value otherwise.

shmget KEY,SIZE,FLAGS

Calls the System V IPC function shmget. Returns the shared memory segment id, or the undefined value if there is an error.

shmread ID,VAR,POS,SIZE

shmwrite ID,STRING,POS,SIZE

Reads or writes the System V shared memory segment ID starting at position POS for size SIZE by attaching to it, copying in/out, and detaching from it. When reading, VAR must be a variable which will hold the data read. When writing, if STRING is too long, only SIZE bytes are used; if STRING is too short, nulls are written to fill out SIZE bytes. Return TRUE if successful, or FALSE if there is an error.

shutdown SOCKET,HOW

Shuts down a socket connection in the manner indicated by HOW, which has the same interpretation as in the system call of the same name.

sin EXPR

Returns the sine of EXPR (expressed in radians). If EXPR is omitted, returns sine of **$_** .

sleep EXPR

sleep

Causes the script to sleep for EXPR seconds, or forever if no EXPR. May be interrupted by sending the process a SIGALRM. Returns the number of seconds actually slept. You probably cannot mix alarm() and sleep() calls, since sleep() is often implemented using alarm() .

On some older systems, it may sleep up to a full second less than what you requested, depending on how it counts seconds. Most modern systems always sleep the full amount.

socket SOCKET,DOMAIN,TYPE,PROTOCOL

Opens a socket of the specified kind and attaches it to filehandle SOCKET. DOMAIN, TYPE and PROTOCOL are specified the same as for the system call of the same name. You should "use Socket;" first to get the proper definitions imported. See the example in the *perlipc* manpage .

socketpair SOCKET1,SOCKET2,DOMAIN,TYPE,PROTOCOL

Creates an unnamed pair of sockets in the specified domain, of the specified type. DOMAIN, TYPE and PROTOCOL are specified the same as for the system call of the same name. If unimplemented, yields a fatal error. Returns TRUE if successful.

sort SUBNAME LIST

sort BLOCK LIST

sort LIST

Sorts the LIST and returns the sorted list value. Nonexistent values of arrays are stripped out. If SUBNAME or BLOCK is omitted, sorts in standard string comparison order. If SUBNAME is specified, it gives the name of a subroutine that returns an integer less than, equal to, or greater than 0, depending on how the elements of the array are to be ordered. (The<=> and cmp operators are extremely useful in such routines.) SUBNAME may be a scalar variable name, in which case the value provides the name of the subroutine to use. In place of a SUBNAME, you can provide a BLOCK as an anonymous, in-line sort subroutine.

In the interests of efficiency the normal calling code for subroutines is bypassed, with the following effects: the subroutine may not be a recursive subroutine, and the two elements to be compared are passed into the subroutine not via **@_** but as **$a** and **$b** (see example below). They are passed by reference, so don't modify **$a** and **$b** .

Examples:

sort lexically @articles = sort @files; # same thing, but with explicit sort routine @articles = sort {$a cmp $b} @files; # same thing in reversed order @articles = sort {$b cmp $a} @files; # sort numerically ascending @articles = sort {$a <=> $b} @files; # sort numerically descending @articles = sort {$b <=> $a} @files; # sort using explicit subroutine name sub byage { $age{$a} <=> $age{$b}; # presuming integers } @sortedclass = sort byage @class; sub backwards { $b cmp $a; } @harry = ('dog','cat','x','Cain','Abel'); @george = ('gone','chased','yz','Punished','Axed'); print sort @harry; # prints AbelCaincatdogx print sort backwards @harry; # prints xdogcatCainAbel print sort @george, 'to', @harry; # prints AbelAxedCainPunishedcatchaseddoggonetoxyz

splice ARRAY,OFFSET,LENGTH,LIST

splice ARRAY,OFFSET,LENGTH

splice ARRAY,OFFSET

Removes the elements designated by OFFSET and LENGTH from an array, and replaces them with the elements of LIST, if any. Returns the elements removed from the array. The array grows or shrinks as necessary. If LENGTH is omitted, removes everything from OFFSET onward. The following equivalencies hold (assuming $[== 0):

push(@a,$x,$y) splice(@a,$#a+1,0,$x,$y) pop(@a) splice(@a,-1) shift(@a) splice(@a,0,1) unshift(@a,$x,$y) splice(@a,0,0,$x,$y) $a[$x] = $y splice(@a,$x,1,$y);

Example, assuming array lengths are passed before arrays:

sub aeq { # compare two list values local(@a) = splice(@_,0,shift); local(@b) = splice(@_,0,shift); return 0 unless @a == @b; # same len? while (@a) { return 0 if pop(@a) ne pop(@b); } return 1; } if (&aeq($len,@foo[1..$len],0+@bar,@bar)) { ... }

split /PATTERN/,EXPR,LIMIT

split /PATTERN/,EXPR

split /PATTERN/

split

Splits a string into an array of strings, and returns it.

If not in a list context, returns the number of fields found and splits into the **@_** array. (In a list context, you can force the split into **@_** by using **??** as the pattern delimiters, but it still returns the array value.) The use of implicit split to **@_** is deprecated, however.

If EXPR is omitted, splits the **$_** string. If PATTERN is also omitted, splits on whitespace (after skipping any leading whitespace). Anything matching PATTERN is taken to be a delimiter separating the fields. (Note that the delimiter may be longer than one character.) If LIMIT is specified and is not negative, splits into no more than that many fields (though it may split into fewer). If LIMIT is unspecified, trailing null fields are stripped (which potential users of pop() would do well to remember). If LIMIT is negative, it is treated as if an arbitrarily large LIMIT had been specified.

A pattern matching the null string (not to be confused with a null pattern // , which is just one member of the set of patterns matching a null string) will split the value of EXPR into separate characters at each point it matches that way. For example:

print join(':', split(/ */, 'hi there'));

produces the output 'h:i:t:h:e:r:e'.

The LIMIT parameter can be used to partially split a line

($login, $passwd, $remainder) = split(/:/, $_, 3);

When assigning to a list, if LIMIT is omitted, Perl supplies a LIMIT one larger than the number of variables in the list, to avoid unnecessary work. For the list above LIMIT would have been 4 by default. In time critical applications it behooves you not to split into more fields than you really need.

If the PATTERN contains parentheses, additional array elements are created from each matching substring in the delimiter.

split(/([,-])/, "1-10,20");

produces the list value

(1, '-', 10, ',', 20)

The pattern **/PATTERN/** may be replaced with an expression to specify patterns that vary at runtime. (To do runtime compilation only once, use **/ $variable /o** .)

As a special case, specifying a PATTERN of space (' ') will split on white space just as split with no arguments does. Thus, split(' ') can be used to emulate **awk** 's default behavior, whereas split(/ /) will give you as many null initial fields as there are leading spaces. A split on /\s+/ is like a split(' ') except that any leading whitespace produces a null first field. A split with no arguments really does a split(' ', $_) internally.

Example:

open(passwd, '/etc/passwd'); while (<passwd>) { ($login, $passwd, $uid, $gid, $gcos, $home, $shell) = split(/:/); ... }

(Note that **$shell** above will still have a newline on it. See *chop* , *chomp* , and *join* .)

sprintf FORMAT,LIST

Returns a string formatted by the usual printf conventions of the C language. (The * character for an indirectly specified length is not supported, but you can get the same effect by interpolating a variable into the pattern.)

sqrt EXPR

Return the square root of EXPR. If EXPR is omitted, returns square root of **$_** .

srand EXPR

Sets the random number seed for the rand operator. If EXPR is omitted, does srand(time) . Of course, you'd need something much more random than that for cryptographic purposes, since it's easy to guess the current time. Checksumming the compressed output of rapidly changing operating system status programs is the usual method. Examples are posted regularly to comp.security.unix.

stat FILEHANDLE

stat EXPR

Returns a 13-element array giving the status info for a file, either the file opened via FILEHANDLE, or named by EXPR. Returns a null list if the stat fails. Typically used as follows:

($dev,$ino,$mode,$nlink,$uid,$gid,$rdev,$size, $atime,$mtime,$ctime,$blksize,$blocks) = stat($filename);

If stat is passed the special filehandle consisting of an underline, no stat is done, but the current contents of the stat structure from the last stat or filetest are returned. Example:

if (-x $file && (($d) = stat(_)) && $d < 0) { print "$file is executable NFS file\n"; }

(This only works on machines for which the device number is negative under NFS.)

study SCALAR

study

Takes extra time to study SCALAR (**$_** if unspecified) in anticipation of doing many pattern matches on the string before it is next modified. This may or may not save time, depending on the

nature and number of patterns you are searching on, and on the distribution of character frequencies in the string to be searched--you probably want to compare runtimes with and without it to see which runs faster. Those loops which scan for many short constant strings (including the constant parts of more complex patterns) will benefit most. You may have only one study active at a time--if you study a different scalar the first is "unstudied". (The way study works is this: a linked list of every character in the string to be searched is made, so we know, for example, where all the 'k' characters are. From each search string, the rarest character is selected, based on some static frequency tables constructed from some C programs and English text. Only those places that contain this "rarest" character are examined.)

For example, here is a loop which inserts index producing entries before any line containing a certain pattern:

while (<>) { study; print ".IX foo\n" if /\bfoo\b/; print ".IX bar\n" if /\bbar\b/; print ".IX blurfl\n" if /\bblurfl\b/; ... print; }

In searching for /\bfoo\b/, only those locations in **$_** that contain "f" will be looked at, because "f" is rarer than "o". In general, this is a big win except in pathological cases. The only question is whether it saves you more time than it took to build the linked list in the first place.

Note that if you have to look for strings that you don't know till runtime, you can build an entire loop as a string and eval that to avoid recompiling all your patterns all the time. Together with undefining $/ to input entire files as one record, this can be very fast, often faster than specialized programs like fgrep(1). The following scans a list of files (**@files**) for a list of words (**@words**), and prints out the names of those files that contain a match:

$search = 'while (<>) { study;'; foreach $word (@words) { $search .= "++\$seen{\$ARGV} if /\\b$word\\b/;\n"; } $search .= "}"; @ARGV = @files; undef $/; eval $search; # this screams $/ = "\n"; # put back to normal input delim foreach $file (sort keys(%seen)) { print $file, "\n"; }

substr EXPR,OFFSET,LEN

substr EXPR,OFFSET

Extracts a substring out of EXPR and returns it. First character is at offset 0, or whatever you've set $[to. If OFFSET is negative, starts that far from the end of the string. If LEN is omitted, returns everything to the end of the string. If LEN is negative, leaves that many characters off the end of the string.

You can use the substr() function as an lvalue, in which case EXPR must be an lvalue. If you assign something shorter than LEN, the string will shrink, and if you assign something longer than LEN, the string will grow to accommodate it. To keep the string the same length you may need to pad or chop your value using sprintf() .

symlink OLDFILE,NEWFILE

Creates a new filename symbolically linked to the old filename. Returns 1 for success, 0 otherwise. On systems that don't support symbolic links, produces a fatal error at run time. To check for that, use eval:

$symlink_exists = (eval 'symlink("","");', $@ eq '');

syscall LIST

Calls the system call specified as the first element of the list, passing the remaining elements as arguments to the system call. If unimplemented, produces a fatal error. The arguments are interpreted as follows: if a given argument is numeric, the argument is passed as an int. If not, the pointer to the string value is passed. You are responsible to make sure a string is pre-extended long enough to receive any result that might be written into a string. If your integer arguments are not literals and have never been interpreted in a numeric context, you may need to add 0 to them to force them to look like numbers.

require 'syscall.ph'; # may need to run h2ph syscall(&SYS_write, fileno(STDOUT), "hi there\n", 9);

Note that Perl only supports passing of up to 14 arguments to your system call, which in practice should usually suffice.

sysread FILEHANDLE,SCALAR,LENGTH,OFFSET

sysread FILEHANDLE,SCALAR,LENGTH

Attempts to read LENGTH bytes of data into variable SCALAR from the specified FILEHANDLE, using the system call read(2). It bypasses stdio, so mixing this with other kinds of reads may cause confusion. Returns the number of bytes actually read, or undef if there was an error. SCALAR will be grown or shrunk to the length actually read. An OFFSET may be specified to place the read data at some other place than the beginning of the string.

system LIST

Does exactly the same thing as "exec LIST" except that a fork is done first, and the parent process waits for the child process to complete. Note that argument processing varies depending on the number of arguments. The return value is the exit status of the program as returned by the wait() call. To get the actual exit value divide by 256. See also *exec* .

syswrite FILEHANDLE,SCALAR,LENGTH,OFFSET

syswrite FILEHANDLE,SCALAR,LENGTH

Attempts to write LENGTH bytes of data from variable SCALAR to the specified FILEHANDLE, using the system call write(2). It bypasses stdio, so mixing this with prints may cause confusion. Returns the number of bytes actually written, or undef if there was an error. An OFFSET may be specified to place the read data at some other place than the beginning of the string.

tell FILEHANDLE

tell

Returns the current file position for FILEHANDLE. FILEHANDLE may be an expression whose value gives the name of the actual filehandle. If FILEHANDLE is omitted, assumes the file last read.

telldir DIRHANDLE

Returns the current position of the readdir() routines on DIRHANDLE. Value may be given to seekdir() to access a particular location in a directory. Has the same caveats about possible directory compaction as the corresponding system library routine.

tie VARIABLE,PACKAGENAME,LIST

This function binds a variable to a package that will provide the implementation for the variab VARIABLE is the name of the variable to be enchanted. PACKAGENAME is the name of a package implementing objects of correct type. Any additional arguments are passed to the "new" method of the package (meaning TIESCALAR, TIEARRAY, or TIEHASH). Typically these are arguments such as might be passed to the *dbm_open()* function of C.

Note that functions such as keys() and values() may return huge array values when used on large objects, like DBM files. You may prefer to use the each() function to iterate over such. Example:

print out history file offsets tie(%HIST, NDBM_File, '/usr/lib/news/history', 1, 0); while (($key,$val) = each %HIST) { print $key, ' = ', unpack('L',$val), "\n"; } untie(%HIST);

A package implementing an associative array should have the following methods:

TIEHASH objectname, LIST DESTROY this FETCH this, key STORE this, key, value DELETE this, key EXISTS this, key FIRSTKEY this NEXTKEY this, lastkey

A package implementing an ordinary array should have the following methods:

TIEARRAY objectname, LIST DESTROY this FETCH this, key STORE this, key, value [others TBD]

A package implementing a scalar should have the following methods:

TIESCALAR objectname, LIST DESTROY this FETCH this, STORE this, value

time

Returns the number of non-leap seconds since 00:00:00 UTC, January 1, 1970. Suitable for feeding to gmtime() and localtime() .

times

Returns a four-element array giving the user and system times, in seconds, for this process and the children of this process.

($user,$system,$cuser,$csystem) = times;

tr///

The translation operator. See the *perlop* manpage .

truncate FILEHANDLE,LENGTH

truncate EXPR,LENGTH

Truncates the file opened on FILEHANDLE, or named by EXPR, to the specified length. Produces a fatal error if truncate isn't implemented on your system.

uc EXPR

Returns an uppercased version of EXPR. This is the internal function implementing the \U escape in double-quoted strings.

ucfirst EXPR

Returns the value of EXPR with the first character uppercased. This is the internal function implementing the \u escape in double-quoted strings.

umask EXPR

umask

Sets the umask for the process and returns the old one. If EXPR is omitted, merely returns current umask.

undef EXPR

undef

Undefines the value of EXPR, which must be an lvalue. Use only on a scalar value, an entire array, or a subroutine name (using "&"). (Using undef() will probably not do what you expect on most predefined variables or DBM list values, so don't do that.) Always returns the undefined value. You can omit the EXPR, in which case nothing is undefined, but you still get an undefined value that you could, for instance, return from a subroutine. Examples:

undef $foo; undef $bar{'blurfl'}; undef @ary; undef %assoc; undef &mysub; return (wantarray ? () : undef) if $they_blew_it;

unlink LIST

Deletes a list of files. Returns the number of files successfully deleted.

$cnt = unlink 'a', 'b', 'c'; unlink @goners; unlink <*.bak>;

Note: unlink will not delete directories unless you are superuser and the **-U** flag is supplied to Perl. Even if these conditions are met, be warned that unlinking a directory can inflict damage on your filesystem. Use rmdir instead.

unpack TEMPLATE,EXPR

Unpack does the reverse of pack: it takes a string representing a structure and expands it out into a list value, returning the array value. (In a scalar context, it merely returns the first value produced.) The TEMPLATE has the same format as in the pack function. Here's a subroutine that does substring:

sub substr { local($what,$where,$howmuch) = @_; unpack("x$where a$howmuch", $what); }

and then there's

sub ordinal { unpack("c",$_[0]); } # same as ord()

In addition, you may prefix a field with a <number> to indicate that you want a<number>-bit checksum of the items instead of the items themselves. Default is a 16-bit checksum. For example, the following computes the same number as the System V sum program:

while (<>) { $checksum += unpack("%16C*", $_); } $checksum %= 65536;

The following efficiently counts the number of set bits in a bit vector:

$setbits = unpack("%32b*", $selectmask);

untie VARIABLE

Breaks the binding between a variable and a package. (See tie() .)

unshift ARRAY,LIST

Does the opposite of a shift . Or the opposite of a push , depending on how you look at it. Prepends list to the front of the array, and returns the new number of elements in the array.

unshift(ARGV, '-e') unless $ARGV[0] =~ /^-/;

Note the LIST is prepended whole, not one element at a time, so the prepended elements stay in the same order. Use reverse to do the reverse.

use Module LIST

use Module

Imports some semantics into the current package from the named module, generally by aliasing certain subroutine or variable names into your package. It is exactly equivalent to

BEGIN { require Module; import Module LIST; }

If you don't want your namespace altered, use require instead.

The BEGIN forces the require and import to happen at compile time. The require makes sure the module is loaded into memory if it hasn't been yet. The import is not a builtin--it's just an ordinary static method call into the "Module" package to tell the module to import the list of features back into the current package. The module can implement its import method any way it likes, though most modules just choose to derive their import method via inheritance from the Exporter class that is defined in the Exporter module.

Because this is a wide-open interface, pragmas (compiler directives) are also implemented this way. Currently implemented pragmas are:

use integer; use sigtrap qw(SEGV BUS); use strict qw(subs vars refs); use subs qw(afunc blurfl);

These pseudomodules import semantics into the current block scope, unlike ordinary modules, which import symbols into the current package (which are effective through the end of the file).

There's a corresponding "no" command that unimports meanings imported by use.

no integer; no strict 'refs';

See the *perlmod* manpage for a list of standard modules and pragmas.

utime LIST

Changes the access and modification times on each file of a list of files. The first two elements of the list must be the NUMERICAL access and modification times, in that order. Returns the number of files successfully changed. The inode modification time of each file is set to the current time. Example of a "touch" command:

#!/usr/bin/perl $now = time; utime $now, $now, @ARGV;

values ASSOC_ARRAY

Returns a normal array consisting of all the values of the named associative array. (In a scalar context, returns the number of values.) The values are returned in an apparently random order, but it is the same order as either the keys() or each() function would produce on the same array. See also keys() and each() .

vec EXPR,OFFSET,BITS

Treats a string as a vector of unsigned integers, and returns the value of the bitfield specified. May also be assigned to. BITS must be a power of two from 1 to 32.

Vectors created with vec() can also be manipulated with the logical operators |, & and ^, which will assume a bit vector operation is desired when both operands are strings.

To transform a bit vector into a string or array of 0's and 1's, use these:

$bits = unpack("b*", $vector); @bits = split(//, unpack("b*", $vector));

If you know the exact length in bits, it can be used in place of the *.

wait

Waits for a child process to terminate and returns the pid of the deceased process, or -1 if there are no child processes. The status is returned in $?.

waitpid PID,FLAGS

Waits for a particular child process to terminate and returns the pid of the deceased process, or -1 if there is no such child process. The status is returned in $?. If you say

use POSIX "wait_h"; ... waitpid(-1,&WNOHANG);

then you can do a non-blocking wait for any process. Non-blocking wait is only available on machines supporting either the waitpid(2) or wait4(2) system calls. However, waiting for a particular pid with FLAGS of 0 is implemented everywhere. (Perl emulates the system call by remembering the status values of processes that have exited but have not been harvested by the Perl script yet.)

wantarray

Returns TRUE if the context of the currently executing subroutine is looking for a list value. Returns FALSE if the context is looking for a scalar.

return wantarray ? () : undef;

warn LIST

Produces a message on STDERR just like die() , but doesn't exit or throw an exception.

write FILEHANDLE

write EXPR

write

Writes a formatted record (possibly multi-line) to the specified file, using the format associated with that file. By default the format for a file is the one having the same name is the filehandle, but the format for the current output channel (see the select() function) may be set explicitly by assigning the name of the format to the $~ variable.

Top of form processing is handled automatically: if there is insufficient room on the current page for the formatted record, the page is advanced by writing a form feed, a special top-of-page format is used to format the new page header, and then the record is written. By default the top-of-page format is the name of the filehandle with "_TOP" appended, but it may be dynamically set to the

format of your choice by assigning the name to the $^ variable while the filehandle is selected. The number of lines remaining on the current page is in variable $-, which can be set to 0 to force a new page.

If FILEHANDLE is unspecified, output goes to the current default output channel, which starts out as STDOUT but may be changed by the select operator. If the FILEHANDLE is an EXPR, then the expression is evaluated and the resulting string is used to look up the name of the FILEHANDLE at run time. For more on formats, see the *perlform* manpage .

Note that write is *NOT* the opposite of read. Unfortunately.

y///

The translation operator. See *tr///* .

.

NAME

perlvar - Perl predefined variables

DESCRIPTION

Predefined Names

The following names have special meaning to Perl. Most of the punctuational names have reasonable mnemonics, or analogues in one of the shells. Nevertheless, if you wish to use the long variable names, you just need to say

use English;

at the top of your program. This will alias all the short names to the long names in the current package. Some of them even have medium names, generally borrowed from **awk** .

To go a step further, those variables that depend on the currently selected filehandle may instead be set by calling an object method on the FileHandle object. (Summary lines below for this contain the word HANDLE.) First you must say

use FileHandle;

after which you may use either

method HANDLE EXPR

or

HANDLE->method(EXPR)

Each of the methods returns the old value of the FileHandle attribute. The methods each take an optional EXPR, which if supplied specifies the new value for the FileHandle attribute in question. If not supplied, most of the methods do nothing to the current value, except for autoflush() , which will assume a 1 for you, just to be different.

A few of these variables are considered "read-only". This means that if you try to assign to this variable, either directly or indirectly through a reference, you'll raise a run-time exception.

$ARG

$_

The default input and pattern-searching space. The following pairs are equivalent:

while (<>) {...} # only equivalent in while! while ($_ = <>) {...} /^Subject:/ $_ =~ /^Subject:/

tr/a-z/A-Z/ $_ =~ tr/a-z/A-Z/ chop chop($_)

(Mnemonic: underline is understood in certain operations.)

< *digit* >

Contains the subpattern from the corresponding set of parentheses in the last pattern matched, not counting patterns matched in nested blocks that have been exited already. (Mnemonic: like \digit.) These variables are all read-only.

$MATCH

$&

The string matched by the last successful pattern match (not counting any matches hidden within a BLOCK or *eval()* enclosed by the current BLOCK). (Mnemonic: like & in some editors.) This variable is read-only.

$PREMATCH

$`

The string preceding whatever was matched by the last successful pattern match (not counting any matches hidden within a BLOCK or eval enclosed by the current BLOCK). (Mnemonic: ` often precedes a quoted string.) This variable is read-only.

$POSTMATCH

$'

The string following whatever was matched by the last successful pattern match (not counting any matches hidden within a BLOCK or *eval()* enclosed by the current BLOCK). (Mnemonic: ' often follows a quoted string.) Example:

$_ = 'abcdefghi'; /def/; print "$`:$&:$'\n"; # prints abc:def:ghi

This variable is read-only.

$LAST_PAREN_MATCH

$+

The last bracket matched by the last search pattern. This is useful if you don't know which of a set of alternative patterns matched. For example:

/Version: (.*)|Revision: (.*)/ && ($rev = $+);

(Mnemonic: be positive and forward looking.) This variable is read-only.

$MULTILINE_MATCHING

$*

Set to 1 to do multiline matching within a string, 0 to tell Perl that it can assume that strings contain a single line, for the purpose of optimizing pattern matches. Pattern matches on strings containing multiple newlines can produce confusing results when " $* " is 0. Default is 0. (Mnemonic: * matches multiple things.) Note that this variable only influences the interpretation of " ^ " and " **$** ". A literal newline can be searched for even when **$* == 0** .

Use of " $* " is deprecated in Perl 5.

input_line_number HANDLE EXPR

$INPUT_LINE_NUMBER

$NR

$.

The current input line number of the last filehandle that was read. This variable should be considered read-only. Remember that only an explicit close on the filehandle resets the line number. Since " <> " never does an explicit close, line numbers increase across ARGV files (but see examples under *eof()*). (Mnemonic: many programs use "." to mean the current line number.)

input_record_separator HANDLE EXPR

$INPUT_RECORD_SEPARATOR

$RS

$/

The input record separator, newline by default. Works like **awk** 's RS variable, including treating blank lines as delimiters if set to the null string. You may set it to a multicharacter string to match a multi-character delimiter. Note that setting it to **"\n\n"** means something slightly different than setting it to "" , if the file contains consecutive blank lines. Setting it to "" will treat two or more consecutive blank lines as a single blank line. Setting it to **"\n\n"** will blindly assume that the next input character belongs to the next paragraph, even if it's a newline. (Mnemonic: / is used to delimit line boundaries when quoting poetry.)

undef $/; $_ = <FH>; # whole file now here s/\n[\t]+/ /g;

autoflush HANDLE EXPR

$OUTPUT_AUTOFLUSH

$|

If set to nonzero, forces a flush after every write or print on the currently selected output channel. Default is 0. Note that STDOUT will typically be line buffered if output is to the terminal and block buffered otherwise. Setting this variable is useful primarily when you are outputting to a pipe, such as when you are running a Perl script under rsh and want to see the output as it's happening. (Mnemonic: when you want your pipes to be piping hot.)

output_field_separator HANDLE EXPR

$OUTPUT_FIELD_SEPARATOR

$OFS

$,

The output field separator for the print operator. Ordinarily the print operator simply prints out the comma separated fields you specify. In order to get behavior more like **awk** , set this variable as you would set **awk** 's OFS variable to specify what is printed between fields. (Mnemonic: what is printed when there is a , in your print statement.)

output_record_separator HANDLE EXPR

$OUTPUT_RECORD_SEPARATOR

$ORS

$

The output record separator for the print operator. Ordinarily the print operator simply prints out the comma separated fields you specify, with no trailing newline or record separator assumed. In order to get behavior more like **awk** , set this variable as you would set **awk** 's ORS variable to specify what is printed at the end of the print. (Mnemonic: you set " $\ " instead of adding \n at the end of the print. Also, it's just like /, but it's what you get "back" from Perl.)

$LIST_SEPARATOR

$"

This is like " $, " except that it applies to array values interpolated into a double-quoted string (or similar interpreted string). Default is a space. (Mnemonic: obvious, I think.)

$SUBSCRIPT_SEPARATOR

$SUBSEP

$;

The subscript separator for multi-dimensional array emulation. If you refer to a hash element as

$foo{$a,$b,$c}

it really means

$foo{join($;, $a, $b, $c)}

But don't put

@foo{$a,$b,$c} # a slice--note the @

which means

($foo{$a},$foo{$b},$foo{$c})

Default is "\034", the same as SUBSEP in **awk** . Note that if your keys contain binary data there might not be any safe value for " $; ". (Mnemonic: comma (the syntactic subscript separator) is a semi-semicolon. Yeah, I know, it's pretty lame, but " $, " is already taken for something more important.)

Consider using "real" multi-dimensional arrays in Perl 5.

$OFMT

$#

The output format for printed numbers. This variable is a half-hearted attempt to emulate **awk** 's OFMT variable. There are times, however, when **awk** and Perl have differing notions of what is in fact numeric. Also, the initial value is **%.** 20g rather than **%.** 6g, so you need to set " $# " explicitly to get **awk** 's value. (Mnemonic: # is the number sign.)

Use of " $# " is deprecated in Perl 5.

format_page_number HANDLE EXPR

$FORMAT_PAGE_NUMBER

$%

The current page number of the currently selected output channel. (Mnemonic: **%** is page number in **nroff** .)

format_lines_per_page HANDLE EXPR

$FORMAT_LINES_PER_PAGE

$=

The current page length (printable lines) of the currently selected output channel. Default is 60. (Mnemonic: = has horizontal lines.)

format_lines_left HANDLE EXPR

$FORMAT_LINES_LEFT

$-

The number of lines left on the page of the currently selected output channel. (Mnemonic: lines_on_page - lines_printed.)

format_name HANDLE EXPR

$FORMAT_NAME

$~

The name of the current report format for the currently selected output channel. Default is name of the filehandle. (Mnemonic: brother to " $^ ".)

format_top_name HANDLE EXPR

$FORMAT_TOP_NAME

$^

The name of the current top-of-page format for the currently selected output channel. Default is name of the filehandle with _TOP appended. (Mnemonic: points to top of page.)

format_line_break_characters HANDLE EXPR

$FORMAT_LINE_BREAK_CHARACTERS

$:

The current set of characters after which a string may be broken to fill continuation fields (starting with ^) in a format. Default is S<" \n-">, to break on whitespace or hyphens. (Mnemonic: a "colon" in poetry is a part of a line.)

format_formfeed HANDLE EXPR

$FORMAT_FORMFEED

$^ L

What formats output to perform a formfeed. Default is \f.

$ACCUMULATOR

$^ A

The current value of the *write()* accumulator for *format()* lines. A format contains *formline()* commands that put their result into $^ A . After calling its format, *write()* prints out the contents of $^ A and empties. So you never actually see the contents of $^ A unless you call *formline()*

yourself and then look at it. See the *perlform* manpage and *formline* .

$CHILD_ERROR

$?

The status returned by the last pipe close, backtick (``) command, or *system()* operator. Note that this is the status word returned by the *wait()* system call, so the exit value of the subprocess is actually (**$? >> 8**). Thus on many systems, **$? & 255** gives which signal, if any, the process died from, and whether there was a core dump. (Mnemonic: similar to **sh** and **ksh** .)

$OS_ERROR

$ERRNO

$!

If used in a numeric context, yields the current value of errno, with all the usual caveats. (This means that you shouldn't depend on the value of " $! " to be anything in particular unless you've gotten a specific error return indicating a system error.) If used in a string context, yields the corresponding system error string. You can assign to " $! " in order to set *errno* if, for instance, you want " $! " to return the string for error *n* , or you want to set the exit value for the *die()* operator. (Mnemonic: What just went bang?)

$EVAL_ERROR

$@

The Perl syntax error message from the last *eval()* command. If null, the last *eval()* parsed and executed correctly (although the operations you invoked may have failed in the normal fashion). (Mnemonic: Where was the syntax error "at"?)

Note that warning messages are not collected in this variable. You can, however, set up a routine to process warnings by setting **$SIG** {__WARN__} below.

$PROCESS_ID

$PID

$$

The process number of the Perl running this script. (Mnemonic: same as shells.)

$REAL_USER_ID

$UID

<

The real uid of this process. (Mnemonic: it's the uid you came *FROM* , if you're running setuid.)

$EFFECTIVE_USER_ID

$EUID

$>

The effective uid of this process. Example:

$< = $>; # set real to effective uid ($<,$>) = ($>,$<); # swap real and effective uid

(Mnemonic: it's the uid you went *TO* , if you're running setuid.) Note: " **$& lt;** " and " **$& gt;** " can only be swapped on machines supporting *setreuid()* .

$REAL_GROUP_ID

$GID

$(

The real gid of this process. If you are on a machine that supports membership in multiple groups simultaneously, gives a space separated list of groups you are in. The first number is the one returned by *getgid()* , and the subsequent ones by *getgroups()* , one of which may be the same as the first number. (Mnemonic: parentheses are used to *GROUP* things. The real gid is the group you *LEFT* , if you're running setgid.)

$EFFECTIVE_GROUP_ID

$EGID

$)

The effective gid of this process. If you are on a machine that supports membership in multiple groups simultaneously, gives a space separated list of groups you are in. The first number is the one returned by *getegid()* , and the subsequent ones by *getgroups()* , one of which may be the same as the first number. (Mnemonic: parentheses are used to *GROUP* things. The effective gid is the group that's *RIGHT* for you, if you're running setgid.)

Note: " **$& lt;** ", " **$& gt;** ", " $(" and " $) " can only be set on machines that support the corresponding *set[re][ug] id()* routine. " $(" and " $) " can only be swapped on machines supporting *setregid()* .

$PROGRAM_NAME

$0

Contains the name of the file containing the Perl script being executed. Assigning to " $0 " modifies the argument area that the ps(1) program sees. This is more useful as a way of indicating the current program state than it is for hiding the program you're running. (Mnemonic: same as **sh** and **ksh** .)

$[

The index of the first element in an array, and of the first character in a substring. Default is 0, but you could set it to 1 to make Perl behave more like **awk** (or Fortran) when subscripting and when evaluating the *index()* and *substr()* functions. (Mnemonic: [begins subscripts.)

As of Perl 5, assignment to " $[" is treated as a compiler directive, and cannot influence the behavior of any other file. Its use is discouraged.

$PERL_VERSION

$]

The string printed out when you say **perl -v** . It can be used to determine at the beginning of a script whether the perl interpreter executing the script is in the right range of versions. If used in a numeric context, returns the version + patchlevel / 1000. Example:

see if getc is available ($version,$patchlevel) = $] =~ /(\d+\.\d+).*\nPatch level: (\d+)/; print STDERR "(No filename completion available.)\n" if $version * 1000 + $patchlevel < 2016;

or, used numerically,

warn "No checksumming!\n" if $] < 3.019;

(Mnemonic: Is this version of perl in the right bracket?)

$DEBUGGING

$^ D

The current value of the debugging flags. (Mnemonic: value of **-D** switch.)

$SYSTEM_FD_MAX

$^ F

The maximum system file descriptor, ordinarily 2. System file descriptors are passed to *exec()* ed processes, while higher file descriptors are not. Also, during an *open()* , system file descriptors are preserved even if the *open()* fails. (Ordinary file descriptors are closed before the *open()* is attempted.) Note that the close-on-exec status of a file descriptor will be decided according to the value of $^ F at the time of the open, not the time of the exec.

$INPLACE_EDIT

$^ I

The current value of the inplace-edit extension. Use **undef** to disable inplace editing. (Mnemonic: value of **-i** switch.)

$PERLDB

$^ P

The internal flag that the debugger clears so that it doesn't debug itself. You could conceivable disable debugging yourself by clearing it.

$BASETIME

$^ T

The time at which the script began running, in seconds since the epoch (beginning of 1970). The values returned by the **-M** , **-A** and **-C** filetests are based on this value.

$WARNING

$^ W

The current value of the warning switch, either TRUE or FALSE. (Mnemonic: related to the **-w** switch.)

$EXECUTABLE_NAME

$^ X

The name that the Perl binary itself was executed as, from C's **argv[0]** .

$ARGV

contains the name of the current file when reading from<>.

@ARGV

The array @ARGV contains the command line arguments intended for the script. Note that **$# ARGV** is the generally number of arguments minus one, since **$ARGV [0]** is the first argument, *NOT* the command name. See " $0 " for the command name.

@INC

The array @INC contains the list of places to look for Perl scripts to be evaluated by the **do EXPR** , **require** , or **use** constructs. It initially consists of the arguments to any **-I** command line switches, followed by the default Perl library, probably "/usr/local/lib/perl", followed by ".", to represent the current directory.

%INC

The hash %INC contains entries for each filename that has been included via **do** or **require** . The key is the filename you specified, and the value is the location of the file actually found. The **require** command uses this array to determine whether a given file has already been included.

$ENV {expr}

The hash **%ENV** contains your current environment. Setting a value in **ENV** changes the environment for child processes.

$SIG {expr}

The hash **%SIG** is used to set signal handlers for various signals. Example:

sub handler { # 1st argument is signal name local($sig) = @_; print "Caught a SIG$sig--shutting down\n"; close(LOG); exit(0); } $SIG{'INT'} = 'handler'; $SIG{'QUIT'} = 'handler'; ... $SIG{'INT'} = 'DEFAULT'; # restore default action $SIG{'QUIT'} = 'IGNORE'; # ignore SIGQUIT

The **%SIG** array only contains values for the signals actually set within the Perl script. Here are some other examples:

$SIG{PIPE} = Plumber; # SCARY!! $SIG{"PIPE"} = "Plumber"; # just fine, assumes main::Plumber $SIG{"PIPE"} = \&Plumber; # just fine; assume current Plumber $SIG{"PIPE"} = Plumber(); # oops, what did Plumber() return??

The one marked scary is problematic because it's a bareword, which means sometimes it's a string representing the function, and sometimes it's going to call the subroutine call right then and there! Best to be sure and quote it or take a reference to it. *Plumber works too. See the *perlsubs* manpage .

Certain internal hooks can be also set using the **%SIG** hash. The routine indicated by **$SIG** {__WARN__} is called when a warning message is about to be printed. The warning message is passed as the first argument. The presence of a __WARN__ hook causes the ordinary printing of warnings to STDERR to be suppressed. You can use this to save warnings in a variable, or turn warnings into fatal errors, like this:

local $SIG{__WARN__} = sub { die $_[0] }; eval $proggie;

The routine indicated by **$SIG** {__DIE__} is called when a fatal exception is about to be thrown. The error message is passed as the first argument. When a __DIE__ hook routine returns, the exception processing continues as it would have in the absence of the hook, unless the hook routine itself exits via a goto, a loop exit, or a die.

.

NAME

perlsub - Perl subroutines

SYNOPSIS

To declare subroutines:

sub NAME; # A "forward" declaration. sub NAME BLOCK # A declaration and a definition.

To define an anonymous subroutine at runtime:

$subref = sub BLOCK;

To import subroutines:

use PACKAGE qw(NAME1 NAME2 NAME3);

To call subroutines:

&NAME # Passes current @_ to subroutine. &NAME(LIST); # Parens required with & form. NAME(LIST); # & is optional with parens. NAME LIST; # Parens optional if predeclared/imported.

DESCRIPTION

Any arguments passed to the routine come in as array **@_** , that is (**$_** [0], **$_** [1], ...). The array **@_** is a local array, but its values are references to the actual scalar parameters. The return value of the subroutine is the value of the last expression evaluated, and can be either an array value or a scalar value. Alternatively, a return statement may be used to specify the returned value and exit the subroutine. To create local variables see the *local()* and *my()* operators.

A subroutine may be called using the "&" prefix. The "&" is optional in Perl 5, and so are the parens if the subroutine has been predeclared. (Note, however, that the "&" is *NOT* optional when you're just naming the subroutine, such as when it's used as an argument to *defined()* or *undef()* . Nor is it optional when you want to do an indirect subroutine call with a subroutine name or reference using the **& $< EM> subref()** or **&{ $subref }()** constructs. See the *perlref* manpage for more on that.)

Example:

sub MAX { my $max = pop(@_); foreach $foo (@_) { $max = $foo if $max < $foo; } $max; } ... $bestday = &MAX($mon,$tue,$wed,$thu,$fri);

Example:

get a line, combining continuation lines # that start with whitespace sub get_line { $thisline = $lookahead; LINE: while ($lookahead = <STDIN>) { if ($lookahead =~ /^[\t]/) { $thisline .= $lookahead; } else { last LINE; } } $thisline; } $lookahead = <STDIN>; # get first line while ($_ = get_line()) { ... }

Use array assignment to a local list to name your formal arguments:

sub maybeset { my($key, $value) = @_; $foo{$key} = $value unless $foo{$key}; }

This also has the effect of turning call-by-reference into call-by-value, since the assignment copies the values.

Subroutines may be called recursively. If a subroutine is called using the "&" form, the argument list is optional. If omitted, no **@_** array is set up for the subroutine; the **@_** array at the time of the call is visible to subroutine instead.

&foo(1,2,3); # pass three arguments foo(1,2,3); # the same foo(); # pass a null list &foo(); # the same &foo; # pass no arguments--more efficient

If a module wants to create a private subroutine that cannot be called from outside the module, it can declare a lexical variable containing an anonymous sub reference:

my $subref = sub { ... } &$subref(1,2,3);

As long as the reference is never returned by any function within the module, no outside module can see the subroutine, since its name is not in any package's symbol table.

Passing Symbol Table Entries

[Note: The mechanism described in this section works fine in Perl 5, but the new reference mechanism is generally easier to work with. See the *perlref* manpage .]

Sometimes you don't want to pass the value of an array to a subroutine but rather the name of it, so that the subroutine can modify the global copy of it rather than working with a local copy. In perl you can refer to all the objects of a particular name by prefixing the name with a star: ***foo** . This is often known as a "type glob", since the star on the front can be thought of as a wildcard match for all the funny prefix characters on variables and subroutines and such.

When evaluated, the type glob produces a scalar value that represents all the objects of that name, including any filehandle, format or subroutine. When assigned to, it causes the name mentioned to refer to whatever "*" value was assigned to it. Example:

sub doubleary { local(*someary) = @_; foreach $elem (@someary) { $elem *= 2; } } doubleary(*foo); doubleary(*bar);

Note that scalars are already passed by reference, so you can modify scalar arguments without using this mechanism by referring explicitly to **$_** [0] etc. You can modify all the elements of an array by passing all the elements as scalars, but you have to use the * mechanism (or the equivalent reference mechanism)

to push, pop or change the size of an array. It will certainly be faster to pass the typeglob (or referenc

Even if you don't want to modify an array, this mechanism is useful for passing multiple arrays in a single LIST, since normally the LIST mechanism will merge all the array values so that you can't extract out the individual arrays.

Overriding builtin functions

Many builtin functions may be overridden, though this should only be tried occasionally and for good reason. Typically this might be done by a package attempting to emulate missing builtin functionality on a non-Unix system.

Overriding may only be done by importing the name from a module--ordinary predeclaration isn't good enough. However, the **subs** pragma (compiler directive) lets you, in effect, predeclare subs via the import syntax, and these names may then override the builtin ones:

use subs 'chdir', 'chroot', 'chmod', 'chown'; chdir $somewhere; sub chdir { ... }

Library modules should not in general export builtin names like "open" or "chdir" as part of their default **@EXPORT** list, since these may sneak into someone else's namespace and change the semantics unexpectedly. Instead, if the module adds the name to the **@EXPORT_OK** list, then it's possible for a user to import the name explicitly, but not implicitly. That is, they could say

use Module 'open';

and it would import the open override, but if they said

use Module;

they would get the default imports without the overrides.

Autoloading

If you call a subroutine that is undefined, you would ordinarily get an immediate fatal error complaining that the subroutine doesn't exist. (Likewise for subroutines being used as methods, when the method doesn't exist in any of the base classes of the class package.) If, however, there is an **AUTOLOAD** subroutine defined in the package or packages that were searched for the original subroutine, then that **AUTOLOAD** subroutine is called with the arguments that would have been passed to the original subroutine. The fully qualified name of the original subroutine magically appears in the **$AUTOLOAD** variable in the same package as the **AUTOLOAD** routine. The name is not passed as an ordinary argument because, er, well, just because, that's why...

Most **AUTOLOAD** routines will load in a definition for the subroutine in question using eval, and then execute that subroutine using a special form of "goto" that erases the stack frame of the **AUTOLOAD** routine without a trace. (See the standard **AutoLoader** module, for example.) But an **AUTOLOAD** routine can also just emulate the routine and never define it. A good example of this is the standard Shell module, which can treat undefined subroutine calls as calls to Unix programs.

There are mechanisms available for modules to help them split themselves up into autoloadable files be used with the standard AutoLoader module. See the document on extensions.

NAME

perlmod - Perl modules (packages)

DESCRIPTION

Packages

Perl provides a mechanism for alternative namespaces to protect packages from stomping on each others variables. In fact, apart from certain magical variables, there's really no such thing as a global variable in Perl. By default, a Perl script starts compiling into the package known as **main** . You can switch namespaces using the **package** declaration. The scope of the package declaration is from the declaration itself to the end of the enclosing block (the same scope as the *local()* operator). Typically it would be the first declaration in a file to be included by the **require** operator. You can switch into a package in more than one place; it merely influences which symbol table is used by the compiler for the rest of that block. You can refer to variables and filehandles in other packages by prefixing the identifier with the package name and a double colon: **$Package::Variable** . If the package name is null, the **main** package as assumed. That is, **$::sail** is equivalent to **$main::sail** .

(The old package delimiter was a single quote, but double colon is now the preferred delimiter, in part because it's more readable to humans, and in part because it's more readable to **emacs** macros. It also makes C++ programmers feel like they know what's going on.)

Packages may be nested inside other packages: **$OUTER::INNER::var** . This implies nothing about the order of name lookups, however. All symbols are either local to the current package, or must be fully qualified from the outer package name down. For instance, there is nowhere within package **OUTER** that **$INNER::var** refers to **$OUTER::INNER::var** . It would treat package **INNER** as a totally separate global package.

Only identifiers starting with letters (or underscore) are stored in a package's symbol table. All other symbols are kept in package **main** . In addition, the identifiers STDIN, STDOUT, STDERR, ARGV, ARGVOUT, ENV, INC and SIG are forced to be in package **main** , even when used for other purposes than their built-in one. Note also that, if you have a package called **m** , **s** or **y** , then you can't use the qualified form of an identifier because it will be interpreted instead as a pattern match, a substitution, or a translation.

(Variables beginning with underscore used to be forced into package main, but we decided it was more useful for package writers to be able to use leading underscore to indicate private variables and method names.)

Eval() ed strings are compiled in the package in which the *eval()* was compiled. (Assignments to **$SIG {}**

, however, assume the signal handler specified is in the **main** package. Qualify the signal handler na you wish to have a signal handler in a package.) For an example, examine *perldb.pl* in the Perl libra initially switches to the **DB** package so that the debugger doesn't interfere with variables in the script you are trying to debug. At various points, however, it temporarily switches back to the **main** package to evaluate various expressions in the context of the **main** package (or wherever you came from). See the *perldebug* manpage .

Symbol Tables

The symbol table for a package happens to be stored in the associative array of that name appended with two colons. The main symbol table's name is thus **%main::** , or **%::** for short. Likewise the nested package mentioned earlier is named **%OUTER::INNER::** .

The value in each entry of the associative array is what you are referring to when you use the ***name** notation. In fact, the following have the same effect, though the first is more efficient because it does the symbol table lookups at compile time:

local(*main::foo) = *main::bar; local($main::{'foo'}) = $main::{'bar'};

You can use this to print out all the variables in a package, for instance. Here is *dumpvar.pl* from the Perl library:

package dumpvar; sub main::dumpvar { ($package) = @_; local(*stab) = eval("*${package}::"); while (($key,$val) = each(%stab)) { local(*entry) = $val; if (defined $entry) { print "\$$key = '$entry'\n"; } if (defined @entry) { print "\@$key = (\n"; foreach $num ($[.. $#entry) { print " $num\t'",$entry[$num],"'\n"; } print ")\n"; } if ($key ne "${package}::" && defined %entry) { print "\%$key = (\n"; foreach $key (sort keys(%entry)) { print " $key\t'",$entry{$key},"'\n"; } print ")\n"; } } }

Note that even though the subroutine is compiled in package **dumpvar** , the name of the subroutine is qualified so that its name is inserted into package **main** .

Assignment to a symbol table entry performs an aliasing operation, i.e.,

*dick = *richard;

causes variables, subroutines and file handles accessible via the identifier **richard** to also be accessible via the symbol **dick** . If you only want to alias a particular variable or subroutine, you can assign a reference instead:

*dick = \$richard;

makes **$richard** and **$dick** the same variable, but leaves **@richard** and **@dick** as separate arrays. Tricky, eh?

Package Constructors and Destructors

There are two special subroutine definitions that function as package constructors and destructors. These are the **BEGIN** and **END** routines. The **sub** is optional for these routines.

A **BEGIN** subroutine is executed as soon as possible, that is, the moment it is completely defined, even before the rest of the containing file is parsed. You may have multiple **BEGIN** blocks within a file--they will execute in order of definition. Because a **BEGIN** block executes immediately, it can pull in definitions of subroutines and such from other files in time to be visible to the rest of the file.

An **END** subroutine is executed as late as possible, that is, when the interpreter is being exited, even if it is exiting as a result of a *die()* function. (But not if it's is being blown out of the water by a signal--you have to trap that yourself (if you can).) You may have multiple **END** blocks within a file--they will execute in reverse order of definition; that is: last in, first out (LIFO).

Note that when you use the **-n** and **-p** switches to Perl, **BEGIN** and **END** work just as they do in **awk** , as a degenerate case.

Perl Classes

There is no special class syntax in Perl 5, but a package may function as a class if it provides subroutines that function as methods. Such a package may also derive some of its methods from another class package by listing the other package name in its **@ISA** array. For more on this, see the *perlobj* manpage .

Perl Modules

In Perl 5, the notion of packages has been extended into the notion of modules. A module is a package that is defined in a library file of the same name, and is designed to be reusable. It may do this by providing a mechanism for exporting some of its symbols into the symbol table of any package using it. Or it may function as a class definition and make its semantics available implicitly through method calls on the class and its objects, without explicit exportation of any symbols. Or it can do a little of both.

Perl modules are included by saying

use Module;

or

use Module LIST;

This is exactly equivalent to

BEGIN { require "Module.pm"; import Module; }

or

BEGIN { require "Module.pm"; import Module LIST; }

All Perl module files have the extension *.pm* . **use** assumes this so that you don't have to spell out " *Module.pm* " in quotes. This also helps to differentiate new modules from old *.pl* and *.ph* files. Modu names are also capitalized unless they're functioning as pragmas, "Pragmas" are in effect compiler directives, and are sometimes called "pragmatic modules" (or even "pragmata" if you're a classicist).

Because the **use** statement implies a **BEGIN** block, the importation of semantics happens at the moment the **use** statement is compiled, before the rest of the file is compiled. This is how it is able to function as a pragma mechanism, and also how modules are able to declare subroutines that are then visible as list operators for the rest of the current file. This will not work if you use **require** instead of **use** . Therefore, if you're planning on the module altering your namespace, use **use** ; otherwise, use **require** . Otherwise you can get into this problem:

require Cwd; # make Cwd:: accessible $here = Cwd::getcwd(); use Cwd; # import names from Cwd:: $here = getcwd(); require Cwd; # make Cwd:: accessible $here = getcwd(); # oops! no main::getcwd()

Perl packages may be nested inside other package names, so we can have package names containing **::** . But if we used that package name directly as a filename it would makes for unwieldy or impossible filenames on some systems. Therefore, if a module's name is, say, **Text::Soundex** , then its definition is actually found in the library file *Text/Soundex.pm* .

Perl modules always have a *.pm* file, but there may also be dynamically linked executables or autoloaded subroutine definitions associated with the module. If so, these will be entirely transparent to the user of the module. It is the responsibility of the *.pm* file to load (or arrange to autoload) any additional functionality. The POSIX module happens to do both dynamic loading and autoloading, but the user can just say **use POSIX** to get it all.

For more information on writing extension modules, see the *perlapi* manpage and the *perlguts* manpage .

NOTE

Perl does not enforce private and public parts of its modules as you may have been used to in other languages like C++, Ada, or Modula-17. Perl doesn't have an infatuation with enforced privacy. It would prefer that you stayed out of its living room because you weren't invited, not because it has a shotgun.

The module and its user have a contract, part of which is common law, and part of which is "written". Part of the common law contract is that a module doesn't pollute any namespace it wasn't asked to. The written contract for the module (AKA documentation) may make other provisions. But then you know when you **use RedefineTheWorld** that you're redefining the world and willing to take the consequences.

THE PERL MODULE LIBRARY

A number of modules are included the the Perl distribution. These are described below, and all end in *.pm* . You may also discover files in the library directory that end in either *.pl* or *.ph* . These are old libraries supplied so that old programs that use them still run. The *.pl* files will all eventually be converted into standard modules, and the *.ph* files made by **h2ph** will probably end up as extension modules made by **h2xs** . (Some *.ph* values may already be available through the POSIX module.) The **pl2pm** file in the distribution may help in your conversion, but it's just a mechanical process, so is far from bullet proof.

Pragmatic Modules

They work somewhat like pragmas in that they tend to affect the compilation of your program, and thus will usually only work well when used within a **use** , or **no** . These are locally scoped, so an inner BLOCK may countermand any of these by saying

no integer; no strict 'refs';

which lasts until the end of that BLOCK.

The following programs are defined (and have their own documentation).

integer
: Perl pragma to compute arithmetic in integer instead of double

less
: Perl pragma to request less of something from the compiler

sigtrap
: Perl pragma to enable stack backtrace on unexpected signals

strict
: Perl pragma to restrict unsafe constructs

subs
: Perl pragma to predeclare sub names

.

Standard Modules

The following modules are all expected to behave in a well-defined manner with respect to namespace pollution because they use the Exporter module. See their own documentation for details.

Abbrev
: create an abbreviation table from a list

AnyDBM_File
: provide framework for multiple DBMs

AutoLoader

load functions only on demand

AutoSplit

split a package for autoloading

Basename

parse file name and path from a specification

Benchmark

benchmark running times of code

Carp

warn or die of errors (from perspective of caller)

CheckTree

run many filetest checks on a tree

Collate

compare 8-bit scalar data according to the current locale

Config

access Perl configuration option

Cwd

get pathname of current working directory

DynaLoader

Dynamically load C libraries into Perl code

English

use nice English (or **awk**) names for ugly punctuation variables

Env

Perl module that imports environment variables

Exporter

module to control namespace manipulations

Fcntl

load the C Fcntl.h defines

FileHandle

supply object methods for filehandles

Find

traverse a file tree

Finddepth

traverse a directory structure depth-first

Getopt

basic and extended getopt(3) processing

MakeMaker

generate a Makefile for Perl extension

Open2

open a process for both reading and writing

Open3

open a process for reading, writing, and error handling

POSIX

Perl interface to IEEE 1003.1 namespace

Ping

check a host for upness

Socket

load the C socket.h defines

.

Extension Modules

Extension modules are written in C (or a mix of Perl and C) and get dynamically loaded into Perl if and when you need them. Supported extension modules include the Socket, Fcntl, and POSIX modules.

The following are popular C extension modules, which while available at Perl 5.0 release time, do not come bundled (at least, not completely) due to their size, volatility, or simply lack of time for adequate testing and configuration across the multitude of platforms on which Perl was beta-tested. You are encouraged to look for them in archie(1L), the Perl FAQ or Meta-FAQ, the WWW page, and even with their authors before randomly posting asking for their present condition and disposition. There's no guarantee that the names or addresses below have not changed since printing, and in fact, they probably have!

Curses

Written by William Setzer< *William_Setzer* ***@ncsu*** *.edu* >, while not included with the standard distribution, this extension module ports to most systems. FTP from your nearest Perl archive site, or try

ftp://ftp.ncsu.edu/pub/math/wsetzer/cursperl5??.tar.gz

It is currently in alpha test, so the name and ftp location may change.

DBI

This is the portable database interface written by < *Tim.Bunce* ***@ig*** *.co.uk* >. This supersedes the many perl4 ports for database extensions. The official archive for DBperl extensions is *ftp.demon.co.uk:/pub/perl/db* . This archive contains copies of perl4 ports for Ingres, Oracle, Sybase, Informix, Unify, Postgres, and Interbase, as well as rdb and shql and other non-SQL systems.

DB_File

Fastest and most restriction-free of the DBM bindings, this extension module uses the popular Berkeley DB to *tie()* into your hashes. This has a standardly-distributed man page and dynamic

loading extension module, but you'll have to fetch the Berkeley code yourself. See *DB_File* fo where.

Sx

This extension module is a front to the Athena and Xlib libraries for Perl GUI programming, originally written by by Dominic Giampaolo < *dbg* ***@sgi*** *.com* >, then and rewritten for Sx by Frédéric Chauveau< *fmc* ***@pasteur*** *.fr* >. It's available for FTP from

ftp.pasteur.fr:/pub/Perl/Sx.tar.gz

Tk

This extension module is an object-oriented Perl5 binding to the popular tcl/tk X11 package. However, you need know no TCL to use it! It was written by Malcolm Beattie< *mbeattie* ***@sable*** *.ox.ac.uk* >. If you are unable to locate it using archie(1L) or a similar tool, you may try retrieving it from */private/Tk-october.tar.gz* from Malcolm's machine listed above.

.

NAME

perlref - Perl references and nested data structures

DESCRIPTION

In Perl 4 it was difficult to represent complex data structures, because all references had to be symbolic, and even that was difficult to do when you wanted to refer to a variable rather than a symbol table entry. Perl 5 not only makes it easier to use symbolic references to variables, but lets you have "hard" references to any piece of data. Any scalar may hold a hard reference. Since arrays and hashes contain scalars, you can now easily build arrays of arrays, arrays of hashes, hashes of arrays, arrays of hashes of functions, and so on.

Hard references are smart--they keep track of reference counts for you, automatically freeing the thing referred to when its reference count goes to zero. If that thing happens to be an object, the object is destructed. See the *perlobj* manpage for more about objects. (In a sense, everything in Perl is an object, but we usually reserve the word for references to objects that have been officially "blessed" into a class package.)

A symbolic reference contains the name of a variable, just as a symbolic link in the filesystem merely contains the name of a file. The ***glob** notation is a kind of symbolic reference. Hard references are more like hard links in the file system: merely another way at getting at the same underlying object, irrespective of its name.

"Hard" references are easy to use in Perl. There is just one overriding principle: Perl does no implicit referencing or dereferencing. When a scalar is holding a reference, it always behaves as a scalar. It doesn't magically start being an array or a hash unless you tell it so explicitly by dereferencing it.

References can be constructed several ways.

1. By using the backslash operator on a variable, subroutine, or value. (This works much like the & (address-of) operator works in C.) Note that this typically creates *ANOTHER* reference to a variable, since there's already a reference to the variable in the symbol table. But the symbol table reference might go away, and you'll still have the reference that the backslash returned. Here are some examples:

   $scalarref = \$foo; $arrayref = \@ARGV; $hashref = \%ENV; $coderef = \&handler;
2. A reference to an anonymous array can be constructed using square brackets:

   $arrayref = [1, 2, ['a', 'b', 'c']];

   Here we've constructed a reference to an anonymous array of three elements whose final element is itself reference to another anonymous array of three elements. (The multidimensional syntax

described later can be used to access this. For example, after the above, **$arrayref** ->[2][1] would have the value "b".)

3. A reference to an anonymous hash can be constructed using curly brackets:

   $hashref = { 'Adam' => 'Eve', 'Clyde' => 'Bonnie', };

   Anonymous hash and array constructors can be intermixed freely to produce as complicated a structure as you want. The multidimensional syntax described below works for these too. The values above are literals, but variables and expressions would work just as well, because assignment operators in Perl (even within *local()* or *my()*) are executable statements, not compile-time declarations.

   Because curly brackets (braces) are used for several other things including BLOCKs, you may occasionally have to disambiguate braces at the beginning of a statement by putting a **+** or a **return** in front so that Perl realizes the opening brace isn't starting a BLOCK. The economy and mnemonic value of using curlies is deemed worth this occasional extra hassle.

   For example, if you wanted a function to make a new hash and return a reference to it, you have these options:

   sub hashem { { @_ } } # silently wrong sub hashem { +{ @_ } } # ok sub hashem { return { @_ } } # ok

4. A reference to an anonymous subroutine can be constructed by using **sub** without a subname:

   $coderef = sub { print "Boink!\n" };

   Note the presence of the semicolon. Except for the fact that the code inside isn't executed immediately, a **sub {}** is not so much a declaration as it is an operator, like **do{}** or **eval{}** . (However, no matter how many times you execute that line (unless you're in an **eval("...")**), **$coderef** will still have a reference to the *SAME* anonymous subroutine.)

   Anonymous subroutines act as closures with respect to *my()* variables, that is, variables visible lexically within the current scope. Closure is a notion out of the Lisp world that says if you define an anonymous function in a particular lexical context, it pretends to run in that context even when it's called outside of the context.

   In human terms, it's a funny way of passing arguments to a subroutine when you define it as well as when you call it. It's useful for setting up little bits of code to run later, such as callbacks. You can even do object-oriented stuff with it, though Perl provides a different mechanism to do that already--see the *perlobj* manpage .

   You can also think of closure as a way to write a subroutine template without using eval. (In fact, in version 5.000, eval was the *only* way to get closures. You may wish to use "require 5.001" if you use closures.)

   Here's a small example of how closures works:

   sub newprint { my $x = shift; return sub { my $y = shift; print "$x, $y!\n"; }; } $h = newprint("Howdy"); $g = newprint("Greetings"); # Time passes... &$h("world"); &$g("earthlings");

This prints

Howdy, world! Greetings, earthlings!

Note particularly that **$x** continues to refer to the value passed into *newprint()* *despite* the fact that the "my **$x** " has seemingly gone out of scope by the time the anonymous subroutine runs. That's what closure is all about.

This only applies to lexical variables, by the way. Dynamic variables continue to work as they have always worked. Closure is not something that most Perl programmers need trouble themselves about to begin with.

5. References are often returned by special subroutines called constructors. Perl objects are just references to a special kind of object that happens to know which package it's associated with. Constructors are just special subroutines that know how to create that association. They do so by starting with an ordinary reference, and it remains an ordinary reference even while it's also being an object. Constructors are customarily named *new()* , but don't have to be:

   $objref = new Doggie (Tail => 'short', Ears => 'long');

6. References of the appropriate type can spring into existence if you dereference them in a context that assumes they exist. Since we haven't talked about dereferencing yet, we can't show you any examples yet.

That's it for creating references. By now you're probably dying to.know how to use references to get back to your long-lost data. There are several basic methods.

1. Anywhere you'd put an identifier as part of a variable or subroutine name, you can replace the identifier with a simple scalar variable containing a reference of the correct type:

   $bar = $$scalarref; push(@$arrayref, $filename); $$arrayref[0] = "January"; $$hashref{"KEY"} = "VALUE"; &$coderef(1,2,3);

   It's important to understand that we are specifically *NOT* dereferencing **$arrayref [0]** or **$hashref {"KEY"}** there. The dereference of the scalar variable happens *BEFORE* it does any key lookups. Anything more complicated than a simple scalar variable must use methods 2 or 3 below. However, a "simple scalar" includes an identifier that itself uses method 1 recursively. Therefore, the following prints "howdy".

   $refrefref = \\\"howdy"; print $$$$refrefref;

2. Anywhere you'd put an identifier as part of a variable or subroutine name, you can replace the identifier with a BLOCK returning a reference of the correct type. In other words, the previous examples could be written like this:

   $bar = ${$scalarref}; push(@{$arrayref}, $filename); ${$arrayref}[0] = "January"; ${$hashref}{"KEY"} = "VALUE"; &{$coderef}(1,2,3);

   Admittedly, it's a little silly to use the curlies in this case, but the BLOCK can contain any arbitrary expression, in particular, subscripted expressions:

   &{ $dispatch{$index} }(1,2,3); # call correct routine

Because of being able to omit the curlies for the simple case of **$$ x** , people often make the mistake of viewing the dereferencing symbols as proper operators, and wonder about their precedence. If they were, though, you could use parens instead of braces. That's not the case. Consider the difference below; case 0 is a short-hand version of case 1, *NOT* case 2:

$$hashref{"KEY"} = "VALUE"; # CASE 0 ${$hashref}{"KEY"} = "VALUE"; # CASE 1 ${$hashref{"KEY"}} = "VALUE"; # CASE 2 ${$hashref->{"KEY"}} = "VALUE"; # CASE 3

Case 2 is also deceptive in that you're accessing a variable called **%hashref** , not dereferencing through **$hashref** to the hash it's presumably referencing. That would be case 3.

3. The case of individual array elements arises often enough that it gets cumbersome to use method 2. As a form of syntactic sugar, the two lines like that above can be written:

   $arrayref->[0] = "January"; $hashref->{"KEY"} = "VALUE";

   The left side of the array can be any expression returning a reference, including a previous dereference. Note that **$array [$x]** is *NOT* the same thing as **$array ->[$x]** here:

   $array[$x]->{"foo"}->[0] = "January";

   This is one of the cases we mentioned earlier in which references could spring into existence when in an lvalue context. Before this statement, **$array [$x]** may have been undefined. If so, it's automatically defined with a hash reference so that we can look up **{"foo"}** in it. Likewise **$array [$x]->{"foo"}** will automatically get defined with an array reference so that we can look up **[0]** in it.

   One more thing here. The arrow is optional *BETWEEN* brackets subscripts, so you can shrink the above down to

   $array[$x]{"foo"}[0] = "January";

   Which, in the degenerate case of using only ordinary arrays, gives you multidimensional arrays just like C's:

   $score[$x][$y][$z] += 42;

   Well, okay, not entirely like C's arrays, actually. C doesn't know how to grow its arrays on demand. Perl does.

4. If a reference happens to be a reference to an object, then there are probably methods to access the things referred to, and you should probably stick to those methods unless you're in the class package that defines the object's methods. In other words, be nice, and don't violate the object's encapsulation without a very good reason. Perl does not enforce encapsulation. We are not totalitarians here. We do expect some basic civility though.

The *ref()* operator may be used to determine what type of thing the.reference is pointing to. See the *perlfunc* manpage .

The *bless()* operator may be used to associate a reference with a package functioning as an object class. See the *perlobj* manpage .

A type glob may be dereferenced the same way a reference can, since the dereference syntax always

indicates the kind of reference desired. So **${*foo}** and **${\ $foo }** both indicate the same scalar variable.

Here's a trick for interpolating a subroutine call into a string:

print "My sub returned ${\mysub(1,2,3)}\n";

The way it works is that when the **${...}** is seen in the double-quoted string, it's evaluated as a block. The block executes the call to **mysub(1,2,3)** , and then takes a reference to that. So the whole block returns a reference to a scalar, which is then dereferenced by **${...}** and stuck into the double-quoted string.

Symbolic references

We said that references spring into existence as necessary if they are undefined, but we didn't say what happens if a value used as a reference is already defined, but *ISN'T* a hard reference. If you use it as a reference in this case, it'll be treated as a symbolic reference. That is, the value of the scalar is taken to be the NAME of a variable, rather than a direct link to a (possibly) anonymous value.

People frequently expect it to work like this. So it does.

$name = "foo"; $$name = 1; # Sets $foo ${$name} = 2; # Sets $foo ${$name x 2} = 3; # Sets $foofoo $name->[0] = 4; # Sets $foo[0] @$name = (); # Clears @foo &$name(); # Calls &foo() (as in Perl 4) $pack = "THAT"; ${"${pack}::$name"} = 5; # Sets $THAT::foo without eval

This is very powerful, and slightly dangerous, in that it's possible to intend (with the utmost sincerity) to use a hard reference, and accidentally use a symbolic reference instead. To protect against that, you can say

use strict 'refs';

and then only hard references will be allowed for the rest of the enclosing block. An inner block may countermand that with

no strict 'refs';

Only package variables are visible to symbolic references. Lexical variables (declared with *my()*) aren't in a symbol table, and thus are invisible to this mechanism. For example:

local($value) = 10; $ref = \$value; { my $value = 20; print $$ref; }

This will still print 10, not 20. Remember that *local()* affects package variables, which are all "global" to the package.

Not-so-symbolic references

A new feature contributing to readability in 5.001 is that the brackets around a symbolic reference behave more like quotes, just as they always have within a string. That is,

$push = "pop on "; print "${push}over";

TOC

has always meant to print "pop on over", despite the fact that push is a reserved word. This has been generalized to work the same outside of quotes, so that

print ${push} . "over";

and even

print ${ push } . "over";

will have the same effect. (This would have been a syntax error in 5.000, though Perl 4 allowed it in the spaceless form.) Note that this construct is *not* considered to be a symbolic reference when you're using strict refs:

use strict 'refs'; ${ bareword }; # Okay, means $bareword. ${ "bareword" }; # Error, symbolic reference.

Similarly, because of all the subscripting that is done using single words, we've applied the same rule to any bareword that is used for subscripting a hash. So now, instead of writing

$array{ "aaa" }{ "bbb" }{ "ccc" }

you can just write

$array{ aaa }{ bbb }{ ccc }

and not worry about whether the subscripts are reserved words. In the rare event that you do wish to do something like

$array{ shift }

you can force interpretation as a reserved word by adding anything that makes it more than a bareword:

$array{ shift() } $array{ +shift } $array{ shift @_ }

The **-w** switch will warn you if it interprets a reserved word as a string. But it will no longer warn you about using lowercase words, since the string is effectively quoted.

WARNING

You may not (usefully) use a reference as the key to a hash. It will be converted into a string:

$x{ \$a } = $a;

If you try to dereference the key, it won't do a hard dereference, and you won't accomplish what you're attemping.

Further Reading

Besides the obvious documents, source code can be instructive. Some rather pathological examples of the use of references can be found in the *t/op/ref.t* regression test in the Perl source directory.

NAME

perlobj - Perl objects

DESCRIPTION

First of all, you need to understand what references are in Perl. See the *perlref* manpage for that.

Here are three very simple definitions that you should find reassuring.

1. An object is simply a reference that happens to know which class it belongs to.
2. A class is simply a package that happens to provide methods to deal with object references.
3. A method is simply a subroutine that expects an object reference (or a package name, for static methods) as the first argument.

We'll cover these points now in more depth..

An Object is Simply a Reference

Unlike say C++, Perl doesn't provide any special syntax for constructors. A constructor is merely a subroutine that returns a reference that has been "blessed" into a class, generally the class that the subroutine is defined in. Here is a typical constructor:

package Critter; sub new { bless {} }

The **{}** constructs a reference to an anonymous hash containing no key/value pairs. The *bless()* takes that reference and tells the object it references that it's now a Critter, and returns the reference. This is for convenience, since the referenced object itself knows that it has been blessed, and its reference to it could have been returned directly, like this:

sub new { my $self = {}; bless $self; return $self; }

In fact, you often see such a thing in more complicated constructors that wish to call methods in the class as part of the construction:

sub new { my $self = {} bless $self; $self->initialize(); $self; }

Within the class package, the methods will typically deal with the reference as an ordinary reference. Outside the class package, the reference is generally treated as an opaque value that may only be accessed through the class's methods.

A constructor may re-bless a referenced object currently belonging to another class, but then the new class is responsible for all cleanup later. The previous blessing is forgotten, as an object may only belong to one class at a time. (Although of course it's free to inherit methods from many classes.)

A clarification: Perl objects are blessed. References are not. Objects know which package they belon References do not. The *bless()* function simply uses the reference in order to find the object. Conside following example:

$a = {}; $b = $a; bless $a, BLAH; print "\$b is a ", ref($b), "\n";

This reports **$b** as being a BLAH, so obviously *bless()* operated on the object and not on the reference.

A Class is Simply a Package

Unlike say C++, Perl doesn't provide any special syntax for class definitions. You just use a package as a class by putting method definitions into the class.

There is a special array within each package called **@ISA** which says where else to look for a method if you can't find it in the current package. This is how Perl implements inheritance. Each element of the **@ISA** array is just the name of another package that happens to be a class package. The classes are searched (depth first) for missing methods in the order that they occur in **@ISA** . The classes accessible through **@ISA** are known as base classes of the current class.

If a missing method is found in one of the base classes, it is cached in the current class for efficiency. Changing **@ISA** or defining new subroutines invalidates the cache and causes Perl to do the lookup again.

If a method isn't found, but an AUTOLOAD routine is found, then that is called on behalf of the missing method.

If neither a method nor an AUTOLOAD routine is found in **@ISA** , then one last try is made for the method (or an AUTOLOAD routine) in a class called UNIVERSAL. If that doesn't work, Perl finally gives up and complains.

Perl classes only do method inheritance. Data inheritance is left up to the class itself. By and large, this is not a problem in Perl, because most classes model the attributes of their object using an anonymous hash, which serves as its own little namespace to be carved up by the various classes that might want to do something with the object.

A Method is Simply a Subroutine

Unlike say C++, Perl doesn't provide any special syntax for method definition. (It does provide a little syntax for method invocation though. More on that later.) A method expects its first argument to be the object or package it is being invoked on. There are just two types of methods, which we'll call static and virtual, in honor of the two C++ method types they most closely resemble.

A static method expects a class name as the first argument. It provides functionality for the class as a whole, not for any individual object belonging to the class. Constructors are typically static methods. Many static methods simply ignore their first argument, since they already know what package they're in, and don't care what package they were invoked via. (These aren't necessarily the same, since static methods follow the inheritance tree just like ordinary virtual methods.) Another typical use for static

methods is to look up an object by name:

sub find { my ($class, $name) = @_; $objtable{$name}; }

A virtual method expects an object reference as its first argument. Typically it shifts the first argument into a "self" or "this" variable, and then uses that as an ordinary reference.

sub display { my $self = shift; my @keys = @_ ? @_ : sort keys %$self; foreach $key (@keys) { print "\t$key => $self->{$key}\n"; } }

Method Invocation

There are two ways to invoke a method, one of which you're already familiar with, and the other of which will look familiar. Perl 4 already had an "indirect object" syntax that you use when you say

print STDERR "help!!!\n";

This same syntax can be used to call either static or virtual methods. We'll use the two methods defined above, the static method to lookup an object reference and the virtual method to print out its attributes.

$fred = find Critter "Fred"; display $fred 'Height', 'Weight';

These could be combined into one statement by using a BLOCK in the indirect object slot:

display {find Critter "Fred"} 'Height', 'Weight';

For C++ fans, there's also a syntax using -> notation that does exactly the same thing. The parentheses are required if there are any arguments.

$fred = Critter->find("Fred"); $fred->display('Height', 'Weight');

or in one statement,

Critter->find("Fred")->display('Height', 'Weight');

There are times when one syntax is more readable, and times when the other syntax is more readable. The indirect object syntax is less cluttered, but it has the same ambiguity as ordinary list operators. Indirect object method calls are parsed using the same rule as list operators: "If it looks like a function, it is a function". (Presuming for the moment that you think two words in a row can look like a function name. C++ programmers seem to think so with some regularity, especially when the first word is "new".) Thus, the parens of

new Critter ('Barney', 1.5, 70)

are assumed to surround ALL the arguments of the method call, regardless of what comes after. Saying

new Critter ('Bam' x 2), 1.4, 45

would be equivalent to

Critter->new('Bam' x 2), 1.4, 45

which is unlikely to do what you want.

There are times when you wish to specify which class's method to use. In this case, you can call your method as an ordinary subroutine call, being sure to pass the requisite first argument explicitly:

$fred = MyCritter::find("Critter", "Fred"); MyCritter::display($fred, 'Height', 'Weight');

Note however, that this does not do any inheritance. If you merely wish to specify that Perl should *START* looking for a method in a particular package, use an ordinary method call, but qualify the method name with the package like this:

$fred = Critter->MyCritter::find("Fred"); $fred->MyCritter::display('Height', 'Weight');

Sometimes you want to call a method when you don't know the method name ahead of time. You can use the arrow form, replacing the method name with a simple scalar variable containing the method name:

$method = $fast ? "findfirst" : "findbest"; $fred->$method(@args);

Destructors

When the last reference to an object goes away, the object is automatically destroyed. (This may even be after you exit, if you've stored references in global variables.) If you want to capture control just before the object is freed, you may define a DESTROY method in your class. It will automatically be called at the appropriate moment, and you can do any extra cleanup you need to do.

Perl doesn't do nested destruction for you. If your constructor reblessed a reference from one of your base classes, your DESTROY may need to call DESTROY for any base classes that need it. But this only applies to reblessed objects--an object reference that is merely *CONTAINED* in the current object will be freed and destroyed automatically when the current object is freed.

WARNING

An indirect object is limited to a name, a scalar variable, or a block, because it would have to do too much lookahead otherwise, just like any other postfix dereference in the language. The left side of -> is not so limited, because it's an infix operator, not a postfix operator.

That means that below, A and B are equivalent to each other, and C and D are equivalent, but AB and CD are different:

A: method $obref->{"fieldname"} B: (method $obref)->{"fieldname"} C: $obref->{"fieldname"}->method() D: method {$obref->{"fieldname"}}

Summary

That's about all there is to it. Now you just need to go off and buy a book about object-oriented design methodology, and bang your forehead with it for the next six months or so.

You should also check out the *perlbot* manpage for other object tricks, traps, and tips.

TOC

NAME

perlbot - Bag'o Object Tricks For Perl5 (the BOT)

INTRODUCTION

The following collection of tricks and hints is intended to whet curious appetites about such things as the use of instance variables and the mechanics of object and class relationships. The reader is encouraged to consult relevant textbooks for discussion of Object Oriented definitions and methodology. This is not intended as a comprehensive guide to Perl5's object oriented features, nor should it be construed as a style guide.

The Perl motto still holds: There's more than one way to do it.

INSTANCE VARIABLES

An anonymous array or anonymous hash can be used to hold instance variables. Named parameters are also demonstrated.

package Foo; sub new { my $type = shift; my %params = @_; my $self = {}; $self->{'High'} = $params{'High'}; $self->{'Low'} = $params{'Low'}; bless $self; } package Bar; sub new { my $type = shift; my %params = @_; my $self = []; $self->[0] = $params{'Left'}; $self->[1] = $params{'Right'}; bless $self; } package main; $a = new Foo ('High' => 42, 'Low' => 11); print "High=$a->{'High'}\n"; print "Low=$a->{'Low'}\n"; $b = new Bar ('Left' => 78, 'Right' => 40); print "Left=$b->[0]\n"; print "Right=$b->[1]\n";

SCALAR INSTANCE VARIABLES

An anonymous scalar can be used when only one instance variable is needed.

package Foo; sub new { my $type = shift; my $self; $self = shift; bless \$self; } package main; $a = new Foo 42; print "a=$$a\n";

INSTANCE VARIABLE INHERITANCE

This example demonstrates how one might inherit instance variables from a superclass for inclusion in the new class. This requires calling the superclass's constructor and adding one's own instance variables to the new object.

package Bar; sub new { my $self = {}; $self->{'buz'} = 42; bless $self; } package Foo; @ISA = qw(Bar); sub new { my $self = new Bar; $self->{'biz'} = 11; bless $self; } package main; $a = new Foo; print "buz = ", $a->{'buz'}, "\n"; print "biz = ", $a->{'biz'}, "\n";

OBJECT RELATIONSHIPS

The following demonstrates how one might implement "containing" and "using" relationships between objects.

package Bar; sub new { my $self = {}; $self->{'buz'} = 42; bless $self; } package Foo; sub new { my $self = {}; $self->{'Bar'} = new Bar (); $self->{'biz'} = 11; bless $self; } package main; $a = new Foo; print "buz = ", $a->{'Bar'}->{'buz'}, "\n"; print "biz = ", $a->{'biz'}, "\n";

OVERRIDING SUPERCLASS METHODS

The following example demonstrates how one might override a superclass method and then call the method after it has been overridden. The Foo::Inherit class allows the programmer to call an overridden superclass method without actually knowing where that method is defined.

package Buz; sub goo { print "here's the goo\n" } package Bar; @ISA = qw(Buz); sub google { print "google here\n" } package Baz; sub mumble { print "mumbling\n" } package Foo; @ISA = qw(Bar Baz); @Foo::Inherit::ISA = @ISA; # Access to overridden methods. sub new { bless [] } sub grr { print "grumble\n" } sub goo { my $self = shift; $self->Foo::Inherit::goo(); } sub mumble { my $self = shift; $self->Foo::Inherit::mumble(); } sub google { my $self = shift; $self->Foo::Inherit::google(); } package main; $foo = new Foo; $foo->mumble; $foo->grr; $foo->goo; $foo->google;

USING RELATIONSHIP WITH SDBM

This example demonstrates an interface for the SDBM class. This creates a "using" relationship between the SDBM class and the new class Mydbm.

use SDBM_File; use POSIX; package Mydbm; sub TIEHASH { my $self = shift; my $ref = SDBM_File->new(@_); bless {'dbm' => $ref}; } sub FETCH { my $self = shift; my $ref = $self->{'dbm'}; $ref->FETCH(@_); } sub STORE { my $self = shift; if (defined $_[0]){ my $ref = $self->{'dbm'}; $ref->STORE(@_); } else { die "Cannot STORE an undefined key in Mydbm\n"; } } package main; tie %foo, Mydbm, "Sdbm", O_RDWR|O_CREAT, 0640; $foo{'bar'} = 123; print "foo-bar = $foo{'bar'}\n"; tie %bar, Mydbm, "Sdbm2", O_RDWR|O_CREAT, 0640; $bar{'Cathy'} = 456; print "bar-Cathy = $bar{'Cathy'}\n";

THINKING OF CODE REUSE

One strength of Object-Oriented languages is the ease with which old code can use new code. The following examples will demonstrate first how one can hinder code reuse and then how one can promote code reuse.

This first example illustrates a class which uses a fully-qualified method call to access the "private" method *BAZ()* . The second example will show that it is impossible to override the *BAZ()* method.

package FOO; sub new { bless {} } sub bar { my $self = shift; $self->FOO::private::BAZ; } package FOO::private; sub BAZ { print "in BAZ\n"; } package main; $a = FOO->new; $a->bar;

Now we try to override the *BAZ()* method. We would like FOO:: *bar()* to call GOOP:: *BAZ()* , but this cannot happen since FOO:: *bar()* explicitly calls FOO::private:: *BAZ()* .

package FOO; sub new { bless {} } sub bar { my $self = shift; $self->FOO::private::BAZ; } package FOO::private; sub BAZ { print "in BAZ\n"; } package GOOP; @ISA = qw(FOO); sub new { bless {} } sub BAZ { print "in GOOP::BAZ\n"; } package main; $a = GOOP->new; $a->bar;

To create reusable code we must modify class FOO, flattening class FOO::private. The next example shows a reusable class FOO which allows the method GOOP:: *BAZ()* to be used in place of FOO:: *BAZ()* .

package FOO; sub new { bless {} } sub bar { my $self = shift; $self->BAZ; } sub BAZ { print "in BAZ\n"; } package GOOP; @ISA = qw(FOO); sub new { bless {} } sub BAZ { print "in GOOP::BAZ\n"; } package main; $a = GOOP->new; $a->bar;

CLASS CONTEXT AND THE OBJECT

TOC

Use the object to solve package and class context problems. Everything a method needs should be available via the object or should be passed as a parameter to the method.

A class will sometimes have static or global data to be used by the methods. A subclass may want to override that data and replace it with new data. When this happens the superclass may not know how to find the new copy of the data.

This problem can be solved by using the object to define the context of the method. Let the method look in the object for a reference to the data. The alternative is to force the method to go hunting for the data ("Is it in my class, or in a subclass? Which subclass?"), and this can be inconvenient and will lead to hackery. It is better to just let the object tell the method where that data is located.

package Bar; %fizzle = ('Password' => 'XYZZY'); sub new { my $self = {}; $self->{'fizzle'} = \%fizzle; bless $self; } sub enter { my $self = shift; # Don't try to guess if we should use %Bar::fizzle # or %Foo::fizzle. The object already knows which # we should use, so just ask it. # my $fizzle = $self->{'fizzle'}; print "The word is ", $fizzle->{'Password'}, "\n"; } package Foo; @ISA = qw(Bar); %fizzle = ('Password' => 'Rumple'); sub new { my $self = Bar->new; $self->{'fizzle'} = \%fizzle; bless $self; } package main; $a = Bar->new; $b = Foo->new; $a->enter; $b->enter;

NAME

perldebug - Perl debugging

DESCRIPTION

First of all, have you tried using the **-w** switch?

Debugging

If you invoke Perl with a **-d** switch, your script will be run under the debugger. However, the Perl debugger is not a separate program as it is in a C environment. Instead, the **-d** flag tells the compiler to insert source information into the pseudocode it's about to hand to the interpreter. (That means your code must compile correctly for the debugger to work on it.) Then when the interpreter starts up, it pre-loads a Perl library file containing the debugger itself. The program will halt before the first executable statement (but see below) and ask you for one of the following commands:

h

Prints out a help message.

T

Stack trace. If you do bizarre things to your **@_** arguments in a subroutine, the stack backtrace will not always show the original values.

s

Single step. Executes until it reaches the beginning of another statement.

n

Next. Executes over subroutine calls, until it reaches the beginning of the next statement.

f

Finish. Executes statements until it has finished the current subroutine.

c

Continue. Executes until the next breakpoint is reached.

c line

Continue to the specified line. Inserts a one-time-only breakpoint at the specified line.

Repeat last n or s.

l min+incr

List incr+1 lines starting at min. If min is omitted, starts where last listing left off. If incr is omitted, previous value of incr is used.

l min-max

List lines in the indicated range.

l line

List just the indicated line.

l

List next window.

-

List previous window.

w line

List window (a few lines worth of code) around line.

l subname

List subroutine. If it's a long subroutine it just lists the beginning. Use "l" to list more.

/pattern/

Regular expression search forward in the source code for pattern; the final / is optional.

?pattern?

Regular expression search backward in the source code for pattern; the final ? is optional.

L

List lines that have breakpoints or actions.

S

Lists the names of all subroutines.

t

Toggle trace mode on or off.

b line [condition]

Set a breakpoint. If line is omitted, sets a breakpoint on the line that is about to be executed. If a condition is specified, it is evaluated each time the statement is reached and a breakpoint is taken only if the condition is true. Breakpoints may only be set on lines that begin an executable statement. Conditions don't use **if** :

b 237 $x > 30 b 33 /pattern/i

b subname [condition]

Set breakpoint at first executable line of subroutine.

d line

Delete breakpoint. If line is omitted, deletes the breakpoint on the line that is about to be executed.

D

Delete all breakpoints.

a line command

Set an action for line. A multiline command may be entered by backslashing the newlines. This command is Perl code, not another debugger command.

A

Delete all line actions.

< command

Set an action to happen before every debugger prompt. A multiline command may be entered by backslashing the newlines.

> command

Set an action to happen after the prompt when you've just given a command to return to executing the script. A multiline command may be entered by backslashing the newlines.

V package [symbols]

Display all (or some) variables in package (defaulting to the **main** package) using a data pretty-printer (hashes show their keys and values so you see what's what, control characters are made printable, etc.). Make sure you don't put the type specifier (like $) there, just the symbol names, like this:

V DB filename line

X [symbols]

Same as as "V" command, but within the current package.

! number

Redo a debugging command. If number is omitted, redoes the previous command.

! -number

Redo the command that was that many commands ago.

H -number

Display last n commands. Only commands longer than one character are listed. If number is omitted, lists them all.

q or ^D

Quit. ("quit" doesn't work for this.)

command

Execute command as a Perl statement. A missing semicolon will be supplied.

p expr

Same as **print DB::OUT expr** . The DB::OUT filehandle is opened to /dev/tty, regardless of where STDOUT may be redirected to.

Any command you type in that isn't recognized by the debugger will be.directly executed (**eval** 'd) as Perl code. Leading white space will cause the debugger to think it's **NOT** a debugger command.

If you have any compile-time executable statements (code within a BEGIN block or a **use** statement), these will *NOT* be stopped by debugger, although **require** s will. From your own code, however, you can transfer control back to the debugger using the following statement, which is harmless if the debugger is not running:

$DB::single = 1;

Customization

If you want to modify the debugger, copy *perl5db.pl* from the Perl library to another name and modify it as necessary. You'll also want to set environment variable PERL5DB to say something like this:

BEGIN { require "myperl5db.pl" }

You can do some customization by setting up a *.perldb* file which contains initialization code. For instance, you could make aliases like these (the last one in particular most people seem to expect to be there):

$DB::alias{'len'} = 's/^len(.*)/p length($1)/'; $DB::alias{'stop'} = 's/^stop (at|in)/b/'; $DB::alias{'.'} = 's/^\./p ' . '"\$DB::sub(\$DB::filename:\$DB::line):\t"' . ',\$DB::dbline[\$DB::line]/' ;

Other resources

You did try the **-w** switch, didn't you?

BUGS

If your program *exit()* s or *die()* s, so does the debugger.

There's no builtin way to restart the debugger without exiting and coming back into it. You could use an alias like this:

$DB::alias{'rerun'} = 'exec "perl -d $DB::filename"';

But you'd lose any pending breakpoint information, and that might not be the right path, etc.

NAME

perldiag - various Perl diagnostics

DESCRIPTION

These messages are classified as follows (listed in increasing order of desperation):

(W) A warning (optional). (D) A deprecation (optional). (S) A severe warning (mandatory). (F) A fatal error (trappable). (P) An internal error you should never see (trappable). (X) A very fatal error (non-trappable).

Optional warnings are enabled by using the **-w** switch. Warnings may be captured by setting **$^ Q** to a reference to a routine that will be called on each warning instead of printing it. See the *perlvar* manpage . Trappable errors may be trapped using the eval operator. See *eval* .

Some of these messages are generic. Spots that vary are denoted with a %s , just as in a printf format. Note that some message start with a %s ! The symbols **"%-?@** sort before the letters, while **[** and \ sort after.

"my" variable %s can't be in a package

(F) Lexically scoped variables aren't in a package, so it doesn't make sense to try to declare one with a package qualifier on the front. Use *local()* if you want to localize a package variable.

"no" not allowed in expression

(F) The "no" keyword is recognized and executed at compile time, and returns no useful value. See the *perlmod* manpage .

"use" not allowed in expression

(F) The "use" keyword is recognized and executed at compile time, and returns no useful value. See the *perlmod* manpage .

% may only be used in unpack

(F) You can't pack a string by supplying a checksum, since the checksumming process loses information, and you can't go the other way. See *unpack* .

%s (...) interpreted as function

(W) You've run afoul of the rule that says that any list operator followed by parentheses turns into a function, with all the list operators arguments found inside the parens. See *Terms and List Operators (Leftward)* .

%s argument is not a HASH element

(F) The argument to *delete()* or *exists()* must be a hash element, such as

$foo{$bar} $ref->[12]->{"susie"}

%s did not return a true value

(F) A required (or used) file must return a true value to indicate that it compiled correctly and ran its initialization code correctly. It's traditional to end such a file with a "1;", though any true value would do. See *require* .

%s found where operator expected

(S) The Perl lexer knows whether to expect a term or an operator. If it sees what it knows to be a term when it was expecting to see an operator, it gives you this warning. Usually it indicates that an operator or delimiter was omitted, such as a semicolon.

%s had compilation errors.

(F) The final summary message when a **perl -c** fails.

%s has too many errors.

(F) The parser has given up trying to parse the program after 10 errors. Further error messages would likely be uninformative.

%s matches null string many times

(W) The pattern you've specified would be an infinite loop if the regular expression engine didn't specifically check for that. See the *perlre* manpage .

%s never introduced

(S) The symbol in question was declared but somehow went out of scope before it could possibly have been used.

%s syntax OK

(F) The final summary message when a **perl -c** succeeds.

-P not allowed for setuid/setgid script

(F) The script would have to be opened by the C preprocessor by name, which provides a race condition that breaks security.

-T and -B not implemented on filehandles

(F) Perl can't peek at the stdio buffer of filehandles when it doesn't know about your kind of stdio. You'll have to use a filename instead.

?+* follows nothing in regexp

(F) You started a regular expression with a quantifier. Backslash it if you meant it literally. See the *perlre* manpage .

@ outside of string

(F) You had a pack template that specified an absolution position outside the string being unpacked. See *pack* .

accept() on closed fd

(W) You tried to do an accept on a closed socket. Did you forget to check the return value of your *socket()* call? See *accept* .

Allocation too large: %lx

(F) You can't allocate more than 64K on an MSDOS machine.

Arg too short for msgsnd

(F) *msgsnd()* requires a string at least as long as sizeof(long).

Ambiguous use of %s resolved as %s

(W)(S) You said something that may not be interpreted the way you thought. Normally it's pretty easy to disambiguate it by supplying a missing quote, operator, paren pair or declaration.

Args must match #! line

(F) The setuid emulator requires that the arguments Perl was invoked with match the arguments specified on the #! line.

Argument " %s " isn't numeric

(W) The indicated string was fed as an argument to an operator that expected a numeric value instead. If you're fortunate the message will identify which operator was so unfortunate.

Array @% s missing the @ in argument %d of %< EM> s()

(D) Really old Perl let you omit the **@** on array names in some spots. This is now heavily deprecated.

assertion botched: %s

(P) The malloc package that comes with Perl had an internal failure.

Assertion failed: file " %s "

(P) A general assertion failed. The file in question must be examined.

Assignment to both a list and a scalar

(F) If you assign to a conditional operator, the 2nd and 3rd arguments must either both be scalars or both be lists. Otherwise Perl won't know which context to supply to the right side.

Attempt to free non-arena SV: 0x %lx

(P) All SV objects are supposed to be allocated from arenas that will be garbage collected on exit. An SV was discovered to be outside any of those arenas.

Attempt to free temp prematurely

(W) Mortalized values are supposed to be freed by the *free_tmps()* routine. This indicates that something else is freeing the SV before the *free_tmps()* routine gets a chance, which means that the *free_tmps()* routine will be freeing an unreferenced scalar when it does try to free it.

Attempt to free unreferenced glob pointers

(P) The reference counts got screwed up on symbol aliases.

Attempt to free unreferenced scalar

(W) Perl went to decrement the reference count of a scalar to see if it would go to 0, and discovered that it had already gone to 0 earlier, and should have been freed, and in fact, probably was freed. This could indicate that *SvREFCNT_dec()* was called too many times, or that *SvREFCNT_inc()* was called too few times, or that the SV was mortalized when it shouldn't have been, or that memory has been corrupted.

Bad arg length for %s , is %d , should be %d

(F) You passed a buffer of the wrong size to one of *msgctl()* , *semctl()* or *shmctl()* . In C parlance, the correct sized are, respectively, S

Bad associative array

(P) One of the internal hash routines was passed a null HV pointer.

Bad filehandle: %s

(F) A symbol was passed to something wanting a filehandle, but the symbol has no filehandle associated with it. Perhaps you didn't do an *open()* , or did it in another package.

Bad *free()* ignored

(S) An internal routine called *free()* on something that had never been *malloc()* ed in the first place.

Bad name after %s::

(F) You started to name a symbol by using a package prefix, and then didn't finish the symbol. In particular, you can't interpolate outside of quotes, so

$var = 'myvar'; $sym = mypack::$var;

is not the same as

$var = 'myvar'; $sym = "mypack::$var";

Bad symbol for array

(P) An internal request asked to add an array entry to something that wasn't a symbol table entry.

Bad symbol for filehandle

(P) An internal request asked to add a filehandle entry to something that wasn't a symbol table entry.

Bad symbol for hash

(P) An internal request asked to add a hash entry to something that wasn't a symbol table entry.

BEGIN failed--compilation aborted

(F) An untrapped exception was raised while executing a BEGIN subroutine. Compilation stops immediately and the interpreter is exited.

bind() on closed fd

(W) You tried to do a bind on a closed socket. Did you forget to check the return value of your *socket()* call? See *bind* .

Callback called exit

(F) A subroutine invoked from an external package via *perl_call_sv()* exited by calling exit.

Can't "last" outside a block

(F) A "last" statement was executed to break out of the current block, except that there's this itty bitty problem called there isn't a current block. Note that an "if" or "else" block doesn't count as a "loopish" block. You can usually double the curlies to get the same effect though, since the inner curlies will be considered a block that loops once. See *last* .

Can't "next" outside a block

(F) A "next" statement was executed to reiterate the current block, but there isn't a current block. Note that an "if" or "else" block doesn't count as a "loopish" block. You can usually double the curlies to get the same effect though, since the inner curlies will be considered a block that loops once. See *last* .

Can't "redo" outside a block

(F) A "redo" statement was executed to restart the current block, but there isn't a current block. Note that an "if" or "else" block doesn't count as a "loopish" block. You can usually double the curlies to get the same effect though, since the inner curlies will be considered a block that loops once. See *last* .

Can't bless non-reference value

(F) Only hard references may be blessed. This is how Perl "enforces" encapsulation of objects. See the *perlobj* manpage .

Can't break at that line

(S) A warning intended for while running within the debugger, indicating the line number specified wasn't the location of a statement that could be stopped at.

Can't call method " %s " in empty package " %s "

(F) You called a method correctly, and it correctly indicated a package functioning as a class, but that package doesn't have ANYTHING defined in it, let alone methods. See the *perlobj* manpage .

Can't call method " %s " on unblessed reference

(F) A method call must know what package it's supposed to run in. It ordinarily finds this out from the object reference you supply, but you didn't supply an object reference in this case. A reference isn't an object reference until it has been blessed. See the *perlobj* manpage .

Can't call method " %s " without a package or object reference

(F) You used the syntax of a method call, but the slot filled by the object reference or package name contains an expression that returns neither an object reference nor a package name. (Perhaps it's null?) Something like this will reproduce the error:

$BADREF = undef; process $BADREF 1,2,3; $BADREF->process(1,2,3);

Can't chdir to %s

(F) You called **perl -x/foo/bar** , but **/foo/bar** is not a directory that you can chdir to, possibly because it doesn't exist.

Can't coerce %s to integer in %s

(F) Certain types of SVs, in particular real symbol table entries (type GLOB), can't be forced to stop being what they are. So you can't say things like:

*foo += 1;

You CAN say

$foo = *foo; $foo += 1;

but then **$foo** no longer contains a glob.

Can't coerce %s to number in %s

(F) Certain types of SVs, in particular real symbol table entries (type GLOB), can't be forced to stop being what they are.

Can't coerce %s to string in %s

(F) Certain types of SVs, in particular real symbol table entries (type GLOB), can't be forced to

stop being what they are.

Can't create pipe mailbox

(P) An error peculiar to VMS. The process is suffering from exhausted quotas or other plumbing problems.

Can't declare %s in my

(F) Only scalar, array and hash variables may be declared as lexical variables. They must have ordinary identifiers as names.

Can't do inplace edit on %s: %s

(S) The creation of the new file failed for the indicated reason.

Can't do inplace edit without backup

(F) You're on a system such as MSDOS that gets confused if you try reading from a deleted (but still opened) file. You have to say **-i .bak** , or some such.

Can't do inplace edit: %s > 14 characters

(S) There isn't enough room in the filename to make a backup name for the file.

Can't do inplace edit: %s is not a regular file

(S) You tried to use the **-i** switch on a special file, such as a file in /dev, or a FIFO. The file was ignored.

Can't do setegid!

(P) The setegid() call failed for some reason in the setuid emulator of suidperl.

Can't do seteuid!

(P) The setuid emulator of suidperl failed for some reason.

Can't do setuid

(F) This typically means that ordinary perl tried to exec suidperl to do setuid emulation, but couldn't exec it. It looks for a name of the form sperl5.000 in the same directory that the perl executable resides under the name perl5.000, typically /usr/local/bin on Unix machines. If the file is there, check the execute permissions. If it isn't, ask your sysadmin why he and/or she removed it.

Can't do waitpid with flags

(F) This machine doesn't have either *waitpid()* or *wait4()* , so only *waitpid()* without flags is emulated.

Can't do {n,m} with n > m

(F) Minima must be less than or equal to maxima. If you really want your regexp to match something 0 times, just put {0}. See the *perlre* manpage .

Can't emulate - %s on #! line

(F) The #! line specifies a switch that doesn't make sense at this point. For example, it'd be kind of silly to put a **-x** on the #! line.

Can't exec " %s ": %s

(W) An *system()* , *exec()* or piped open call could not execute the named program for the indicated reason. Typical reasons include: the permissions were wrong on the file, the file wasn't found in **$ENV {PATH}** , the executable in question was compiled for another architecture, or the #! line in

a script points to an interpreter that can't be run for similar reasons. (Or maybe your system doesn't support #! at all.)

Can't exec %s

(F) Perl was trying to execute the indicated program for you because that's what the #! line said. If that's not what you wanted, you may need to mention "perl" on the #! line somewhere.

Can't execute %s

(F) You used the **-S** switch, but the script to execute could not be found in the PATH, or at least not with the correct permissions.

Can't find label %s

(F) You said to goto a label that isn't mentioned anywhere that it's possible for us to go to. See *goto* .

Can't find string terminator %s anywhere before EOF

(F) Perl strings can stretch over multiple lines. This message means that the closing delimiter was omitted. Since bracketed quotes count nesting levels, the following is missing its final parenthesis:

print q(The character '(' starts a side comment.)

Can't fork

(F) A fatal error occurred while trying to fork while opening a pipeline.

Can't get filespec - stale stat buffer?

(S) A warning peculiar to VMS. This arises because of the difference between access checks under VMS and under the Unix model Perl assumes. Under VMS, access checks are done by filename, rather than by bits in the stat buffer, so that ACLs and other protections can be taken into account. Unfortunately, Perl assumes that the stat buffer contains all the necessary information, and passes it, instead of the filespec, to the access checking routine. It will try to retrieve the filespec using the device name and FID present in the stat buffer, but this works only if you haven't made a subsequent call to the CRTL *stat()* routine, since the device name is overwritten with each call. If this warning appears, the name lookup failed, and the access checking routine gave up and returned FALSE, just to be conservative. (Note: The access checking routine knows about the Perl **stat** operator and file tests, so you shouldn't ever see this warning in response to a Perl command; it arises only if some internal code takes stat buffers lightly.)

Can't get pipe mailbox device name

(P) An error peculiar to VMS. After creating a mailbox to act as a pipe, Perl can't retrieve its name for later use.

Can't get SYSGEN parameter value for MAXBUF

(P) An error peculiar to VMS. Perl asked **$GETSYI** how big you want your mailbox buffers to be, and didn't get an answer.

Can't goto subroutine outside a subroutine

(F) The deeply magical "goto subroutine" call can only replace one subroutine call for another. It can't manufacture one out of whole cloth. In general you should only be calling it out of an AUTOLOAD routine anyway. See *goto* .

Can't localize lexical variable %s

(F) You used local on a variable name that was previous declared as a lexical variable using "r This is not allowed. If you want to localize a package variable of the same name, qualify it wit the package name.

Can't locate %s in @INC

(F) You said to do (or require, or use) a file that couldn't be found in any of the libraries mentioned in **@INC** . Perhaps you need to set the PERL5LIB environment variable to say where the extra library is, or maybe the script needs to add the library name to **@INC** . Or maybe you just misspelled the name of the file. See *require* .

Can't locate object method " %s " via package " %s "

(F) You called a method correctly, and it correctly indicated a package functioning as a class, but that package doesn't define that particular method, nor does any of it's base classes. See the *perlobj* manpage .

Can't locate package %s for @% s::ISA

(W) The **@ISA** array contained the name of another package that doesn't seem to exist.

Can't *mktemp()*

(F) The *mktemp()* routine failed for some reason while trying to process a **-e** switch. Maybe your /tmp partition is full, or clobbered.

Can't modify %s in %s

(F) You aren't allowed to assign to the item indicated, or otherwise try to change it, such as with an autoincrement.

Can't modify non-existent substring

(P) The internal routine that does assignment to a substr() was handed a NULL.

Can't msgrcv to readonly var

(F) The target of a msgrcv must be modifiable in order to be used as a receive buffer.

Can't open %s: %s

(S) An inplace edit couldn't open the original file for the indicated reason. Usually this is because you don't have read permission for the file.

Can't open bidirectional pipe

(W) You tried to say **open(CMD, "|cmd|")** , which is not supported. You can try any of several modules in the Perl library to do this, such as "open2.pl". Alternately, direct the pipe's output to a file using ">", and then read it in under a different file handle.

Can't open error file %s as stderr

(F) An error peculiar to VMS. Perl does its own command line redirection, and couldn't open the file specified after '2>' or '>>' on the command line for writing.

Can't open input file %s as stdin

(F) An error peculiar to VMS. Perl does its own command line redirection, and couldn't open the file specified after <' on the command line for reading.

Can't open output file %s as stdout

(F) An error peculiar to VMS. Perl does its own command line redirection, and couldn't open the

file specified after '>' or >>' on the command line for writing.

Can't open output pipe (name: %s)

(P) An error peculiar to VMS. Perl does its own command line redirection, and couldn't open the pipe into which to send data destined for stdout.

Can't open perl script " %s ": %s

(F) The script you specified can't be opened for the indicated reason.

Can't rename %s to %s: %s , skipping file

(S) The rename done by the **-i** switch failed for some reason, probably because you don't have write permission to the directory.

Can't reopen input pipe (name: %s) in binary mode

(P) An error peculiar to VMS. Perl thought stdin was a pipe, and tried to reopen it to accept binary data. Alas, it failed.

Can't reswap uid and euid

(P) The *setreuid()* call failed for some reason in the setuid emulator of suidperl.

Can't return outside a subroutine

(F) The return statement was executed in mainline code, that is, where there was no subroutine call to return out of. See the *perlsub* manpage .

Can't stat script " %s "

(P) For some reason you can't *fstat()* the script even though you have it open already. Bizarre.

Can't swap uid and euid

(P) The *setreuid()* call failed for some reason in the setuid emulator of suidperl.

Can't take log of %g

(F) Logarithms are only defined on positive real numbers.

Can't take sqrt of %g

(F) For ordinary real numbers, you can't take the square root of a negative number. There's a Complex package available for Perl, though, if you really want to do that.

Can't undef active subroutine

(F) You can't undefine a routine that's currently running. You can, however, redefine it while it's running, and you can even undef the redefined subroutine while the old routine is running. Go figure.

Can't unshift

(F) You tried to unshift an "unreal" array that can't be unshifted, such as the main Perl stack.

Can't upgrade that kind of scalar

(P) The internal sv_upgrade routine adds "members" to an SV, making it into a more specialized kind of SV. The top several SV types are so specialized, however, that they cannot be interconverted. This message indicates that such a conversion was attempted.

Can't upgrade to undef

(P) The undefined SV is the bottom of the totem pole, in the scheme of upgradability. Upgrading to undef indicates an error in the code calling sv_upgrade.

Can't use %s for loop variable

(F) Only a simple scalar variable may be used as a loop variable on a foreach.

Can't use %s ref as %s ref

(F) You've mixed up your reference types. You have to dereference a reference of the type needed. You can use the *ref()* function to test the type of the reference, if need be.

Can't use \1 to mean $1 in expression

(W) In an ordinary expression, backslash is a unary operator that creates a reference to its argument. The use of backslash to indicate a backreference to a matched substring is only valid as part of a regular expression pattern. Trying to do this in ordinary Perl code produces a value that prints out looking like SCALAR(0xdecaf). Use the **$1** form instead.

Can't use string (" %s ") as %s ref while "strict refs" in use

(F) Only hard references are allowed by "strict refs". Symbolic references are disallowed. See the *perlref* manpage .

Can't use an undefined value as %s reference

(F) A value used as either a hard reference or a symbolic reference must be a defined value. This helps to de-lurk some insidious errors.

Can't use delimiter brackets within expression

(F) The **${** name} construct is for disambiguating identifiers in strings, not in ordinary code.

Can't use global %s in "my"

(F) You tried to declare a magical variable as a lexical variable. This is not allowed, because the magic can only be tied to one location (namely the global variable) and it would be incredibly confusing to have variables in your program that looked like magical variables but weren't.

Can't use subscript on %s

(F) The compiler tried to interpret a bracketed expression as a subscript. But to the left of the brackets was an expression that didn't look like an array reference, or anything else subscriptable.

Can't write to temp file for -e : %s

(F) The write routine failed for some reason while trying to process a **-e** switch. Maybe your /tmp partition is full, or clobbered.

Can't x= to readonly value

(F) You tried to repeat a constant value (often the undefined value) with an assignment operator, which implies modifying the value itself. Perhaps you need to copy the value to a temporary, and repeat that.

Cannot open temporary file

(F) The create routine failed for some reaon while trying to process a **-e** switch. Maybe your /tmp partition is full, or clobbered.

chmod: mode argument is missing initial 0

(W) A novice will sometimes say

chmod 777, $filename

not realizing that 777 will be interpreted as a decimal number, equivalent to 01411. Octal constants

are introduced with a leading 0 in Perl, as in C.

Close on unopened file< %s >

(W) You tried to close a filehandle that was never opened.

connect() on closed fd

(W) You tried to do a connect on a closed socket. Did you forget to check the return value of your *socket()* call? See *connect* .

Corrupt malloc ptr 0x %lx at 0x %lx

(P) The malloc package that comes with Perl had an internal failure.

corrupted regexp pointers

(P) The regular expression engine got confused by what the regular expression compiler gave it.

corrupted regexp program

(P) The regular expression engine got passed a regexp program without a valid magic number.

Deep recursion on subroutine " %s "

(W) This subroutine has called itself (directly or indirectly) 100 times than it has returned. This probably indicates an infinite recursion, unless you're writing strange benchmark programs, in which case it indicates something else.

Did you mean $ or @ instead of %?

(W) You probably said **%hash** { **$key** } when you meant **$hash** { **$key** } or **@hash** { **@keys** }. On the other hand, maybe you just meant **%hash** and got carried away.

Do you need to predeclare %s ?

(S) This is an educated guess made in conjunction with the message " %s found where operator expected". It often means a subroutine or module name is being referenced that hasn't been declared yet. This may be because of ordering problems in your file, or because of a missing "sub", "package", "require", or "use" statement. If you're referencing something that isn't defined yet, you don't actually have to define the subroutine or package before the current location. You can use an empty "sub foo;" or "package FOO;" to enter a "forward" declaration.

Don't know how to handle magic of type ' %s '

(P) The internal handling of magical variables has been cursed.

do_study: out of memory

(P) This should have been caught by *safemalloc()* instead.

Duplicate *free()* ignored

(S) An internal routine called *free()* on something that had already been freed.

END failed--cleanup aborted

(F) An untrapped exception was raised while executing an END subroutine. The interpreter is immediately exited.

Error converting file specification %s

(F) An error peculiar to VMS. Since Perl may have to deal with file specifications in either VMS or Unix syntax, it converts them to a single form when it must operate on them directly. Either you've passed an invalid file specification to Perl, or you've found a case the conversion routines

don't handle. Drat.

Execution of %s aborted due to compilation errors.

(F) The final summary message when a Perl compilation fails.

Exiting eval via %s

(W) You are exiting an eval by unconventional means, such as a a goto, or a loop control statement.

Exiting subroutine via %s

(W) You are exiting a subroutine by unconventional means, such as a a goto, or a loop control statement.

Exiting substitution via %s

(W) You are exiting a substitution by unconventional means, such as a a return, a goto, or a loop control statement.

Fatal VMS error at %s , line %d

(P) An error peculiar to VMS. Something untoward happened in a VMS system service or RTL routine; Perl's exit status should provide more details. The filename in "at %s " and the line number in "line **%d** " tell you which section of the Perl source code is distressed.

fcntl is not implemented

(F) Your machine apparently doesn't implement fcntl() . What is this, a PDP-11 or something?

Filehandle %s never opened

(W) An I/O operation was attempted on a filehandle that was never initialized. You need to do an *open()* or a *socket()* call, or call a constructor from the FileHandle package.

Filehandle %s opened only for input

(W) You tried to write on a read-only filehandle. If you intended it to be a read-write filehandle, you needed to open it with "<" or "+>" or ">>" instead of with <" or nothing. If you only intended to write the file, use ">" or >>". See *open* .

Filehandle only opened for input

(W) You tried to write on a read-only filehandle. If you intended it to be a read-write filehandle, you needed to open it with "<" or "+>" or ">>" instead of with <" or nothing. If you only intended to write the file, use ">" or >>". See *open* .

Final $ should be \ $ or $name

(F) You must now decide whether the final **$** in a string was meant to be a literal dollar sign, or was meant to introduce a variable name that happens to be missing. So you have to put either the backslash or the name.

Final @ should be \ @ or @name

(F) You must now decide whether the final **@** in a string was meant to be a literal "at" sign, or was meant to introduce a variable name that happens to be missing. So you have to put either the backslash or the name.

Format %s redefined

(W) You redefined a format. To suppress this warning, say

{ local $^W = 0; eval "format NAME =..."; }

Format not terminated

(F) A format must be terminated by a line with a solitary dot. Perl got to the end of your file without finding such a line.

Found = in conditional, should be ==

(W) You said

if ($foo = 123)

when you meant

if ($foo == 123)

(or something like that).

gdbm store returned %d , errno %d , key " %s "

(S) A warning from the GDBM_File extension that a store failed.

gethostent not implemented

(F) Your C library apparently doesn't implement gethostent() , probably because if it did, it'd feel morally obligated to return every hostname on the Internet.

get{sock,peer} *name()* on closed fd

(W) You tried to get a socket or peer socket name on a closed socket. Did you forget to check the return value of your *socket()* call?

getpwnam returned invalid UIC %# o for user " %s "

(S) A warning peculiar to VMS. The call to **sys $getuai** underlying the getpwnam operator returned an invalid UIC.

Glob not terminated

(F) The lexer saw a left angle bracket in a place where it was expecting a term, so it's looking for the corresponding right angle bracket, and not finding it. Chances are you left some needed parentheses out earlier in the line, and you really meant a "less than".

Global symbol " %s " requires explicit package name

(F) You've said "use strict vars", which indicates that all variables must either be lexically scoped (using "my"), or explicitly qualified to say which package the global variable is in (using "::").

goto must have label

(F) Unlike with "next" or "last", you're not allowed to goto an unspecified destination. See *goto* .

Had to create %s unexpectedly

(S) A routine asked for a symbol from a symbol table that ought to have existed already, but for some reason it didn't, and had to be created on an emergency basis to prevent a core dump.

Hash %% s missing the % in argument %d of %< EM> s()

(D) Really old Perl let you omit the **%** on hash names in some spots. This is now heavily deprecated.

Identifier " %s:: %s " used only once: possible typo

(W) Typographical errors often show up as unique identifiers. If you had a good reason for ha a unique identifier, then just mention it again somehow to suppress the message.

Illegal division by zero

(F) You tried to divide a number by 0. Either something was wrong in your logic, or you need to put a conditional in to guard against meaningless input.

Illegal modulus zero

(F) You tried to divide a number by 0 to get the remainder. Most numbers don't take to this kindly.

Illegal octal digit

(F) You used an 8 or 9 in a octal number.

Illegal octal digit ignored

(W) You may have tried to use an 8 or 9 in a octal number. Interpretation of the octal number stopped before the 8 or 9.

Insecure dependency in %s

(F) You tried to do something that the tainting mechanism didn't like. The tainting mechanism is turned on when you're running setuid or setgid, or when you specify -T to turn it on explicitly. The tainting mechanism labels all data that's derived directly or indirectly from the user, who is considered to be unworthy of your trust. If any such data is used in a "dangerous" operation, you get this error. See the *perlsec* manpage for more information.

Insecure directory in %s

(F) You can't use *system()* , *exec()* , or a piped open in a setuid or setgid script if **$ENV** {PATH} contains a directory that is writable by the world. See the *perlsec* manpage .

Insecure PATH

(F) You can't use *system()* , *exec()* , or a piped open in a setuid or setgid script if **$ENV** {PATH} is derived from data supplied (or potentially supplied) by the user. The script must set the path to a known value, using trustworthy data. See the *perlsec* manpage .

Internal inconsistency in tracking vforks

(S) A warning peculiar to VMS. Perl keeps track of the number of times you've called **fork** and **exec** , in order to determine whether the current call to **exec** should be affect the current script or a subprocess (see *exec*). Somehow, this count has become scrambled, so Perl is making a guess and treating this **exec** as a request to terminate the Perl script and execute the specified command.

internal disaster in regexp

(P) Something went badly wrong in the regular expression parser.

internal urp in regexp at / %s /

(P) Something went badly awry in the regular expression parser.

invalid [] range in regexp

(F) The range specified in a character class had a minimum character greater than the maximum character. See the *perlre* manpage .

ioctl is not implemented

(F) Your machine apparently doesn't implement ioctl() , which is pretty strange for a machine that

supports C.

junk on end of regexp

(P) The regular expression parser is confused.

Label not found for "last %s "

(F) You named a loop to break out of, but you're not currently in a loop of that name, not even if you count where you were called from. See *last* .

Label not found for "next %s "

(F) You named a loop to continue, but you're not currently in a loop of that name, not even if you count where you were called from. See *last* .

Label not found for "redo %s "

(F) You named a loop to restart, but you're not currently in a loop of that name, not even if you count where you were called from. See *last* .

listen() on closed fd

(W) You tried to do a listen on a closed socket. Did you forget to check the return value of your *socket()* call? See *listen* .

Literal @% s now requires backslash

(F) It used to be that Perl would try to guess whether you wanted an array interpolated or a literal @. It did this when the string was first used at runtime. Now strings are parsed at compile time, and ambiguous instances of **@** must be disambiguated, either by putting a backslash to indicate a literal, or by declaring (or using) the array within the program before the string (lexically). (Someday it will simply assume that an unbackslashed **@** interpolates an array.)

Method for operation %s not found in package %s during blessing

(F) An attempt was made to specify an entry in an overloading table that doesn't somehow point to a valid method. See the *perlovl* manpage .

Might be a runaway multi-line %s string starting on line %d

(S) An advisory indicating that the previous error may have been caused by a missing delimiter on a string or pattern, because it eventually ended earlier on the current line.

Misplaced _ in number

(W) An underline in a decimal constant wasn't on a 3-digit boundary.

Missing $ on loop variable

(F) Apparently you've been programming in csh too much. Variables are always mentioned with the **$** in Perl, unlike in the shells, where it can vary from one line to the next.

Missing comma after first argument to %s function

(F) While certain functions allow you to specify a filehandle or an "indirect object" before the argument list, this ain't one of them.

Missing operator before %s ?

(S) This is an educated guess made in conjunction with the message " %s found where operator expected". Often the missing operator is a comma.

Missing right bracket

(F) The lexer counted more opening curly brackets (braces) than closing ones. As a general rul you'll find it's missing near the place you were last editing.

Missing semicolon on previous line?

(S) This is an educated guess made in conjunction with the message " %s found where operator expected". Don't automatically put a semicolon on the previous line just because you saw this message.

Modification of a read-only value attempted

(F) You tried, directly or indirectly, to change the value of a constant. You didn't, of course, try "2 = 1", since the compiler catches that. But an easy way to do the same thing is:

sub mod { $_[0] = 1 } mod(2);

Another way is to assign to a substr() that's off the end of the string.

Modification of non-creatable array value attempted, subscript %d

(F) You tried to make an array value spring into existence, and the subscript was probably negative, even counting from end of the array backwards.

Modification of non-creatable hash value attempted, subscript " %s "

(F) You tried to make a hash value spring into existence, and it couldn't be created for some peculiar reason.

Module name must be constant

(F) Only a bare module name is allowed as the first argument to a "use".

msg %s not implemented

(F) You don't have System V message IPC on your system.

Multidimensional syntax %s not supported

(W) Multidimensional arrays aren't written like **$foo** [1,2,3]. They're written like **$foo** [1][2][3], as in C.

Negative length

(F) You tried to do a read/write/send/recv operation with a buffer length that is less than 0. This is difficult to imagine.

nested *?+ in regexp

(F) You can't quantify a quantifier without intervening parens. So things like ** or +* or ?* are illegal.

Note, however, that the minimal matching quantifiers, *?, +? and ?? appear to be nested quantifiers, but aren't. See the *perlre* manpage .

No #! line

(F) The setuid emulator requires that scripts have a well-formed #! line even on machines that don't support the #! construct.

No %s allowed while running setuid

(F) Certain operations are deemed to be too insecure for a setuid or setgid script to even be allowed to attempt. Generally speaking there will be another way to do what you want that is, if not secure,

at least securable. See the *perlsec* manpage .

No -e allowed in setuid scripts

(F) A setuid script can't be specified by the user.

No comma allowed after %s

(F) A list operator that has a filehandle or "indirect object" is not allowed to have a comma between that and the following arguments. Otherwise it'd be just another one of the arguments.

No command into which to pipe on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a '|' at the end of the command line, so it doesn't know whither you want to pipe the output from this command.

No DB::DB routine defined

(F) The currently executing code was compiled with the **-d** switch, but for some reason the perl5db.pl file (or some facsimile thereof) didn't define a routine to be called at the beginning of each statement. Which is odd, because the file should have been required automatically, and should have blown up the require if it didn't parse right.

No dbm on this machine

(P) This is counted as an internal error, because every machine should supply dbm nowadays, since Perl comes with SDBM. See *SDBM_File* .

No DBsub routine

(F) The currently executing code was compiled with the **-d** switch, but for some reason the perl5db.pl file (or some facsimile thereof) didn't define a DB::sub routine to be called at the beginning of each ordinary subroutine call.

No error file after 2> or >> on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a '2>' or a '>>' on the command line, but can't find the name of the file to which to write data destined for stderr.

No input file after< on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a <' on the command line, but can't find the name of the file from which to read data for stdin.

No output file after > on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a lone '>' at the end of the command line, so it doesn't know whither you wanted to redirect stdout.

No output file after > or>> on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a '>' or a >>' on the command line, but can't find the name of the file to which to write data destined for stdout.

No Perl script found in input

(F) You called **perl -x** , but no line was found in the file beginning with #! and containing the word "perl".

No setregid available

(F) Configure didn't find anything resembling the *setregid()* call for your system.

No setreuid available

(F) Configure didn't find anything resembling the *setreuid()* call for your system.

No space allowed after -I

(F) The argument to **-I** must follow the **-I** immediately with no intervening space.

No such pipe open

(P) An error peculiar to VMS. The internal routine *my_pclose()* tried to close a pipe which hadn't been opened. This should have been caught earlier as an attempt to close an unopened filehandle.

No such signal: SIG %s

(W) You specified a signal name as a subscript to **%SIG** that was not recognized. Say **kill -l** in your shell to see the valid signal names on your system.

Not a CODE reference

(F) Perl was trying to evaluate a reference to a code value (that is, a subroutine), but found a reference to something else instead. You can use the *ref()* function to find out what kind of ref it really was. See also the *perlref* manpage .

Not a format reference

(F) I'm not sure how you managed to generate a reference to an anonymous format, but this indicates you did, and that it didn't exist.

Not a GLOB reference

(F) Perl was trying to evaluate a reference to a "type glob" (that is, a symbol table entry that looks like ***foo**), but found a reference to something else instead. You can use the *ref()* function to find out what kind of ref it really was. See the *perlref* manpage .

Not a HASH reference

(F) Perl was trying to evaluate a reference to a hash value, but found a reference to something else instead. You can use the *ref()* function to find out what kind of ref it really was. See the *perlref* manpage .

Not a perl script

(F) The setuid emulator requires that scripts have a well-formed #! line even on machines that don't support the #! construct. The line must mention perl.

Not a SCALAR reference

(F) Perl was trying to evaluate a reference to a scalar value, but found a reference to something else instead. You can use the *ref()* function to find out what kind of ref it really was. See the *perlref* manpage .

Not a subroutine reference

(F) Perl was trying to evaluate a reference to a code value (that is, a subroutine), but found a reference to something else instead. You can use the *ref()* function to find out what kind of ref it really was. See also the *perlref* manpage .

Not a subroutine reference in %OVERLOAD

(F) An attempt was made to specify an entry in an overloading table that doesn't somehow point to

a valid subroutine. See the *perlovl* manpage .

Not an ARRAY reference

(F) Perl was trying to evaluate a reference to an array value, but found a reference to something else instead. You can use the *ref()* function to find out what kind of ref it really was. See the *perlref* manpage .

Not enough arguments for %s

(F) The function requires more arguments than you specified.

Not enough format arguments

(W) A format specified more picture fields than the next line supplied. See the *perlform* manpage .

Null filename used

(F) You can't require the null filename, especially since on many machines that means the current directory! See *require* .

NULL OP IN RUN

(P) Some internal routine called *run()* with a null opcode pointer.

Null realloc

(P) An attempt was made to realloc NULL.

NULL regexp argument

(P) The internal pattern matching routines blew it bigtime.

NULL regexp parameter

(P) The internal pattern matching routines are out of their gourd.

Odd number of elements in hash list

(S) You specified an odd number of elements to a hash list, which is odd, since hash lists come in key/value pairs.

oops: oopsAV

(S) An internal warning that the grammar is screwed up.

oops: oopsHV

(S) An internal warning that the grammar is screwed up.

Operation ` %s ' %s: no method found,

(F) An attempt was made to use an entry in an overloading table that somehow no longer points to a valid method. See the *perlovl* manpage .

Operator or semicolon missing before %s

(S) You used a variable or subroutine call where the parser was expecting an operator. The parser has assumed you really meant to use an operator, but this is highly likely to be incorrect. For example, if you say "*foo *foo" it will be interpreted as if you said "*foo * 'foo'".

Out of memory for yacc stack

(F) The yacc parser wanted to grow its stack so it could continue parsing, but *realloc()* wouldn't give it more memory, virtual or otherwise.

Out of memory!

(X) The *malloc()* function returned 0, indicating there was insufficient remaining memory (or virtual memory) to satisfy the request.

page overflow

(W) A single call to *write()* produced more lines than can fit on a page. See the *perlform* manpage .

panic: ck_grep

(P) Failed an internal consistency check trying to compile a grep.

panic: ck_split

(P) Failed an internal consistency check trying to compile a split.

panic: corrupt saved stack index

(P) The savestack was requested to restore more localized values than there are in the savestack.

panic: die %s

(P) We popped the context stack to an eval context, and then discovered it wasn't an eval context.

panic: do_match

(P) The internal *pp_match()* routine was called with invalid operational data.

panic: do_split

(P) Something terrible went wrong in setting up for the split.

panic: do_subst

(P) The internal *pp_subst()* routine was called with invalid operational data.

panic: do_trans

(P) The internal *do_trans()* routine was called with invalid operational data.

panic: goto

(P) We popped the context stack to a context with the specified label, and then discovered it wasn't a context we know how to do a goto in.

panic: INTERPCASEMOD

(P) The lexer got into a bad state at a case modifier.

panic: INTERPCONCAT

(P) The lexer got into a bad state parsing a string with brackets.

panic: last

(P) We popped the context stack to a block context, and then discovered it wasn't a block context.

panic: leave_scope clearsv

(P) A writable lexical variable became readonly somehow within the scope.

panic: leave_scope inconsistency

(P) The savestack probably got out of sync. At least, there was an invalid enum on the top of it.

panic: malloc

(P) Something requested a negative number of bytes of malloc.

panic: mapstart

(P) The compiler is screwed up with respect to the *map()* function.

panic: null array

(P) One of the internal array routines was passed a null AV pointer.

panic: pad_alloc

(P) The compiler got confused about which scratch pad it was allocating and freeing temporaries and lexicals from.

panic: pad_free curpad

(P) The compiler got confused about which scratch pad it was allocating and freeing temporaries and lexicals from.

panic: pad_free po

(P) An invalid scratch pad offset was detected internally.

panic: pad_reset curpad

(P) The compiler got confused about which scratch pad it was allocating and freeing temporaries and lexicals from.

panic: pad_sv po

(P) An invalid scratch pad offset was detected internally.

panic: pad_swipe curpad

(P) The compiler got confused about which scratch pad it was allocating and freeing temporaries and lexicals from.

panic: pad_swipe po

(P) An invalid scratch pad offset was detected internally.

panic: pp_iter

(P) The foreach iterator got called in a non-loop context frame.

panic: realloc

(P) Something requested a negative number of bytes of realloc.

panic: restartop

(P) Some internal routine requested a goto (or something like it), and didn't supply the destination.

panic: return

(P) We popped the context stack to a subroutine or eval context, and then discovered it wasn't a subroutine or eval context.

panic: scan_num

(P) *scan_num()* got called on something that wasn't a number.

panic: sv_insert

(P) The *sv_insert()* routine was told to remove more string than there was string.

panic: top_env

(P) The compiler attempted to do a goto, or something weird like that.

panic: yylex

(P) The lexer got into a bad state while processing a case modifier.

Parens missing around " %s " list

(W) You said something like

my $foo, $bar = @_;

when you meant

my ($foo, $bar) = @_;

Remember that "my" and "local" bind closer than comma.

Perl %3 .3f required--this is only version %s , stopped

(F) The module in question uses features of a version of Perl more recent than the currently running version. How long has it been since you upgraded, anyway? See *require* .

Permission denied

(F) The setuid emulator in suidperl decided you were up to no good.

pid %d not a child

(W) A warning peculiar to VMS. *Waitpid()* was asked to wait for a process which isn't a subprocess of the current process. While this is fine from VMS' perspective, it's probably not what you intended.

POSIX getpgrp can't take an argument

(F) Your C compiler uses POSIX *getpgrp()* , which takes no argument, unlike the BSD version, which takes a pid.

Possible memory corruption: %s overflowed 3rd argument

(F) An ioctl() or fcntl() returned more than Perl was bargaining for. Perl guesses a reasonable buffer size, but puts a sentinel byte at the end of the buffer just in case. This sentinel byte got clobbered, and Perl assumes that memory is now corrupted. See *ioctl* .

Precedence problem: open %s should be open(%s)

(S) The old irregular construct open FOO || die;

is now misinterpreted as

open(FOO || die);

because of the strict regularization of Perl 5's grammar into unary and list operators. (The old open was a little of both.) You must put parens around the filehandle, or use the new "or" operator instead of "||".

print on closed filehandle %s

(W) The filehandle you're printing on got itself closed sometime before now. Check your logic flow.

printf on closed filehandle %s

(W) The filehandle you're writing to got itself closed sometime before now. Check your logic flow.

Probable precedence problem on %s

(W) The compiler found a bare word where it expected a conditional, which often indicates that an

|| or && was parsed as part of the last argument of the previous construct, for example:

open FOO || die;

Read on closed filehandle< %s >

(W) The filehandle you're reading from got itself closed sometime before now. Check your logic flow.

Reallocation too large: %lx

(F) You can't allocate more than 64K on an MSDOS machine.

Recompile perl with -D DEBUGGING to use -D switch

(F) You can't use the **-D** option unless the code to produce the desired output is compiled into Perl, which entails some overhead, which is why it's currently left out of your copy.

Recursive inheritance detected

(F) More than 100 levels of inheritance were used. Probably indicates an unintended loop in your inheritance hierarchy.

Reference miscount in *sv_replace()*

(W) The internal *sv_replace()* function was handed a new SV with a reference count of other than 1.

regexp memory corruption

(P) The regular expression engine got confused by what the regular expression compiler gave it.

regexp out of space

(P) A "can't happen" error, because *safemalloc()* should have caught it earlier.

regexp too big

(F) The current implementation of regular expression uses shorts as address offsets within a string. Unfortunately this means that if the regular expression compiles to longer than 32767, it'll blow up. Usually when you want a regular expression this big, there is a better way to do it with multiple statements. See the *perlre* manpage .

Reversed %s = operator

(W) You wrote your assignment operator backwards. The = must always comes last, to avoid ambiguity with subsequent unary operators.

Runaway format

(F) Your format contained the ~~ repeat-until-blank sequence, but it produced 200 lines at once, and the 200th line looked exactly like the 199th line. Apparently you didn't arrange for the arguments to exhaust themselves, either by using ^ instead of @ (for scalar variables), or by shifting or popping (for array variables). See the *perlform* manpage .

Scalar value @% s[%s] better written as $% s[%s]

(W) You've used an array slice (indicated by @) to select a single value of an array. Generally it's better to ask for a scalar value (indicated by $). The difference is that **$foo** [&bar] always behaves like a scalar, both when assigning to it and when evaluating its argument, while **@foo** [&bar] behaves like a list when you assign to it, and provides a list context to its subscript, which can do weird things if you're only expecting one subscript.

On the other hand, if you were actually hoping to treat the array element as a list, you need to l
into how references work, since Perl will not magically convert between scalars and lists for y
See the *perlref* manpage .

Script is not setuid/setgid in suidperl

(F) Oddly, the suidperl program was invoked on a script with its setuid or setgid bit set. This doesn't make much sense.

Search pattern not terminated

(F) The lexer couldn't find the final delimiter of a // or m{} construct. Remember that bracketing delimiters count nesting level.

seek() on unopened file

(W) You tried to use the seek() function on a filehandle that was either never opened or has been closed since.

select not implemented

(F) This machine doesn't implement the select() system call.

sem %s not implemented

(F) You don't have System V semaphore IPC on your system.

semi-panic: attempt to dup freed string

(S) The internal *newSVsv()* routine was called to duplicate a scalar that had previously been marked as free.

Semicolon seems to be missing

(W) A nearby syntax error was probably caused by a missing semicolon, or possibly some other missing operator, such as a comma.

Send on closed socket

(W) The filehandle you're sending to got itself closed sometime before now. Check your logic flow.

Sequence (?#... not terminated

(F) A regular expression comment must be terminated by a closing parenthesis. Embedded parens aren't allowed. See the *perlre* manpage .

Sequence (? %s ...) not implemented

(F) A proposed regular expression extension has the character reserved but has not yet been written. See the *perlre* manpage .

Sequence (? %s ...) not recognized

(F) You used a regular expression extension that doesn't make sense. See the *perlre* manpage .

setegid() not implemented

(F) You tried to assign to $), and your operating system doesn't support the setegid() system call (or equivalent), or at least Configure didn't think so.

seteuid() not implemented

(F) You tried to assign to $>, and your operating system doesn't support the seteuid() system call (or equivalent), or at least Configure didn't think so.

setrgid() not implemented

(F) You tried to assign to $(, and your operating system doesn't support the setrgid() system call (or equivalent), or at least Configure didn't think so.

setruid() not implemented

(F) You tried to assign to <, and your operating system doesn't support the setruid() system call (or equivalent), or at least Configure didn't think so.

Setuid/gid script is writable by world

(F) The setuid emulator won't run a script that is writable by the world, because the world might have written on it already.

shm %s not implemented

(F) You don't have System V shared memory IPC on your system.

shutdown() on closed fd

(W) You tried to do a shutdown on a closed socket. Seems a bit superfluous.

SIG %s handler " %s " not defined.

(W) The signal handler named in **%SIG** doesn't, in fact, exist. Perhaps you put it into the wrong package?

sort is now a reserved word

(F) An ancient error message that almost nobody ever runs into anymore. But before sort was a keyword, people sometimes used it as a filehandle.

Sort subroutine didn't return a numeric value

(F) A sort comparison routine must return a number. You probably blew it by not using **<=> or C, or by not using them correctly. See *sort* .**

Sort subroutine didn't return single value

(F) A sort comparison subroutine may not return a list value with more or less than one element. See *sort* .

Split loop

(P) The split was looping infinitely. (Obviously, a split shouldn't iterate more times than there are characters of input, which is what happened.) See *split* .

Stat on unopened file< %s >

(W) You tried to use the *stat()* function (or an equivalent file test) on a filehandle that was either never opened or has been closed since.

Statement unlikely to be reached

(W) You did an *exec()* with some statement after it other than a *die()* . This is almost always an error, because *exec()* never returns unless there was a failure. You probably wanted to use *system()* instead, which does return. To suppress this warning, put the *exec()* in a block by itself.

Subroutine %s redefined

(W) You redefined a subroutine. To suppress this warning, say

{ local $^W = 0; eval "sub name { ... }"; }

Substitution loop

(P) The substitution was looping infinitely. (Obviously, a substitution shouldn't iterate more times than there are characters of input, which is what happened.) See the discussion of substitution in *Quote and Quotelike Operators* .

Substitution pattern not terminated

(F) The lexer couldn't find the interior delimiter of a s/// or s{}{} construct. Remember that bracketing delimiters count nesting level.

Substitution replacement not terminated

(F) The lexer couldn't find the final delimiter of a s/// or s{}{} construct. Remember that bracketing delimiters count nesting level.

substr outside of string

(W) You tried to reference a substr() that pointed outside of a string. That is, the absolute value of the offset was larger than the length of the string. See *substr* .

suidperl is no longer needed since...

(F) Your Perl was compiled with -D SETUID_SCRIPTS_ARE_SECURE_NOW, but a version of the setuid emulator somehow got run anyway.

syntax error

(F) Probably means you had a syntax error. Common reasons include:

A keyword is misspelled. A semicolon is missing. A comma is missing. An opening or closing parenthesis is missing. An opening or closing brace is missing. A closing quote is missing.

Often there will be another error message associated with the syntax error giving more information. (Sometimes it helps to turn on -w .) The error message itself often tells you where it was in the line when it decided to give up. Sometimes the actual error is several tokens before this, since Perl is good at understanding random input. Occasionally the line number may be misleading, and once in a blue moon the only way to figure out what's triggering the error is to call perl -c repeatedly, chopping away half the program each time to see if the error went away. Sort of the cybernetic version of S<20 questions>.

System V IPC is not implemented on this machine

(F) You tried to do something with a function beginning with "sem", "shm" or "msg". See *semctl* , for example.

Syswrite on closed filehandle

(W) The filehandle you're writing to got itself closed sometime before now. Check your logic flow.

tell() on unopened file

(W) You tried to use the tell() function on a filehandle that was either never opened or has been closed since.

Test on unopened file< %s >

(W) You tried to invoke a file test operator on a filehandle that isn't open. Check your logic.

See also -*X* .

That use of $[is unsupported

(F) Assignment to $[is now strictly circumscribed, and interpreted as a compiler directive. You may only say one of

$[= 0; $[= 1; ... local $[= 0; local $[= 1; ...

This is to prevent the problem of one module changing the array base out from under another module inadvertently. See *$[* .

The %s function is unimplemented

The function indicated isn't implemented on this architecture, according to the probings of Configure.

The *crypt()* function is unimplemented due to excessive paranoia.

(F) Configure couldn't find the *crypt()* function on your machine, probably because your vendor didn't supply it, probably because they think the U.S. Govermnment thinks it's a secret, or at least that they will continue to pretend that it is. And if you quote me on that, I will deny it.

The stat preceding -l _ wasn't an lstat

(F) It makes no sense to test the current stat buffer for symbolic linkhood if the last stat that wrote to the stat buffer already went past the symlink to get to the real file. Use an actual filename instead.

times not implemented

(F) Your version of the C library apparently doesn't do times() . I suspect you're not running on Unix.

Too few args to syscall

(F) There has to be at least one argument to *syscall()* to specify the system call to call, silly dilly.

Too many args to syscall

(F) Perl only supports a maximum of 14 args to *syscall()* .

Too many arguments for %s

(F) The function requires fewer arguments than you specified.

trailing \ in regexp

(F) The regular expression ends with an unbackslashed backslash. Backslash it. See the *perlre* manpage .

Translation pattern not terminated

(F) The lexer couldn't find the interior delimiter of a tr/// or tr[][] construct.

Translation replacement not terminated

(F) The lexer couldn't find the final delimiter of a tr/// or tr[][] construct.

truncate not implemented

(F) Your machine doesn't implement a file truncation mechanism that Configure knows

about.

Type of arg %d to %s must be %s (not %s)

(F) This function requires the argument in that position to be of a certain type. Arrays must be @NAME or @{ EXPR}. Hashes must be %NAME or %{ EXPR}. No implicit dereferencing is allowed--use the {EXPR} forms as an explicit dereference. See the *perlref* manpage .

umask: argument is missing initial 0

(W) A umask of 222 is incorrect. It should be 0222, since octal literals always start with 0 in Perl, as in C.

Unbalanced context: %d more PUSHes than POPs

(W) The exit code detected an internal inconsistency in how many execution contexts were entered and left.

Unbalanced saves: %d more saves than restores

(W) The exit code detected an internal inconsistency in how many values were temporarily localized.

Unbalanced scopes: %d more ENTERs than LEAVEs

(W) The exit code detected an internal inconsistency in how many blocks were entered and left.

Unbalanced tmps: %d more allocs than frees

(W) The exit code detected an internal inconsistency in how many mortal scalars were allocated and freed.

Undefined format " %s " called

(F) The format indicated doesn't seem to exist. Perhaps it's really in another package? See the *perlform* manpage .

Undefined sort subroutine " %s " called

(F) The sort comparison routine specified doesn't seem to exist. Perhaps it's in a different package? See *sort* .

Undefined subroutine & %s called

(F) The subroutine indicated hasn't been defined, or if it was, it has since been undefined.

Undefined subroutine called

(F) The anonymous subroutine you're trying to call hasn't been defined, or if it was, it has since been undefined.

Undefined subroutine in sort

(F) The sort comparison routine specified is declared but doesn't seem to have been defined yet. See *sort* .

unexec of %s into %s failed!

(F) The unexec() routine failed for some reason. See your local FSF representative, who probably put it there in the first place.

Unknown BYTEORDER

(F) There are no byteswapping functions for a machine with this byte order.

unmatched () in regexp

(F) Unbackslashed parentheses must always be balanced in regular expressions. If you're a vi user, the % key is valuable for finding the matching paren. See the *perlre* manpage .

Unmatched right bracket

(F) The lexer counted more closing curly brackets (braces) than opening ones, so you're probably missing an opening bracket. As a general rule, you'll find the missing one (so to speak) near the place you were last editing.

unmatched [] in regexp

(F) The brackets around a character class must match. If you wish to include a closing bracket in a character class, backslash it or put it first. See the *perlre* manpage .

Unquoted string " %s " may clash with future reserved word

(W) You used a bare word that might someday be claimed as a reserved word. It's best to put such a word in quotes, or capitalize it somehow, or insert an underbar into it. You might also declare it as a subroutine.

Unrecognized character \ %03o ignored

(S) A garbage character was found in the input, and ignored, in case it's a weird control character on an EBCDIC machine, or some such.

Unrecognized signal name " %s "

(F) You specified a signal name to the *kill()* function that was not recognized. Say kill -l in your shell to see the valid signal names on your system.

Unrecognized switch: - %s

(F) You specified an illegal option to Perl. Don't do that. (If you think you didn't do that, check the #! line to see if it's supplying the bad switch on your behalf.)

Unsuccessful %s on filename containing newline

(W) A file operation was attempted on a filename, and that operation failed, PROBABLY because the filename contained a newline, PROBABLY because you forgot to *chop()* or *chomp()* it off. See *chop* .

Unsupported directory function " %s " called

(F) Your machine doesn't support *opendir()* and *readdir()* .

Unsupported function %s

(F) This machines doesn't implement the indicated function, apparently. At least, Configure doesn't think so.

Unsupported socket function " %s " called

(F) Your machine doesn't support the Berkeley socket mechanism, or at least that's what Configure thought.

Unterminated<> operator

(F) The lexer saw a left angle bracket in a place where it was expecting a term, so it's looking for the corresponding right angle bracket, and not finding it. Chances are you left some needed parentheses out earlier in the line, and you really meant a "less than".

Use of $# is deprecated

(D) This was an ill-advised attempt to emulate a poorly defined awk feature. Use an explicit printf() or *sprintf()* instead.

Use of $* is deprecated

(D) This variable magically turned on multiline pattern matching, both for you and for any luckless subroutine that you happen to call. You should use the new //m and //s modifiers now to do that without the dangerous action-at-a-distance effects of $* .

Use of %s in printf format not supported

(F) You attempted to use a feature of printf that is accessible only from C. This usually means there's a better way to do it in Perl.

Use of %s is deprecated

(D) The construct indicated is no longer recommended for use, generally because there's a better way to do it, and also because the old way has bad side effects.

Use of implicit split to @_ is deprecated

(D) It makes a lot of work for the compiler when you clobber a subroutine's argument list, so it's better if you assign the results of a *split()* explicitly to an array (or list).

Use of uninitialized value

(W) An undefined value was used as if it were already defined. It was interpreted as a "" or a 0, but maybe it was a mistake. To suppress this warning assign an initial value to your variables.

Useless use of %s in void context

(W) You did something without a side effect in a context that does nothing with the return value, such as a statement that doesn't return a value from a block, or the left side of a scalar comma operator. Very often this points not to stupidity on your part, but a failure of Perl to parse your program the way you thought it would. For example, you'd get this if you mixed up your C precedence with Python precedence and said

$one, $two = 1, 2;

when you meant to say

($one, $two) = (1, 2);

Another common error is to use ordinary parentheses to construct a list reference when you should be using square or curly brackets, for example, if you say

$array = (1,2);

when you should have said

$array = [1,2];

The square brackets explicitly turn a list value into a scalar value, while parentheses do not. So when a parenthesized list is evaluated in a scalar context, the comma is treated like C's comma operator, which throws away the left argument, which is not what you want. See the

perlref manpage for more on this.

Warning: unable to close filehandle %s properly.

(S) The implicit _close()_ done by an _open()_ got an error indication on the close(0. This usually indicates your filesystem ran out of disk space.

Warning: Use of " %s " without parens is ambiguous

(S) You wrote a unary operator followed by something that looks like a binary operator that could also have been interpreted as a term or unary operator. For instance, if you know that the rand function has a default argument of 1.0, and you write

rand + 5;

you may THINK you wrote the same thing as

rand() + 5;

but in actual fact, you got

rand(+5);

So put in parens to say what you really mean.

Write on closed filehandle

(W) The filehandle you're writing to got itself closed sometime before now. Check your logic flow.

X outside of string

(F) You had a pack template that specified a relative position before the beginning of the string being unpacked. See _pack_ .

x outside of string

(F) You had a pack template that specified a relative position after the end of the string being unpacked. See _pack_ .

Xsub " %s " called in sort

(F) The use of an external subroutine as a sort comparison is not yet supported.

Xsub called in sort

(F) The use of an external subroutine as a sort comparison is not yet supported.

You can't use -l on a filehandle

(F) A filehandle represents an opened file, and when you opened the file it already went past any symlink you are presumably trying to look for. Use a filename instead.

YOU HAVEN'T DISABLED SET-ID SCRIPTS IN THE KERNEL YET!

(F) And you probably never will, since you probably don't have the sources to your kernel, and your vendor probably doesn't give a rip about what you want. Your best bet is to use the wrapsuid script in the eg directory to put a setuid C wrapper around your script.

You need to quote " %s "

(W) You assigned a bareword as a signal handler name. Unfortunately, you already have a subroutine of that name declared, which means that Perl 5 will try to call the subroutine

when the assignment is executed, which is probably not what you want. (If it IS what you want, put an & in front.)

[gs] *etsockopt()* on closed fd

(W) You tried to get or set a socket option on a closed socket. Did you forget to check the return value of your *socket()* call? See *getsockopt* .

\1 better written as $1

(W) Outside of patterns, backreferences live on as variables. The use of backslashes is grandfathered on the righthand side of a substitution, but stylistically it's better to use the variable form because other Perl programmers will expect it, and it works better if there are more than 9 backreferences.

'|' and <' may not both be specified on command line

(F) An error peculiar to VMS. Perl does its own command line redirection, and found that STDIN was a pipe, and that you also tried to redirect STDIN using <'. Only one STDIN stream to a customer, please.

'|' and '>' may not both be specified on command line

(F) An error peculiar to VMS. Perl does its own command line redirection, and thinks you tried to redirect stdout both to a file and into a pipe to another command. You need to choose one or the other, though nothing's stopping you from piping into a program or Perl script which 'splits' output into two streams, such as

open(OUT,">$ARGV[0]") or die "Can't write to $ARGV[0]: $!"; while (<STDIN>) { print; print OUT; } close OUT;

.

NAME

perlform - Perl formats

DESCRIPTION

Perl has a mechanism to help you generate simple reports and charts. To facilitate this, Perl helps you lay out your output page in your code in a fashion that's close to how it will look when it's printed. It can keep track of things like how many lines on a page, what page you're, when to print page headers, etc. Keywords are borrowed from FORTRAN: *format()* to declare and *write()* to execute; see their entries in the *perlfunc* manpage . Fortunately, the layout is much more legible, more like BASIC's PRINT USING statement. Think of it as a poor man's nroff(1).

Formats, like packages and subroutines, are declared rather than executed, so they may occur at any point in your program. (Usually it's best to keep them all together though.) They have their own namespace apart from all the other "types" in Perl. This means that if you have a function named "Foo", it is not the same thing as having a format named "Foo". However, the default name for the format associated with a given filehandle is the same as the name of the filehandle. Thus, the default format for STDOUT is name "STDOUT", and the default format for filehandle TEMP is name "TEMP". They just look the same. They aren't.

Output record formats are declared as follows:

format NAME = FORMLIST .

If name is omitted, format "STDOUT" is defined. FORMLIST consists of a sequence of lines, each of which may be of one of three types:

1. A comment, indicated by putting a '#' in the first column.
2. A "picture" line giving the format for one output line.
3. An argument line supplying values to plug into the previous picture line.

Picture lines are printed exactly as they look, except for certain fields.that substitute values into the line. Each field in a picture line starts with either "@" (at) or "^" (caret). These lines do not undergo any kind of variable interpolation. The at field (not to be confused with the array marker @) is the normal kind of field; the other kind, caret fields, are used to do rudimentary multi-line text block filling. The length of the field is supplied by padding out the field with multiple <", ">", or "|" characters to specify, respectively, left justification, right justification, or centering. If the variable would exceed the width specified, it is truncated.

As an alternate form of right justification, you may also use "#" characters (with an optional ".") to specify a numeric field. This way you can line up the decimal points. If any value supplied for these fields contains a newline, only the text up to the newline is printed. Finally, the special field "@*" can be

used for printing multi-line, non-truncated values; it should appear by itself on a line.

The values are specified on the following line in the same order as the picture fields. The expressions providing the values should be separated by commas. The expressions are all evaluated in a list context before the line is processed, so a single list expression could produce multiple list elements. The expressions may be spread out to more than one line if enclosed in braces. If so, the opening brace must be the first token on the first line.

Picture fields that begin with ^ rather than **@** are treated specially. With a # field, the field is blanked out if the value is undefined. For other field types, the caret enables a kind of fill mode. Instead of an arbitrary expression, the value supplied must be a scalar variable name that contains a text string. Perl puts as much text as it can into the field, and then chops off the front of the string so that the next time the variable is referenced, more of the text can be printed. (Yes, this means that the variable itself is altered during execution of the *write()* call, and is not returned.) Normally you would use a sequence of fields in a vertical stack to print out a block of text. You might wish to end the final field with the text "...", which will appear in the output if the text was too long to appear in its entirety. You can change which characters are legal to break on by changing the variable **$:** (that's **$FORMAT_LINE_BREAK_CHARACTERS** if you're using the English module) to a list of the desired characters.

Using caret fields can produce variable length records. If the text to be formatted is short, you can suppress blank lines by putting a "~" (tilde) character anywhere in the line. The tilde will be translated to a space upon output. If you put a second tilde contiguous to the first, the line will be repeated until all the fields on the line are exhausted. (If you use a field of the at variety, the expression you supply had better not give the same value every time forever!)

Top-of-form processing is by default handled by a format with the same name as the current filehandle with "_TOP" concatenated to it. It's triggered at the top of each page. See<perlfunc/ *write()* >.

Examples:

```
# a report on the /etc/passwd file
format STDOUT_TOP =
                        Passwd File
Name                Login    Office   Uid   Gid Home
------------------------------------------------------------------
.
format STDOUT =
@<<<<<<<<<<<<<<<<<< @||||||| @<<<<<<>>>> >>>> @<<<<<<<<<<<<<<<<<
 $name ,              $login ,   $office , $uid , $gid ,  $home
.
# a report from a bug report form
format STDOUT_TOP =
                        Bug Reports
@<<<<<<<<<<<<<<<<<<<<<<     @|||         >>>>>>>>>>>>>>>>
 $system ,                     $%,           $date
------------------------------------------------------------------
```

```
.
format STDOUT =
Subject: @<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<
          $subject
Index: @<<<<<<<<<<<<<<<<<<<<<<<<<<<< ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
        $index ,                        $description
Priority: @<<<<<<<<<< Date: @<<<<<<< ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
           $priority ,         $date ,    $description
From: @<<<<<<<<<<<<<<<<<<<<<<<<<<<<< ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
       $from ,                          $description
Assigned to: @<<<<<<<<<<<<<<<<<<<<<< ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
              $programmer ,             $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
                                      $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
                                      $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
                                      $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
                                      $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<...
                                      $description
.
```

It is possible to intermix *print()* s with *write()* s on the same output channel, but you'll have to handle $- (**$FORMAT_LINES_LEFT**) yourself.

Format Variables

The current format name is stored in the variable **$~** (**$FORMAT_NAME**), and the current top of form format name is in **$^** (**$FORMAT_TOP_NAME**). The current output page number is stored in **$%** (**$FORMAT_PAGE_NUMBER**), and the number of lines on the page is in **$=** (**$FORMAT_LINES_PER_PAGE**). Whether to autoflush output on this handle is stored in **$|** (**$OUTPUT_AUTOFLUSH**). The string output before each top of page (except the first) is stored in **$^ L** (**$FORMAT_FORMFEED**). These variables are set on a per-filehandle basis, so you'll need to *select()* into a different one to affect them:

select((select(OUTF), $~ = "My_Other_Format", $^ = "My_Top_Format")[0]);

Pretty ugly, eh? It's a common idiom though, so don't be too surprised when you see it. You can at least use a temporary variable to hold the previous filehandle: (this is a much better approach in general, because not only does legibility improve, you now have intermediary stage in the expression to single-step the debugger through):

$ofh = select(OUTF); $~ = "My_Other_Format"; $^ = "My_Top_Format"; select($ofh);

If you use the English module, you can even read the variable names:

use English; $ofh = select(OUTF); $FORMAT_NAME = "My_Other_Format"; $FORMAT_TOP_NAME = "My_Top_Format"; select($ofh);

But you still have those funny *select()* s. So just use the FileHandle module. Now, you can access these special variables using lower-case method names instead:

use FileHandle; format_name OUTF "My_Other_Format"; format_top_name OUTF "My_Top_Format";

Much better!

NOTES

Since the values line may contain arbitrary expressions (for at fields, not caret fields), you can farm out more sophisticated processing to other functions, like *sprintf()* or one of your own. For example:

```
    format Ident =
        @<<<<<<<<<<<<<<<
        &commify( $n )
    .
```

To get a real at or caret into the field, do this:

format Ident = I have an @ here. "@" .

To center a whole line of text, do something like this:

format Ident = @||||||||||||||||||||||||||||||||||||||| "Some text line" .

There is no builtin way to say "float this to the right hand side of the page, however wide it is." You have to specify where it goes. The truly desperate can generate their own format on the fly, based on the current number of columns, and then *eval()* it:

$format = "format STDOUT = \n"; . '^' . '<' x $cols . "\n"; . '$entry' . "\n"; . "\t^" . "<" x ($cols-8) . "~~\n"; . '$entry' . "\n"; . ".\n"; print $format if $Debugging; eval $format; die $@ if $@;

Which would generate a format looking something like this:

```
 format STDOUT =
^<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<
 $entry
        ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<~~
 $entry
 .
```

Here's a little program that's somewhat like fmt(1):

```
format =
^<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<< ~~
 $_
.
$/ = '';
while (<>) {
    s/\s*\n\s*/ /g;
    write;
}
```

Footers

While **$FORMAT_TOP_NAME** contains the name of the current header format, there is no corresponding mechanism to automatically do the same thing for a footer. Not knowing how big a format is going to be until you evaluate it is one of the major problems. It's on the TODO list.

Here's one strategy: If you have a fixed-size footer, you can get footers by checking **$FORMAT_LINES_LEFT** before each *write()* and print the footer yourself if necessary.

Here's another strategy; open a pipe to yourself, using **open(MESELF, "|-")** (see *open*) and always *write()* to MESELF instead of STDOUT. Have your child process postprocesses its STDIN to rearrange headers and footers however you like. Not very convenient, but doable.

Accessing Formatting Internals

For low-level access to the formatting mechanism. you may use *formline()* and access **$^ A** (the **$ACCUMULATOR** variable) directly.

For example:

```
 $str  = formline <<'END', 1,2,3;
@<<<  @|||  >>>
END
print "Wow, I just stored `$^A' in the accumulator!\n";
```

Or to make an *swrite()* subroutine which is to *write()* what *sprintf()* is to *printf()* , do this:

use Carp; sub swrite { croak "usage: swrite PICTURE ARGS" unless @_; my $format = shift; $^A = ""; formline($format,@_); return $^A; }

```
$string  = swrite(<<'END', 1, 2, 3);
```

```
Check me out
@<<<  @|||  >>>
END
   print  $string ;
```

TOC

WARNING

Lexical variables (declared with "my") are not visible within a format unless the format is declared within the scope of the lexical variable. (They weren't visiblie at all before version 5.001.)

TOC

NAME

perlipc - Perl interprocess communication

DESCRIPTION

The IPC facilities of Perl are built on the Berkeley socket mechanism. If you don't have sockets, you can ignore this section. The calls have the same names as the corresponding system calls, but the arguments tend to differ, for two reasons. First, Perl file handles work differently than C file descriptors. Second, Perl already knows the length of its strings, so you don't need to pass that information.

Client/Server Communication

Here's a sample TCP client.

($them,$port) = @ARGV; $port = 2345 unless $port; $them = 'localhost' unless $them; $SIG{'INT'} = 'dokill'; sub dokill { kill 9,$child if $child; } use Socket; $sockaddr = 'S n a4 x8'; chop($hostname = `hostname`); ($name, $aliases, $proto) = getprotobyname('tcp'); ($name, $aliases, $port) = getservbyname($port, 'tcp') unless $port =~ /^\d+$/; ($name, $aliases, $type, $len, $thisaddr) = gethostbyname($hostname); ($name, $aliases, $type, $len, $thataddr) = gethostbyname($them); $this = pack($sockaddr, AF_INET, 0, $thisaddr); $that = pack($sockaddr, AF_INET, $port, $thataddr); socket(S, PF_INET, SOCK_STREAM, $proto) || die "socket: $!"; bind(S, $this) || die "bind: $!"; connect(S, $that) || die "connect: $!"; select(S); $| = 1; select(stdout); if ($child = fork) { while (<>) { print S; } sleep 3; do dokill(); } else { while (<S>) { print; } }

And here's a server:

($port) = @ARGV; $port = 2345 unless $port; use Socket; $sockaddr = 'S n a4 x8'; ($name, $aliases, $proto) = getprotobyname('tcp'); ($name, $aliases, $port) = getservbyname($port, 'tcp') unless $port =~ /^\d+$/; $this = pack($sockaddr, AF_INET, $port, "\0\0\0\0"); select(NS); $| = 1; select(stdout); socket(S, PF_INET, SOCK_STREAM, $proto) || die "socket: $!"; bind(S, $this) || die "bind: $!"; listen(S, 5) || die "connect: $!"; select(S); $| = 1; select(stdout); for (;;) { print "Listening again\n"; ($addr = accept(NS,S)) || die $!; print "accept ok\n"; ($af,$port,$inetaddr) = unpack($sockaddr,$addr); @inetaddr = unpack('C4',$inetaddr); print "$af $port @inetaddr\n"; while (<NS>) { print; print NS; } }

SysV IPC

Here's a small example showing shared memory usage:

$IPC_PRIVATE = 0; $IPC_RMID = 0; $size = 2000; $key = shmget($IPC_PRIVATE, $size , 0777);

die if !defined($key); $message = "Message #1"; shmwrite($key, $message, 0, 60) || die "$!"; shmread($key,$buff,0,60) || die "$!"; print $buff,"\n"; print "deleting $key\n"; shmctl($key ,$IPC_RMID, 0) || die "$!";

Here's an example of a semaphore:

$IPC_KEY = 1234; $IPC_RMID = 0; $IPC_CREATE = 0001000; $key = semget($IPC_KEY, $nsems , 0666 | $IPC_CREATE); die if !defined($key); print "$key\n";

Put this code in a separate file to be run in more that one process Call the file *take* :

create a semaphore $IPC_KEY = 1234; $key = semget($IPC_KEY, 0 , 0); die if !defined($key); $semnum = 0; $semflag = 0; # 'take' semaphore # wait for semaphore to be zero $semop = 0; $opstring1 = pack("sss", $semnum, $semop, $semflag); # Increment the semaphore count $semop = 1; $opstring2 = pack("sss", $semnum, $semop, $semflag); $opstring = $opstring1 . $opstring2; semop($key,$opstring) || die "$!";

Put this code in a separate file to be run in more that one process Call this file *give* :

#'give' the semaphore # run this in the original process and you will see # that the second process continues $IPC_KEY = 1234; $key = semget($IPC_KEY, 0, 0); die if !defined($key); $semnum = 0; $semflag = 0; # Decrement the semaphore count $semop = -1; $opstring = pack("sss", $semnum, $semop, $semflag); semop($key,$opstring) || die "$!";

NAME

perlsec - Perl security

DESCRIPTION

Perl is designed to make it easy to write secure setuid and setgid scripts. Unlike shells, which are based on multiple substitution passes on each line of the script, Perl uses a more conventional evaluation scheme with fewer hidden "gotchas". Additionally, since the language has more built-in functionality, it has to rely less upon external (and possibly untrustworthy) programs to accomplish its purposes.

Beyond the obvious problems that stem from giving special privileges to such flexible systems as scripts, on many operating systems, setuid scripts are inherently insecure right from the start. This is because that between the time that the kernel opens up the file to see what to run, and when the now setuid interpreter it ran turns around and reopens the file so it can interpret it, things may have changed, especially if you have symbolic links on your system.

Fortunately, sometimes this kernel "feature" can be disabled. Unfortunately, there are two ways to disable it. The system can simply outlaw scripts with the setuid bit set, which doesn't help much. Alternately, it can simply ignore the setuid bit on scripts. If the latter is true, Perl can emulate the setuid and setgid mechanism when it notices the otherwise useless setuid/gid bits on Perl scripts. It does this via a special executable called **suidperl** that is automatically invoked for you if it's needed.

If, however, the kernel setuid script feature isn't disabled, Perl will complain loudly that your setuid script is insecure. You'll need to either disable the kernel setuid script feature, or put a C wrapper around the script. See the program **wrapsuid** in the *eg* directory of your Perl distribution for how to go about doing this.

There are some systems on which setuid scripts are free of this inherent security bug. For example, recent releases of Solaris are like this. On such systems, when the kernel passes the name of the setuid script to open to the interpreter, rather than using a pathname subject to mettling, it instead passes /dev/fd/3. This is a special file already opened on the script, so that there can be no race condition for evil scripts to exploit. On these systems, Perl should be compiled with **-DSETUID_SCRIPTS_ARE_SECURE_NOW** . The **Configure** program that builds Perl tries to figure this out for itself.

When Perl is executing a setuid script, it takes special precautions to prevent you from falling into any obvious traps. (In some ways, a Perl script is more secure than the corresponding C program.) Any command line argument, environment variable, or input is marked as "tainted", and may not be used, directly or indirectly, in any command that invokes a subshell, or in any command that modifies files, directories, or processes. Any variable that is set within an expression that has previously referenced a tainted value also becomes tainted (even if it is logically impossible for the tainted value to influence the

TOC

variable). For example:

$foo = shift; # $foo is tainted $bar = $foo,'bar'; # $bar is also tainted $xxx = <>; # Tainted $path = $ENV{'PATH'}; # Tainted, but see below $abc = 'abc'; # Not tainted system "echo $foo"; # Insecure system "/bin/echo", $foo; # Secure (doesn't use sh) system "echo $bar"; # Insecure system "echo $abc"; # Insecure until PATH set $ENV{'PATH'} = '/bin:/usr/bin'; $ENV{'IFS'} = " if $ENV{'IFS'} ne "; $path = $ENV{'PATH'}; # Not tainted system "echo $abc"; # Is secure now! open(FOO,"$foo"); # OK open(FOO,">$foo"); # Not OK open(FOO,"echo $foo|"); # Not OK, but... open(FOO,"-|") || exec 'echo', $foo; # OK $zzz = `echo $foo`; # Insecure, zzz tainted unlink $abc,$foo; # Insecure umask $foo; # Insecure exec "echo $foo"; # Insecure exec "echo", $foo; # Secure (doesn't use sh) exec "sh", '-c', $foo; # Considered secure, alas

The taintedness is associated with each scalar value, so some elements of an array can be tainted, and others not.

If you try to do something insecure, you will get a fatal error saying something like "Insecure dependency" or "Insecure PATH". Note that you can still write an insecure system call or exec, but only by explicitly doing something like the last example above. You can also bypass the tainting mechanism by referencing subpatterns--Perl presumes that if you reference a substring using **$1** , **$2** , etc, you knew what you were doing when you wrote the pattern:

$ARGV[0] =~ /^-P(\w+)$/; $printer = $1; # Not tainted

This is fairly secure since **\w+** doesn't match shell metacharacters. Use of **/.+/** would have been insecure, but Perl doesn't check for that, so you must be careful with your patterns. This is the *ONLY* mechanism for untainting user supplied filenames if you want to do file operations on them (unless you make **$& gt;** equal to **$& lt;**).

For "Insecure **$ENV** {PATH}" messages, you need to set **$ENV {'PATH'}** to a known value, and each directory in the path must be non-writable by the world. A frequently voiced gripe is that you can get this message even if the pathname to an executable is fully qualified. But Perl can't know that the executable in question isn't going to execute some other program depending on the PATH.

It's also possible to get into trouble with other operations that don't care whether they use tainted values. Make judicious use of the file tests in dealing with any user-supplied filenames. When possible, do opens and such after setting **$& gt; = $& lt;** . (Remember group IDs, too!) Perl doesn't prevent you from opening tainted filenames for reading, so be careful what you print out. The tainting mechanism is intended to prevent stupid mistakes, not to remove the need for thought.

TOC

NAME

perltrap - Perl traps for the unwary

DESCRIPTION

The biggest trap of all is forgetting to use the **-w** switch; see the *perlrun* manpage . Making your entire program runnable under

use strict;

can help make your program more bullet-proof, but sometimes it's too annoying for quick throw-away programs.

Awk Traps

Accustomed **awk** users should take special note of the following:

- * The English module, loaded via

  use English;

  allows you to refer to special variables (like **$RS**) as though they were in **awk** ; see the *perlvar* manpage for details.
- * Semicolons are required after all simple statements in Perl (except at the end of a block). Newline is not a statement delimiter.
- * Curly brackets are required on **if** s and **while** s.
- * Variables begin with "$" or "@" in Perl.
- * Arrays index from 0. Likewise string positions in *substr()* and *index()* .
- * You have to decide whether your array has numeric or string indices.
- * Associative array values do not spring into existence upon mere reference.
- * You have to decide whether you want to use string or numeric comparisons.
- * Reading an input line does not split it for you. You get to split it yourself to an array. And *split()* operator has different arguments.
- * The current input line is normally in **$_** , not **$0** . It generally does not have the newline stripped. (**$0** is the name of the program executed.) See the *perlvar* manpage .
- * < *digit* > does not refer to fields--it refers to substrings matched by the last match pattern.
- * The *print()* statement does not add field and record separators unless you set **$,** and **$.** . You can set **$OFS** and **$ORS** if you're using the English module.

- * You must open your files before you print to them.
- * The range operator is "..", not comma. The comma operator works as in C.
- * The match operator is "=~", not "~". ("~" is the one's complement operator, as in C.)
- * The exponentiation operator is "**", not "^". "^" is the XOR operator, as in C. (You know, one could get the feeling that **awk** is basically incompatible with C.)
- * The concatenation operator is ".", not the null string. (Using the null string would render **/pat/ /pat/** unparsable, since the third slash would be interpreted as a division operator--the tokener is in fact slightly context sensitive for operators like "/", "?", and ">". And in fact, "." itself can be the beginning of a number.)
- * The **next** , **exit** , and **continue** keywords work differently.
- *

  The following variables work differently:

  - Awk Perl
  - ARGC $#ARGV or scalar @ARGV
  - ARGV[0] $0
  - FILENAME $ARGV
  - FNR $. - something
  - FS (whatever you like)
  - NF $#Fld, or some such
  - NR $.
  - OFMT $#
  - OFS $,
  - ORS $\
  - RLENGTH length($&)
  - RS $/
  - RSTART length($`)
  - SUBSEP $;
- * You cannot set **$RS** to a pattern, only a string.
- * When in doubt, run the **awk** construct through **a2p** and see what it gives you.

.

C Traps

Cerebral C programmers should take note of the following:

- * Curly brackets are required on **if** 's and **while** 's.
- * You must use **elsif** rather than **else if** .
- * The **break** and **continue** keywords from C become in Perl **last** and **next** , respectively. Unlike in C, these do *NOT* work within a **do { } while** construct.

- * There's no switch statement. (But it's easy to build one on the fly.)
- * Variables begin with "$" or "@" in Perl.
- * *printf()* does not implement the "*" format for interpolating field widths, but it's trivial to use interpolation of double-quoted strings to achieve the same effect.
- * Comments begin with "#", not "/*".
- * You can't take the address of anything, although a similar operator in Perl 5 is the backslash, which creates a reference.
- * **ARGV** must be capitalized.
- * System calls such as *link()* , *unlink()* , *rename()* , etc. return nonzero for success, not 0.
- * Signal handlers deal with signal names, not numbers. Use **kill -l** to find their names on your system.

.

Sed Traps

Seasoned **sed** programmers should take note of the following:

- * Backreferences in substitutions use "$" rather than "\".
- * The pattern matching metacharacters "(", ")", and "|" do not have backslashes in front.
- * The range operator is **...** , rather than comma.

.

Shell Traps

Sharp shell programmers should take note of the following:

- * The backtick operator does variable interpretation without regard to the presence of single quotes in the command.
- * The backtick operator does no translation of the return value, unlike **csh** .
- * Shells (especially **csh**) do several levels of substitution on each command line. Perl does substitution only in certain constructs such as double quotes, backticks, angle brackets, and search patterns.
- * Shells interpret scripts a little bit at a time. Perl compiles the entire program before executing it (except for **BEGIN** blocks, which execute at compile time).
- * The arguments are available via **@ARGV** , not **$1** , **$2** , etc.
- * The environment is not automatically made available as separate scalar variables.

.

Perl Traps

Practicing Perl Programmers should take note of the following:

- * Remember that many operations behave differently in a list context than they do in a scalar one. See the *perldata* manpage for details.
- * Avoid barewords if you can, especially all lower-case ones. You can't tell just by looking at it whether a bareword is a function or a string. By using quotes on strings and parens on function calls, you won't ever get them confused.
- * You cannot discern from mere inspection which built-ins are unary operators (like *chop()* and *chdir()*) and which are list operators (like *print()* and *unlink()*). (User-defined subroutines can **only** be list operators, never unary ones.) See the *perlop* manpage .
- * People have a hard time remembering that some functions default to **$_** , or **@ARGV** , or whatever, but that others which you might expect to do not.
- * The<FH> construct is not the name of the filehandle, it is a readline operation on that handle. The data read is only assigned to **$_** if the file read is the sole condition in a while loop:

  while (<FH>) { } while ($_ = <FH>) { }.. <FH>; # data discarded!
- * Remember not to use " = " when you need " =~ "; these two constructs are quite different:

  $x = /foo/; $x =~ /foo/;
- * The **do {}** construct isn't a real loop that you can use loop control on.
- * Use *my()* for local variables whenever you can get away with it (but see the *perlform* manpage for where you can't). Using *local()* actually gives a local value to a global variable, which leaves you open to unforeseen side-effects of dynamic scoping.

.

Perl4 Traps

Penitent Perl 4 Programmers should take note of the following incompatible changes that occurred between release 4 and release 5:

- * **@** now always interpolates an array in double-quotish strings. Some programs may now need to use backslash to protect any **@** that shouldn't interpolate.
- * Barewords that used to look like strings to Perl will now look like subroutine calls if a subroutine by that name is defined before the compiler sees them. For example:

  sub SeeYa { die "Hasta la vista, baby!" } $SIG{'QUIT'} = SeeYa;

  In Perl 4, that set the signal handler; in Perl 5, it actually calls the function! You may use the **-w** switch to find such places.
- * Symbols starting with **_** are no longer forced into package **main** , except for **$_** itself (and **@_** , etc.).
- * **s' $lhs ' $rhs '** now does no interpolation on either side. It used to interpolate **$lhs** but not **$rhs** .

- * The second and third arguments of *splice()* are now evaluated in scalar context (as the book s rather than list context.
- * These are now semantic errors because of precedence:

  shift @list + 20; $n = keys %map + 20;

  Because if that were to work, then this couldn't:

  sleep $dormancy + 20;
- * **open FOO || die** is now incorrect. You need parens around the filehandle. While temporarily supported, using such a construct will generate a non-fatal (but non-suppressible) warning.
- * The elements of argument lists for formats are now evaluated in list context. This means you can interpolate list values now.
- * You can't do a **goto** into a block that is optimized away. Darn.
- * It is no longer syntactically legal to use whitespace as the name of a variable, or as a delimiter for any kind of quote construct. Double darn.
- * The *caller()* function now returns a false value in a scalar context if there is no caller. This lets library files determine if they're being required.
- * **m//g** now attaches its state to the searched string rather than the regular expression.
- * **reverse** is no longer allowed as the name of a sort subroutine.
- * **taintperl** is no longer a separate executable. There is now a **-T** switch to turn on tainting when it isn't turned on automatically.
- * Double-quoted strings may no longer end with an unescaped **$** or **@** .
- * The archaic **while/if** BLOCK BLOCK syntax is no longer supported.
- * Negative array subscripts now count from the end of the array.
- * The comma operator in a scalar context is now guaranteed to give a scalar context to its arguments.
- * The ****** operator now binds more tightly than unary minus. It was documented to work this way before, but didn't.
- * Setting **$# array** lower now discards array elements.
- * *delete()* is not guaranteed to return the old value for *tie()* d arrays, since this capability may be onerous for some modules to implement.
- * The construct "this is **$$** x" used to interpolate the pid at that point, but now tries to dereference **$x** . **$$** by itself still works fine, however.
- * Some error messages will be different.
- * Some bugs may have been inadvertently removed.

.

NAME

perlstyle - Perl style guide

DESCRIPTION

Style

Each programmer will, of course, have his or her own preferences in regards to formatting, but there are some general guidelines that will make your programs easier to read, understand, and maintain.

Regarding aesthetics of code lay out, about the only thing Larry cares strongly about is that the closing curly brace of a multi-line BLOCK should line up with the keyword that started the construct. Beyond that, he has other preferences that aren't so strong:

- * 4-column indent.
- * Opening curly on same line as keyword, if possible, otherwise line up.
- * Space before the opening curly of a multiline BLOCK.
- * One-line BLOCK may be put on one line, including curlies.
- * No space before the semicolon.
- * Semicolon omitted in "short" one-line BLOCK.
- * Space around most operators.
- * Space around a "complex" subscript (inside brackets).
- * Blank lines between chunks that do different things.
- * Uncuddled elses.
- * No space between function name and its opening paren.
- * Space after each comma.
- * Long lines broken after an operator (except "and" and "or").
- * Space after last paren matching on current line.
- * Line up corresponding items vertically.
- * Omit redundant punctuation as long as clarity doesn't suffer.

Larry has his reasons for each of these things, but he doen't claim that.everyone else's mind works the same as his does.

Here are some other more substantive style issues to think about:

- * Just because you *CAN* do something a particular way doesn't mean that you *SHOULD* do it that way. Perl is designed to give you several ways to do anything, so consider picking the most

readable one. For instance

open(FOO,$foo) || die "Can't open $foo: $!";

is better than

die "Can't open $foo: $!" unless open(FOO,$foo);

because the second way hides the main point of the statement in a modifier. On the other hand

print "Starting analysis\n" if $verbose;

is better than

$verbose && print "Starting analysis\n";

since the main point isn't whether the user typed **-v** or not.

Similarly, just because an operator lets you assume default arguments doesn't mean that you have to make use of the defaults. The defaults are there for lazy systems programmers writing one-shot programs. If you want your program to be readable, consider supplying the argument.

Along the same lines, just because you *CAN* omit parentheses in many places doesn't mean that you ought to:

return print reverse sort num values %array; return print(reverse(sort num (values(%array))));

When in doubt, parenthesize. At the very least it will let some poor schmuck bounce on the **%** key in **vi** .

Even if you aren't in doubt, consider the mental welfare of the person who has to maintain the code after you, and who will probably put parens in the wrong place.

- * Don't go through silly contortions to exit a loop at the top or the bottom, when Perl provides the **last** operator so you can exit in the middle. Just "outdent" it a little to make it more visible:

  LINE: for (;;) { statements; last LINE if $foo; next LINE if /^#/; statements; }
- * Don't be afraid to use loop labels--they're there to enhance readability as well as to allow multi-level loop breaks. See the previous example.
- * For portability, when using features that may not be implemented on every machine, test the construct in an eval to see if it fails. If you know what version or patchlevel a particular feature was implemented, you can test **$]** (**$PERL_VERSION** in **English**) to see if it will be there. The **Config** module will also let you interrogate values determined by the **Configure** program when Perl was installed.
- * Choose mnemonic identifiers. If you can't remember what mnemonic means, you've got a problem.
- * If you have a really hairy regular expression, use the **/x** modifier and put in some whitespace to make it look a little less like line noise. Don't use slash as a delimiter when your regexp has slashes or backslashes.
- * Use the new "and" and "or" operators to avoid having to parenthesize list operators so much, and

to reduce the incidence of punctuational operators like **&&** and || . Call your subroutines as if they were functions or list operators to avoid excessive ampersands and parens.

- * Use here documents instead of repeated *print()* statements.
- * Line up corresponding things vertically, especially if it'd be too long to fit on one line anyway.

  $IDX = $ST_MTIME; $IDX = $ST_ATIME if $opt_u; $IDX = $ST_CTIME if $opt_c; $IDX = $ST_SIZE if $opt_s; mkdir $tmpdir, 0700 or die "can't mkdir $tmpdir: $!"; chdir($tmpdir) or die "can't chdir $tmpdir: $!"; mkdir 'tmp', 0777 or die "can't mkdir $tmpdir/tmp: $!";
- * Line up your translations when it makes sense:

  tr [abc] [xyz];
- * Think about reusability. Why waste brainpower on a one-shot when you might want to do something like it again? Consider generalizing your code. Consider writing a module or object class. Consider making your code run cleanly with **use strict** and **-w** in effect. Consider giving away your code. Consider changing your whole world view. Consider... oh, never mind.
- * Be consistent.
- * Be nice.

.

TOC

NAME

perlguts - Perl's Internal Functions

DESCRIPTION

This document attempts to describe some of the internal functions of the Perl executable. It is far from complete and probably contains many errors. Please refer any questions or comments to the author below.

Datatypes

Perl has three typedefs that handle Perl's three main data types:

SV Scalar Value AV Array Value HV Hash Value

Each typedef has specific routines that manipulate the various data type.

What is an "IV"?

Perl uses a special typedef IV which is large enough to hold either an integer or a pointer.

Perl also uses a special typedef I32 which will always be a 32-bit integer.

Working with SV's

An SV can be created and loaded with one command. There are four types of values that can be loaded: an integer value (IV), a double (NV), a string, (PV), and another scalar (SV).

The four routines are:

SV* newSViv(IV); SV* newSVnv(double); SV* newSVpv(char*, int); SV* newSVsv(SV*);

To change the value of an *already-existing* scalar, there are five routines:

void sv_setiv(SV*, IV); void sv_setnv(SV*, double); void sv_setpvn(SV*, char*, int) void sv_setpv(SV*, char*); void sv_setsv(SV*, SV*);

Notice that you can choose to specify the length of the string to be assigned by using **sv_setpvn** , or

allow Perl to calculate the length by using **sv_setpv** . Be warned, though, that **sv_setpv** determines th string's length by using **strlen** , which depends on the string terminating with a NUL character.

To access the actual value that an SV points to, you can use the macros:

SvIV(SV*) SvNV(SV*) SvPV(SV*, STRLEN len)

which will automatically coerce the actual scalar type into an IV, double, or string.

In the **SvPV** macro, the length of the string returned is placed into the variable **len** (this is a macro, so you do *not* use **&len**). If you do not care what the length of the data is, use the global variable **na** . Remember, however, that Perl allows arbitrary strings of data that may both contain NUL's and not be terminated by a NUL.

If you simply want to know if the scalar value is TRUE, you can use:

SvTRUE(SV*)

Although Perl will automatically grow strings for you, if you need to force Perl to allocate more memory for your SV, you can use the macro

SvGROW(SV*, STRLEN newlen)

which will determine if more memory needs to be allocated. If so, it will call the function **sv_grow** . Note that **SvGROW** can only increase, not decrease, the allocated memory of an SV.

If you have an SV and want to know what kind of data Perl thinks is stored in it, you can use the following macros to check the type of SV you have.

SvIOK(SV*) SvNOK(SV*) SvPOK(SV*)

You can get and set the current length of the string stored in an SV with the following macros:

SvCUR(SV*) SvCUR_set(SV*, I32 val)

But note that these are valid only if ***SvPOK()*** is true.

If you know the name of a scalar variable, you can get a pointer to its SV by using the following:

SV* perl_get_sv("varname", FALSE);

This returns NULL if the variable does not exist.

If you want to know if this variable (or any other SV) is actually defined, you can call:

SvOK(SV*)

The scalar **undef** value is stored in an SV instance called **sv_undef** . Its address can be used whenever an **SV*** is needed.

There are also the two values **sv_yes** and **sv_no** , which contain Boolean TRUE and FALSE values, respectively. Like **sv_undef** , their addresses can be used whenever an **SV*** is needed.

Do not be fooled into thinking that **(SV *) 0** is the same as **&sv_undef** . Take this code:

SV* sv = (SV*) 0; if (I-am-to-return-a-real-value) { sv = sv_2mortal(newSViv(42)); } sv_setsv(ST(0), sv);

This code tries to return a new SV (which contains the value 42) if it should return a real value, or undef otherwise. Instead it has returned a null pointer which, somewhere down the line, will cause a segmentation violation, or just weird results. Change the zero to **&sv_undef** in the first line and all will be well.

To free an SV that you've created, call **SvREFCNT_dec(SV*)** . Normally this call is not necessary. See the section on **MORTALITY** .

Private and Public Values

Recall that the usual method of determining the type of scalar you have is to use **Sv[INP]OK** macros. Since a scalar can be both a number and a string, usually these macros will always return TRUE and calling the **Sv[INP]V** macros will do the appropriate conversion of string to integer/double or integer/double to string.

If you *really* need to know if you have an integer, double, or string pointer in an SV, you can use the following three macros instead:

SvIOKp(SV*) SvNOKp(SV*) SvPOKp(SV*)

These will tell you if you truly have an integer, double, or string pointer stored in your SV.

In general, though, it's best to just use the **Sv[INP]V** macros.

Working with AV's

There are two ways to create and load an AV. The first method just creates an empty AV:

AV* newAV();

The second method both creates the AV and initially populates it with SV's:

AV* av_make(I32 num, SV **ptr);

The second argument points to an array containing **num SV*** 's.

Once the AV has been created, the following operations are possible on AV's:

void av_push(AV*, SV*); SV* av_pop(AV*); SV* av_shift(AV*); void av_unshift(AV*, I32 num);

These should be familiar operations, with the exception of **av_unshift** . This routine adds **num** elements at the front of the array with the **undef** value. You must then use **av_store** (described below) to assign values to these new elements.

Here are some other functions:

I32 av_len(AV*); /* Returns length of array */ SV** av_fetch(AV*, I32 key, I32 lval); /* Fetches va at key offset, but it seems to set the value to lval if lval is non-zero */ SV** av_store(AV*, I32 key, S val); /* Stores val at offset key */ void av_clear(AV*); /* Clear out all elements, but leave the array */ void av_undef(AV*); /* Undefines the array, removing all elements */

If you know the name of an array variable, you can get a pointer to its AV by using the following:

AV* perl_get_av("varname", FALSE);

This returns NULL if the variable does not exist.

Working with HV's

To create an HV, you use the following routine:

HV* newHV();

Once the HV has been created, the following operations are possible on HV's:

SV** hv_store(HV*, char* key, U32 klen, SV* val, U32 hash); SV** hv_fetch(HV*, char* key, U32 klen, I32 lval);

The **klen** parameter is the length of the key being passed in. The **val** argument contains the SV pointer to the scalar being stored, and **hash** is the pre-computed hash value (zero if you want **hv_store** to calculate it for you). The **lval** parameter indicates whether this fetch is actually a part of a store operation.

Remember that **hv_store** and **hv_fetch** return **SV**** 's and not just **SV*** . In order to access the scalar value, you must first dereference the return value. However, you should check to make sure that the return value is not NULL before dereferencing it.

These two functions check if a hash table entry exists, and deletes it.

bool hv_exists(HV*, char* key, U32 klen); SV* hv_delete(HV*, char* key, U32 klen);

And more miscellaneous functions:

void hv_clear(HV*); /* Clears all entries in hash table */ void hv_undef(HV*); /* Undefines the hash table */ I32 hv_iterinit(HV*); /* Prepares starting point to traverse hash table */ HE* hv_iternext(HV*); /* Get the next entry, and return a pointer to a structure that has both the key and value */ char* hv_iterkey(HE* entry, I32* retlen); /* Get the key from an HE structure and also return the length of the key string */ SV* hv_iterval(HV*, HE* entry); /* Return a SV pointer to the value of the HE structure */

If you know the name of a hash variable, you can get a pointer to its HV by using the following:

HV* perl_get_hv("varname", FALSE);

This returns NULL if the variable does not exist.

The hash algorithm, for those who are interested, is:

i = klen; hash = 0; s = key; while (i--) hash = hash * 33 + *s++;

References

References are a special type of scalar that point to other scalar types (including references). To treat an AV or HV as a scalar, it is simply a matter of casting an AV or HV to an SV.

To create a reference, use the following command:

SV* newRV((SV*) pointer);

Once you have a reference, you can use the following macro with a cast to the appropriate typedef (SV, AV, HV):

SvRV(SV*)

then call the appropriate routines, casting the returned **SV*** to either an **AV*** or **HV*** .

To determine, after dereferencing a reference, if you still have a reference, you can use the following macro:

SvROK(SV*)

XSUB'S and the Argument Stack

The XSUB mechanism is a simple way for Perl programs to access C subroutines. An XSUB routine will have a stack that contains the arguments from the Perl program, and a way to map from the Perl data structures to a C equivalent.

The stack arguments are accessible through the **ST(n)** macro, which returns the **n** 'th stack argument. Argument 0 is the first argument passed in the Perl subroutine call. These arguments are **SV*** , and can be used anywhere an **SV*** is used.

Most of the time, output from the C routine can be handled through use of the RETVAL and OUTPUT directives. However, there are some cases where the argument stack is not already long enough to handle all the return values. An example is the POSIX *tzname()* call, which takes no arguments, but returns two, the local timezone's standard and summer time abbreviations.

To handle this situation, the PPCODE directive is used and the stack is extended using the macro:

EXTEND(sp, num);

where **sp** is the stack pointer, and **num** is the number of elements the stack should be extended by.

Now that there is room on the stack, values can be pushed on it using the macros to push IV's, doubles, strings, and SV pointers respectively:

PUSHi(IV) PUSHn(double) PUSHp(char*, I32) PUSHs(SV*)

And now the Perl program calling **tzname** , the two values will be assigned as in:

($standard_abbrev, $summer_abbrev) = POSIX::tzname;

An alternate (and possibly simpler) method to pushing values on the stack is to use the macros:

XPUSHi(IV) XPUSHn(double) XPUSHp(char*, I32) XPUSHs(SV*)

These macros automatically adjust the stack for you, if needed.

Mortality

In Perl, values are normally "immortal" -- that is, they are not freed unless explicitly done so (via the Perl **undef** call or other routines in Perl itself).

In the above example with **tzname** , we needed to create two new SV's to push onto the argument stack, that being the two strings. However, we don't want these new SV's to stick around forever because they will eventually be copied into the SV's that hold the two scalar variables.

An SV (or AV or HV) that is "mortal" acts in all ways as a normal "immortal" SV, AV, or HV, but is only valid in the "current context". When the Perl interpreter leaves the current context, the mortal SV, AV, or HV is automatically freed. Generally the "current context" means a single Perl statement.

To create a mortal variable, use the functions:

SV* sv_newmortal() SV* sv_2mortal(SV*) SV* sv_mortalcopy(SV*)

The first call creates a mortal SV, the second converts an existing SV to a mortal SV, the third creates a mortal copy of an existing SV.

The mortal routines are not just for SV's -- AV's and HV's can be made mortal by passing their address (and casting them to **SV***) to the **sv_2mortal** or **sv_mortalcopy** routines.

Creating New Variables

To create a new Perl variable, which can be accessed from your Perl script, use the following routines, depending on the variable type.

SV* perl_get_sv("varname", TRUE); AV* perl_get_av("varname", TRUE); HV* perl_get_hv("varname", TRUE);

Notice the use of TRUE as the second parameter. The new variable can now be set, using the routines appropriate to the data type.

Stashes and Objects

A stash is a hash table (associative array) that contains all of the different objects that are contained within a package. Each key of the hash table is a symbol name (shared by all the different types of objects that have the same name), and each value in the hash table is called a GV (for Glob Value). The GV in turn contains references to the various objects of that name, including (but not limited to) the following: Scalar Value Array Value Hash Value File Handle Directory Handle Format Subroutine

Perl stores various stashes in a GV structure (for global variable) but represents them with an HV structure.

To get the HV pointer for a particular package, use the function:

HV* gv_stashpv(char* name, I32 create) HV* gv_stashsv(SV*, I32 create)

The first function takes a literal string, the second uses the string stored in the SV.

The name that **gv_stash*v** wants is the name of the package whose symbol table you want. The default package is called **main** . If you have multiply nested packages, it is legal to pass their names to **gv_stash*v** , separated by **::** as in the Perl language itself.

Alternately, if you have an SV that is a blessed reference, you can find out the stash pointer by using:

HV* SvSTASH(SvRV(SV*));

then use the following to get the package name itself:

char* HvNAME(HV* stash);

If you need to return a blessed value to your Perl script, you can use the following function:

SV* sv_bless(SV*, HV* stash)

where the first argument, an **SV*** , must be a reference, and the second argument is a stash. The returned **SV*** can now be used in the same way as any other SV.

Magic

[This section under construction]

Double-Typed SV's

Scalar variables normally contain only one type of value, an integer, double, pointer, or reference. Perl will automatically convert the actual scalar data from the stored type into the requested type.

Some scalar variables contain more than one type of scalar data. For example, the variable **$!** contains either the numeric value of **errno** or its string equivalent from **sys_errlist[]** .

To force multiple data values into an SV, you must do two things: use the **sv_set*v** routines to add the additional scalar type, then set a flag so that Perl will believe it contains more than one type of data. The four macros to set the flags are:

SvIOK_on SvNOK_on SvPOK_on SvROK_on

The particular macro you must use depends on which **sv_set*v** routine you called first. This is because every **sv_set*v** routine turns on only the bit for the particular type of data being set, and turns off all the rest.

For example, to create a new Perl variable called "dberror" that contains both the numeric and descriptive string error values, you could use the following code:

extern int dberror; extern char *dberror_list; SV* sv = perl_get_sv("dberror", TRUE); sv_setiv(sv, (IV) dberror); sv_setpv(sv, dberror_list[dberror]); SvIOK_on(sv);

If the order of **sv_setiv** and **sv_setpv** had been reversed, then the macro **SvPOK_on** would need to be called instead of **SvIOK_on** .

Calling Perl Routines from within C Programs

There are four routines that can be used to call a Perl subroutine from within a C program. These four are:

I32 perl_call_sv(SV*, I32); I32 perl_call_pv(char*, I32); I32 perl_call_method(char*, I32); I32 perl_call_argv(char*, I32, register char**);

The routine most often used should be **perl_call_sv** . The **SV*** argument contains either the name of the Perl subroutine to be called, or a reference to the subroutine. The second argument tells the appropriate routine what, if any, variables are being returned by the Perl subroutine.

All four routines return the number of arguments that the subroutine returned on the Perl stack.

When using these four routines, the programmer must manipulate the Perl stack. These include the following macros and functions:

dSP PUSHMARK() PUTBACK SPAGAIN ENTER SAVETMPS FREETMPS LEAVE XPUSH*()

For more information, consult the *perlcall* manpage .

Memory Allocation

[This section under construction]

NAME

perlcall - Perl calling conventions from C

DESCRIPTION

BThe purpose of this document is to show you how to write *callbacks* , i.e. how to call Perl from C. The main focus is on how to interface back to Perl from a bit of C code that has itself been run by Perl, i.e. the 'main' program is a Perl script; you are using it to execute a section of code written in C; that bit of C code wants you to do something with a particular event, so you want a Perl sub to be executed whenever it happens.

Examples where this is necessary include

- * You have created an XSUB interface to an application's C API.

  A fairly common feature in applications is to allow you to define a C function that will get called whenever something nasty occurs. What we would like is for a Perl sub to be called instead.
- * The classic example of where callbacks are used is in an event driven program like for X-windows. In this case your register functions to be called whenever a specific events occur, e.g. a mouse button is pressed.

Although the techniques described are applicable to embedding Perl.in a C program, this is not the primary goal of this document. For details on embedding Perl in C refer to the *perlembed* manpage (currently unwritten).

Before you launch yourself head first into the rest of this document, it would be a good idea to have read the following two documents - the *perlapi* manpage and the *perlguts* manpage .

This stuff is easier to explain using examples. But first here are a few definitions anyway.

Definitions

Perl has a number of C functions which allow you to call Perl subs. They are

I32 perl_call_sv(SV* sv, I32 flags) ; I32 perl_call_pv(char *subname, I32 flags) ; I32 perl_call_method(char *methname, I32 flags) ; I32 perl_call_argv(char *subname, I32 flags, register char **argv) ;

The key function is *perl_call_sv* . All the other functions make use of *perl_call_sv* to do what they do.

perl_call_sv takes two parameters, the first is an SV*. This allows you to specify the Perl sub to be called either as a C string (which has first been converted to an SV) or a reference to a sub. Example 7, shows

you how you can make use of *perl_call_sv* . The second parameter, **flags** , is a general purpose optio command. This parameter is common to all the *perl_call_** functions. It is discussed in the next sect

The function, *perl_call_pv* , is similar as *perl_call_sv* except it expects it's first parameter has to be a C char* which identifies the Perl sub you want to call, e.g. **perl_call_pv("fred", 0)** .

The function *perl_call_method* expects its first argument to contain a blessed reference to a class. Using that reference it looks up and calls **methname** from that class. See example 9.

perl_call_argv calls the Perl sub specified by the **subname** parameter. It also takes the usual **flags** parameter. The final parameter, **argv** , consists of a list of C strings to be sent to the Perl sub. See example 8.

All the functions return a number. This is a count of the number of items returned by the Perl sub on the stack.

As a general rule you should *always* check the return value from these functions. Even if you are only expecting a particular number of values to be returned from the Perl sub, there is nothing to stop someone from doing something unexpected - don't say you havn't been warned.

Flag Values

The **flags** parameter in all the *perl_call_** functions consists of any combination of the symbols defined below, OR'ed together.

G_SCALAR

Calls the Perl sub in a scalar context.

Whatever the Perl sub actually returns, we only want a scalar. If the perl sub does return a scalar, the return value from the *perl_call_** function will be 1 or 0. If 1, then the value actually returned by the Perl sub will be contained on the top of the stack. If 0, then the sub has probably called *die* or you have used the G_DISCARD flag.

If the Perl sub returns a list, the *perl_call_** function will still only return 1 or 0. If 1, then the number of elements in the list will be stored on top of the stack. The actual values of the list will not be accessable.

G_SCALAR is the default flag setting for all the functions.

G_ARRAY

Calls the Perl sub in a list context.

The return code from the *perl_call_** functions will indicate how many elements of the stack are used to store the array.

G_DISCARD

If you are not interested in the values returned by the Perl sub then setting this flag will make Perl get rid of them automatically for you. This will take precedence to either G_SCALAR or G_ARRAY.

If you do not set this flag then you may need to explicitly get rid of temporary values. See exa
3 for details.

G_NOARGS

If you are not passing any parameters to the Perl sub, you can save a bit of time by setting this flag. It has the effect of of not creating the **@_** array for the Perl sub.

A point worth noting is that if this flag is specified the Perl sub called can still access an **@_** array from a previous Perl sub. This functionality can be illustrated with the perl code below

sub fred { print "@_\n" } sub joe { &fred } &joe(1,2,3) ;

This will print

1 2 3

What has happened is that **fred** accesses the **@_** array which belongs to **joe** .

G_EVAL

If the Perl sub you are calling has the ability to terminate abnormally, e.g. by calling *die* or by not actually existing, and you want to catch this type of event, specify this flag setting. It will put an *eval { }* around the sub call.

Whenever control returns from the *perl_call_** function you need to check the **$@** variable as you would in a normal Perl script. See example 6 for details of how to do this.

.

EXAMPLES

Enough of the definition talk, let's have a few examples.

Perl provides many macros to assist in accessing the Perl stack. These macros should always be used when interfacing to Perl internals. Hopefully this should make the code less vulnerable to changes made to Perl in the future.

Another point worth noting is that in the first series of examples I have only made use of the *perl_call_pv* function. This has only been done to ease you into the topic. Wherever possible, if the choice is between using *perl_call_pv* and *perl_call_sv* , I would always try to use *perl_call_sv* .

The code for these examples is stored in the file *perlcall.tar* . (Once this document settles down, all the example code will be available in the file).

Example1: No Parameters, Nothing returned

This first trivial example will call a Perl sub, *PrintUID* , to print out the UID of the process.

sub PrintUID { print "UID is $<\n" ; }

and here is the C to call it

```
void call_PrintUID() { dSP ; PUSHMARK(sp) ; perl_call_pv("PrintUID", G_DISCARD|G_NOARGS) ;
}
```

Simple, eh.

A few points to note about this example.

1. We aren't passing any parameters to *PrintUID* so G_NOARGS can be specified.
2. Ignore **dSP** and **PUSHMARK(sp)** for now. They will be discussed in the next example.
3. We aren't interested in anything returned from *PrintUID* , so G_DISCARD is specified. Even if *PrintUID* was changed to actually return some value(s), having specified G_DISCARD will mean that they will be wiped by the time control returns from *perl_call_pv* .
4. Because we specified G_DISCARD, it is not necessary to check the value returned from *perl_call_sv* . It will always be 0.
5. As *perl_call_pv* is being used, the Perl sub is specified as a C string.

.

Example 2: Passing Parameters

Now let's make a slightly more complex example. This time we want to call a Perl sub which will take 2 parameters - a string (**$s**) and an integer (**$n**). The sub will simply print the first **$n** characters of the string.

So the Perl sub would look like this

```
sub LeftString { my($s, $n) = @_ ; print substr($s, 0, $n), "\n" ; }
```

The C function required to call *LeftString* would look like this.

```
static void call_LeftString(a, b) char * a ; int b ; { dSP ; PUSHMARK(sp) ;
XPUSHs(sv_2mortal(newSVpv(a, 0))); XPUSHs(sv_2mortal(newSViv(b))); PUTBACK ;
perl_call_pv("LeftString", G_DISCARD); }
```

Here are a few notes on the C function *call_LeftString* .

1. The only flag specified this time is G_DISCARD. As we are passing 2 parameters to the Perl sub this time, we have not specified G_NOARGS.
2. Parameters are passed to the Perl sub using the Perl stack. This is the purpose of the code beginning with the line **dSP** and ending with the line **PUTBACK** .
3. If you are going to put something onto the Perl stack, you need to know where to put it. This is the purpose of the macro **dSP** - it declares and initialises a local copy of the Perl stack pointer.

   All the other macros which will be used in this example require you to have used this macro.

   If you are calling a Perl sub directly from an XSUB function, it is not necessary to explicitly use the **dSP** macro - it will be declared for you.

4. Any parameters to be pushed onto the stack should be bracketed by the **PUSHMARK** and **PUTBACK** macros. The purpose of these two macros, in this context, is to automatically count the number of parameters you are pushing. Then whenever Perl is creating the **@_** array for the sub, it knows how big to make it.

   The **PUSHMARK** macro tells Perl to make a mental note of the current stack pointer. Even if you aren't passing any parameters (like in Example 1) you must still call the **PUSHMARK** macro before you can call any of the *perl_call_** functions - Perl still needs to know that there are no parameters.

   The **PUTBACK** macro sets the global copy of the stack pointer to be the same as our local copy. If we didn't do this *perl_call_pv* wouldn't know where the two parameters we pushed were - remember that up to now all the stack pointer manipulation we have done is with our local copy, *not* the global copy.
5. Next, we come to XPUSHs. This is where the parameters actually get pushed onto the stack. In this case we are pushing a string and an integer.

   See the section *XSUB's AND THE ARGUMENT STACK* in the *perlguts* manpage for details on how the XPUSH macros work.
6. Finally, *LeftString* can now be called via the *perl_call_pv* function.

.

Example 3: Returning a Scalar

Now for an example of dealing with the values returned from a Perl sub.

Here is a Perl sub, *Adder* , which takes 2 integer parameters and simply returns their sum.

sub Adder { my($a, $b) = @_ ; $a + $b ; }

As we are now concerned with the return value from *Adder* , the C function is now a bit more complex.

static void call_Adder(a, b) int a ; int b ; { dSP ; int count ; ENTER ; SAVETMPS; PUSHMARK(sp) ; XPUSHs(sv_2mortal(newSViv(a))); XPUSHs(sv_2mortal(newSViv(b))); PUTBACK ; count = perl_call_pv("Adder", G_SCALAR); SPAGAIN ; if (count != 1) croak("Big trouble\n") ; printf ("The sum of %d and %d is %d\n", a, b, POPi) ; PUTBACK ; FREETMPS ; LEAVE ; }

Points to note this time are

1. The only flag specified this time was G_SCALAR. That means the **@_** array will be created and that the value returned by *Adder* will still exist after the call to *perl_call_pv* .
2. Because we are interested in what is returned from *Adder* we cannot specify G_DISCARD. This means that we will have to tidy up the Perl stack and dispose of any temporary values ourselves. This is the purpose of

   ENTER ; SAVETMPS ;

   at the start of the function, and

FREETMPS ; LEAVE ;

at the end. The **ENTER** / **SAVETMPS** pair creates a boundary for any temporaries we create. This means that the temporaries we get rid of will be limited to those which were created after these calls.

The **FREETMPS** / **LEAVE** pair will get rid of any values returned by the Perl sub, plus it will also dump the mortal SV's we created. Having **ENTER** / **SAVETMPS** at the beginning of the code makes sure that no other mortals are destroyed.

3. The purpose of the macro **SPAGAIN** is to refresh the local copy of the stack pointer. This is necessary because it is possible that the memory allocated to the Perl stack has been re-allocated whilst in the *perl_call_pv* call.

   If you are making use of the Perl stack pointer in your code you must always refresh the your local copy using SPAGAIN whenever you make use of of the *perl_call_** functions or any other Perl internal function.

4. Although only a single value was expected to be returned from *Adder* , it is still good practice to check the return code from *perl_call_pv* anyway.

   Expecting a single value is not quite the same as knowing that there will be one. If someone modified *Adder* to return a list and we didn't check for that possibility and take appropriate action the Perl stack would end up in an inconsistant state. That is something you *really* don't want to ever happen.

5. The **POPi** macro is used here to pop the return value from the stack. In this case we wanted an integer, so **POPi** was used.

   Here is the complete list of POP macros available, along with the types they return.

   - POPs SV
   - POPp pointer
   - POPn double
   - POPi integer
   - POPl long

6. The final **PUTBACK** is used to leave the Perl stack in a consistant state before exiting the function. This is necessary because when we popped the return value from the stack with **POPi** it only updated our local copy of the stack pointer. Remember, **PUTBACK** sets the global stack pointer to be the same as our local copy.

.

Example 4: Returning a list of values

Now, let's extend the previous example to return both the sum of the parameters and the difference.

Here is the Perl sub

sub AddSubtract { my($a, $b) = @_ ; ($a+$b, $a-$b) ; }

and this is the C function

static void call_AddSubtract(a, b) int a ; int b ; { dSP ; int count ; ENTER ; SAVETMPS; PUSHMARK(sp) ; XPUSHs(sv_2mortal(newSViv(a))); XPUSHs(sv_2mortal(newSViv(b))); PUTBACK ; count = perl_call_pv("AddSubtract", G_ARRAY); SPAGAIN ; if (count != 2) croak("Big trouble\n") ; printf ("%d - %d = %d\n", a, b, POPi) ; printf ("%d + %d = %d\n", a, b, POPi) ; PUTBACK ; FREETMPS ; LEAVE ; }

Notes

1. We wanted array context, so we used G_ARRAY.
2. Not surprisingly there are 2 POPi's this time because we were retrieving 2 values from the stack. The main point to note is that they came off the stack in reverse order.

.

Example 5: Returning Data from Perl via the parameter list

It is also possible to return values directly via the parameter list - whether it is actually desirable to do it is another matter entirely.

The Perl sub, *Inc* , below takes 2 parameters and increments each.

sub Inc { ++ $_[0] ; ++ $_[1] ; }

and here is a C function to call it.

static void call_Inc(a, b) int a ; int b ; { dSP ; int count ; SV * sva ; SV * svb ; ENTER ; SAVETMPS; sva = sv_2mortal(newSViv(a)) ; svb = sv_2mortal(newSViv(b)) ; PUSHMARK(sp) ; XPUSHs(sva); XPUSHs(svb); PUTBACK ; count = perl_call_pv("Inc", G_DISCARD); if (count != 0) croak ("call_Inc : expected 0 return value from 'Inc', got %d\n", count) ; printf ("%d + 1 = %d\n", a, SvIV(sva)) ; printf ("%d + 1 = %d\n", b, SvIV(svb)) ; FREETMPS ; LEAVE ; }

To be able to access the two parameters that were pushed onto the stack after they return from *perl_call_pv* it is necessary to make a note of their addresses - thus the two variables **sva** and **svb** .

The reason this is necessary is that the area of the Perl stack which held them will very likely have been overwritten by something else by the time control returns from *perl_call_pv* .

Example 6: Using G_EVAL

Now an example using G_EVAL. Below is a Perl sub which computes the difference of its 2 parameters. If this would result in a negative result, the sub calls *die* .

sub Subtract { my ($a, $b) = @_ ; die "death can be fatal\n" if $a < $b ; $a - $b ; }

and some C to call it

static void call_Subtract(a, b) int a ; int b ; { dSP ; int count ; SV * sv ; ENTER ; SAVETMPS; PUSHMARK(sp) ; XPUSHs(sv_2mortal(newSViv(a))); XPUSHs(sv_2mortal(newSViv(b))); PUTBACK ; count = perl_call_pv("Subtract", G_EVAL|G_SCALAR); /* Check the eval first */ sv = GvSV(gv_fetchpv("@", TRUE, SVt_PV)); if (SvTRUE(sv)) printf ("Uh oh - %s\n", SvPV(sv, na)) ; SPAGAIN ; if (count != 1) croak ("call_Subtract : expected 1 return value from 'Subtract', got %d\n", count) ; printf ("%d - %d = %d\n", a, b, POPi) ; PUTBACK ; FREETMPS ; LEAVE ; }

If *call_Subtract* is called thus

call_Subtract(4, 5)

the following will be printed

Uh oh - death can be fatal

Notes

1. We want to be able to catch the *die* so we have used the G_EVAL flag. Not specifying this flag would mean that the program would terminate.
2. The code

   sv = GvSV(gv_fetchpv("@", TRUE, SVt_PV)); if (SvTRUE(sv)) printf ("Uh oh - %s\n", SvPVx(sv, na)) ;

   is the equivalent of this bit of Perl

   print "Uh oh - $@\n" if $@ ;

.

Example 7: Using perl_call_sv

In all the previous examples I have 'hard-wried' the name of the Perl sub to be called from C. Sometimes though, it is necessary to be able to specify the name of the Perl sub from within the Perl script.

Consider the Perl code below

sub fred { print "Hello there\n" ; } CallSub("fred") ;

here is a snippet of XSUB which defines *CallSub* .

void CallSub(name) char * name CODE: PUSHMARK(sp) ; perl_call_pv(name, G_DISCARD|G_NOARGS) ;

That is fine as far as it goes. The thing is, it only allows the Perl sub to be specified as a string. For perl 4 this was adequate, but Perl 5 allows references to subs and anonymous subs. This is where *perl_call_sv* is useful.

The code below for *CallSub* is identical to the previous time except that the **name** parameter is now defined as an SV* and we use *perl_call_sv* instead of *perl_call_pv* .

void CallSub(name) SV* name CODE: PUSHMARK(sp) ; perl_call_sv(name,

G_DISCARD|G_NOARGS) ;

As we are using an SV to call *fred* the following can all be used

CallSub("fred") ; Callsub(\&fred) ; $ref = \&fred ; CallSub($ref) ; CallSub(sub { print "Hello there\n" }) ;

As you can see, *perl_call_sv* gives you greater flexibility in how you can specify the Perl sub.

Example 8: Using perl_call_argv

Here is a Perl sub which prints whatever parameters are passed to it.

sub PrintList { my(@list) = @_ ; foreach (@list) { print "$_\n" } }

and here is an example of *perl_call_argv* which will call *PrintList* .

call_PrintList { dSP ; char * words[] = {"alpha", "beta", "gamma", "delta", NULL } ; perl_call_argv("PrintList", words, G_DISCARD) ; }

Note that it is not necessary to call **PUSHMARK** in this instance. This is because *perl_call_argv* will do it for you.

Example 9: Using perl_call_method

[This section is under construction]

Consider the following Perl code

{ package Mine ; sub new { bless [@_] } sub Display { print $_[0][1], "\n" } } $a = new Mine ('red', 'green', 'blue') ; call_Display($a, 'Display') ;

The method **Display** just prints out the first element of the list. Here is a XSUB implementation of *call_Display* .

void call_Display(ref, method) SV * ref char * method CODE: PUSHMARK(sp); XPUSHs(ref); PUTBACK; perl_call_method(method, G_DISCARD) ;

Strategies for storing Context Information

[This section is under construction]

One of the trickiest problems to overcome when designing a callback interface is figuring out how to store the mapping between the C callback functions and the Perl equivalent.

Consider the following example.

Alternate Stack Manipulation

TOC

[This section is under construction]

Although I have only made use of the POP* macros to access values returned from Perl subs, it is also possible to bypass these macros and read the stack directly.

The code below is example 4 recoded to

NAME

perlovl - perl overloading semantics

SYNOPSIS

package SomeThing;

%OVERLOAD = ('+' => \&myadd, '-' => \&mysub, # etc); ... package main; $a = new SomeThing 57; $b=5+$a;

CAVEAT SCRIPTOR

Overloading of operators is a subject not to be taken lightly. Neither its precise implementation, syntax, nor semantics are 100 **%** endorsed by Larry Wall. So any of these may be changed at some point in the future.

DESCRIPTION

Declaration of overloaded functions

package Number; **%OVERLOAD** = ("+" => \&add, "*=" => "muas");

declares function Number:: *add()* for addition, and method *muas()* in the "class" **Number** (or one of its base classes) for the assignment form ***=** of multiplication. Legal values of this hash array are values legal inside **&{ ... }** call, so the name of a subroutine, a reference to a subroutine, or an anonymous subroutine will all work.

The subroutine **$OVERLOAD {"+"}** will be called to execute **$a + $b** if **$a** is a reference to an object blessed into the package **Number** , or **$a** is not an object from a package with defined mathemagic addition, but **$b** is a reference to a **Number** . It can be called also in other situations, like **$a +=7** , or **$a ++** . See *MAGIC AUTOGENERATION* . (Mathemagical methods refer to methods triggered by an overloaded mathematical operator.)

Calling Conventions for Binary Operations

The functions in **values %OVERLOAD** are called with three (in one particular case with four, see *Last Resort*) arguments. If the corresponding operation is binary, then the first two arguments are the two arguments of the operation. However, due to general object calling conventions, the first argument should be always an object in the package, so in the situation of **7+ $a** , the order of arguments is interchanged. Most probably it does not matter for implementation of the addition method, but whether the arguments are reversed is vital for the subtraction method. The subroutine can query this information by examining the third argument, which can take three different values:

FALSE

the order of arguments is as in the current operation.

TRUE

the arguments are reversed.

undef

the current operation is an assignment variant (as in **$a +=7**), but the usual function is called instead. This additional information can be used to generate some optimizations.

.

Calling Conventions for Unary Operations

Unary operation are considered binary operations with the second argument being undef . Thus **$OVERLOAD {"++"}** is called with arguments **($a ,undef,'')** when **$a** ++ is executed.

Overloadable Operations

The following keys of **%OVERLOAD** are recognized:

*** *Arithmetic operations***

"+", "+=", "-", "-=", "*", "*=", "/", "/=", "%", "%=", "**", "**=", "<<", "<<=", >>", >>=", "x", "x=", ".", ".=",

For these operations a substituted non-assignment variant can be called if the assignment variant is not available. Methods for operations " + ", " - ", " += ", and " -= " can be called to automatically generate increment and decrement methods. The operations " - " can be used to autogenerate missing methods for unary minus or **abs** .

*** Comparison operations**

<", <=", ">", ">=", "==", "!=", <=>", "lt", "le", "gt", "ge", "eq", "ne", "cmp",

If the corresponding "spaceship" variant is available, it can be used to substitute for the missing operation. During **sort** ing arrays, **cmp** is used to compare values subject to **%OVERLOAD** .

*** *Bit operations***

"&", "^", "|", "&=", "^=", "|=", "neg", "!", "~",

" **neg** " stands for unary minus. If the method for **neg** is not specified, it can be autogenerated using on the method for subtraction.

*** Increment and decrement**

"++", "--",

If undefined, addition and subtraction methods can be used instead. These operations are called both in prefix and postfix form.

**** Transcendental functions***

"atan2", "cos", "sin", "exp", "abs", "log", "sqrt",

If **abs** is unavailable, it can be autogenerated using methods for <" or <=>" combined with either unary minus or subtraction.

**** Boolean, string and numeric conversion***

"bool", "\"\"", "0+",

If one or two of these operations are unavailable, the remaining ones can be used instead. **bool** is used in the flow control operators (like **while**) and for the ternary " **?:** " operation. These functions can return any arbitrary Perl value. If the corresponding operation for this value is overloaded too, that operation will be called again with this value.

**** Special***

"nomethod", "fallback", "=",

see *SPECIAL KEYS OF %OVERLOAD* .

See *Fallback* for an explanation of when a missing method can be autogenerated..

SPECIAL KEYS OF %OVERLOAD

Three keys are recognized by Perl that are not covered by the above description.

Last Resort

$OVERLOAD {"nomethod"} is a reference to a function of four parameters. If defined, it is called when the overloading mechanism cannot find a method for some operation. The first three arguments of this function coincide with arguments for the corresponding method if it were found, the fourth argument is the key of **%OVERLOAD** corresponding to the missing method. If several methods are tried, the last one is used. Say, **1- $a** can be equivalent to

&{ $Pack::OVERLOAD{"nomethod"} }($a,1,1,"-").

If some operation cannot be resolved, and there is no **$OVERLOAD {"nomethod"}** , then an exception will be raised via *die()* -- unless **$OVERLOAD {"fallback"}** is true.

Fallback

$OVERLOAD {"fallback"}** governs what to do if a method for a particular operation is not found. Three different cases are possible depending on value of **$OVERLOAD {"fallback"} :

*** undef**

Perl tries to use a substituted method (see *MAGIC AUTOGENERATION*). If this fails, it then tries to calls **$OVERLOAD {"nomethod"}** ; if missing, an exception will be raised.

*** TRUE**

The same as for the undef value, but no exception is raised. Instead, it silently reverts to what it would have done were there no **%OVERLOAD** is present.

*** defined, but FALSE**

No autogeneration is tried. Perl tries to call **$OVERLOAD {"nomethod"}** , and if this is missing, raises an exception.

.

Copy Constructor

$OVERLOAD {"="} is a reference to a function with three arguments, i.e., it looks like a usual value of **%OVERLOAD** . This operation is called in the situations when a mutator is applied to a reference that shares its object with some other reference, such as

$a=$b; $a++;

To make this change to **$a** and not to change **$b** , a freshly made copy of **$$ a** is made, and **$a** is assigned a reference to this object. This operation is executed during **$a ++** , (so before this **$$ a** coincides with **$$ b**), and only if ++ is expressed via **$OPERATOR {'++'}** or **$OPERATOR {'+='}** . Note that if this operation is expressed via ' + ', i.e., as

$a=$b; $a=$a+1;

then **$$ a** and **$$ b** do not appear as lvalues.

If the copy constructor is required during execution of some mutator, but **$OPERATOR {'='}** is missing, it can be autogenerated as a string copy if an object of the package is a plain scalar.

MAGIC AUTOGENERATION

If a method for an operation is not found, and **$OVERLOAD {"fallback"}** is TRUE or undefined, Perl tries to to autogenerate a substitute method for the missing operation based on defined operations. Autogenerated method substitutions are possible for the following operations:

Assignment forms of arithmetic operations

$a =+ $b can use the **$OVERLOAD {"+"}** method if **$OVERLOAD {"+="}** is not defined.

Conversion operations

String, numeric, and boolean conversion are calculated in terms of one another if not all of them are defined.

Increment and decrement

The **++ $a** operation can be expressed in terms of **$a +=1** or **$a +1** , and **$a --** in terms of **$a -=1** and **$a -1** .

abs($a)

can be expressed in terms of **$a <0** and **- $a** (or **0- $a**).

Unary minus

can be expressed in terms of subtraction.

Concatenation

can be expressed in terms of string conversion.

Comparison operations

can be expressed in terms of its "spaceship" counterpart: either **<=>** or **cmp** : <, >,<=, >=, ==, != in terms of<=> lt, gt, le, ge, eq, ne in terms of cmp

Copy operator

can be expressed in terms of assignment to the dereferenced value, if this value is scalar but not a reference.

.

WARNING

The restriction for the comparison operation is that even if, for example, ` **cmp** ' should return a reference to a blessed object, the autogenerated ` **lt** ' function will produce only a standard logical value based on the numerical value of the result of ` **cmp** '. In particular, a working numeric conversion is needed in this case (possibly expressed in terms of other conversions).

Similarly, **.=** and **x=** operators lose their mathemagical properties if the string conversion substitution is applied.

When you *chop()* a mathemagical object, it becomes promoted to a string first, and its mathemagical

qualities is lost. The same can happen with other operations as well.

TOC

IMPLEMENTATION

The table of methods for all operations is cached as a magic for the symbol table hash of the package. It is rechecked for changes of **%OVERLOAD** and **@ISA** only during **bless** ing; so if it is changed dynamically, you'll need an additional fake **bless** ing to update the table.

(Every SVish thing has a magic queue, and a magic is an entry in that queue. This is how a single variable may participate in multiple forms of magic simultaneously. For instance, environment variables regularly have two forms at once: their **%ENV** magic and their taint magic.)

If an object belongs to a package with **%OVERLOAD** , it carries a special flag. Thus the only speed penalty during arithmetic operations without overload is the check of this flag.

In fact, if no **%OVERLOAD** is ever accessed, there is almost no overhead for overloadable operations, so most programs should not suffer measurable performance penalties. Considerable effort was made minimize overhead when **%OVERLOAD** is accessed and the current operation is overloadable but the arguments in question do not belong to packages with **%OVERLOAD** . When in doubt, test your speed with **%OVERLOAD** and without it. So far there have been no reports of substantial speed degradation if Perl is compiled with optimization turned on.

There is no size penalty for data if there is no **%OVERLOAD** .

The copying like **$a = $b** is shallow; however, a one-level-deep copying is carried out before any operation that can imply an assignment to the object **$b** (or **$a**) refers to, like **$b ++** . You can override this behavior by defining your copy constructor (see *Copy Constructor*).

It is expected that arguments to methods that are not explicitly supposed to be changed are constant (but this is not enforced).

AUTHOR

Ilya Zakharevich< *ilya* ***@math*** *.mps.ohio-state.edu* >.

DIAGNOSTICS

When Perl is run with the **-Do** switch or its equivalent, overloading induces diagnostic messages.

BUGS

Because it's used for overloading, the per-package associative array **%OVERLOAD** now has a special meaning in Perl.

As shipped, **%OVERLOAD** is not inherited via the **@ISA** tree. A patch for this is available from the author.

This document is confusing.

NAME

perlbook - Perl book information

DESCRIPTION

You can order Perl books from O'Reilly & Associates, 1-800-998-9938. Local/overseas is +1 707 829 0515. If you can locate an O'Reilly order form, you can also fax to +1 707 829 0104. *Programming Perl* is a reference work that covers nearly all of Perl (version 4, alas), while *Learning Perl* is a tutorial that covers the most frequently used subset of the language.

Programming Perl (the Camel Book): ISBN 0-937175-64-1 (English) ISBN 4-89052-384-7 (Japanese)
Learning Perl (the Llama Book): ISBN 1-56592-042-2 (English)

Python library reference

Guido van Rossum

Go to the next section.

Introduction

The "Python library" contains several different kinds of components.

It contains data types that would normally be considered part of the "core" of a language, such as numbers and lists. For these types, the Python language core defines the form of literals and places some constraints on their semantics, but does not fully define the semantics. (On the other hand, the language core does define syntactic properties like the spelling and priorities of operators.)

The library also contains built-in functions and exceptions --- objects that can be used by all Python code without the need of an `import` statement. Some of these are defined by the core language, but many are not essential for the core semantics and are only described here.

The bulk of the library, however, consists of a collection of modules. There are many ways to dissect this collection. Some modules are written in C and built in to the Python interpreter; others are written in Python and imported in source form. Some modules provide interfaces that are highly specific to Python, like printing a stack trace; some provide interfaces that are specific to particular operating systems, like socket I/O; others provide interfaces that are specific to a particular application domain, like the World-Wide Web. Some modules are avaiable in all versions and ports of Python; others are only available when the underlying system supports or requires them; yet others are available only when a particular configuration option was chosen at the time when Python was compiled and installed.

This manual is organized "from the inside out": it first describes the built-in data types, then the built-in functions and exceptions, and finally the modules, grouped in chapters of related modules. The ordering of the chapters as well as the ordering of the modules within each chapter is roughly from most relevant to least important.

This means that if you start reading this manual from the start, and skip to the next chapter when you get bored, you will get a reasonable overview of the available modules and application areas that are supported by the Python library. Of course, you don't *have* to read it like a novel -- you can also browse the table of contents (in front of the manual), or look for a specific function, module or term in the index (in the back). And finally, if you enjoy learning about random subjects, you choose a random page number (see module `rand`) and read a section or two.

Let the show begin!

Go to the next section.

Go to the previous, next section.

Built-in Types, Exceptions and Functions

Names for built-in exceptions and functions are found in a separate symbol table. This table is searched last when the interpreter looks up the meaning of a name, so local and global user-defined names can override built-in names. Built-in types are described together here for easy reference.(1)

The tables in this chapter document the priorities of operators by listing them in order of ascending priority (within a table) and grouping operators that have the same priority in the same box. Binary operators of the same priority group from left to right. (Unary operators group from right to left, but there you have no real choice.) See Chapter 5 of the Python Reference Manual for the complete picture on operator priorities.

Built-in Types

The following sections describe the standard types that are built into the interpreter. These are the numeric types, sequence types, and several others, including types themselves. There is no explicit Boolean type; use integers instead.

Some operations are supported by several object types; in particular, all objects can be compared, tested for truth value, and converted to a string (with the `` `...` `` notation). The latter conversion is implicitly used when an object is written by the `print` statement.

Truth Value Testing

Any object can be tested for truth value, for use in an `if` or `while` condition or as operand of the Boolean operations below. The following values are considered false:

- `None`
- zero of any numeric type, e.g., `0`, `0L`, `0.0`.
- any empty sequence, e.g., `''`, `()`, `[]`.
- any empty mapping, e.g., `{}`.
- instances of user-defined classes, if the class defines a `__nonzero__()` or `__len__()` method, when that method returns zero.

All other values are considered true -- so objects of many types are always true.

Operations and built-in functions that have a Boolean result always return `0` for false and `1` for true, unless otherwise stated. (Important exception: the Boolean operations `or' and `and' always return one of their operands.)

Boolean Operations

These are the Boolean operations, ordered by ascending priority:

Operation

Result -- *Notes*

`x or y`

if x is false, then y, else x -- (1) @hline

`x and y`

if x is false, then x, else y -- (1) @hline

`not x`

if x is false, then `1`, else `0` -- (2)

Notes:

(1)

These only evaluate their second argument if needed for their outcome.

(2)

`not' has a lower priority than non-Boolean operators, so e.g. `not a == b` is interpreted as `not(a == b)`, and `a == not b` is a syntax error.

Comparisons

Comparison operations are supported by all objects. They all have the same priority (which is higher than that of the Boolean operations). Comparisons can be chained arbitrarily, e.g. `x < y <= z` is equivalent to `x < y and y <= z`, except that `y` is evaluated only once (but in both cases `z` is not evaluated at all when `x < y` is found to be false).

This table summarizes the comparison operations:

Operation

Meaning -- *Notes*

`<`

strictly less than

`<=`

less than or equal

`>`

strictly greater than

`>=`

greater than or equal

`==`

equal

`<>`

not equal -- (1)

`!=`

not equal -- (1)

`is`

object identity

`is not`

negated object identity

Notes:

(1)

<> and `!=` are alternate spellings for the same operator. (I couldn't choose between ABC and C! :-)

Objects of different types, except different numeric types, never compare equal; such objects are ordered consistently but arbitrarily (so that sorting a heterogeneous array yields a consistent result). Furthermore, some types (e.g., windows) support only a degenerate notion of comparison where any two objects of that type are unequal. Again, such objects are ordered arbitrarily but consistently.

(Implementation note: objects of different types except numbers are ordered by their type names; objects of the same types that don't support proper comparison are ordered by their address.)

Two more operations with the same syntactic priority, `in` and `not in`, are supported only by sequence types (below).

Numeric Types

There are three numeric types: plain integers, long integers, and floating point numbers. Plain integers (also just called integers) are implemented using `long` in C, which gives them at least 32 bits of precision. Long integers have unlimited precision. Floating point numbers are implemented using `double` in C. All bets on their precision are off unless you happen to know the machine you are working with.

Numbers are created by numeric literals or as the result of built-in functions and operators. Unadorned integer literals (including hex and octal numbers) yield plain integers. Integer literals with an `L' or `l' suffix yield long integers (`L' is preferred because `1l` looks too much like eleven!). Numeric literals containing a decimal point or an exponent sign yield floating point numbers.

Python fully supports mixed arithmetic: when a binary arithmetic operator has operands of different numeric types, the operand with the "smaller" type is converted to that of the other, where plain integer is smaller than long integer is smaller than floating point. Comparisons between numbers of mixed type use the same rule.(2) The functions `int()`, `long()` and `float()` can be used to coerce numbers to a specific type.

All numeric types support the following operations, sorted by ascending priority (operations in the same box have the same priority; all numeric operations have a higher priority than comparison operations):

Operation
: *Result -- Notes*

`x + y`
: sum of x and y

`x - y`
: difference of x and y @hline

`x * y`
: product of x and y

`x / y`
: quotient of x and y -- (1)

`x % y`
: remainder of `x / y` @hline

`-x`
: x negated

`+x`
: x unchanged @hline

`abs(x)`
: absolute value of x

`int(x)`
: x converted to integer -- (2)

`long(x)`
: x converted to long integer -- (2)

`float(x)`
: x converted to floating point

`divmod(x, y)`
: the pair `(x / y, x % y)` -- (3)

`pow(x, y)`
: x to the power y

Notes:

(1)
: For (plain or long) integer division, the result is an integer; it always truncates towards zero.

(2)
: Conversion from floating point to (long or plain) integer may round or truncate as in C; see functions `floor()` and `ceil()` in module `math` for well-defined conversions.

(3)
: See the section on built-in functions for an exact definition.

Bit-string Operations on Integer Types

Plain and long integer types support additional operations that make sense only for bit-strings. Negative numbers are treated as their 2's complement value (for long integers, this assumes a sufficiently large number of bits that no overflow occurs during the operation).

The priorities of the binary bit-wise operations are all lower than the numeric operations and higher than the comparisons; the unary operation `~' has the same priority as the other unary numeric operations (`+' and `-').

This table lists the bit-string operations sorted in ascending priority (operations in the same box have the same priority):

Operation

Result -- Notes

`x | y`

bitwise or of x and y @hline

`x ^ y`

bitwise exclusive or of x and y @hline

`x & y`

bitwise and of x and y @hline

`x << n`

x shifted left by n bits -- (1), (2)

`x >> n`

x shifted right by n bits -- (1), (3) @hline@hline

`~x`

the bits of x inverted

Notes:

(1)

Negative shift counts are illegal.

(2)

A left shift by n bits is equivalent to multiplication by `pow(2, n)` without overflow check.

(3)

A right shift by n bits is equivalent to division by `pow(2, n)` without overflow check.

Sequence Types

There are three sequence types: strings, lists and tuples.

Strings literals are written in single or double quotes: `'xyzzy'`, `"frobozz"`. See Chapter 2 of the Python Reference Manual for more about string literals. Lists are constructed with square brackets, separating items with commas: `[a, b, c]`. Tuples are constructed by the comma operator (not within

square brackets), with or without enclosing parentheses, but an empty tuple must have the enclosing parentheses, e.g., `a, b, c` or `()`. A single item tuple must have a trailing comma, e.g., `(d,)`.

Sequence types support the following operations. The `in' and `not@,in' operations have the same priorities as the comparison operations. The `+' and `*' operations have the same priority as the corresponding numeric operations.(3)

This table lists the sequence operations sorted in ascending priority (operations in the same box have the same priority). In the table, s and t are sequences of the same type; n, i and j are integers:

Operation

Result -- Notes

`x in s`

`1` if an item of s is equal to x, else `0`

`x not in s`

`0` if an item of s is equal to x, else `1` @hline

`s + t`

the concatenation of s and t @hline

`s * n, n * s`

n copies of s concatenated @hline

`s[i]`

i'th item of s, origin 0 -- (1)

`s[i:j]`

slice of s from i to j -- (1), (2) @hline

`len(s)`

length of s

`min(s)`

smallest item of s

`max(s)`

largest item of s

Notes:

(1)

If i or j is negative, the index is relative to the end of the string, i.e., `len(s) + i` or `len(s) + j` is substituted. But note that `-0` is still `0`.

(2)

The slice of s from i to j is defined as the sequence of items with index k such that `i <= k < j`. If i or j is greater than `len(s)`, use `len(s)`. If i is omitted, use `0`. If j is omitted, use `len(s)`. If i is greater than or equal to j, the slice is empty.

More String Operations

String objects have one unique built-in operation: the % operator (modulo) with a string left argument interprets this string as a C sprintf format string to be applied to the right argument, and returns the string resulting from this formatting operation.

The right argument should be a tuple with one item for each argument required by the format string; if the string requires a single argument, the right argument may also be a single non-tuple object.(4) The following format characters are understood: %, c, s, i, d, u, o, x, X, e, E, f, g, G. Width and precision may be a * to specify that an integer argument specifies the actual width or precision. The flag characters -, +, blank, # and 0 are understood. The size specifiers h, l or L may be present but are ignored. The `%s` conversion takes any Python object and converts it to a string using `str()` before formatting it. The ANSI features `%p` and `%n` are not supported. Since Python strings have an explicit length, `%s` conversions don't assume that `'\0'` is the end of the string.

For safety reasons, floating point precisions are clipped to 50; `%f` conversions for numbers whose absolute value is over 1e25 are replaced by `%g` conversions.(5) All other errors raise exceptions.

If the right argument is a dictionary (or any kind of mapping), then the formats in the string must have a parenthesized key into that dictionary inserted immediately after the % character, and each format formats the corresponding entry from the mapping. E.g.

```
>>> count = 2
>>> language = 'Python'
>>> print '%(language)s has %(count)03d quote types.' % vars()
Python has 002 quote types.
>>>
```

In this case no * specifiers may occur in a format (since they a require sequential parameter list).

Additional string operations are defined in standard module `string` and in built-in module `regex`.

Mutable Sequence Types

List objects support additional operations that allow in-place modification of the object. These operations would be supported by other mutable sequence types (when added to the language) as well. Strings and tuples are immutable sequence types and such objects cannot be modified once created. The following operations are defined on mutable sequence types (where x is an arbitrary object):

Operation

Result -- Notes

`s[i] = x`

item i of s is replaced by x

`s[i:j] = t`

slice of s from i to j is replaced by t

`del s[i:j]`

same as `s[i:j] = []`

`s.append(x)`

same as `s[len(s):len(s)] = [x]`

`s.count(x)`

return number of i's for which `s[i] == x`

`s.index(x)`

return smallest i such that `s[i] == x` -- (1)

`s.insert(i, x)`

same as `s[i:i] = [x]`

`s.remove(x)`

same as `del s[s.index(x)]` -- (1)

`s.reverse()`

reverses the items of s in place

`s.sort()`

permutes the items of s to satisfy `s[i] <= s[j]`, for `i < j` -- (2)

Notes:

(1)

Raises an exception when x is not found in s.

(2)

The `sort()` method takes an optional argument specifying a comparison function of two arguments (list items) which should return `-1`, `0` or `1` depending on whether the first argument is considered smaller than, equal to, or larger than the second argument. Note that this slows the sorting process down considerably; e.g. to sort a list in reverse order it is much faster to use calls to `sort()` and `reverse()` than to use `sort()` with a comparison function that reverses the ordering of the elements.

Mapping Types

A mapping object maps values of one type (the key type) to arbitrary objects. Mappings are mutable objects. There is currently only one standard mapping type, the dictionary. A dictionary's keys are almost arbitrary values. The only types of values not acceptable as keys are values containing lists or dictionaries or other mutable types that are compared by value rather than by object identity. Numeric types used for keys obey the normal rules for numeric comparison: if two numbers compare equal (e.g. 1 and 1.0) then they can be used interchangeably to index the same dictionary entry.

Dictionaries are created by placing a comma-separated list of `key:@,var{value}` pairs within braces, for example: `{'jack':@,4098, 'sjoerd':@,4127}` or `{4098:@,'jack', 4127:@,'sjoerd'}`.

The following operations are defined on mappings (where a is a mapping, k is a key and x is an arbitrary object):

Operation

Result -- *Notes*

`len(a)`
: the number of items in a

`a[k]`
: the item of a with key k -- (1)

`a[k] = x`
: set `a[k]` to x

`del a[k]`
: remove `a[k]` from a -- (1)

`a.items()`
: a copy of a's list of (key, item) pairs -- (2)

`a.keys()`
: a copy of a's list of keys -- (2)

`a.values()`
: a copy of a's list of values -- (2)

`a.has_key(k)`
: `1` if a has a key k, else `0`

Notes:

(1)
: Raises an exception if k is not in the map.

(2)
: Keys and values are listed in random order.

Other Built-in Types

The interpreter supports several other kinds of objects. Most of these support only one or two operations.

Modules

The only special operation on a module is attribute access: `m.name`, where m is a module and name accesses a name defined in m's symbol table. Module attributes can be assigned to. (Note that the `import` statement is not, strictly spoken, an operation on a module object; `import foo` does not require a module object named foo to exist, rather it requires an (external) *definition* for a module named foo somewhere.)

A special member of every module is `__dict__`. This is the dictionary containing the module's symbol table. Modifying this dictionary will actually change the module's symbol table, but direct assignment to the `__dict__` attribute is not possible (i.e., you can write `m.__dict__['a'] = 1`, which defines `m.a` to be `1`, but you can't write `m.__dict__ = {}`.

Modules are written like this: `<module 'sys'>`.

Classes and Class Instances

(See Chapters 3 and 7 of the Python Reference Manual for these.)

Functions

Function objects are created by function definitions. The only operation on a function object is to call it: `func(argument-list)`.

There are really two flavors of function objects: built-in functions and user-defined functions. Both support the same operation (to call the function), but the implementation is different, hence the different object types.

The implementation adds two special read-only attributes: `f.func_code` is a function's code object (see below) and `f.func_globals` is the dictionary used as the function's global name space (this is the same as `m.__dict__` where m is the module in which the function f was defined).

Methods

Methods are functions that are called using the attribute notation. There are two flavors: built-in methods (such as `append()` on lists) and class instance methods. Built-in methods are described with the types that support them.

The implementation adds two special read-only attributes to class instance methods: `m.im_self` is the object whose method this is, and `m.im_func` is the function implementing the method. Calling `m(arg-1, arg-2, ..., arg-n)` is completely equivalent to calling `m.im_func(m.im_self, arg-1, arg-2, ..., arg-n)`.

(See the Python Reference Manual for more info.)

Code Objects

Code objects are used by the implementation to represent "pseudo-compiled" executable Python code such as a function body. They differ from function objects because they don't contain a reference to their global execution environment. Code objects are returned by the built-in `compile()` function and can be extracted from function objects through their `func_code` attribute.

A code object can be executed or evaluated by passing it (instead of a source string) to the `exec` statement or the built-in `eval()` function.

(See the Python Reference Manual for more info.)

Type Objects

Type objects represent the various object types. An object's type is accessed by the built-in function `type()`. There are no special operations on types. The standard module `types` defines names for all standard built-in types.

Types are written like this: `<type 'int'>`.

The Null Object

This object is returned by functions that don't explicitly return a value. It supports no special operations. There is exactly one null object, named `None` (a built-in name).

It is written as `None`.

File Objects

File objects are implemented using C's `stdio` package and can be created with the built-in function `open()` described under Built-in Functions below. They are also returned by some other built-in functions and methods, e.g. `posix.popen()` and `posix.fdopen()` and the `makefile()` method of socket objects.

When a file operation fails for an I/O-related reason, the exception `IOError` is raised. This includes situations where the operation is not defined for some reason, like `seek()` on a tty device or writing a file opened for reading.

Files have the following methods:

Method: file **close** *()*

Close the file. A closed file cannot be read or written anymore.

Method: file **flush** *()*

Flush the internal buffer, like `stdio`'s `fflush()`.

Method: file **isatty** *()*

Return `1` if the file is connected to a tty(-like) device, else `0`.

Method: file **read** *(size)*

Read at most size bytes from the file (less if the read hits EOF or no more data is immediately available on a pipe, tty or similar device). If the size argument is omitted, read all data until EOF is reached. The bytes are returned as a string object. An empty string is returned when EOF is encountered immediately. (For certain files, like ttys, it makes sense to continue reading after an EOF is hit.)

Method: file **readline** *()*

Read one entire line from the file. A trailing newline character is kept in the string(6) (but may be absent when a file ends with an incomplete line). An empty string is returned when EOF is hit immediately. Note: unlike `stdio`'s `fgets()`, the returned string contains null characters (`'\0'`) if they occurred in the input.

Method: file **readlines** *()*

Read until EOF using `readline()` and return a list containing the lines thus read.

Method: file **seek** *(offset, whence)*

Set the file's current position, like `stdio`'s `fseek()`. The whence argument is optional and default `0` (absolute file positioning); other values are `1` (seek relative to the current position) and `2` (seek relative to the file's end). There is no return value.

Method: file **tell** *()*

Return the file's current position, like `stdio`'s `ftell()`.

Method: file **write** *(str)*

Write a string to the file. There is no return value.

Method: file **writelines** *(list)*

Write a list of strings to the file. There is no return value. (The name is intended to match `readlines`; `writelines` does not add line separators.)

Internal Objects

(See the Python Reference Manual for these.)

Special Attributes

The implementation adds a few special read-only attributes to several object types, where they are relevant:

- `x.__dict__` is a dictionary of some sort used to store an object's (writable) attributes;
- `x.__methods__` lists the methods of many built-in object types, e.g., `[].__methods__` yields `['append', 'count', 'index', 'insert', 'remove', 'reverse', 'sort']`;
- `x.__members__` lists data attributes;
- `x.__class__` is the class to which a class instance belongs;
- `x.__bases__` is the tuple of base classes of a class object.

Built-in Exceptions

Exceptions are string objects. Two distinct string objects with the same value are different exceptions. This is done to force programmers to use exception names rather than their string value when specifying exception handlers. The string value of all built-in exceptions is their name, but this is not a requirement for user-defined exceptions or exceptions defined by library modules.

The following exceptions can be generated by the interpreter or built-in functions. Except where mentioned, they have an `associated value' indicating the detailed cause of the error. This may be a string or a tuple containing several items of information (e.g., an error code and a string explaining the code).

User code can raise built-in exceptions. This can be used to test an exception handler or to report an error condition `just like' the situation in which the interpreter raises the same exception; but beware that there

is nothing to prevent user code from raising an inappropriate error.

built-in exception: **AttributeError**

Raised when an attribute reference or assignment fails. (When an object does not support attribute references or attribute assignments at all, `TypeError` is raised.)

built-in exception: **EOFError**

Raised when one of the built-in functions (`input()` or `raw_input()`) hits an end-of-file condition (EOF) without reading any data. (N.B.: the `read()` and `readline()` methods of file objects return an empty string when they hit EOF.) No associated value.

built-in exception: **IOError**

Raised when an I/O operation (such as a `print` statement, the built-in `open()` function or a method of a file object) fails for an I/O-related reason, e.g., `file not found', `disk full'.

built-in exception: **ImportError**

Raised when an `import` statement fails to find the module definition or when a `from ... import` fails to find a name that is to be imported.

built-in exception: **IndexError**

Raised when a sequence subscript is out of range. (Slice indices are silently truncated to fall in the allowed range; if an index is not a plain integer, `TypeError` is raised.)

built-in exception: **KeyError**

Raised when a mapping (dictionary) key is not found in the set of existing keys.

built-in exception: **KeyboardInterrupt**

Raised when the user hits the interrupt key (normally Control-C or DEL). During execution, a check for interrupts is made regularly. Interrupts typed when a built-in function `input()` or `raw_input()`) is waiting for input also raise this exception. No associated value.

built-in exception: **MemoryError**

Raised when an operation runs out of memory but the situation may still be rescued (by deleting some objects). The associated value is a string indicating what kind of (internal) operation ran out of memory. Note that because of the underlying memory management architecture (C's `malloc()` function), the interpreter may not always be able to completely recover from this situation; it nevertheless raises an exception so that a stack traceback can be printed, in case a run-away program was the cause.

built-in exception: **NameError**

Raised when a local or global name is not found. This applies only to unqualified names. The associated value is the name that could not be found.

built-in exception: **OverflowError**

Raised when the result of an arithmetic operation is too large to be represented. This cannot occur for long integers (which would rather raise `MemoryError` than give up). Because of the lack of standardization of floating point exception handling in C, most floating point operations also aren't checked. For plain integers, all operations that can overflow are checked except left shift, where typical applications prefer to drop bits than raise an exception.

built-in exception: **RuntimeError**

Raised when an error is detected that doesn't fall in any of the other categories. The associated value is a string indicating what precisely went wrong. (This exception is a relic from a previous version of the interpreter; it is not used any more except by some extension modules that haven't been converted to define their own exceptions yet.)

built-in exception: **SyntaxError**

Raised when the parser encounters a syntax error. This may occur in an `import` statement, in an `exec` statement, in a call to the built-in function `eval()` or `input()`, or when reading the initial script or standard input (also interactively).

built-in exception: **SystemError**

Raised when the interpreter finds an internal error, but the situation does not look so serious to cause it to abandon all hope. The associated value is a string indicating what went wrong (in low-level terms).

You should report this to the author or maintainer of your Python interpreter. Be sure to report the version string of the Python interpreter (`sys.version`; it is also printed at the start of an interactive Python session), the exact error message (the exception's associated value) and if possible the source of the program that triggered the error.

built-in exception: **SystemExit**

This exception is raised by the `sys.exit()` function. When it is not handled, the Python interpreter exits; no stack traceback is printed. If the associated value is a plain integer, it specifies the system exit status (passed to C's `exit()` function); if it is `None`, the exit status is zero; if it has another type (such as a string), the object's value is printed and the exit status is one.

A call to `sys.exit` is translated into an exception so that clean-up handlers (`finally` clauses of `try` statements) can be executed, and so that a debugger can execute a script without running the risk of losing control. The `posix._exit()` function can be used if it is absolutely positively necessary to exit immediately (e.g., after a `fork()` in the child process).

built-in exception: **TypeError**

Raised when a built-in operation or function is applied to an object of inappropriate type. The associated value is a string giving details about the type mismatch.

built-in exception: **ValueError**

Raised when a built-in operation or function receives an argument that has the right type but an inappropriate value, and the situation is not described by a more precise exception such as `IndexError`.

built-in exception: **ZeroDivisionError**

Raised when the second argument of a division or modulo operation is zero. The associated value is a string indicating the type of the operands and the operation.

Built-in Functions

The Python interpreter has a number of functions built into it that are always available. They are listed here in alphabetical order.

built-in function: **abs** *(x)*

Return the absolute value of a number. The argument may be a plain or long integer or a floating point number.

built-in function: **apply** *(function, args)*

The function argument must be a callable object (a user-defined or built-in function or method, or a class object) and the args argument must be a tuple. The function is called with args as argument list; the number of arguments is the the length of the tuple. (This is different from just calling `func(args)`, since in that case there is always exactly one argument.)

built-in function: **chr** *(i)*

Return a string of one character whose ASCII code is the integer i, e.g., `chr(97)` returns the string `'a'`. This is the inverse of `ord()`. The argument must be in the range [0..255], inclusive.

built-in function: **cmp** *(x, y)*

Compare the two objects x and y and return an integer according to the outcome. The return value is negative if `x < y`, zero if `x == y` and strictly positive if `x > y`.

built-in function: **coerce** *(x, y)*

Return a tuple consisting of the two numeric arguments converted to a common type, using the same rules as used by arithmetic operations.

built-in function: **compile** *(string, filename, kind)*

Compile the string into a code object. Code objects can be executed by an `exec` statement or evaluated by a call to `eval()`. The filename argument should give the file from which the code was read; pass e.g. `'<string>'` if it wasn't read from a file. The kind argument specifies what kind of code must be compiled; it can be `'exec'` if string consists of a sequence of statements, or `'eval'` if it consists of a single expression.

built-in function: **delattr** *(object, name)*

This is a relative of `setattr`. The arguments are an object and a string. The string must be the name of one of the object's attributes. The function deletes the named attribute, provided the object allows it. For example, `delattr(x, 'foobar')` is equivalent to `del x.foobar`.

built-in function: **dir** *()*

Without arguments, return the list of names in the current local symbol table. With a module, class or class instance object as argument (or anything else that has a `__dict__` attribute), returns the list of names in that object's attribute dictionary. The resulting list is sorted. For example:

```
>>> import sys
>>> dir()
['sys']
>>> dir(sys)
['argv', 'exit', 'modules', 'path', 'stderr', 'stdin', 'stdout']
>>>
```

built-in function: **divmod** *(a, b)*

Take two numbers as arguments and return a pair of integers consisting of their integer quotient and remainder. With mixed operand types, the rules for binary arithmetic operators apply. For plain and long integers, the result is the same as `(a / b, a % b)`. For floating point numbers the result is the same as `(math.floor(a / b), a % b)`.

built-in function: **eval** *(expression[, globals[, locals]])*

The arguments are a string and two optional dictionaries. The expression argument is parsed and evaluated as a Python expression (technically speaking, a condition list) using the globals and locals dictionaries as global and local name space. If the locals dictionary is omitted it defaults to the globals dictionary. If both dictionaries are omitted, the expression is executed in the environment where `eval` is called. The return value is the result of the evaluated expression. Syntax errors are reported as exceptions. Example:

```
>>> x = 1
>>> print eval('x+1')
2
>>>
```

This function can also be used to execute arbitrary code objects (e.g. created by `compile()`). In this case pass a code object instead of a string. The code object must have been compiled passing `'eval'` to the kind argument.

Hints: dynamic execution of statements is supported by the `exec` statement. Execution of statements from a file is supported by the `execfile()` function. The `vars()` function returns the current local dictionary, which may be useful to pass around for use by `eval()` or `execfile()`.

built-in function: **execfile** *(file[, globals[, locals]])*

This function is similar to the `exec` statement, but parses a file instead of a string. It is different from the `import` statement in that it does not use the module administration -- it reads the file unconditionally and does not create a new module.(7)

The arguments are a file name and two optional dictionaries. The file is parsed and evaluated as a sequence of Python statements (similarly to a module) using the globals and locals dictionaries as gl and local name space. If the locals dictionary is omitted it defaults to the globals dictionary. If both dictionaries are omitted, the expression is executed in the environment where `execfile()` is called. The return value is `None`.

built-in function: **filter** *(function, list)*

Construct a list from those elements of list for which function returns true. If list is a string or a tuple, the result also has that type; otherwise it is always a list. If function is `None`, the identity function is assumed, i.e. all elements of list that are false (zero or empty) are removed.

built-in function: **float** *(x)*

Convert a number to floating point. The argument may be a plain or long integer or a floating point number.

built-in function: **getattr** *(object, name)*

The arguments are an object and a string. The string must be the name of one of the object's attributes. The result is the value of that attribute. For example, `getattr(x, 'foobar')` is equivalent to `x.foobar`.

built-in function: **hasattr** *(object, name)*

The arguments are an object and a string. The result is 1 if the string is the name of one of the object's attributes, 0 if not. (This is implemented by calling `getattr(object, name)` and seeing whether it raises an exception or not.)

built-in function: **hash** *(object)*

Return the hash value of the object (if it has one). Hash values are 32-bit integers. They are used to quickly compare dictionary keys during a dictionary lookup. Numeric values that compare equal have the same hash value (even if they are of different types, e.g. 1 and 1.0).

built-in function: **hex** *(x)*

Convert an integer number (of any size) to a hexadecimal string. The result is a valid Python expression.

built-in function: **id** *(object)*

Return the `identity' of an object. This is an integer which is guaranteed to be unique and constant for this object during its lifetime. (Two objects whose lifetimes are disjunct may have the same id() value.) (Implementation note: this is the address of the object.)

built-in function: **input** *([prompt])*

Almost equivalent to `eval(raw_input(prompt))`. Like `raw_input()`, the prompt argument is optional. The difference is that a long input expression may be broken over multiple lines using the backslash convention.

built-in function: **int** *(x)*

Convert a number to a plain integer. The argument may be a plain or long integer or a floating point number. Conversion of floating point numbers to integers is defined by the C semantics; normally the conversion truncates towards zero.(8)

built-in function: **len** *(s)*

Return the length (the number of items) of an object. The argument may be a sequence (string, tuple or list) or a mapping (dictionary).

built-in function: **long** *(x)*

Convert a number to a long integer. The argument may be a plain or long integer or a floating point number.

built-in function: **map** *(function, list, ...)*

Apply function to every item of list and return a list of the results. If additional list arguments are passed, function must take that many arguments and is applied to the items of all lists in parallel; if a list is shorter than another it is assumed to be extended with `None` items. If function is `None`, the identity function is assumed; if there are multiple list arguments, `map` returns a list consisting of tuples containing the corresponding items from all lists (i.e. a kind of transpose operation). The list arguments may be any kind of sequence; the result is always a list.

built-in function: **max** *(s)*

Return the largest item of a non-empty sequence (string, tuple or list).

built-in function: **min** *(s)*

Return the smallest item of a non-empty sequence (string, tuple or list).

built-in function: **oct** *(x)*

Convert an integer number (of any size) to an octal string. The result is a valid Python expression.

built-in function: **open** *(filename[, mode[, bufsize]])*

Return a new file object (described earlier under Built-in Types). The first two arguments are the same as for `stdio`'s `fopen()`: filename is the file name to be opened, mode indicates how the file is to be opened: `'r'` for reading, `'w'` for writing (truncating an existing file), and `'a'` opens it for appending. Modes `'r+'`, `'w+'` and `'a+'` open the file for updating, provided the underlying `stdio` library understands this. On systems that differentiate between binary and text files, `'b'` appended to the mode opens the file in binary mode. If the file cannot be opened, `IOError` is raised. If mode is omitted, it defaults to `'r'`. The optional bufsize argument specifies the file's desired buffer size: 0 means unbuffered, 1 means line buffered, any other positive value means use a buffer of (approximately) that size. A negative bufsize means to use the system default, which is usually line buffered for for tty devices and fully buffered for other files.(9)

built-in function: **ord** *(c)*

Return the ASCII value of a string of one character. E.g., `ord('a')` returns the integer `97`. This is the

inverse of `chr()`.

built-in function: **pow** *(x, y[, z])*

Return x to the power y; if z is present, return x to the power y, modulo z (computed more efficiently than `pow(x, y) % z`). The arguments must have numeric types. With mixed operand types, the rules for binary arithmetic operators apply. The effective operand type is also the type of the result; if the result is not expressible in this type, the function raises an exception; e.g., `pow(2, -1)` or `pow(2, 35000)` is not allowed.

built-in function: **range** *([start,] end[, step])*

This is a versatile function to create lists containing arithmetic progressions. It is most often used in `for` loops. The arguments must be plain integers. If the step argument is omitted, it defaults to `1`. If the start argument is omitted, it defaults to `0`. The full form returns a list of plain integers `[start, start + step, start + 2 * step, ...]`. If step is positive, the last element is the largest `start + i * step` less than end; if step is negative, the last element is the largest `start + i * step` greater than end. step must not be zero (or else an exception is raised). Example:

```
>>> range(10)
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
>>> range(1, 11)
[1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
>>> range(0, 30, 5)
[0, 5, 10, 15, 20, 25]
>>> range(0, 10, 3)
[0, 3, 6, 9]
>>> range(0, -10, -1)
[0, -1, -2, -3, -4, -5, -6, -7, -8, -9]
>>> range(0)
[]
>>> range(1, 0)
[]
>>>
```

built-in function: **raw_input** *([prompt])*

If the prompt argument is present, it is written to standard output without a trailing newline. The function then reads a line from input, converts it to a string (stripping a trailing newline), and returns that. When EOF is read, `EOFError` is raised. Example:

```
>>> s = raw_input('--> ')
--> Monty Python's Flying Circus
>>> s
"Monty Python's Flying Circus"
>>>
```

built-in function: **reduce** *(function, list[, initializer])*

Apply the binary function to the items of list so as to reduce the list to a single value. E.g., `reduce(lambda x, y: x*y, list, 1)` returns the product of the elements of list. The optional initializer can be thought of as being prepended to list so as to allow reduction of an empty list. The list arguments may be any kind of sequence.

built-in function: **reload** *(module)*

Re-parse and re-initialize an already imported module. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (i.e. the same as the module argument).

There are a number of caveats:

If a module is syntactically correct but its initialization fails, the first `import` statement for it does not bind its name locally, but does store a (partially initialized) module object in `sys.modules`. To reload the module you must first `import` it again (this will bind the name to the partially initialized module object) before you can `reload()` it.

When a module is reloaded, its dictionary (containing the module's global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module's advantage if it maintains a global table or cache of objects --- with a `try` statement it can test for the table's presence and skip its initialization if desired.

It is legal though generally not very useful to reload built-in or dynamically loaded modules, except for `sys`, `__main__` and `__builtin__`. In certain cases, however, extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using `from` {...} `import` {...}, calling `reload()` for the other module does not redefine the objects imported from it -- one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (module.name) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances -- they continue to use the old class definition. The same is true for derived classes.

built-in function: **repr** *(object)*

Return a string containing a printable representation of an object. This is the same value yielded by conversions (reverse quotes). It is sometimes useful to be able to access this operation as an ordinary function. For many types, this function makes an attempt to return a string that would yield an object with the same value when passed to `eval()`.

built-in function: **round** *(x, n)*

Return the floating point value x rounded to n digits after the decimal point. If n is omitted, it defaults to zero. The result is a floating point number. Values are rounded to the closest multiple of 10 to the power minus n; if two multiples are equally close, rounding is done away from 0 (so e.g. `round(0.5)` is `1.0`

and `round(-0.5)` is `-1.0`).

built-in function: **setattr** *(object, name, value)*

This is the counterpart of `getattr`. The arguments are an object, a string and an arbitrary value. The string must be the name of one of the object's attributes. The function assigns the value to the attribute, provided the object allows it. For example, `setattr(x, 'foobar', 123)` is equivalent to `x.foobar = 123`.

built-in function: **str** *(object)*

Return a string containing a nicely printable representation of an object. For strings, this returns the string itself. The difference with `repr(object)` is that `str(object)` does not always attempt to return a string that is acceptable to `eval()`; its goal is to return a printable string.

built-in function: **tuple** *(sequence)*

Return a tuple whose items are the same and in the same order as sequence's items. If sequence is alread a tuple, it is returned unchanged. For instance, `tuple('abc')` returns returns `('a', 'b', 'c')` and `tuple([1, 2, 3])` returns `(1, 2, 3)`.

built-in function: **type** *(object)*

Return the type of an object. The return value is a type object. The standard module `types` defines names for all built-in types. For instance:

```
>>> import types
>>> if type(x) == types.StringType: print "It's a string"
```

built-in function: **vars** *([object])*

Without arguments, return a dictionary corresponding to the current local symbol table. With a module, class or class instance object as argument (or anything else that has a `__dict__` attribute), returns a dictionary corresponding to the object's symbol table. The returned dictionary should not be modified: the effects on the corresponding symbol table are undefined.(10)

built-in function: **xrange** *([start,] end[, step])*

This function is very similar to `range()`, but returns an "xrange object" instead of a list. This is an opaque sequence type which yields the same values as the corresponding list, without actually storing them all simultaneously. The advantage of `xrange()` over `range()` is minimal (since `xrange()` still has to create the values when asked for them) except when a very large range is used on a memory-starved machine (e.g. MS-DOS) or when all of the range's elements are never used (e.g. when the loop is usually terminated with `break`).

TOC

Python Services

The modules described in this chapter provide a wide range of services related to the Python interpreter and its interaction with its environment. Here's an overview:

sys
--- Access system specific parameters and functions.

types
--- Names for all built-in types.

traceback
--- Print or retrieve a stack traceback.

pickle
--- Convert Python objects to streams of bytes and back.

shelve
--- Python object persistency.

copy
--- Shallow and deep copy operations.

marshal
--- Convert Python objects to streams of bytes and back (with different constraints).

imp
--- Access the implementation of the `import` statement.

__builtin__
--- The set of built-in functions.

__main__
--- The environment where the top-level script is run.

Built-in Module sys

This module provides access to some variables used or maintained by the interpreter and to functions that interact strongly with the interpreter. It is always available.

data: module sys **argv**

The list of command line arguments passed to a Python script. `sys.argv[0]` is the script name (it is operating system dependent whether this is a full pathname or not). If the command was executed using the `-c' command line option to the interpreter, `sys.argv[0]` is set to the string `"-c"`. If no script name was passed to the Python interpreter, `sys.argv` has zero length.

data: module sys **builtin_module_names**

A list of strings giving the names of all modules that are compiled into this Python interpreter. (This information is not available in any other way -- `sys.modules.keys()` only lists the imported modules.)

data: module sys **exc_type**

data: module sys **exc_value**

data: module sys **exc_traceback**

These three variables are not always defined; they are set when an exception handler (an `except` clause of a `try` statement) is invoked. Their meaning is: `exc_type` gets the exception type of the exception being handled; `exc_value` gets the exception parameter (its associated value or the second argument to `raise`); `exc_traceback` gets a traceback object (see the Reference Manual) which encapsulates the call stack at the point where the exception originally occurred.

function of module sys: **exit** *(n)*

Exit from Python with numeric exit status n. This is implemented by raising the `SystemExit` exception, so cleanup actions specified by `finally` clauses of `try` statements are honored, and it is possible to catch the exit attempt at an outer level.

data: module sys **exitfunc**

This value is not actually defined by the module, but can be set by the user (or by a program) to specify a clean-up action at program exit. When set, it should be a parameterless function. This function will be called when the interpreter exits in any way (except not when a fatal error occurs: in that case the interpreter's internal state cannot be trusted).

data: module sys **last_type**

data: module sys **last_value**

data: module sys **last_traceback**

These three variables are not always defined; they are set when an exception is not handled and the interpreter prints an error message and a stack traceback. Their intended use is to allow an interactive user to import a debugger module and engage in post-mortem debugging without having to re-execute the command that caused the error (which may be hard to reproduce). The meaning of the variables is the same as that of `exc_type`, `exc_value` and `exc_tracaback`, respectively.

data: module sys **modules**

Gives the list of modules that have already been loaded. This can be manipulated to force reloading of modules and other tricks.

data: module sys **path**

A list of strings that specifies the search path for modules. Initialized from the environment variable `PYTHONPATH`, or an installation-dependent default.

data: module sys **ps1**

data: module sys **ps2**

Strings specifying the primary and secondary prompt of the interpreter. These are only defined if the interpreter is in interactive mode. Their initial values in this case are `'>>> '` and `'... '`.

function of module sys: **setcheckinterval** *(interval)*

Set the interpreter's "check interval". This integer value determines how often the interpreter checks for periodic things such as thread switches and signal handlers. The default is 10, meaning the check is performed every 10 Python virtual instructions. Setting it to a larger value may increase performance for programs using threads. Setting it to a value checks every virtual instruction, maximizing responsiveness as well as overhead.

function of module sys: **settrace** *(tracefunc)*

Set the system's trace function, which allows you to implement a Python source code debugger in Python. See section "How It Works" in the chapter on the Python Debugger.

function of module sys: **setprofile** *(profilefunc)*

Set the system's profile function, which allows you to implement a Python source code profiler in Python. See the chapter on the Python Profiler. The system's profile function is called similarly to the system's trace function (see `sys.settrace`), but it isn't called for each executed line of code (only on call and return and when an exception occurs). Also, its return value is not used, so it can just return `None`.

data: module sys **stdin**

data: module sys **stdout**

data: module sys **stderr**

File objects corresponding to the interpreter's standard input, output and error streams. `sys.stdin` is used for all interpreter input except for scripts but including calls to `input()` and `raw_input()`. `sys.stdout` is used for the output of `print` and expression statements and for the prompts of `input()` and `raw_input()`. The interpreter's own prompts and (almost all of) its error messages go to `sys.stderr`. `sys.stdout` and `sys.stderr` needn't be built-in file objects: any object is acceptable as long as it has a `write` method that takes a string argument. (Changing these objects doesn't affect the standard I/O streams of processes executed by `popen()`, `system()` or the `exec*()` family of functions in the `os` module.)

data: module sys **tracebacklimit**

When this variable is set to an integer value, it determines the maximum number of levels of traceback information printed when an unhandled exception occurs. The default is 1000. When set to 0 or less, all traceback information is suppressed and only the exception type and value are printed.

Standard Module types

This module defines names for all object types that are used by the standard Python interpreter (but not for the types defined by various extension modules). It is safe to use "`from types import *`" --- the module does not export any other names besides the ones listed here. New names exported by future versions of this module will all end in `Type`.

Typical use is for functions that do different things depending on their argument types, like the following:

```
from types import *
def delete(list, item):
    if type(item) is IntType:
       del list[item]
    else:
       list.remove(item)
```

The module defines the following names:

data: module types **NoneType**

The type of `None`.

data: module types **TypeType**

The type of type objects (such as returned by `type()`).

data: module types **IntType**

The type of integers (e.g. `1`).

data: module types **LongType**

The type of long integers (e.g. `1L`).

data: module types **FloatType**

The type of floating point numbers (e.g. `1.0`).

data: module types **StringType**

The type of character strings (e.g. `'Spam'`).

data: module types **TupleType**

The type of tuples (e.g. `(1, 2, 3, 'Spam')`).

data: module types **ListType**

The type of lists (e.g. `[0, 1, 2, 3]`).

data: module types **DictType**

The type of dictionaries (e.g. `{'Bacon': 1, 'Ham': 0}`).

data: module types **DictionaryType**

An alternative name for `DictType`.

data: module types **FunctionType**

The type of user-defined functions and lambdas.

data: module types **LambdaType**

An alternative name for `FunctionType`.

data: module types **CodeType**

The type for code objects such as returned by `compile()`.

data: module types **ClassType**

The type of user-defined classes.

data: module types **InstanceType**

The type of instances of user-defined classes.

data: module types **MethodType**

The type of methods of user-defined class instances.

data: module types **UnboundMethodType**

An alternative name for `MethodType`.

data: module types **BuiltinFunctionType**

The type of built-in functions like `len` or `sys.exit`.

data: module types **BuiltinMethodType**

An alternative name for `BuiltinFunction`.

data: module types **ModuleType**

The type of modules.

data: module types **FileType**

The type of open file objects such as `sys.stdout`.

data: module types **XRangeType**

The type of range objects returned by `xrange()`.

data: module types **TracebackType**

The type of traceback objects such as found in `sys.exc_traceback`.

data: module types **FrameType**

The type of frame objects such as found in `tb.tb_frame` if `tb` is a traceback object.

Standard Module `traceback`

This module provides a standard interface to format and print stack traces of Python programs. It exactly mimics the behavior of the Python interpreter when it prints a stack trace. This is useful when you want to print stack traces under program control, e.g. in a "wrapper" around the interpreter.

The module uses traceback objects -- this is the object type that is stored in the variables `sys.exc_traceback` and `sys.last_traceback`.

The module defines the following functions:

function of module traceback: **print_tb** *(traceback[, limit])*

Print up to limit stack trace entries from traceback. If limit is omitted or `None`, all entries are printed.

function of module traceback: **extract_tb** *(traceback[, limit])*

Return a list of up to limit "pre-processed" stack trace entries extracted from traceback. It is useful for alternate formatting of stack traces. If limit is omitted or `None`, all entries are extracted. A "pre-processed" stack trace entry is a quadruple (filename, line number, function name, line text) representing the information that is usually printed for a stack trace. The line text is a string with leading and trailing whitespace stripped; if the source is not available it is `None`.

function of module traceback: **print_exception** *(type, value, traceback[, limit])*

Print exception information and up to limit stack trace entries from traceback. This differs from `print_tb` in the following ways: (1) if traceback is not `None`, it prints a header "`Traceback (innermost last):`"; (2) it prints the exception type and value after the stack trace; (3) if type is `SyntaxError` and value has the appropriate format, it prints the line where the syntax error occurred with a caret indication the approximate position of the error.

function of module traceback: **print_exc** *([limit])*

This is a shorthand for `print_exception(sys.exc_type, sys.exc_value, sys.exc_traceback, limit)`.

function of module traceback: **print_last** *([limit])*

This is a shorthand for `print_exception(sys.last_type, sys.last_value, sys.last_traceback, limit)`.

Standard Module `pickle`

The `pickle` module implements a basic but powerful algorithm for "pickling" (a.k.a. serializing, marshalling or flattening) nearly arbitrary Python objects. This is the act of converting objects to a stream of bytes (and back: "unpickling"). This is a more primitive notion than persistency -- although `pickle` reads and writes file objects, it does not handle the issue of naming persistent objects, nor the (even more complicated) area of concurrent access to persistent objects. The `pickle` module can transform a complex object into a byte stream and it can transform the byte stream into an object with the same internal structure. The most obvious thing to do with these byte streams is to write them onto a file, but it is also conceivable to send them across a network or store them in a database. The module `shelve` provides a simple interface to pickle and unpickle objects on "dbm"-style database files.

Unlike the built-in module `marshal`, `pickle` handles the following correctly:

- recursive objects (objects containing references to themselves)
- object sharing (references to the same object in different places)
- user-defined classes and their instances

The data format used by `pickle` is Python-specific. This has the advantage that there are no restrictions imposed by external standards such as CORBA (which probably can't represent pointer sharing or recursive objects); however it means that non-Python programs may not be able to reconstruct pickled Python objects.

The `pickle` data format uses a printable ASCII representation. This is slightly more voluminous than a binary representation. However, small integers actually take *less* space when represented as minimal-size decimal strings than when represented as 32-bit binary numbers, and strings are only much longer if they contain many control characters or 8-bit characters. The big advantage of using printable ASCII (and of some other characteristics of `pickle`'s representation) is that for debugging or recovery purposes it is possible for a human to read the pickled file with a standard text editor. (I could have gone a step further and used a notation like S-expressions, but the parser (currently written in Python) would have been considerably more complicated and slower, and the files would probably have become much larger.)

The `pickle` module doesn't handle code objects, which the `marshal` module does. I suppose `pickle` could, and maybe it should, but there's probably no great need for it right now (as long as `marshal` continues to be used for reading and writing code objects), and at least this avoids the possibility of smuggling Trojan horses into a program.

For the benefit of persistency modules written using `pickle`, it supports the notion of a reference to an object outside the pickled data stream. Such objects are referenced by a name, which is an arbitrary string of printable ASCII characters. The resolution of such names is not defined by the `pickle` module -- the persistent object module will have to implement a method `persistent_load`. To write references to persistent objects, the persistent module must define a method `persistent_id` which returns either `None` or the persistent ID of the object.

There are some restrictions on the pickling of class instances.

First of all, the class must be defined at the top level in a module.

Next, it must normally be possible to create class instances by calling the class without arguments. If is undesirable, the class can define a method `__getinitargs__()`, which should return a *tuple* containing the arguments to be passed to the class constructor (`__init__()`).

Classes can further influence how their instances are pickled -- if the class defines the method `__getstate__()`, it is called and the return state is pickled as the contents for the instance, and if the class defines the method `__setstate__()`, it is called with the unpickled state. (Note that these methods can also be used to implement copying class instances.) If there is no `__getstate__()` method, the instance's `__dict__` is pickled. If there is no `__setstate__()` method, the pickled object must be a dictionary and its items are assigned to the new instance's dictionary. (If a class defines both `__getstate__()` and `__setstate__()`, the state object needn't be a dictionary --- these methods can do what they want.) This protocol is also used by the shallow and deep copying operations defined in the `copy` module.

Note that when class instances are pickled, their class's code and data are not pickled along with them. Only the instance data are pickled. This is done on purpose, so you can fix bugs in a class or add methods and still load objects that were created with an earlier version of the class. If you plan to have long-lived objects that will see many versions of a class, it may be worthwhile to put a version number in the objects so that suitable conversions can be made by the class's `__setstate__()` method.

When a class itself is pickled, only its name is pickled -- the class definition is not pickled, but re-imported by the unpickling process. Therefore, the restriction that the class must be defined at the top level in a module applies to pickled classes as well.

The interface can be summarized as follows.

To pickle an object `x` onto a file `f`, open for writing:

```
p = pickle.Pickler(f)
p.dump(x)
```

A shorthand for this is:

```
pickle.dump(x, f)
```

To unpickle an object `x` from a file `f`, open for reading:

```
u = pickle.Unpickler(f)
x = u.load()
```

A shorthand is:

```
x = pickle.load(f)
```

The `Pickler` class only calls the method `f.write` with a string argument. The `Unpickler` calls the methods `f.read` (with an integer argument) and `f.readline` (without argument), both returning a string. It is explicitly allowed to pass non-file objects here, as long as they have the right methods.

The following types can be pickled:

- `None`
- integers, long integers, floating point numbers
- strings
- tuples, lists and dictionaries containing only picklable objects
- classes that are defined at the top level in a module
- instances of such classes whose `__dict__` or `__setstate__()` is picklable

Attempts to pickle unpicklable objects will raise the `PicklingError` exception; when this happens, an unspecified number of bytes may have been written to the file.

It is possible to make multiple calls to the `dump()` method of the same `Pickler` instance. These must then be matched to the same number of calls to the `load()` instance of the corresponding `Unpickler` instance. If the same object is pickled by multiple `dump()` calls, the `load()` will all yield references to the same object. *Warning*: this is intended for pickling multiple objects without intervening modifications to the objects or their parts. If you modify an object and then pickle it again using the same `Pickler` instance, the object is not pickled again -- a reference to it is pickled and the `Unpickler` will return the old value, not the modified one. (There are two problems here: (a) detecting changes, and (b) marshalling a minimal set of changes. I have no answers. Garbage Collection may also become a problem here.)

Apart from the `Pickler` and `Unpickler` classes, the module defines the following functions, and an exception:

function of module pickle: **dump** *(object, file)*

Write a pickled representation of obect to the open file object file. This is equivalent to `Pickler(file).dump(object)`.

function of module pickle: **load** *(file)*

Read a pickled object from the open file object file. This is equivalent to `Unpickler(file).load()`.

function of module pickle: **dumps** *(object)*

Return the pickled representation of the object as a string, instead of writing it to a file.

function of module pickle: **loads** *(string)*

Read a pickled object from a string instead of a file. Characters in the string past the pickled object's representation are ignored.

exception: module pickle **PicklingError**

This exception is raised when an unpicklable object is passed to `Pickler.dump()`.

Standard Module shelve

A "shelf" is a persistent, dictionary-like object. The difference with "dbm" databases is that the values (not the keys!) in a shelf can be essentially arbitrary Python objects -- anything that the `pickle` module can handle. This includes most class instances, recursive data types, and objects containing lots of shared sub-objects. The keys are ordinary strings.

To summarize the interface (`key` is a string, `data` is an arbitrary object):

```
import shelve

d = shelve.open(filename) # open, with (g)dbm filename -- no suffix

d[key] = data   # store data at key (overwrites old data if
                # using an existing key)
data = d[key]   # retrieve data at key (raise KeyError if no
                # such key)
del d[key]      # delete data stored at key (raises KeyError
                # if no such key)
flag = d.has_key(key)   # true if the key exists
list = d.keys() # a list of all existing keys (slow!)

d.close()       # close it
```

Restrictions:

- The choice of which database package will be used (e.g. dbm or gdbm) depends on which interface is available. Therefore it isn't safe to open the database directly using dbm. The database is also (unfortunately) subject to the limitations of dbm, if it is used --- this means that (the pickled representation of) the objects stored in the database should be fairly small, and in rare cases key collisions may cause the database to refuse updates.
- Dependent on the implementation, closing a persistent dictionary may or may not be necessary to flush changes to disk.
- The `shelve` module does not support *concurrent* read/write access to shelved objects. (Multiple simultaneous read accesses are safe.) When a program has a shelf open for writing, no other program should have it open for reading or writing. UNIX file locking can be used to solve this, but this differs across UNIX versions and requires knowledge about the database implementation used.

Standard Module copy

This module provides generic (shallow and deep) copying operations.

Interface summary:

```
import copy

x = copy.copy(y)        # make a shallow copy of y
x = copy.deepcopy(y)    # make a deep copy of y
```

For module specific errors, `copy.error` is raised.

The difference between shallow and deep copying is only relevant for compound objects (objects that contain other objects, like lists or class instances):

- A *shallow copy* constructs a new compound object and then (to the extent possible) inserts *references* into it to the objects found in the original.
- A *deep copy* constructs a new compound object and then, recursively, inserts *copies* into it of the objects found in the original.

Two problems often exist with deep copy operations that don't exist with shallow copy operations:

- Recursive objects (compound objects that, directly or indirectly, contain a reference to themselves) may cause a recursive loop.
- Because deep copy copies *everything* it may copy too much, e.g. administrative data structures that should be shared even between copies.

Python's `deepcopy()` operation avoids these problems by:

- keeping a table of objects already copied during the current copying pass; and
- letting user-defined classes override the copying operation or the set of components copied.

This version does not copy types like module, class, function, method, nor stack trace, stack frame, nor file, socket, window, nor array, nor any similar types.

Classes can use the same interfaces to control copying that they use to control pickling: they can define methods called `__getinitargs__()`, `__getstate__()` and `__setstate__()`. See the description of module `pickle` for information on these methods.

Built-in Module `marshal`

This module contains functions that can read and write Python values in a binary format. The format is specific to Python, but independent of machine architecture issues (e.g., you can write a Python value to a file on a PC, transport the file to a Sun, and read it back there). Details of the format are undocumented on purpose; it may change between Python versions (although it rarely does).(11)

This is not a general "persistency" module. For general persistency and transfer of Python objects through RPC calls, see the modules `pickle` and `shelve`. The `marshal` module exists mainly to support reading and writing the "pseudo-compiled" code for Python modules of `.pyc' files.

Not all Python object types are supported; in general, only objects whose value is independent from a particular invocation of Python can be written and read by this module. The following types are supported: `None`, integers, long integers, floating point numbers, strings, tuples, lists, dictionaries, and code objects, where it should be understood that tuples, lists and dictionaries are only supported as long

as the values contained therein are themselves supported; and recursive lists and dictionaries should not be written (they will cause infinite loops).

Caveat: On machines where C's `long int` type has more than 32 bits (such as the DEC Alpha or the HP Precision Architecture), it is possible to create plain Python integers that are longer than 32 bits. Since the current `marshal` module uses 32 bits to transfer plain Python integers, such values are silently truncated. This particularly affects the use of very long integer literals in Python modules -- these will be accepted by the parser on such machines, but will be silently be truncated when the module is read from the `.pyc` instead.(12)

There are functions that read/write files as well as functions operating on strings.

The module defines these functions:

function of module marshal: **dump** *(value, file)*

Write the value on the open file. The value must be a supported type. The file must be an open file object such as `sys.stdout` or returned by `open()` or `posix.popen()`.

If the value has an unsupported type, garbage is written which cannot be read back by `load()`.

function of module marshal: **load** *(file)*

Read one value from the open file and return it. If no valid value is read, raise `EOFError`, `ValueError` or `TypeError`. The file must be an open file object.

function of module marshal: **dumps** *(value)*

Return the string that would be written to a file by `dump(value, file)`. The value must be a supported type.

function of module marshal: **loads** *(string)*

Convert the string to a value. If no valid value is found, raise `EOFError`, `ValueError` or `TypeError`. Extra characters in the string are ignored.

Built-in Module `imp`

This module provides an interface to the mechanisms used to implement the `import` statement. It defines the following constants and functions:

function of module struct: **get_magic** *()*

Return the magic string value used to recognize byte-compiled code files ("`.pyc` files").

function of module struct: **get_suffixes** *()*

Return a list of triples, each describing a particular type of file. Each triple has the form `(suffix, mode, type)`, where suffix is a string to be appended to the module name to form the filename to search for, mode is the mode string to pass to the built-in `open` function to open the file (this can be `'r'` for text files or `'rb'` for binary files), and type is the file type, which has one of the values

`PY_SOURCE`, `PY_COMPILED` or `C_EXTENSION`, defined below. (System-dependent values may be returned.)

function of module struct: **find_module** *(name, [path])*

Try to find the module name on the search path path. The default path is `sys.path`. The return value is a triple `(file, pathname, description)` where file is an open file object positioned at the beginning, pathname is the pathname of the file found, and description is a triple as contained in the list returned by `get_suffixes` describing the kind of file found.

function of module struct: **init_builtin** *(name)*

Initialize the built-in module called name and return its module object. If the module was already initialized, it will be initialized *again*. A few modules cannot be initialized twice -- attempting to initialize these again will raise an `ImportError` exception. If there is no built-in module called name, `None` is returned.

function of module struct: **init_frozen** *(name)*

Initialize the frozen module called name and return its module object. If the module was already initialized, it will be initialized *again*. If there is no frozen module called name, `None` is returned. (Frozen modules are modules written in Python whose compiled byte-code object is incorporated into a custom-built Python interpreter by Python's `freeze` utility. See `Tools/freeze` for now.)

function of module struct: **is_builtin** *(name)*

Return `1` if there is a built-in module called name which can be initialized again. Return `-1` if there is a built-in module called name which cannot be initialized again (see `init_builtin`). Return `0` if there is no built-in module called name.

function of module struct: **is_frozen** *(name)*

Return `1` if there is a frozen module (see `init_frozen`) called name, `0` if there is no such module.

function of module struct: **load_compiled** *(name, pathname, [file])*

Load and initialize a module implemented as a byte-compiled code file and return its module object. If the module was already initialized, it will be initialized *again*. The name argument is used to create or access a module object. The pathname argument points to the byte-compiled code file. The optional file argument is the byte-compiled code file, open for reading in binary mode, from the beginning -- if not given, the function opens pathname. It must currently be a real file object, not a user-defined class emulating a file.

function of module struct: **load_dynamic** *(name, pathname, [file])*

Load and initialize a module implemented as a dynamically loadable shared library and return its module object. If the module was already initialized, it will be initialized *again*. Some modules don't like that and may raise an exception. The pathname argument must point to the shared library. The name argument is used to construct the name of the initialization function: an external C function called `initname()` in the shared library is called. The optional file argment is ignored. (Note: using shared libraries is highly system dependent, and not all systems support it.)

function of module struct: **load_source** *(name, pathname, [file])*

Load and initialize a module implemented as a Python source file and return its module object. If the module was already initialized, it will be initialized *again*. The name argument is used to create or access a module object. The pathname argument points to the source file. The optional file argument is the source file, open for reading as text, from the beginning -- if not given, the function opens pathname. It must currently be a real file object, not a user-defined class emulating a file. Note that if a properly matching byte-compiled file (with suffix `.pyc`) exists, it will be used instead of parsing the given source file.

function of module struct: **new_module** *(name)*

Return a new empty module object called name. This object is *not* inserted in `sys.modules`.

The following constants with integer values, defined in the module, are used to indicate the search result of `imp.find_module`.

data: module struct **SEARCH_ERROR**

The module was not found.

data: module struct **PY_SOURCE**

The module was found as a source file.

data: module struct **PY_COMPILED**

The module was found as a compiled code object file.

data: module struct **C_EXTENSION**

The module was found as dynamically loadable shared library.

Examples

The following function emulates the default import statement:

```
import imp
import sys

def __import__(name, globals=None, locals=None, fromlist=None):
    # Fast path: see if the module has already been imported.
    if sys.modules.has_key(name):
        return sys.modules[name]

    # If any of the following calls raises an exception,
    # there's a problem we can't handle -- let the caller handle it.

    # See if it's a built-in module.
```

```
    m = imp.init_builtin(name)
    if m:
        return m

    # See if it's a frozen module.
    m = imp.init_frozen(name)
    if m:
        return m

    # Search the default path (i.e. sys.path).
    fp, pathname, (suffix, mode, type) = imp.find_module(name)

    # See what we got.
    # Note that fp will be closed automatically when we return.
    if type == imp.C_EXTENSION:
        return imp.load_dynamic(name, pathname)
    if type == imp.PY_SOURCE:
        return imp.load_source(name, pathname, fp)
    if type == imp.PY_COMPILED:
        return imp.load_compiled(name, pathname, fp)

    # Shouldn't get here at all.
    raise ImportError, '%s: unknown module type (%d)' % (name, type)
```

Built-in Module `__builtin__`

This module provides direct access to all `built-in' identifiers of Python; e.g. `__builtin__.open` is the full name for the built-in function `open`. See the section on Built-in Functions in the previous chapter.

Built-in Module `__main__`

This module represents the (otherwise anonymous) scope in which the interpreter's main program executes -- commands read either from standard input or from a script file.

Go to the previous, next section.

Go to the previous, next section.

String Services

The modules described in this chapter provide a wide range of string manipulation operations. Here's an overview:

string
--- Common string operations.

regex
--- Regular expression search and match operations.

regsub
--- Substitution and splitting operations that use regular expressions.

struct
--- Interpret strings as packed binary data.

Standard Module `string`

This module defines some constants useful for checking character classes and some useful string functions. See the modules `regex` and `regsub` for string functions based on regular expressions.

The constants defined in this module are are:

data: module string **digits**

The string `'0123456789'`.

data: module string **hexdigits**

The string `'0123456789abcdefABCDEF'`.

data: module string **letters**

The concatenation of the strings `lowercase` and `uppercase` described below.

data: module string **lowercase**

A string containing all the characters that are considered lowercase letters. On most systems this is the string `'abcdefghijklmnopqrstuvwxyz'`. Do not change its definition --- the effect on the routines `upper` and `swapcase` is undefined.

data: module string **octdigits**

The string `'01234567'`.

data: module string **uppercase**

A string containing all the characters that are considered uppercase letters. On most systems this is th string `'ABCDEFGHIJKLMNOPQRSTUVWXYZ'`. Do not change its definition --- the effect on the routines `lower` and `swapcase` is undefined.

data: module string **whitespace**

A string containing all characters that are considered whitespace. On most systems this includes the characters space, tab, linefeed, return, formfeed, and vertical tab. Do not change its definition --- the effect on the routines `strip` and `split` is undefined.

The functions defined in this module are:

function of module string: **atof** *(s)*

Convert a string to a floating point number. The string must have the standard syntax for a floating point literal in Python, optionally preceded by a sign (`+' or `-').

function of module string: **atoi** *(s[, base])*

Convert string s to an integer in the given base. The string must consist of one or more digits, optionally preceded by a sign (`+' or `-'). The base defaults to 10. If it is 0, a default base is chosen depending on the leading characters of the string (after stripping the sign): `0x' or `0X' means 16, `0' means 8, anything else means 10. If base is 16, a leading `0x' or `0X' is always accepted. (Note: for a more flexible interpretation of numeric literals, use the built-in function `eval()`.)

function of module string: **atol** *(s[, base])*

Convert string s to a long integer in the given base. The string must consist of one or more digits, optionally preceded by a sign (`+' or `-'). The base argument has the same meaning as for `atoi()`. A trailing `l' or `L' is not allowed.

function of module string: **expandtabs** *(s, tabsize)*

Expand tabs in a string, i.e. replace them by one or more spaces, depending on the current column and the given tab size. The column number is reset to zero after each newline occurring in the string. This doesn't understand other non-printing characters or escape sequences.

function of module string: **find** *(s, sub[, start])*

Return the lowest index in s not smaller than start where the substring sub is found. Return `-1` when sub does not occur as a substring of s with index at least start. If start is omitted, it defaults to `0`. If start is negative, `len(s)` is added.

function of module string: **rfind** *(s, sub[, start])*

Like `find` but find the highest index.

function of module string: **index** *(s, sub[, start])*

Like `find` but raise `ValueError` when the substring is not found.

function of module string: **rindex** *(s, sub[, start])*

Like `rfind` but raise `ValueError` when the substring is not found.

function of module string: **count** *(s, sub[, start])*

Return the number of (non-overlapping) occurrences of substring sub in string s with index at least start. If start is omitted, it defaults to `0`. If start is negative, `len(s)` is added.

function of module string: **lower** *(s)*

Convert letters to lower case.

function of module string: **split** *(s)*

Return a list of the whitespace-delimited words of the string s.

function of module string: **splitfields** *(s, sep)*

Return a list containing the fields of the string s, using the string sep as a separator. The list will have one more items than the number of non-overlapping occurrences of the separator in the string. Thus, `string.splitfields(s, ' ')` is not the same as `string.split(s)`, as the latter only returns non-empty words. As a special case, `splitfields(s, '')` returns `[s]`, for any string s. (See also `regsub.split()`.)

function of module string: **join** *(words)*

Concatenate a list or tuple of words with intervening spaces.

function of module string: **joinfields** *(words, sep)*

Concatenate a list or tuple of words with intervening separators. It is always true that `string.joinfields(string.splitfields(t, sep), sep)` equals t.

function of module string: **strip** *(s)*

Remove leading and trailing whitespace from the string s.

function of module string: **swapcase** *(s)*

Convert lower case letters to upper case and vice versa.

function of module string: **upper** *(s)*

Convert letters to upper case.

function of module string: **ljust** *(s, width)*

function of module string: **rjust** *(s, width)*

function of module string: **center** *(s, width)*

These functions respectively left-justify, right-justify and center a string in a field of given width. They return a string that is at least width characters wide, created by padding the string s with spaces until the given width on the right, left or both sides. The string is never truncated.

function of module string: **zfill** *(s, width)*

Pad a numeric string on the left with zero digits until the given width is reached. Strings starting with a sign are handled correctly.

This module is implemented in Python. Much of its functionality has been reimplemented in the built-in module `strop`. However, you should *never* import the latter module directly. When `string` discovers that `strop` exists, it transparently replaces parts of itself with the implementation from `strop`. After initialization, there is *no* overhead in using `string` instead of `strop`.

Built-in Module `regex`

This module provides regular expression matching operations similar to those found in Emacs. It is always available.

By default the patterns are Emacs-style regular expressions; there is a way to change the syntax to match that of several well-known UNIX utilities.

This module is 8-bit clean: both patterns and strings may contain null bytes and characters whose high bit is set.

Please note: There is a little-known fact about Python string literals which means that you don't usually have to worry about doubling backslashes, even though they are used to escape special characters in string literals as well as in regular expressions. This is because Python doesn't remove backslashes from string literals if they are followed by an unrecognized escape character. *However*, if you want to include a literal backslash in a regular expression represented as a string literal, you have to *quadruple* it. E.g. to extract LaTeX `\section{...}' headers from a document, you can use this pattern: `'\\\\section{\(.*\)}'`.

The module defines these functions, and an exception:

function of module regex: **match** *(pattern, string)*

Return how many characters at the beginning of string match the regular expression pattern. Return `-1` if the string does not match the pattern (this is different from a zero-length match!).

function of module regex: **search** *(pattern, string)*

Return the first position in string that matches the regular expression pattern. Return -1 if no position in the string matches the pattern (this is different from a zero-length match anywhere!).

function of module regex: **compile** *(pattern[, translate])*

Compile a regular expression pattern into a regular expression object, which can be used for matching using its `match` and `search` methods, described below. The optional argument translate, if present, must be a 256-character string indicating how characters (both of the pattern and of the strings to be matched) are translated before comparing them; the `i`-th element of the string gives the translation for the character with ASCII code `i`. This can be used to implement case-insensitive matching; see the `casefold` data item below.

The sequence

```
prog = regex.compile(pat)
result = prog.match(str)
```

is equivalent to

```
result = regex.match(pat, str)
```

but the version using `compile()` is more efficient when multiple regular expressions are used concurrently in a single program. (The compiled version of the last pattern passed to `regex.match()` or `regex.search()` is cached, so programs that use only a single regular expression at a time needn't worry about compiling regular expressions.)

function of module regex: **set_syntax** *(flags)*

Set the syntax to be used by future calls to `compile`, `match` and `search`. (Already compiled expression objects are not affected.) The argument is an integer which is the OR of several flag bits. The return value is the previous value of the syntax flags. Names for the flags are defined in the standard module `regex_syntax`; read the file `` `regex_syntax.py' `` for more information.

function of module regex: **symcomp** *(pattern[, translate])*

This is like `compile`, but supports symbolic group names: if a parenthesis-enclosed group begins with a group name in angular brackets, e.g. `'\(<id>[a-z][a-z0-9]*\)'`, the group can be referenced by its name in arguments to the `group` method of the resulting compiled regular expression object, like this: `p.group('id')`. Group names may contain alphanumeric characters and `'_'` only.

exception: module regex **error**

Exception raised when a string passed to one of the functions here is not a valid regular expression (e.g., unmatched parentheses) or when some other error occurs during compilation or matching. (It is never an error if a string contains no match for a pattern.)

data: module regex **casefold**

A string suitable to pass as translate argument to `compile` to map all upper case characters to their lowercase equivalents.

Compiled regular expression objects support these methods:

Method: regex **match** *(string[, pos])*

Return how many characters at the beginning of string match the compiled regular expression. Return `-1` if the string does not match the pattern (this is different from a zero-length match!).

The optional second parameter pos gives an index in the string where the search is to start; it defaults to `0`. This is not completely equivalent to slicing the string; the `'^'` pattern character matches at the real begin of the string and at positions just after a newline, not necessarily at the index where the search is to start.

Method: regex **search** *(string[, pos])*

Return the first position in string that matches the regular expression `pattern`. Return `-1` if no position in the string matches the pattern (this is different from a zero-length match anywhere!).

The optional second parameter has the same meaning as for the `match` method.

Method: regex **group** *(index, index, ...)*

This method is only valid when the last call to the `match` or `search` method found a match. It returns one or more groups of the match. If there is a single index argument, the result is a single string; if there are multiple arguments, the result is a tuple with one item per argument. If the index is zero, the corresponding return value is the entire matching string; if it is in the inclusive range [1..99], it is the string matching the the corresponding parenthesized group (using the default syntax, groups are parenthesized using
`(` and
`)`). If no such group exists, the corresponding result is `None`.

If the regular expression was compiled by `symcomp` instead of `compile`, the index arguments may also be strings identifying groups by their group name.

Compiled regular expressions support these data attributes:

attribute: regex **regs**

When the last call to the `match` or `search` method found a match, this is a tuple of pairs of indices corresponding to the beginning and end of all parenthesized groups in the pattern. Indices are relative to the string argument passed to `match` or `search`. The 0-th tuple gives the beginning and end or the whole pattern. When the last match or search failed, this is `None`.

attribute: regex **last**

When the last call to the `match` or `search` method found a match, this is the string argument passed to that method. When the last match or search failed, this is `None`.

attribute: regex **translate**

This is the value of the translate argument to `regex.compile` that created this regular expression object. If the translate argument was omitted in the `regex.compile` call, this is `None`.

attribute: regex **givenpat**

The regular expression pattern as passed to `compile` or `symcomp`.

attribute: regex **realpat**

The regular expression after stripping the group names for regular expressions compiled with `symcomp`. Same as `givenpat` otherwise.

attribute: regex **groupindex**

A dictionary giving the mapping from symbolic group names to numerical group indices for regular

expressions compiled with `symcomp`. `None` otherwise.

Standard Module `regsub`

This module defines a number of functions useful for working with regular expressions (see built-in module `regex`).

function of module regsub: **sub** *(pat, repl, str)*

Replace the first occurrence of pattern pat in string str by replacement repl. If the pattern isn't found, the string is returned unchanged. The pattern may be a string or an already compiled pattern. The replacement may contain references `\digit' to subpatterns and escaped backslashes.

function of module regsub: **gsub** *(pat, repl, str)*

Replace all (non-overlapping) occurrences of pattern pat in string str by replacement repl. The same rules as for `sub()` apply. Empty matches for the pattern are replaced only when not adjacent to a previous match, so e.g. `gsub('', '-', 'abc')` returns `'-a-b-c-'`.

function of module regsub: **split** *(str, pat)*

Split the string str in fields separated by delimiters matching the pattern pat, and return a list containing the fields. Only non-empty matches for the pattern are considered, so e.g. `split('a:b', ':*')` returns `['a', 'b']` and `split('abc', '')` returns `['abc']`.

Built-in Module `struct`

This module performs conversions between Python values and C structs represented as Python strings. It uses format strings (explained below) as compact descriptions of the lay-out of the C structs and the intended conversion to/from Python values.

See also built-in module `array`.

The module defines the following exception and functions:

exception: module struct **error**

Exception raised on various occasions; argument is a string describing what is wrong.

function of module struct: **pack** *(fmt, v1, v2, ...)*

Return a string containing the values `v1, v2, ...` packed according to the given format. The arguments must match the values required by the format exactly.

function of module struct: **unpack** *(fmt, string)*

Unpack the string (presumably packed by `pack(fmt, ...)`) according to the given format. The result is a tuple even if it contains exactly one item. The string must contain exactly the amount of data required by the format (i.e. `len(string)` must equal `calcsize(fmt)`).

function of module struct: **calcsize** *(fmt)*

Return the size of the struct (and hence of the string) corresponding to the given format.

Format characters have the following meaning; the conversion between C and Python values should be obvious given their types:

Format

C -- Python

`x'

pad byte -- no value

`c'

char -- string of length 1

`b'

signed char -- integer

`h'

short -- integer

`i'

int -- integer

`l'

long -- integer

`f'

float -- float

`d'

double -- float

A format character may be preceded by an integral repeat count; e.g. the format string `'4h'` means exactly the same as `'hhhh'`.

C numbers are represented in the machine's native format and byte order, and properly aligned by skipping pad bytes if necessary (according to the rules used by the C compiler).

Examples (all on a big-endian machine):

```
pack('hhl', 1, 2, 3) == '\000\001\000\002\000\000\000\003'
unpack('hhl', '\000\001\000\002\000\000\000\003') == (1, 2, 3)
calcsize('hhl') == 8
```

Hint: to align the end of a structure to the alignment requirement of a particular type, end the format with the code for that type with a repeat count of zero, e.g. the format `'llh0l'` specifies two pad bytes at the end, assuming longs are aligned on 4-byte boundaries.

(More format characters are planned, e.g. `'s'` for character arrays, upper case for unsigned variants, and a way to specify the byte order, which is useful for [de]constructing network packets and reading/writing portable binary file formats like TIFF and AIFF.)

Go to the previous, next section.

Go to the previous, next section.

Miscellaneous Services

The modules described in this chapter provide miscellaneous services that are available in all Python versions. Here's an overview:

math
--- Mathematical functions (`sin()` etc.).

rand
--- Integer random number generator.

whrandom
--- Floating point random number generator.

array
--- Efficient arrays of uniformly typed numeric values.

Built-in Module `math`

This module is always available. It provides access to the mathematical functions defined by the C standard. They are: function of module math: **acos** *(x)*

function of module math: **asin** *(x)*

function of module math: **atan** *(x)*

function of module math: **atan2** *(x, y)*

function of module math: **ceil** *(x)*

function of module math: **cos** *(x)*

function of module math: **cosh** *(x)*

function of module math: **exp** *(x)*

function of module math: **fabs** *(x)*

function of module math: **floor** *(x)*

function of module math: **fmod** *(x, y)*

function of module math: **frexp** *(x)*

function of module math: **hypot** *(x, y)*

function of module math: **ldexp** *(x, y)*

function of module math: **log** *(x)*

function of module math: **log10** *(x)*

function of module math: **modf** *(x)*

function of module math: **pow** *(x, y)*

function of module math: **sin** *(x)*

function of module math: **sinh** *(x)*

function of module math: **sqrt** *(x)*

function of module math: **tan** *(x)*

function of module math: **tanh** *(x)*

Note that `frexp` and `modf` have a different call/return pattern than their C equivalents: they take a single argument and return a pair of values, rather than returning their second return value through an `output parameter' (there is no such thing in Python).

The `hypot` function, which is not standard C, is not available on all platforms.

The module also defines two mathematical constants: data: module math **pi**

data: module math **e**

Standard Module `rand`

This module implements a pseudo-random number generator with an interface similar to `rand()` in C. the following functions:

function of module rand: **rand** *()*

Returns an integer random number in the range [0 ... 32768).

function of module rand: **choice** *(s)*

Returns a random element from the sequence (string, tuple or list) s.

function of module rand: **srand** *(seed)*

Initializes the random number generator with the given integral seed. When the module is first imported, the random number is initialized with the current time.

Standard Module `whrandom`

This module implements a Wichmann-Hill pseudo-random number generator. It defines the following functions:

function of module whrandom: **random** *()*

Returns the next random floating point number in the range [0.0 ... 1.0).

function of module whrandom: **seed** *(x, y, z)*

Initializes the random number generator from the integers x, y and z. When the module is first imported, the random number is initialized using values derived from the current time.

Built-in Module `array`

This module defines a new object type which can efficiently represent an array of basic values: characters, integers, floating point numbers. Arrays are sequence types and behave very much like lists, except that the type of objects stored in them is constrained. The type is specified at object creation time by using a type code, which is a single character. The following type codes are defined:

Typecode

Type -- Minimal size in bytes

`'c'`

character -- 1

`'b'`

signed integer -- 1

`'h'`

signed integer -- 2

`'i'`

signed integer -- 2

`'l'`

signed integer -- 4

`'f'`

floating point -- 4

`'d'`

floating point -- 8

The actual representation of values is determined by the machine architecture (strictly speaking, by the C implementation). The actual size can be accessed through the itemsize attribute.

See also built-in module `struct`.

The module defines the following function:

function of module array: **array** *(typecode[, initializer])*

Return a new array whose items are restricted by typecode, and initialized from the optional initializer value, which must be a list or a string. The list or string is passed to the new array's `fromlist()` or `fromstring()` method (see below) to add initial items to the array.

Array objects support the following data items and methods:

data: module array **typecode**

The typecode character used to create the array.

data: module array **itemsize**

The length in bytes of one array item in the internal representation.

function of module array: **append** *(x)*

Append a new item with value x to the end of the array.

function of module array: **byteswap** *(x)*

"Byteswap" all items of the array. This is only supported for integer values. It is useful when reading data from a file written on a machine with a different byte order.

function of module array: **fromfile** *(f, n)*

Read n items (as machine values) from the file object f and append them to the end of the array. If less than n items are available, `EOFError` is raised, but the items that were available are still inserted into the array. f must be a real built-in file object; something else with a `read()` method won't do.

function of module array: **fromlist** *(list)*

Append items from the list. This is equivalent to `for x in list: a.append(x)` except that if there is a type error, the array is unchanged.

function of module array: **fromstring** *(s)*

Appends items from the string, interpreting the string as an array of machine values (i.e. as if it had been read from a file using the `fromfile()` method).

function of module array: **insert** *(i, x)*

Insert a new item with value x in the array before position i.

function of module array: **tofile** *(f)*

Write all items (as machine values) to the file object f.

function of module array: **tolist** *()*

Convert the array to an ordinary list with the same items.

function of module array: **tostring** *()*

Convert the array to an array of machine values and return the string representation (the same sequence of bytes that would be written to a file by the `tofile()` method.)

When an array object is printed or converted to a string, it is represented as `array(typecode, initializer)`. The initializer is omitted if the array is empty, otherwise it is a string if the typecode

is `'c'`, otherwise it is a list of numbers. The string is guaranteed to be able to be converted back to a array with the same type and value using reverse quotes (`). Examples:

```
array('l')
array('c', 'hello world')
array('l', [1, 2, 3, 4, 5])
array('d', [1.0, 2.0, 3.14])
```

Go to the previous, next section.

Go to the previous, next section.

Generic Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on (almost) all operating systems, such as files and a clock. The interfaces are generally modelled after the UNIX or C interfaces but they are available on most other systems as well. Here's an overview:

os

--- Miscellaneous OS interfaces.

time

--- Time access and conversions.

getopt

--- Parser for command line options.

tempfile

--- Generate temporary file names.

Standard Module os

This module provides a more portable way of using operating system (OS) dependent functionality than importing an OS dependent built-in module like `posix`.

When the optional built-in module `posix` is available, this module exports the same functions and data as `posix`; otherwise, it searches for an OS dependent built-in module like `mac` and exports the same functions and data as found there. The design of all Python's built-in OS dependent modules is such that as long as the same functionality is available, it uses the same interface; e.g., the function `os.stat(file)` returns stat info about a file in a format compatible with the POSIX interface.

Extensions peculiar to a particular OS are also available through the `os` module, but using them is of course a threat to portability!

Note that after the first time `os` is imported, there is *no* performance penalty in using functions from `os` instead of directly from the OS dependent built-in module, so there should be *no* reason not to use `os`!

In addition to whatever the correct OS dependent module exports, the following variables and functions are always exported by `os`:

data: module os **name**

The name of the OS dependent module imported. The following names have currently been registered: `'posix'`, `'nt'`, `'dos'`, `'mac'`.

data: module os **path**

The corresponding OS dependent standard module for pathname operations, e.g., `posixpath` or

`macpath`. Thus, (given the proper imports), `os.path.split(file)` is equivalent to but more portable than `posixpath.split(file)`.

data: module os **curdir**

The constant string used by the OS to refer to the current directory, e.g. `'.'` for POSIX or `':'` for the Mac.

data: module os **pardir**

The constant string used by the OS to refer to the parent directory, e.g. `'..'` for POSIX or `'::'` for the Mac.

data: module os **sep**

The character used by the OS to separate pathname components, e.g. `'/'` for POSIX or `':'` for the Mac. Note that knowing this is not sufficient to be able to parse or concatenate pathnames--better use `os.path.split()` and `os.path.join()`---but it is occasionally useful.

data: module os **pathsep**

The character conventionally used by the OS to separate search patch components (as in `$PATH`), e.g. `':'` for POSIX or `';'` for MS-DOS.

data: module os **defpath**

The default search path used by `os.exec*p*()` if the environment doesn't have a `'PATH'` key.

function of module os: **execl** *(path, arg0, arg1, ...)*

This is equivalent to `os.execv(path, (arg0, arg1, ...))`.

function of module os: **execle** *(path, arg0, arg1, ..., env)*

This is equivalent to `os.execve(path, (arg0, arg1, ...), env)`.

function of module os: **execlp** *(path, arg0, arg1, ...)*

This is equivalent to `os.execvp(path, (arg0, arg1, ...))`.

function of module os: **execvp** *(path, args)*

This is like `os.execv(path, args)` but duplicates the shell's actions in searching for an executable file in a list of directories. The directory list is obtained from `os.environ['PATH']`.

function of module os: **execvpe** *(path, args, env)*

This is a cross between `os.execve()` and `os.execvp()`. The directory list is obtained from `env['PATH']`.

(The functions `os.execv()` and `execve()` are not documented here, since they are implemented by the OS dependent module. If the OS dependent module doesn't define either of these, the functions that rely on it will raise an exception. They are documented in the section on module `posix`, together with

all other functions that `os` imports from the OS dependent module.)

Built-in Module `time`

This module provides various time-related functions. It is always available.

An explanation of some terminology and conventions is in order.

- The "epoch" is the point where the time starts. On January 1st of that year, at 0 hours, the "time since the epoch" is zero. For UNIX, the epoch is 1970. To find out what the epoch is, look at `gmtime(0)`.
- UTC is Coordinated Universal Time (formerly known as Greenwich Mean Time). The acronym UTC is not a mistake but a compromise between English and French.
- DST is Daylight Saving Time, an adjustment of the timezone by (usually) one hour during part of the year. DST rules are magic (determined by local law) and can change from year to year. The C library has a table containing the local rules (often it is read from a system file for flexibility) and is the only source of True Wisdom in this respect.
- The precision of the various real-time functions may be less than suggested by the units in which their value or argument is expressed. E.g. on most UNIX systems, the clock "ticks" only 50 or 100 times a second, and on the Mac, times are only accurate to whole seconds.

The module defines the following functions and data items:

data: module time **altzone**

The offset of the local DST timezone, in seconds west of the 0th meridian, if one is defined. Negative if the local DST timezone is east of the 0th meridian (as in Western Europe, including the UK). Only use this if `daylight` is nonzero.

function of module time: **asctime** *(tuple)*

Convert a tuple representing a time as returned by `gmtime()` or `localtime()` to a 24-character string of the following form: `'Sun Jun 20 23:21:05 1993'`. Note: unlike the C function of the same name, there is no trailing newline.

function of module time: **clock** *()*

Return the current CPU time as a floating point number expressed in seconds. The precision, and in fact the very definiton of the meaning of "CPU time", depends on that of the C function of the same name.

function of module time: **ctime** *(secs)*

Convert a time expressed in seconds since the epoch to a string representing local time. `ctime(t)` is equivalent to `asctime(localtime(t))`.

data: module time **daylight**

Nonzero if a DST timezone is defined.

function of module time: **gmtime** *(secs)*

Convert a time expressed in seconds since the epoch to a tuple of 9 integers, in UTC: year (e.g. 1993), month (1--12), day (1--31), hour (0--23), minute (0--59), second (0--59), weekday (0--6, monday is 0), Julian day (1--366), dst flag (always zero). Fractions of a second are ignored. Note subtle differences with the C function of this name.

function of module time: **localtime** *(secs)*

Like `gmtime` but converts to local time. The dst flag is set to 1 when DST applies to the given time.

function of module time: **mktime** *(tuple)*

This is the inverse function of `localtime`. Its argument is the full 9-tuple (since the dst flag is needed). It returns an integer.

function of module time: **sleep** *(secs)*

Suspend execution for the given number of seconds. The argument may be a floating point number to indicate a more precise sleep time.

function of module time: **time** *()*

Return the time as a floating point number expressed in seconds since the epoch, in UTC. Note that even though the time is always returned as a floating point number, not all systems provide time with a better precision than 1 second.

data: module time **timezone**

The offset of the local (non-DST) timezone, in seconds west of the 0th meridian (i.e. negative in most of Western Europe, positive in the US, zero in the UK).

data: module time **tzname**

A tuple of two strings: the first is the name of the local non-DST timezone, the second is the name of the local DST timezone. If no DST timezone is defined, the second string should not be used.

Standard Module `getopt`

This module helps scripts to parse the command line arguments in `sys.argv`. It uses the same conventions as the UNIX `getopt()` function (including the special meanings of arguments of the form `-' and `--'). It defines the function `getopt.getopt(args, options)` and the exception `getopt.error`.

The first argument to `getopt()` is the argument list passed to the script with its first element chopped off (i.e., `sys.argv[1:]`). The second argument is the string of option letters that the script wants to recognize, with options that require an argument followed by a colon (i.e., the same format that UNIX `getopt()` uses). The return value consists of two elements: the first is a list of option-and-value pairs; the second is the list of program arguments left after the option list was stripped (this is a trailing slice of the first argument). Each option-and-value pair returned has the option as its first element, prefixed with a hyphen (e.g., `'-x'`), and the option argument as its second element, or an empty string if the option

has no argument. The options occur in the list in the same order in which they were found, thus allowing multiple occurrences. Example:

```
>>> import getopt, string
>>> args = string.split('-a -b -cfoo -d bar a1 a2')
>>> args
['-a', '-b', '-cfoo', '-d', 'bar', 'a1', 'a2']
>>> optlist, args = getopt.getopt(args, 'abc:d:')
>>> optlist
[('-a', ''), ('-b', ''), ('-c', 'foo'), ('-d', 'bar')]
>>> args
['a1', 'a2']
>>>
```

The exception `getopt.error = 'getopt error'` is raised when an unrecognized option is found in the argument list or when an option requiring an argument is given none. The argument to the exception is a string indicating the cause of the error.

Standard Module `tempfile`

This module generates temporary file names. It is not UNIX specific, but it may require some help on non-UNIX systems.

Note: the modules does not create temporary files, nor does it automatically remove them when the current process exits or dies.

The module defines a single user-callable function:

function of module tempfile: **mktemp** *()*

Return a unique temporary filename. This is an absolute pathname of a file that does not exist at the time the call is made. No two calls will return the same filename.

The module uses two global variables that tell it how to construct a temporary name. The caller may assign values to them; by default they are initialized at the first call to `mktemp()`.

data: module tempfile **tempdir**

When set to a value other than `None`, this variable defines the directory in which filenames returned by `mktemp()` reside. The default is taken from the environment variable `TMPDIR`; if this is not set, either `/usr/tmp` is used (on UNIX), or the current working directory (all other systems). No check is made to see whether its value is valid.

data: module tempfile **template**

When set to a value other than `None`, this variable defines the prefix of the final component of the filenames returned by `mktemp()`. A string of decimal digits is added to generate unique filenames. The default is either "`@pid.`" where pid is the current process ID (on UNIX), or "`tmp`" (all other systems).

Warning: if a UNIX process uses `mktemp()`, then calls `fork()` and both parent and child continue to use `mktemp()`, the processes will generate conflicting temporary names. To resolve this, the child process should assign `None` to `template`, to force recomputing the default on the next call to `mktemp()`.

Go to the previous, next section.

Go to the previous, next section.

Optional Operating System Services

The modules described in this chapter provide interfaces to operating system features that are available on selected operating systems only. The interfaces are generally modelled after the UNIX or C interfaces but they are available on some other systems as well (e.g. Windows or NT). Here's an overview:

signal
: --- Set handlers for asynchronous events.

socket
: --- Low-level networking interface.

select
: --- Wait for I/O completion on multiple streams.

thread
: --- Create multiple threads of control within one namespace.

Built-in Module `signal`

This module provides mechanisms to use signal handlers in Python. Some general rules for working with signals handlers:

- A handler for a particular signal, once set, remains installed until it is explicitly reset (i.e. Python uses the BSD style interface).
- There is no way to "block" signals temporarily from critical sections (since this is not supported by all UNIX flavors).
- Although Python signal handlers are called asynchronously as far as the Python user is concerned, they can only occur between the "atomic" instructions of the Python interpreter. This means that signals arriving during long calculations implemented purely in C (e.g. regular expression matches on large bodies of text) may be delayed for an arbitrary amount of time.
- When a signal arrives during an I/O operation, it is possible that the I/O operation raises an exception after the signal handler returns. This is dependent on the underlying UNIX system's semantics regarding interrupted system calls.
- Because the C signal handler always returns, it makes little sense to catch synchronous errors like `SIGFPE` or `SIGSEGV`.
- Python installs a small number of signal handlers by default: `SIGPIPE` is ignored (so write errors on pipes and sockets can be reported as ordinary Python exceptions), `SIGINT` is translated into a `KeyboardInterrupt` exception, and `SIGTERM` is caught so that necessary cleanup (especially `sys.exitfunc`) can be performed before actually terminating. All of these can be overridden.
- Some care must be taken if both signals and threads are used in the same program. The fundamental thing to remember in using signals and threads simultaneously is: always perform

`signal()` operations in the main thread of execution. Any thread can perform an `alarm()`, `getsignal()`, or `pause()`; only the main thread can set a new signal handler, and the main thread will be the only one to receive signals (this is enforced by the Python signal module, even if the underlying thread implementation supports sending signals to individual threads). This means that signals can't be used as a means of interthread communication. Use locks instead.

The variables defined in the signal module are:

data: module signal **SIG_DFL**

This is one of two standard signal handling options; it will simply perform the default function for the signal. For example, on most systems the default action for SIGQUIT is to dump core and exit, while the default action for SIGCLD is to simply ignore it.

data: module signal **SIG_IGN**

This is another standard signal handler, which will simply ignore the given signal.

data: module signal **SIG***

All the signal numbers are defined symbolically. For example, the hangup signal is defined as `signal.SIGHUP`; the variable names are identical to the names used in C programs, as found in `` `signal.h' ``. The UNIX man page for `` `signal' `` lists the existing signals (on some systems this is `` `signal(2)' ``, on others the list is in `` `signal(7)' ``). Note that not all systems define the same set of signal names; only those names defined by the system are defined by this module.

data: module signal **NSIG**

One more than the number of the highest signal number.

The signal module defines the following functions:

function of module signal: **alarm** *(time)*

If time is non-zero, this function requests that a `SIGALRM` signal be sent to the process in time seconds. Any previously scheduled alarm is canceled (i.e. only one alarm can be scheduled at any time). The returned value is then the number of seconds before any previously set alarm was to have been delivered. If time is zero, no alarm id scheduled, and any scheduled alarm is canceled. The return value is the number of seconds remaining before a previously scheduled alarm. If the return value is zero, no alarm is currently scheduled. (See the UNIX man page `alarm(2)`.)

function of module signal: **getsignal** *(signalnum)*

Return the current signal handler for the signal signalnum. The returned value may be a callable Python object, or one of the special values `signal.SIG_IGN`, `signal.SIG_DFL` or `None`. Here, `signal.SIG_IGN` means that the signal was previously ignored, `signal.SIG_DFL` means that the default way of handling the signal was previously in use, and `None` means that the previous signal handler was not installed from Python.

function of module signal: **pause** *()*

Cause the process to sleep until a signal is received; the appropriate handler will then be called. Retu nothing. (See the UNIX man page `signal(2)`.)

function of module signal: **signal** *(signalnum, handler)*

Set the handler for signal signalnum to the function handler. handler can be any callable Python object, or one of the special values `signal.SIG_IGN` or `signal.SIG_DFL`. The previous signal handler will be returned (see the description of `getsignal()` above). (See the UNIX man page `signal(2)`.)

When threads are enabled, this function can only be called from the main thread; attempting to call it from other threads will cause a `ValueError` exception to be raised.

The handler is called with two arguments: the signal number and the current stack frame (`None` or a frame object; see the reference manual for a description of frame objects).

Built-in Module socket

This module provides access to the BSD *socket* interface. It is available on UNIX systems that support this interface.

For an introduction to socket programming (in C), see the following papers: *An Introductory 4.3BSD Interprocess Communication Tutorial*, by Stuart Sechrest and *An Advanced 4.3BSD Interprocess Communication Tutorial*, by Samuel J. Leffler et al, both in the UNIX Programmer's Manual, Supplementary Documents 1 (sections PS1:7 and PS1:8). The UNIX manual pages for the various socket-related system calls are also a valuable source of information on the details of socket semantics.

The Python interface is a straightforward transliteration of the UNIX system call and library interface for sockets to Python's object-oriented style: the `socket()` function returns a socket object whose methods implement the various socket system calls. Parameter types are somewhat higer-level than in the C interface: as with `read()` and `write()` operations on Python files, buffer allocation on receive operations is automatic, and buffer length is implicit on send operations.

Socket addresses are represented as a single string for the `AF_UNIX` address family and as a pair `(host, port)` for the `AF_INET` address family, where host is a string representing either a hostname in Internet domain notation like `'daring.cwi.nl'` or an IP address like `'100.50.200.5'`, and port is an integral port number. Other address families are currently not supported. The address format required by a particular socket object is automatically selected based on the address family specified when the socket object was created.

All errors raise exceptions. The normal exceptions for invalid argument types and out-of-memory conditions can be raised; errors related to socket or address semantics raise the error `socket.error`.

Non-blocking mode is supported through the `setblocking()` method.

The module `socket` exports the following constants and functions:

exception: module socket **error**

This exception is raised for socket- or address-related errors. The accompanying value is either a string

telling what went wrong or a pair `(errno, string)` representing an error returned by a system c similar to the value accompanying `posix.error`.

data: module socket **AF_UNIX**

data: module socket **AF_INET**

These constants represent the address (and protocol) families, used for the first argument to `socket()`. If the `AF_UNIX` constant is not defined then this protocol is unsupported.

data: module socket **SOCK_STREAM**

data: module socket **SOCK_DGRAM**

data: module socket **SOCK_RAW**

data: module socket **SOCK_RDM**

data: module socket **SOCK_SEQPACKET**

These constants represent the socket types, used for the second argument to `socket()`. (Only `SOCK_STREAM` and `SOCK_DGRAM` appear to be generally useful.)

data: module socket **SO_***

data: module socket **SOMAXCONN**

data: module socket **MSG_***

data: module socket **SOL_***

data: module socket **IPPROTO_***

data: module socket **IPPORT_***

data: module socket **INADDR_***

data: module socket **IP_***

Many constants of these forms, documented in the UNIX documentation on sockets and/or the IP protocol, are also defined in the socket module. They are generally used in arguments to the `setsockopt` and `getsockopt` methods of socket objects. In most cases, only those symbols that are defined in the UNIX header files are defined; for a few symbols, default values are provided.

function of module socket: **gethostbyname** *(hostname)*

Translate a host name to IP address format. The IP address is returned as a string, e.g., `'100.50.200.5'`. If the host name is an IP address itself it is returned unchanged.

function of module socket: **gethostname** *()*

Return a string containing the hostname of the machine where the Python interpreter is currently executing. If you want to know the current machine's IP address, use `socket.gethostbyname(socket.gethostname())`.

function of module socket: **gethostbyaddr** *(ip_address)*

Return a triple `(hostname, aliaslist, ipaddrlist)` where `hostname` is the primary host name responding to the given ip_address, `aliaslist` is a (possibly empty) list of alternative host names for the same address, and `ipaddrlist` is a list of IP addresses for the same interface on the same host (most likely containing only a single address).

function of module socket: **getservbyname** *(servicename, protocolname)*

Translate an Internet service name and protocol name to a port number for that service. The protocol name should be `'tcp'` or `'udp'`.

function of module socket: **socket** *(family, type[, proto])*

Create a new socket using the given address family, socket type and protocol number. The address family should be `AF_INET` or `AF_UNIX`. The socket type should be `SOCK_STREAM`, `SOCK_DGRAM` or perhaps one of the other `SOCK_' constants. The protocol number is usually zero and may be omitted in that case.

function of module socket: **fromfd** *(fd, family, type[, proto])*

Build a socket object from an existing file descriptor (an integer as returned by a file object's `fileno` method). Address family, socket type and protocol number are as for the `socket` function above. The file descriptor should refer to a socket, but this is not checked -- subsequent operations on the object may fail if the file descriptor is invalid. This function is rarely needed, but can be used to get or set socket options on a socket passed to a program as standard input or output (e.g. a server started by the UNIX inet daemon).

Socket Objects

Socket objects have the following methods. Except for `makefile()` these correspond to UNIX system calls applicable to sockets.

Method: socket **accept** *()*

Accept a connection. The socket must be bound to an address and listening for connections. The return value is a pair `(conn, address)` where conn is a *new* socket object usable to send and receive data on the connection, and address is the address bound to the socket on the other end of the connection.

Method: socket **bind** *(address)*

Bind the socket to address. The socket must not already be bound. (The format of address depends on the address family -- see above.)

Method: socket **close** *()*

Close the socket. All future operations on the socket object will fail. The remote end will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

Method: socket **connect** *(address)*

Connect to a remote socket at address. (The format of address depends on the address family -- see above.)

Method: socket **fileno** *()*

Return the socket's file descriptor (a small integer). This is useful with `select`.

Method: socket **getpeername** *()*

Return the remote address to which the socket is connected. This is useful to find out the port number of a remote IP socket, for instance. (The format of the address returned depends on the address family --- see above.) On some systems this function is not supported.

Method: socket **getsockname** *()*

Return the socket's own address. This is useful to find out the port number of an IP socket, for instance. (The format of the address returned depends on the address family --- see above.)

Method: socket **getsockopt** *(level, optname[, buflen])*

Return the value of the given socket option (see the UNIX man page *getsockopt*(2)). The needed symbolic constants (`SO_*` etc.) are defined in this module. If buflen is absent, an integer option is assumed and its integer value is returned by the function. If buflen is present, it specifies the maximum length of the buffer used to receive the option in, and this buffer is returned as a string. It is up to the caller to decode the contents of the buffer (see the optional built-in module `struct` for a way to decode C structures encoded as strings).

Method: socket **listen** *(backlog)*

Listen for connections made to the socket. The backlog argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).

Method: socket **makefile** *([mode[, bufsize]])*

Return a file object associated with the socket. (File objects were described earlier under Built-in Types.) The file object references a `dup()`ped version of the socket file descriptor, so the file object and socket object may be closed or garbage-collected independently. The optional mode and bufsize arguments are interpreted the same way as by the built-in `open()` function.

Method: socket **recv** *(bufsize[, flags])*

Receive data from the socket. The return value is a string representing the data received. The maximum amount of data to be received at once is specified by bufsize. See the UNIX manual page for the meaning of the optional argument flags; it defaults to zero.

Method: socket **recvfrom** *(bufsize[, flags])*

Receive data from the socket. The return value is a pair `(string, address)` where string is a string representing the data received and address is the address of the socket sending the data. The optional flags argument has the same meaning as for `recv()` above. (The format of address depends on the address family -- see above.)

Method: socket **send** *(string[, flags])*

Send data to the socket. The socket must be connected to a remote socket. The optional flags argument has the same meaning as for `recv()` above. Return the number of bytes sent.

Method: socket **sendto** *(string[, flags], address)*

Send data to the socket. The socket should not be connected to a remote socket, since the destination socket is specified by `address`. The optional flags argument has the same meaning as for `recv()` above. Return the number of bytes sent. (The format of address depends on the address family -- see above.)

Method: socket **setblocking** *(flag)*

Set blocking or non-blocking mode of the socket: if flag is 0, the socket is set to non-blocking, else to blocking mode. Initially all sockets are in blocking mode. In non-blocking mode, if a `recv` call doesn't find any data, or if a `send` call can't immediately dispose of the data, a `socket.error` exception is raised; in blocking mode, the calls block until they can proceed.

Method: socket **setsockopt** *(level, optname, value)*

Set the value of the given socket option (see the UNIX man page *setsockopt*(2)). The needed symbolic constants are defined in the `socket` module (`SO_*` etc.). The value can be an integer or a string representing a buffer. In the latter case it is up to the caller to ensure that the string contains the proper bits (see the optional built-in module `struct` for a way to encode C structures as strings).

Method: socket **shutdown** *(how)*

Shut down one or both halves of the connection. If how is `0`, further receives are disallowed. If how is `1`, further sends are disallowed. If how is `2`, further sends and receives are disallowed.

Note that there are no methods `read()` or `write()`; use `recv()` and `send()` without flags argument instead.

Example

Here are two minimal example programs using the TCP/IP protocol: a server that echoes all data that it receives back (servicing only one client), and a client using it. Note that a server must perform the sequence `socket`, `bind`, `listen`, `accept` (possibly repeating the `accept` to service more than one client), while a client only needs the sequence `socket`, `connect`. Also note that the server does not `send`/`receive` on the socket it is listening on but on the new socket returned by `accept`.

```
# Echo server program
from socket import *
HOST = ''                 # Symbolic name meaning the local host
PORT = 50007              # Arbitrary non-privileged server
s = socket(AF_INET, SOCK_STREAM)
s.bind(HOST, PORT)
s.listen(1)
```

```
conn, addr = s.accept()
print 'Connected by', addr
while 1:
    data = conn.recv(1024)
    if not data: break
    conn.send(data)
conn.close()

# Echo client program
from socket import *
HOST = 'daring.cwi.nl'    # The remote host
PORT = 50007              # The same port as used by the server
s = socket(AF_INET, SOCK_STREAM)
s.connect(HOST, PORT)
s.send('Hello, world')
data = s.recv(1024)
s.close()
print 'Received', `data`
```

Built-in Module `select`

This module provides access to the function `select` available in most UNIX versions. It defines the following:

exception: module select **error**

The exception raised when an error occurs. The accompanying value is a pair containing the numeric error code from `errno` and the corresponding string, as would be printed by the C function `perror()`.

function of module select: **select** *(iwtd, owtd, ewtd[, timeout])*

This is a straightforward interface to the UNIX `select()` system call. The first three arguments are lists of `waitable objects': either integers representing UNIX file descriptors or objects with a parameterless method named `fileno()` returning such an integer. The three lists of waitable objects are for input, output and `exceptional conditions', respectively. Empty lists are allowed. The optional timeout argument specifies a time-out as a floating point number in seconds. When the timeout argument is omitted the function blocks until at least one file descriptor is ready. A time-out value of zero specifies a poll and never blocks.

The return value is a triple of lists of objects that are ready: subsets of the first three arguments. When the time-out is reached without a file descriptor becoming ready, three empty lists are returned.

Amongst the acceptable object types in the lists are Python file objects (e.g. `sys.stdin`, or objects returned by `open()` or `posix.popen()`), socket objects returned by `socket.socket()`, and the module `stdwin` which happens to define a function `fileno()` for just this purpose. You may also define a wrapper class yourself, as long as it has an appropriate `fileno()` method (that really returns a UNIX file descriptor, not just a random integer).

Built-in Module `thread`

This module provides low-level primitives for working with multiple threads (a.k.a. light-weight processes or tasks) -- multiple threads of control sharing their global data space. For synchronization, simple locks (a.k.a. mutexes or binary semaphores) are provided.

The module is optional and supported on SGI IRIX 4.x and 5.x and Sun Solaris 2.x systems, as well as on systems that have a PTHREAD implementation (e.g. KSR).

It defines the following constant and functions:

exception: module thread **error**

Raised on thread-specific errors.

function of module thread: **start_new_thread** *(func, arg)*

Start a new thread. The thread executes the function func with the argument list arg (which must be a tuple). When the function returns, the thread silently exits. When the function terminates with an unhandled exception, a stack trace is printed and then the thread exits (but other threads continue to run).

function of module thread: **exit** *()*

This is a shorthand for `thread.exit_thread()`.

function of module thread: **exit_thread** *()*

Raise the `SystemExit` exception. When not caught, this will cause the thread to exit silently.

function of module thread: **allocate_lock** *()*

Return a new lock object. Methods of locks are described below. The lock is initially unlocked.

function of module thread: **get_ident** *()*

Return the `thread identifier' of the current thread. This is a nonzero integer. Its value has no direct meaning; it is intended as a magic cookie to be used e.g. to index a dictionary of thread-specific data. Thread identifiers may be recycled when a thread exits and another thread is created.

Lock objects have the following methods:

Method: lock **acquire** *([waitflag])*

Without the optional argument, this method acquires the lock unconditionally, if necessary waiting until it is released by another thread (only one thread at a time can acquire a lock -- that's their reason for existence), and returns `None`. If the integer waitflag argument is present, the action depends on its value: if it is zero, the lock is only acquired if it can be acquired immediately without waiting, while if it is nonzero, the lock is acquired unconditionally as before. If an argument is present, the return value is 1 if the lock is acquired successfully, 0 if not.

Method: lock **release** *()*

TOC

Releases the lock. The lock must have been acquired earlier, but not necessarily by the same thread.

Method: lock **locked** *()*

Return the status of the lock: 1 if it has been acquired by some thread, 0 if not.

Caveats:

- Threads interact strangely with interrupts: the `KeyboardInterrupt` exception will be received by an arbitrary thread. (When the `signal` module is available, interrupts always go to the main thread.)
- Calling `sys.exit()` or raising the `SystemExit` is equivalent to calling `thread.exit_thread()`.
- Not all built-in functions that may block waiting for I/O allow other threads to run. (The most popular ones (`sleep`, `read`, `select`) work as expected.)

Go to the previous, next section.

Go to the previous, next section.

UNIX Specific Services

The modules described in this chapter provide interfaces to features that are unique to the UNIX operating system, or in some cases to some or many variants of it. Here's an overview:

posix
--- The most common Posix system calls (normally used via module `os`).

posixpath
--- Common Posix pathname manipulations (normally used via `os.path`).

pwd
--- The password database (`getpwnam()` and friends).

grp
--- The group database (`getgrnam()` and friends).

dbm
--- The standard "database" interface, based on `ndbm`.

gdbm
--- GNU's reinterpretation of dbm.

termios
--- Posix style tty control.

fcntl
--- The `fcntl()` and `ioctl()` system calls.

posixfile
--- A file-like object with support for locking.

Built-in Module `posix`

This module provides access to operating system functionality that is standardized by the C Standard and the POSIX standard (a thinly disguised UNIX interface).

Do not import this module directly. Instead, import the module `os`, which provides a *portable* version of this interface. On UNIX, the `os` module provides a superset of the `posix` interface. On non-UNIX operating systems the `posix` module is not available, but a subset is always available through the `os` interface. Once `os` is imported, there is *no* performance penalty in using it instead of `posix`.

The descriptions below are very terse; refer to the corresponding UNIX manual entry for more information. Arguments called path refer to a pathname given as a string.

Errors are reported as exceptions; the usual exceptions are given for type errors, while errors reported by the system calls raise `posix.error`, described below.

Module `posix` defines the following data items:

data: module posix **environ**

A dictionary representing the string environment at the time the interpreter was started. For example, `posix.environ['HOME']` is the pathname of your home directory, equivalent to `getenv("HOME")` in C. Modifying this dictionary does not affect the string environment passed on by `execv()`, `popen()` or `system()`; if you need to change the environment, pass `environ` to `execve()` or add variable assignments and export statements to the command string for `system()` or `popen()`.(13)

exception: module posix **error**

This exception is raised when a POSIX function returns a POSIX-related error (e.g., not for illegal argument types). Its string value is `'posix.error'`. The accompanying value is a pair containing the numeric error code from `errno` and the corresponding string, as would be printed by the C function `perror()`.

It defines the following functions and constants:

function of module posix: **chdir** *(path)*

Change the current working directory to path.

function of module posix: **chmod** *(path, mode)*

Change the mode of path to the numeric mode.

function of module posix: **chown** *(path, uid, gid)*

Change the owner and group id of path to the numeric uid and gid. (Not on MS-DOS.)

function of module posix: **close** *(fd)*

Close file descriptor fd.

Note: this function is intended for low-level I/O and must be applied to a file descriptor as returned by `posix.open()` or `posix.pipe()`. To close a "file object" returned by the built-in function `open` or by `posix.popen` or `posix.fdopen`, use its `close()` method.

function of module posix: **dup** *(fd)*

Return a duplicate of file descriptor fd.

function of module posix: **dup2** *(fd, fd2)*

Duplicate file descriptor fd to fd2, closing the latter first if necessary. Return `None`.

function of module posix: **execv** *(path, args)*

Execute the executable path with argument list args, replacing the current process (i.e., the Python interpreter). The argument list may be a tuple or list of strings. (Not on MS-DOS.)

function of module posix: **execve** *(path, args, env)*

Execute the executable path with argument list args, and environment env, replacing the current process (i.e., the Python interpreter). The argument list may be a tuple or list of strings. The environment must be a dictionary mapping strings to strings. (Not on MS-DOS.)

function of module posix: **_exit** *(n)*

Exit to the system with status n, without calling cleanup handlers, flushing stdio buffers, etc. (Not on MS-DOS.)

Note: the standard way to exit is `sys.exit(n)`. `posix._exit()` should normally only be used in the child process after a `fork()`.

function of module posix: **fdopen** *(fd[, mode[, bufsize]])*

Return an open file object connected to the file descriptor fd. The mode and bufsize arguments have the same meaning as the corresponding arguments to the built-in `open()` function.

function of module posix: **fork** *()*

Fork a child process. Return 0 in the child, the child's process id in the parent. (Not on MS-DOS.)

function of module posix: **fstat** *(fd)*

Return status for file descriptor fd, like `stat()`.

function of module posix: **getcwd** *()*

Return a string representing the current working directory.

function of module posix: **getegid** *()*

Return the current process's effective group id. (Not on MS-DOS.)

function of module posix: **geteuid** *()*

Return the current process's effective user id. (Not on MS-DOS.)

function of module posix: **getgid** *()*

Return the current process's group id. (Not on MS-DOS.)

function of module posix: **getpid** *()*

Return the current process id. (Not on MS-DOS.)

function of module posix: **getppid** *()*

Return the parent's process id. (Not on MS-DOS.)

function of module posix: **getuid** *()*

Return the current process's user id. (Not on MS-DOS.)

function of module posix: **kill** *(pid, sig)*

Kill the process pid with signal sig. (Not on MS-DOS.)

function of module posix: **link** *(src, dst)*

Create a hard link pointing to src named dst. (Not on MS-DOS.)

function of module posix: **listdir** *(path)*

Return a list containing the names of the entries in the directory. The list is in arbitrary order. It includes the special entries `'.'` and `'..'` if they are present in the directory.

function of module posix: **lseek** *(fd, pos, how)*

Set the current position of file descriptor fd to position pos, modified by how: 0 to set the position relative to the beginning of the file; 1 to set it relative to the current position; 2 to set it relative to the end of the file.

function of module posix: **lstat** *(path)*

Like `stat()`, but do not follow symbolic links. (On systems without symbolic links, this is identical to `posix.stat`.)

function of module posix: **mkdir** *(path, mode)*

Create a directory named path with numeric mode mode.

function of module posix: **nice** *(increment)*

Add incr to the process' "niceness". Return the new niceness. (Not on MS-DOS.)

function of module posix: **open** *(file, flags, mode)*

Open the file file and set various flags according to flags and possibly its mode according to mode. Return the file descriptor for the newly opened file.

Note: this function is intended for low-level I/O. For normal usage, use the built-in function `open`, which returns a "file object" with `read()` and `write()` methods (and many more).

function of module posix: **pipe** *()*

Create a pipe. Return a pair of file descriptors `(r, w)` usable for reading and writing, respectively. (Not on MS-DOS.)

function of module posix: **popen** *(command[, mode[, bufsize]])*

Open a pipe to or from command. The return value is an open file object connected to the pipe, which can be read or written depending on whether mode is `'r'` (default) or `'w'`. The bufsize argument has the same meaning as the corresponding argument to the built-in `open()` function. (Not on MS-DOS.)

function of module posix: **read** *(fd, n)*

Read at most n bytes from file descriptor fd. Return a string containing the bytes read.

Note: this function is intended for low-level I/O and must be applied to a file descriptor as returned by `posix.open()` or `posix.pipe()`. To read a "file object" returned by the built-in function `open` or by `posix.popen` or `posix.fdopen`, or `sys.stdin`, use its `read()` or `readline()` methods.

function of module posix: **readlink** *(path)*

Return a string representing the path to which the symbolic link points. (On systems without symbolic links, this always raises `posix.error`.)

function of module posix: **rename** *(src, dst)*

Rename the file or directory src to dst.

function of module posix: **rmdir** *(path)*

Remove the directory path.

function of module posix: **setgid** *(gid)*

Set the current process's group id. (Not on MS-DOS.)

function of module posix: **setuid** *(uid)*

Set the current process's user id. (Not on MS-DOS.)

function of module posix: **stat** *(path)*

Perform a *stat* system call on the given path. The return value is a tuple of at least 10 integers giving the most important (and portable) members of the *stat* structure, in the order `st_mode`, `st_ino`, `st_dev`, `st_nlink`, `st_uid`, `st_gid`, `st_size`, `st_atime`, `st_mtime`, `st_ctime`. More items may be added at the end by some implementations. (On MS-DOS, some items are filled with dummy values.)

Note: The standard module `stat` defines functions and constants that are useful for extracting information from a stat structure.

function of module posix: **symlink** *(src, dst)*

Create a symbolic link pointing to src named dst. (On systems without symbolic links, this always raises `posix.error`.)

function of module posix: **system** *(command)*

Execute the command (a string) in a subshell. This is implemented by calling the Standard C function `system()`, and has the same limitations. Changes to `posix.environ`, `sys.stdin` etc. are not reflected in the environment of the executed command. The return value is the exit status of the process as returned by Standard C `system()`.

function of module posix: **times** *()*

Return a 4-tuple of floating point numbers indicating accumulated CPU times, in seconds. The items are: user time, system time, children's user time, and children's system time, in that order. See the UNIX manual page *times*(2). (Not on MS-DOS.)

TOC

function of module posix: **umask** *(mask)*

Set the current numeric umask and returns the previous umask. (Not on MS-DOS.)

function of module posix: **uname** *()*

Return a 5-tuple containing information identifying the current operating system. The tuple contains 5 strings: `(sysname, nodename, release, version, machine)`. Some systems truncate the nodename to 8 characters or to the leading component; a better way to get the hostname is `socket.gethostname()`. (Not on MS-DOS, nor on older UNIX systems.)

function of module posix: **unlink** *(path)*

Unlink path.

function of module posix: **utime** *(path, (atime, mtime))*

Set the access and modified time of the file to the given values. (The second argument is a tuple of two items.)

function of module posix: **wait** *()*

Wait for completion of a child process, and return a tuple containing its pid and exit status indication (encoded as by UNIX). (Not on MS-DOS.)

function of module posix: **waitpid** *(pid, options)*

Wait for completion of a child process given by proces id, and return a tuple containing its pid and exit status indication (encoded as by UNIX). The semantics of the call are affected by the value of the integer options, which should be 0 for normal operation. (If the system does not support `waitpid()`, this always raises `posix.error`. Not on MS-DOS.)

function of module posix: **write** *(fd, str)*

Write the string str to file descriptor fd. Return the number of bytes actually written.

Note: this function is intended for low-level I/O and must be applied to a file descriptor as returned by `posix.open()` or `posix.pipe()`. To write a "file object" returned by the built-in function `open` or by `posix.popen` or `posix.fdopen`, or `sys.stdout` or `sys.stderr`, use its `write()` method.

data: module posix **WNOHANG**

The option for `waitpid()` to avoid hanging if no child process status is available immediately.

Standard Module `posixpath`

This module implements some useful functions on POSIX pathnames.

Do not import this module directly. Instead, import the module `os` and use `os.path`.

function of module posixpath: **basename** *(p)*

Return the base name of pathname p. This is the second half of the pair returned by `posixpath.split(p)`.

function of module posixpath: **commonprefix** *(list)*

Return the longest string that is a prefix of all strings in list. If list is empty, return the empty string (").

function of module posixpath: **exists** *(p)*

Return true if p refers to an existing path.

function of module posixpath: **expanduser** *(p)*

Return the argument with an initial component of `~' or `~user' replaced by that user's home directory. An initial `~' is replaced by the environment variable `$HOME`; an initial `~user' is looked up in the password directory through the built-in module `pwd`. If the expansion fails, or if the path does not begin with a tilde, the path is returned unchanged.

function of module posixpath: **expandvars** *(p)*

Return the argument with environment variables expanded. Substrings of the form `$name' or `${name}' are replaced by the value of environment variable name. Malformed variable names and references to non-existing variables are left unchanged.

function of module posixpath: **isabs** *(p)*

Return true if p is an absolute pathname (begins with a slash).

function of module posixpath: **isfile** *(p)*

Return true if p is an existing regular file. This follows symbolic links, so both `islink()` and `isfile()` can be true for the same path.

function of module posixpath: **isdir** *(p)*

Return true if p is an existing directory. This follows symbolic links, so both `islink()` and `isdir()` can be true for the same path.

function of module posixpath: **islink** *(p)*

Return true if p refers to a directory entry that is a symbolic link. Always false if symbolic links are not supported.

function of module posixpath: **ismount** *(p)*

Return true if pathname p is a mount point: a point in a file system where a different file system has been mounted. The function checks whether p's parent, `` `p/..' ``, is on a different device than p, or whether `` `p/..' `` and p point to the same i-node on the same device -- this should detect mount points for all UNIX and POSIX variants.

function of module posixpath: **join** *(p, q)*

Join the paths p and q intelligently: If q is an absolute path, the return value is q. Otherwise, the

TOC

concatenation of p and q is returned, with a slash (`'/'`) inserted unless p is empty or ends in a slash.

function of module posixpath: **normcase** *(p)*

Normalize the case of a pathname. This returns the path unchanged; however, a similar function in `macpath` converts upper case to lower case.

function of module posixpath: **samefile** *(p, q)*

Return true if both pathname arguments refer to the same file or directory (as indicated by device number and i-node number). Raise an exception if a stat call on either pathname fails.

function of module posixpath: **split** *(p)*

Split the pathname p in a pair `(head, tail)`, where tail is the last pathname component and head is everything leading up to that. If p ends in a slash (except if it is the root), the trailing slash is removed and the operation applied to the result; otherwise, `join(head, tail)` equals p. The tail part never contains a slash. Some boundary cases: if p is the root, head equals p and tail is empty; if p is empty, both head and tail are empty; if p contains no slash, head is empty and tail equals p.

function of module posixpath: **splitext** *(p)*

Split the pathname p in a pair `(root, ext)` such that `root + ext == p`, the last component of root contains no periods, and ext is empty or begins with a period.

function of module posixpath: **walk** *(p, visit, arg)*

Calls the function visit with arguments `(arg, dirname, names)` for each directory in the directory tree rooted at p (including p itself, if it is a directory). The argument dirname specifies the visited directory, the argument names lists the files in the directory (gotten from `posix.listdir(dirname)`, so including `.' and `..'). The visit function may modify names to influence the set of directories visited below dirname, e.g., to avoid visiting certain parts of the tree. (The object referred to by names must be modified in place, using `del` or slice assignment.)

Built-in Module pwd

This module provides access to the UNIX password database. It is available on all UNIX versions.

Password database entries are reported as 7-tuples containing the following items from the password database (see `` `<pwd.h>' ``), in order: `pw_name`, `pw_passwd`, `pw_uid`, `pw_gid`, `pw_gecos`, `pw_dir`, `pw_shell`. The uid and gid items are integers, all others are strings. An exception is raised if the entry asked for cannot be found.

It defines the following items:

function of module pwd: **getpwuid** *(uid)*

Return the password database entry for the given numeric user ID.

function of module pwd: **getpwnam** *(name)*

Return the password database entry for the given user name.

function of module pwd: **getpwall** *()*

Return a list of all available password database entries, in arbitrary order.

Built-in Module grp

This module provides access to the UNIX group database. It is available on all UNIX versions.

Group database entries are reported as 4-tuples containing the following items from the group database (see `` `<grp.h>' ``), in order: `gr_name`, `gr_passwd`, `gr_gid`, `gr_mem`. The gid is an integer, name and password are strings, and the member list is a list of strings. (Note that most users are not explicitly listed as members of the group they are in according to the password database.) An exception is raised if the entry asked for cannot be found.

It defines the following items:

function of module grp: **getgrgid** *(gid)*

Return the group database entry for the given numeric group ID.

function of module grp: **getgrnam** *(name)*

Return the group database entry for the given group name.

function of module grp: **getgrall** *()*

Return a list of all available group entries, in arbitrary order.

Built-in Module dbm

Dbm provides python programs with an interface to the unix `ndbm` database library. Dbm objects are of the mapping type, so they can be handled just like objects of the built-in dictionary type, except that keys and values are always strings, and printing a dbm object doesn't print the keys and values.

The module defines the following constant and functions:

exception: module dbm **error**

Raised on dbm-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

function of module dbm: **open** *(filename, rwmode, filemode)*

Open a dbm database and return a mapping object. filename is the name of the database file (without the `` `.dir' `` or `` `.pag' `` extensions), rwmode is `'r'`, `'w'` or `'rw'` to open the database fore reading, writing or both respectively, and filemode is the UNIX mode of the file, used only when the database has to be created (but to be supplied at all times).

Built-in Module gdbm

Gdbm provides python programs with an interface to the GNU `gdbm` database library. Gdbm objects are of the mapping type, so they can be handled just like objects of the built-in dictionary type, except that keys and values are always strings, and printing a gdbm object doesn't print the keys and values.

The module is based on the Dbm module, modified to use GDBM instead.

The module defines the following constant and functions:

exception: module gdbm **error**

Raised on gdbm-specific errors, such as I/O errors. `KeyError` is raised for general mapping errors like specifying an incorrect key.

function of module gdbm: **open** *(filename, rwmode, filemode)*

Open a gdbm database and return a mapping object. filename is the name of the database file, rwmode is `'r'`, `'w'`, `'c'`, or `'n'` for reader, writer (this also gives read access), create (writer, but create the database if it doesn't already exist) and newdb (which will always create a new database). Only one writer may open a gdbm file and many readers may open the file. Readers and writers cannot open the gdbm file at the same time. Note that the `GDBM_FAST` mode of opening the database is not supported. filemode is the UNIX mode of the file, used only when a database is created (but to be supplied at all times).

Built-in Module termios

This module provides an interface to the Posix calls for tty I/O control. For a complete description of these calls, see the Posix or UNIX manual pages. It is only available for those UNIX versions that support Posix `termios` style tty I/O control (and then only if configured at installation time).

All functions in this module take a file descriptor fd as their first argument. This must be an integer file descriptor, such as returned by `sys.stdin.fileno()`.

This module should be used in conjunction with the `TERMIOS` module, which defines the relevant symbolic constants (see the next section).

The module defines the following functions:

function of module termios: **tcgetattr** *(fd)*

Return a list containing the tty attributes for file descriptor fd, as follows: `[iflag, oflag, cflag, lflag, ispeed, ospeed, cc]` where cc is a list of the tty special characters (each a string of length 1, except the items with indices `VMIN` and `VTIME`, which are integers when these fields are defined). The interpretation of the flags and the speeds as well as the indexing in the cc array must be done using the symbolic constants defined in the `TERMIOS` module.

function of module termios: **tcsetattr** *(fd, when, attributes)*

Set the tty attributes for file descriptor fd from the attributes, which is a list like the one returned by `tcgetattr()`. The when argument determines when the attributes are changed: `TERMIOS.TCSA` to change immediately, `TERMIOS.TCSADRAIN` to change after transmitting all queued output, or `TERMIOS.TCSAFLUSH` to change after transmitting all queued output and discarding all queued input.

function of module termios: **tcsendbreak** *(fd, duration)*

Send a break on file descriptor fd. A zero duration sends a break for 0.25--0.5 seconds; a nonzero duration has a system dependent meaning.

function of module termios: **tcdrain** *(fd)*

Wait until all output written to file descriptor fd has been transmitted.

function of module termios: **tcflush** *(fd, queue)*

Discard queued data on file descriptor fd. The queue selector specifies which queue: `TERMIOS.TCIFLUSH` for the input queue, `TERMIOS.TCOFLUSH` for the output queue, or `TERMIOS.TCIOFLUSH` for both queues.

function of module termios: **tcflow** *(fd, action)*

Suspend or resume input or output on file descriptor fd. The action argument can be `TERMIOS.TCOOFF` to suspend output, `TERMIOS.TCOON` to restart output, `TERMIOS.TCIOFF` to suspend input, or `TERMIOS.TCION` to restart input.

Example

Here's a function that prompts for a password with echoing turned off. Note the technique using a separate `termios.tcgetattr()` call and a `try {...` finally} statement to ensure that the old tty attributes are restored exactly no matter what happens:

```
def getpass(prompt = "Password: "):
    import termios, TERMIOS, sys
    fd = sys.stdin.fileno()
    old = termios.tcgetattr(fd)
    new = termios.tcgetattr(fd)
    new[3] = new[3] & ~TERMIOS.ECHO          # lflags
    try:
        termios.tcsetattr(fd, TERMIOS.TCSADRAIN, new)
        passwd = raw_input(prompt)
    finally:
        termios.tcsetattr(fd, TERMIOS.TCSADRAIN, old)
    return passwd
```

Standard Module TERMIOS

This module defines the symbolic constants required to use the `termios` module (see the previous section). See the Posix or UNIX manual pages (or the source) for a list of those constants.

Note: this module resides in a system-dependent subdirectory of the Python library directory. You may have to generate it for your particular system using the script `` `Tools/scripts/h2py.py' ``.

Built-in Module fcntl

This module performs file control and I/O control on file descriptors. It is an interface to the fcntl() and ioctl() UNIX routines. File descriptors can be obtained with the fileno() method of a file or socket object.

The module defines the following functions:

function of module struct: **fcntl** *(fd, op[, arg])*

Perform the requested operation on file descriptor `fd`. The operation is defined by `op` and is operating system dependent. Typically these codes can be retrieved from the library module `FCNTL`. The argument `arg` is optional, and defaults to the integer value `0`. When it is present, it can either be an integer value, or a string. With the argument missing or an integer value, the return value of this function is the integer return value of the real `fcntl()` call. When the argument is a string it represents a binary structure, e.g. created by `struct.pack()`. The binary data is copied to a buffer whose address is passed to the real `fcntl()` call. The return value after a successful call is the contents of the buffer, converted to a string object. In case the `fcntl()` fails, an `IOError` will be raised.

function of module struct: **ioctl** *(fd, op, arg)*

This function is identical to the `fcntl()` function, except that the operations are typically defined in the library module `IOCTL`.

If the library modules `FCNTL` or `IOCTL` are missing, you can find the opcodes in the C include files `sys/fcntl` and `sys/ioctl`. You can create the modules yourself with the h2py script, found in the `Demo/scripts` directory.

Examples (all on a SVR4 compliant system):

```
import struct, FCNTL

file = open(...)
rv = fcntl(file.fileno(), FCNTL.O_NDELAY, 1)

lockdata = struct.pack('hhllhh', FCNTL.F_WRLCK, 0, 0, 0, 0, 0)
rv = fcntl(file.fileno(), FCNTL.F_SETLKW, lockdata)
```

Note that in the first example the return value variable `rv` will hold an integer value; in the second example it will hold a string value.

Standard Module posixfile

This module implements some additional functionality over the built-in file objects. In particular, it implements file locking, control over the file flags, and an easy interface to duplicate the file object. The module defines a new file object, the posixfile object. It has all the standard file object methods and adds the methods described below. This module only works for certain flavors of UNIX, since it uses `fcntl()` for file locking.

To instantiate a posixfile object, use the `open()` function in the posixfile module. The resulting object looks and feels roughly the same as a standard file object.

The posixfile module defines the following constants:

data: module posixfile **SEEK_SET**

offset is calculated from the start of the file

data: module posixfile **SEEK_CUR**

offset is calculated from the current position in the file

data: module posixfile **SEEK_END**

offset is calculated from the end of the file

The posixfile module defines the following functions:

function of module posixfile: **open** *(filename[, mode[, bufsize]])*

Create a new posixfile object with the given filename and mode. The filename, mode and bufsize arguments are interpreted the same way as by the built-in `open()` function.

function of module posixfile: **fileopen** *(fileobject)*

Create a new posixfile object with the given standard file object. The resulting object has the same filename and mode as the original file object.

The posixfile object defines the following additional methods:

Method: posixfile **lock** *(fmt, [len[, start [, whence]]])*

Lock the specified section of the file that the file object is referring to. The format is explained below in a table. The len argument specifies the length of the section that should be locked. The default is `0`. start specifies the starting offset of the section, where the default is `0`. The whence argument specifies where the offset is relative to. It accepts one of the constants `SEEK_SET`, `SEEK_CUR` or `SEEK_END`. The default is `SEEK_SET`. For more information about the arguments refer to the fcntl manual page on your system.

Method: posixfile **flags** *([flags])*

Set the specified flags for the file that the file object is referring to. The new flags are ORed with the old

flags, unless specified otherwise. The format is explained below in a table. Without the flags argume string indicating the current flags is returned (this is the same as the '?' modifier). For more informati about the flags refer to the fcntl manual page on your system.

Method: posixfile **dup** *()*

Duplicate the file object and the underlying file pointer and file descriptor. The resulting object behaves as if it were newly opened.

Method: posixfile **dup2** *(fd)*

Duplicate the file object and the underlying file pointer and file descriptor. The new object will have the given file descriptor. Otherwise the resulting object behaves as if it were newly opened.

Method: posixfile **file** *()*

Return the standard file object that the posixfile object is based on. This is sometimes necessary for functions that insist on a standard file object.

All methods return `IOError` when the request fails.

Format characters for the `lock()` method have the following meaning:

Format

Meaning --

`u'

unlock the specified region

`r'

request a read lock for the specified section

`w'

request a write lock for the specified section

In addition the following modifiers can be added to the format:

Modifier

Meaning -- *Notes*

`|'

wait until the lock has been granted

`?'

return the first lock conflicting with the requested lock, or `None` if there is no conflict. -- (1)

Note:

(1) The lock returned is in the format `(mode, len, start, whence, pid)` where mode is a character representing the type of lock ('r' or 'w'). This modifier prevents a request from being granted; it is for query purposes only.

Format character for the `flags()` method have the following meaning:

Format

Meaning --

`a'

append only flag

`c'

close on exec flag

`n'

no delay flag (also called non-blocking flag)

`s'

synchronization flag

In addition the following modifiers can be added to the format:

Modifier

Meaning -- *Notes*

`!'

turn the specified flags 'off', instead of the default 'on' -- (1)

`='

replace the flags, instead of the default 'OR' operation -- (1)

`?'

return a string in which the characters represent the flags that are set. -- (2)

Note:

(1) The `!` and `=` modifiers are mutually exclusive.

(2) This string represents the flags after they may have been altered by the same call.

Examples:

```
from posixfile import *

file = open('/tmp/test', 'w')
file.lock('w|')
...
file.lock('u')
file.close()
```

Go to the previous, next section.

The Python Debugger

The module `pdb` defines an interactive source code debugger for Python programs. It supports setting breakpoints and single stepping at the source line level, inspection of stack frames, source code listing, and evaluation of arbitrary Python code in the context of any stack frame. It also supports post-mortem debugging and can be called under program control.

The debugger is extensible -- it is actually defined as a class `Pdb`. This is currently undocumented but easily understood by reading the source. The extension interface uses the (also undocumented) modules `bdb` and `cmd`.

A primitive windowing version of the debugger also exists -- this is module `wdb`, which requires STDWIN (see the chapter on STDWIN specific modules).

The debugger's prompt is "`(Pdb) `". Typical usage to run a program under control of the debugger is:

```
>>> import pdb
>>> import mymodule
>>> pdb.run('mymodule.test()')
> <string>(0)?()
(Pdb) continue
> <string>(1)?()
(Pdb) continue
NameError: 'spam'
> <string>(1)?()
(Pdb)
```

Typical usage to inspect a crashed program is:

```
>>> import pdb
>>> import mymodule
>>> mymodule.test()
Traceback (innermost last):
  File "<stdin>", line 1, in ?
  File "./mymodule.py", line 4, in test
    test2()
  File "./mymodule.py", line 3, in test2
    print spam
NameError: spam
>>> pdb.pm()
> ./mymodule.py(3)test2()
-> print spam
(Pdb)
```

The module defines the following functions; each enters the debugger in a slightly different way:

function of module pdb: **run** *(statement[, globals[, locals]])*

Execute the statement (given as a string) under debugger control. The debugger prompt appears before any code is executed; you can set breakpoints and type `continue`, or you can step through the statement using `step` or `next` (all these commands are explained below). The optional globals and locals arguments specify the environment in which the code is executed; by default the dictionary of the module `__main__` is used. (See the explanation of the `exec` statement or the `eval()` built-in function.)

function of module pdb: **runeval** *(expression[, globals[, locals]])*

Evaluate the expression (given as a a string) under debugger control. When `runeval()` returns, it returns the value of the expression. Otherwise this function is similar to `run()`.

function of module pdb: **runcall** *(function[, argument, ...])*

Call the function (a function or method object, not a string) with the given arguments. When `runcall()` returns, it returns whatever the function call returned. The debugger prompt appears as soon as the function is entered.

function of module pdb: **set_trace** *()*

Enter the debugger at the calling stack frame. This is useful to hard-code a breakpoint at a given point in a program, even if the code is not otherwise being debugged (e.g. when an assertion fails).

function of module pdb: **post_mortem** *(traceback)*

Enter post-mortem debugging of the given traceback object.

function of module pdb: **pm** *()*

Enter post-mortem debugging of the traceback found in `sys.last_traceback`.

Debugger Commands

The debugger recognizes the following commands. Most commands can be abbreviated to one or two letters; e.g. "`h(elp)`" means that either "`h`" or "`help`" can be used to enter the help command (but not "`he`" or "`hel`", nor "`H`" or "`Help` or "`HELP`"). Arguments to commands must be separated by whitespace (spaces or tabs). Optional arguments are enclosed in square brackets ("`[]`") in the command syntax; the square brackets must not be typed. Alternatives in the command syntax are separated by a vertical bar ("`|`").

Entering a blank line repeats the last command entered. Exception: if the last command was a "`list`" command, the next 11 lines are listed.

Commands that the debugger doesn't recognize are assumed to be Python statements and are executed in the context of the program being debugged. Python statements can also be prefixed with an exclamation point ("`!`"). This is a powerful way to inspect the program being debugged; it is even possible to change

a variable or call a function. When an exception occurs in such a statement, the exception name is pr
but the debugger's state is not changed.

h(elp) [command

]

Without argument, print the list of available commands. With a command as argument, print help about that command. "`help pdb`" displays the full documentation file; if the environment variable `PAGER` is defined, the file is piped through that command instead. Since the command argument must be an identifier, "`help exec`" must be entered to get help on the "`!`" command.

w(here)

Print a stack trace, with the most recent frame at the bottom. An arrow indicates the current frame, which determines the context of most commands.

d(own)

Move the current frame one level down in the stack trace (to an older frame).

u(p)

Move the current frame one level up in the stack trace (to a newer frame).

b(reak) [lineno | function

]

With a lineno argument, set a break there in the current file. With a function argument, set a break at the entry of that function. Without argument, list all breaks.

cl(ear) [lineno

]

With a lineno argument, clear that break in the current file. Without argument, clear all breaks (but first ask confirmation).

s(tep)

Execute the current line, stop at the first possible occasion (either in a function that is called or on the next line in the current function).

n(ext)

Continue execution until the next line in the current function is reached or it returns. (The difference between `next` and `step` is that `step` stops inside a called function, while `next` executes called functions at (nearly) full speed, only stopping at the next line in the current function.)

r(eturn)

Continue execution until the current function returns.

c(ont(inue))

Continue execution, only stop when a breakpoint is encountered.

l(ist) [first [, last

]]

List source code for the current file. Without arguments, list 11 lines around the current line or continue the previous listing. With one argument, list 11 lines around at that line. With two arguments, list the given range; if the second argument is less than the first, it is interpreted as a count.

a(rgs)

Print the argument list of the current function.

p expression

Evaluate the expression in the current context and print its value. (Note: `print` can also be used, but is not a debugger command -- this executes the Python `print` statement.)

[!

statement]

Execute the (one-line) statement in the context of the current stack frame. The exclamation point can be omitted unless the first word of the statement resembles a debugger command. To set a global variable, you can prefix the assignment command with a "`global`" command on the same line, e.g.:

```
(Pdb) global list_options; list_options = ['-l']
(Pdb)
```

q(uit)

Quit from the debugger. The program being executed is aborted.

How It Works

Some changes were made to the interpreter:

- sys.settrace(func) sets the global trace function
- there can also a local trace function (see later)

Trace functions have three arguments: (frame, event, arg)

frame

is the current stack frame

event

is a string: `'call'`, `'line'`, `'return'` or `'exception'`

arg

is dependent on the event type

A trace function should return a new trace function or None. Class methods are accepted (and most useful!) as trace methods.

The events have the following meaning:

`'call'`

A function is called (or some other code block entered). The global trace function is called; arg is the argument list to the function; the return value specifies the local trace function.

`'line'`

The interpreter is about to execute a new line of code (sometimes multiple line events on one line exist). The local trace function is called; arg in None; the return value specifies the new local trace function.

`'return'`

A function (or other code block) is about to return. The local trace function is called; arg is the value that will be returned. The trace function's return value is ignored.

`'exception'`

An exception has occurred. The local trace function is called; arg is a triple (exception, value, traceback); the return value specifies the new local trace function

Note that as an exception is propagated down the chain of callers, an `'exception'` event is generated at each level.

Stack frame objects have the following read-only attributes:

f_code

the code object being executed

f_lineno

the current line number (`-1` for `'call'` events)

f_back

the stack frame of the caller, or None

f_locals

dictionary containing local name bindings

f_globals

dictionary containing global name bindings

Code objects have the following read-only attributes:

co_code

the code string

co_names

the list of names used by the code

co_consts

the list of (literal) constants used by the code

co_filename

the filename from which the code was compiled

The Python Profiler

Written by James Roskind(14)

The profiler was written after only programming in Python for 3 weeks. As a result, it is probably clumsy code, but I don't know for sure yet 'cause I'm a beginner :-). I did work hard to make the code run fast, so that profiling would be a reasonable thing to do. I tried not to repeat code fragments, but I'm sure I did some stuff in really awkward ways at times. Please send suggestions for improvements to: `jar@infoseek.com`. I won't promise *any* support. ...but I'd appreciate the feedback.

Introduction to the profiler

A profiler is a program that describes the run time performance of a program, providing a variety of statistics. This documentation describes the profiler functionality provided in the modules `profile` and `pstats`. This profiler provides deterministic profiling of any Python programs. It also provides a series of report generation tools to allow users to rapidly examine the results of a profile operation.

How Is This Profiler Different From The Old Profiler?

The big changes from old profiling module are that you get more information, and you pay less CPU time. It's not a trade-off, it's a trade-up.

To be specific:

Bugs removed:

Local stack frame is no longer molested, execution time is now charged to correct functions.

Accuracy increased:

Profiler execution time is no longer charged to user's code, calibration for platform is supported, file reads are not done *by* profiler *during* profiling (and charged to user's code!).

Speed increased:

Overhead CPU cost was reduced by more than a factor of two (perhaps a factor of five), lightweight profiler module is all that must be loaded, and the report generating module (`pstats`) is not needed during profiling.

Recursive functions support:

Cumulative times in recursive functions are correctly calculated; recursive entries are counted.

Large growth in report generating UI:

Distinct profiles runs can be added together forming a comprehensive report; functions that import statistics take arbitrary lists of files; sorting criteria is now based on keywords (instead of 4 integer options); reports shows what functions were profiled as well as what profile file was referenced; output format has been improved.

Instant Users Manual

This section is provided for users that "don't want to read the manual." It provides a very brief overview, and allows a user to rapidly perform profiling on an existing application.

To profile an application with a main entry point of `foo()', you would add the following to your module:

```
import profile
profile.run("foo()")
```

The above action would cause `foo()' to be run, and a series of informative lines (the profile) to be printed. The above approach is most useful when working with the interpreter. If you would like to save the results of a profile into a file for later examination, you can supply a file name as the second argument to the `run()` function:

```
import profile
profile.run("foo()", 'fooprof')
```

When you wish to review the profile, you should use the methods in the `pstats` module. Typically you would load the statistics data as follows:

```
import pstats
p = pstats.Stats('fooprof')
```

The class `Stats` (the above code just created an instance of this class) has a variety of methods for

manipulating and printing the data that was just read into `p'. When you ran `profile.run()` above what was printed was the result of three method calls:

```
p.strip_dirs().sort_stats(-1).print_stats()
```

The first method removed the extraneous path from all the module names. The second method sorted all the entries according to the standard module/line/name string that is printed (this is to comply with the semantics of the old profiler). The third method printed out all the statistics. You might try the following sort calls:

```
p.sort_stats('name')
p.print_stats()
```

The first call will actually sort the list by function name, and the second call will print out the statistics. The following are some interesting calls to experiment with:

```
p.sort_stats('cumulative').print_stats(10)
```

This sorts the profile by cumulative time in a function, and then only prints the ten most significant lines. If you want to understand what algorithms are taking time, the above line is what you would use.

If you were looking to see what functions were looping a lot, and taking a lot of time, you would do:

```
p.sort_stats('time').print_stats(10)
```

to sort according to time spent within each function, and then print the statistics for the top ten functions.

You might also try:

```
p.sort_stats('file').print_stats('__init__')
```

This will sort all the statistics by file name, and then print out statistics for only the class init methods ('cause they are spelled with `__init__` in them). As one final example, you could try:

```
p.sort_stats('time', 'cum').print_stats(.5, 'init')
```

This line sorts statistics with a primary key of time, and a secondary key of cumulative time, and then prints out some of the statistics. To be specific, the list is first culled down to 50% (re: `.5') of its original size, then only lines containing `init` are maintained, and that sub-sub-list is printed.

If you wondered what functions called the above functions, you could now (`p' is still sorted according to the last criteria) do:

```
p.print_callers(.5, 'init')
```

and you would get a list of callers for each of the listed functions.

If you want more functionality, you're going to have to read the manual, or guess what the following

functions do:

```
p.print_callees()
p.add('fooprof')
```

What Is Deterministic Profiling?

Deterministic profiling is meant to reflect the fact that all function call, function return, and exception events are monitored, and precise timings are made for the intervals between these events (during which time the user's code is executing). In contrast, statistical profiling (which is not done by this module) randomly samples the effective instruction pointer, and deduces where time is being spent. The latter technique traditionally involves less overhead (as the code does not need to be instrumented), but provides only relative indications of where time is being spent.

In Python, since there is an interpreter active during execution, the presence of instrumented code is not required to do deterministic profiling. Python automatically provides a hook (optional callback) for each event. In addition, the interpreted nature of Python tends to add so much overhead to execution, that deterministic profiling tends to only add small processing overhead in typical applications. The result is that deterministic profiling is not that expensive, yet provides extensive run time statistics about the execution of a Python program.

Call count statistics can be used to identify bugs in code (surprising counts), and to identify possible inline-expansion points (high call counts). Internal time statistics can be used to identify "hot loops" that should be carefully optimized. Cumulative time statistics should be used to identify high level errors in the selection of algorithms. Note that the unusual handling of cumulative times in this profiler allows statistics for recursive implementations of algorithms to be directly compared to iterative implementations.

Reference Manual

The primary entry point for the profiler is the global function `profile.run()`. It is typically used to create any profile information. The reports are formatted and printed using methods of the class `pstats.Stats`. The following is a description of all of these standard entry points and functions. For a more in-depth view of some of the code, consider reading the later section on Profiler Extensions, which includes discussion of how to derive "better" profilers from the classes presented, or reading the source code for these modules.

profiler function: **profile.run** *(string[, filename[, ...]])*

This function takes a single argument that has can be passed to the `exec` statement, and an optional file name. In all cases this routine attempts to `exec` its first argument, and gather profiling statistics from the execution. If no file name is present, then this function automatically prints a simple profiling report, sorted by the standard name string (file/line/function-name) that is presented in each line. The following is a typical output from such a call:

@small{

```
      main()
      2706 function calls (2004 primitive calls) in 4.504 CPU seconds

Ordered by: standard name

ncalls  tottime  percall  cumtime  percall filename:lineno(function)
     2    0.006    0.003    0.953    0.477 pobject.py:75(save_objects)
  43/3    0.533    0.012    0.749    0.250 pobject.py:99(evaluate)
  ...
}
```

The first line indicates that this profile was generated by the call: `profile.run('main()')`, and hence the exec'ed string is `'main()'`. The second line indicates that 2706 calls were monitored. Of those calls, 2004 were primitive. We define primitive to mean that the call was not induced via recursion. The next line: `Ordered by: standard name`, indicates that the text string in the far right column was used to sort the output. The column headings include:

ncalls

for the number of calls,

tottime

for the total time spent in the given function (and excluding time made in calls to sub-functions),

percall

is the quotient of `tottime` divided by `ncalls`

cumtime

is the total time spent in this and all subfunctions (i.e., from invocation till exit). This figure is accurate *even* for recursive functions.

percall

is the quotient of `cumtime` divided by primitive calls

filename:lineno(function)

provides the respective data of each function

When there are two numbers in the first column (e.g.: `43/3'), then the latter is the number of primitive calls, and the former is the actual number of calls. Note that when the function does not recurse, these two values are the same, and only the single figure is printed.

profiler function: **pstats.Stats** *(filename[, ...])*

This class constructor creates an instance of a "statistics object" from a filename (or set of filenames). `Stats` objects are manipulated by methods, in order to print useful reports.

The file selected by the above constructor must have been created by the corresponding version of `profile`. To be specific, there is *NO* file compatibility guaranteed with future versions of this profiler, and there is no compatibility with files produced by other profilers (e.g., the old system profiler).

If several files are provided, all the statistics for identical functions will be coalesced, so that an overview of several processes can be considered in a single report. If additional files need to be combined with data in an existing `Stats` object, the `add()` method can be used.

The `Stats` Class

Method: Stats **strip_dirs** *()*

This method for the `Stats` class removes all leading path information from file names. It is very useful in reducing the size of the printout to fit within (close to) 80 columns. This method modifies the object, and the stripped information is lost. After performing a strip operation, the object is considered to have its entries in a "random" order, as it was just after object initialization and loading. If `strip_dirs()` causes two function names to be indistinguishable (i.e., they are on the same line of the same filename, and have the same function name), then the statistics for these two entries are accumulated into a single entry.

Method: Stats **add** *(filename[, ...])*

This method of the `Stats` class accumulates additional profiling information into the current profiling object. Its arguments should refer to filenames created by the corresponding version of `profile.run()`. Statistics for identically named (re: file, line, name) functions are automatically accumulated into single function statistics.

Method: Stats **sort_stats** *(key[, ...])*

This method modifies the `Stats` object by sorting it according to the supplied criteria. The argument is typically a string identifying the basis of a sort (example: `"time"` or `"name"`).

When more than one key is provided, then additional keys are used as secondary criteria when the there is equality in all keys selected before them. For example, sort_stats('name', 'file') will sort all the entries according to their function name, and resolve all ties (identical function names) by sorting by file name.

Abbreviations can be used for any key names, as long as the abbreviation is unambiguous. The following are the keys currently defined:

Valid Arg

-- *Meaning*

`"calls"`

call count

`"cumulative"`

cumulative time

`"file"`

file name

`"module"`

file name

`"pcalls"`

primitive call count

`"line"`
: line number

`"name"`
: function name

`"nfl"`
: name/file/line

`"stdname"`
: standard name

`"time"`
: internal time

Note that all sorts on statistics are in descending order (placing most time consuming items first), where as name, file, and line number searches are in ascending order (i.e., alphabetical). The subtle distinction between `"nfl"` and `"stdname"` is that the standard name is a sort of the name as printed, which means that the embedded line numbers get compared in an odd way. For example, lines 3, 20, and 40 would (if the file names were the same) appear in the string order 20, 3 and 40. In contrast, `"nfl"` does a numeric compare of the line numbers. In fact, `sort_stats("nfl")` is the same as `sort_stats("name", "file", "line")`.

For compatibility with the old profiler, the numeric arguments `-1', `0', `1', and `2' are permitted. They are interpreted as `"stdname"`, `"calls"`, `"time"`, and `"cumulative"` respectively. If this old style format (numeric) is used, only one sort key (the numeric key) will be used, and additional arguments will be silently ignored.

Method: Stats **reverse_order** *()*

This method for the `Stats` class reverses the ordering of the basic list within the object. This method is provided primarily for compatibility with the old profiler. Its utility is questionable now that ascending vs descending order is properly selected based on the sort key of choice.

Method: Stats **print_stats** *(restriction[, ...])*

This method for the `Stats` class prints out a report as described in the `profile.run()` definition.

The order of the printing is based on the last `sort_stats()` operation done on the object (subject to caveats in `add()` and `strip_dirs()`).

The arguments provided (if any) can be used to limit the list down to the significant entries. Initially, the list is taken to be the complete set of profiled functions. Each restriction is either an integer (to select a count of lines), or a decimal fraction between 0.0 and 1.0 inclusive (to select a percentage of lines), or a regular expression (to pattern match the standard name that is printed). If several restrictions are provided, then they are applied sequentially. For example:

```
print_stats(.1, "foo:")
```

would first limit the printing to first 10% of list, and then only print functions that were part of filena `.*foo:'. In contrast, the command:

```
print_stats("foo:", .1)
```

would limit the list to all functions having file names `.*foo:', and then proceed to only print the first 10% of them.

Method: Stats **print_callers** *(restrictions[, ...])*

This method for the `Stats` class prints a list of all functions that called each function in the profiled database. The ordering is identical to that provided by `print_stats()`, and the definition of the restricting argument is also identical. For convenience, a number is shown in parentheses after each caller to show how many times this specific call was made. A second non-parenthesized number is the cumulative time spent in the function at the right.

Method: Stats **print_callees** *(restrictions[, ...])*

This method for the `Stats` class prints a list of all function that were called by the indicated function. Aside from this reversal of direction of calls (re: called vs was called by), the arguments and ordering are identical to the `print_callers()` method.

Method: Stats **ignore** *()*

This method of the `Stats` class is used to dispose of the value returned by earlier methods. All standard methods in this class return the instance that is being processed, so that the commands can be strung together. For example:

```
pstats.Stats('foofile').strip_dirs().sort_stats('cum') \
                       .print_stats().ignore()
```

would perform all the indicated functions, but it would not return the final reference to the `Stats` instance.(15)

Limitations

There are two fundamental limitations on this profiler. The first is that it relies on the Python interpreter to dispatch call, return, and exception events. Compiled C code does not get interpreted, and hence is "invisible" to the profiler. All time spent in C code (including builtin functions) will be charged to the Python function that invoked the C code. If the C code calls out to some native Python code, then those calls will be profiled properly.

The second limitation has to do with accuracy of timing information. There is a fundamental problem with deterministic profilers involving accuracy. The most obvious restriction is that the underlying "clock" is only ticking at a rate (typically) of about .001 seconds. Hence no measurements will be more accurate that that underlying clock. If enough measurements are taken, then the "error" will tend to average out. Unfortunately, removing this first error induces a second source of error...

The second problem is that it "takes a while" from when an event is dispatched until the profiler's call to get the time actually *gets* the state of the clock. Similarly, there is a certain lag when exiting the profiler event handler from the time that the clock's value was obtained (and then squirreled away), until the user's code is once again executing. As a result, functions that are called many times, or call many functions, will typically accumulate this error. The error that accumulates in this fashion is typically less than the accuracy of the clock (i.e., less than one clock tick), but it *can* accumulate and become very significant. This profiler provides a means of calibrating itself for a given platform so that this error can be probabilistically (i.e., on the average) removed. After the profiler is calibrated, it will be more accurate (in a least square sense), but it will sometimes produce negative numbers (when call counts are exceptionally low, and the gods of probability work against you :-).) Do *NOT* be alarmed by negative numbers in the profile. They should *only* appear if you have calibrated your profiler, and the results are actually better than without calibration.

Calibration

The profiler class has a hard coded constant that is added to each event handling time to compensate for the overhead of calling the time function, and socking away the results. The following procedure can be used to obtain this constant for a given platform (see discussion in section Limitations above).

```
import profile
pr = profile.Profile()
pr.calibrate(100)
pr.calibrate(100)
pr.calibrate(100)
```

The argument to calibrate() is the number of times to try to do the sample calls to get the CPU times. If your computer is *very* fast, you might have to do:

```
pr.calibrate(1000)
```

or even:

```
pr.calibrate(10000)
```

The object of this exercise is to get a fairly consistent result. When you have a consistent answer, you are ready to use that number in the source code. For a Sun Sparcstation 1000 running Solaris 2.3, the magical number is about .00053. If you have a choice, you are better off with a smaller constant, and your results will "less often" show up as negative in profile statistics.

The following shows how the trace_dispatch() method in the Profile class should be modified to install the calibration constant on a Sun Sparcstation 1000:

```
def trace_dispatch(self, frame, event, arg):
    t = self.timer()
    t = t[0] + t[1] - self.t - .00053 # Calibration constant
```

```
        if self.dispatch[event](frame,t):
            t = self.timer()
            self.t = t[0] + t[1]
        else:
            r = self.timer()
            self.t = r[0] + r[1] - t # put back unrecorded delta
        return
```

Note that if there is no calibration constant, then the line containing the callibration constant should simply say:

```
        t = t[0] + t[1] - self.t  # no calibration constant
```

You can also achieve the same results using a derived class (and the profiler will actually run equally fast!!), but the above method is the simplest to use. I could have made the profiler "self calibrating", but it would have made the initialization of the profiler class slower, and would have required some *very* fancy coding, or else the use of a variable where the constant `.00053' was placed in the code shown. This is a **VERY** critical performance section, and there is no reason to use a variable lookup at this point, when a constant can be used.

Extensions -- Deriving Better Profilers

The `Profile` class of module `profile` was written so that derived classes could be developed to extend the profiler. Rather than describing all the details of such an effort, I'll just present the following two examples of derived classes that can be used to do profiling. If the reader is an avid Python programmer, then it should be possible to use these as a model and create similar (and perchance better) profile classes.

If all you want to do is change how the timer is called, or which timer function is used, then the basic class has an option for that in the constructor for the class. Consider passing the name of a function to call into the constructor:

```
    pr = profile.Profile(your_time_func)
```

The resulting profiler will call `your_time_func()` instead of `os.times()`. The function should return either a single number or a list of numbers (like what `os.times()` returns). If the function returns a single time number, or the list of returned numbers has length 2, then you will get an especially fast version of the dispatch routine.

Be warned that you *should* calibrate the profiler class for the timer function that you choose. For most machines, a timer that returns a lone integer value will provide the best results in terms of low overhead during profiling. (os.times is *pretty* bad, 'cause it returns a tuple of floating point values, so all arithmetic is floating point in the profiler!). If you want to substitute a better timer in the cleanest fashion, you should derive a class, and simply put in the replacement dispatch method that better handles your timer call, along with the appropriate calibration constant :-).

OldProfile Class

The following derived profiler simulates the old style profiler, providing errant results on recursive functions. The reason for the usefulness of this profiler is that it runs faster (i.e., less overhead) than the old profiler. It still creates all the caller stats, and is quite useful when there is *no* recursion in the user's code. It is also a lot more accurate than the old profiler, as it does not charge all its overhead time to the user's code.

```
class OldProfile(Profile):

    def trace_dispatch_exception(self, frame, t):
        rt, rtt, rct, rfn, rframe, rcur = self.cur
        if rcur and not rframe is frame:
            return self.trace_dispatch_return(rframe, t)
        return 0

    def trace_dispatch_call(self, frame, t):
        fn = `frame.f_code`

        self.cur = (t, 0, 0, fn, frame, self.cur)
        if self.timings.has_key(fn):
            tt, ct, callers = self.timings[fn]
            self.timings[fn] = tt, ct, callers
        else:
            self.timings[fn] = 0, 0, {}
        return 1

    def trace_dispatch_return(self, frame, t):
        rt, rtt, rct, rfn, frame, rcur = self.cur
        rtt = rtt + t
        sft = rtt + rct

        pt, ptt, pct, pfn, pframe, pcur = rcur
        self.cur = pt, ptt+rt, pct+sft, pfn, pframe, pcur

        tt, ct, callers = self.timings[rfn]
        if callers.has_key(pfn):
            callers[pfn] = callers[pfn] + 1
        else:
            callers[pfn] = 1
        self.timings[rfn] = tt+rtt, ct + sft, callers

        return 1
```

```
    def snapshot_stats(self):
        self.stats = {}
        for func in self.timings.keys():
            tt, ct, callers = self.timings[func]
            nor_func = self.func_normalize(func)
            nor_callers = {}
            nc = 0
            for func_caller in callers.keys():
                nor_callers[self.func_normalize(func_caller)]=\
                      callers[func_caller]
                nc = nc + callers[func_caller]
            self.stats[nor_func] = nc, nc, tt, ct, nor_callers
```

HotProfile Class

This profiler is the fastest derived profile example. It does not calculate caller-callee relationships, and does not calculate cumulative time under a function. It only calculates time spent in a function, so it runs very quickly (re: very low overhead). In truth, the basic profiler is so fast, that is probably not worth the savings to give up the data, but this class still provides a nice example.

```
class HotProfile(Profile):

    def trace_dispatch_exception(self, frame, t):
        rt, rtt, rfn, rframe, rcur = self.cur
        if rcur and not rframe is frame:
            return self.trace_dispatch_return(rframe, t)
        return 0

    def trace_dispatch_call(self, frame, t):
        self.cur = (t, 0, frame, self.cur)
        return 1

    def trace_dispatch_return(self, frame, t):
        rt, rtt, frame, rcur = self.cur

        rfn = `frame.f_code`

        pt, ptt, pframe, pcur = rcur
        self.cur = pt, ptt+rt, pframe, pcur

        if self.timings.has_key(rfn):
            nc, tt = self.timings[rfn]
            self.timings[rfn] = nc + 1, rt + rtt + tt
        else:
            self.timings[rfn] =      1, rt + rtt
```

```
        return 1

    def snapshot_stats(self):
        self.stats = {}
        for func in self.timings.keys():
            nc, tt = self.timings[func]
            nor_func = self.func_normalize(func)
            self.stats[nor_func] = nc, nc, tt, 0, {}
```

Internet and WWW Services

The modules described in this chapter provide various services to World-Wide Web (WWW) clients and/or services, and a few modules related to news and email. They are all implemented in Python. Some of these modules require the presence of the system-dependent module `sockets`, which is currently only fully supported on Unix and Windows NT. Here is an overview:

cgi
--- Common Gateway Interface, used to interpret forms in server-side scripts.

urllib
--- Open an arbitrary object given by URL (requires sockets).

httplib
--- HTTP protocol client (requires sockets).

ftplib
--- FTP protocol client (requires sockets).

gopherlib
--- Gopher protocol client (requires sockets).

nntplib
--- NNTP protocol client (requires sockets).

urlparse
--- Parse a URL string into a tuple (addressing scheme identifier, network location, path, parameters, query string, fragment identifier).

htmllib
--- A (slow) parser for HTML files.

sgmllib
--- Only as much of an SGML parser as needed to parse HTML.

rfc822
--- Parse RFC-822 style mail headers.

mimetools
--- Tools for parsing MIME style message bodies.

Standard Module `cgi`

This module makes it easy to write Python scripts that run in a WWW server using the Common Gateway Interface. It was written by Michael McLay and subsequently modified by Steve Majewski and Guido van Rossum.

When a WWW server finds that a URL contains a reference to a file in a particular subdirectory (usually `/cgibin`), it runs the file as a subprocess. Information about the request such as the full URL, the originating host etc., is passed to the subprocess in the shell environment; additional input from the client may be read from

standard input. Standard output from the subprocess is sent back across the network to the client as the resp from the request. The CGI protocol describes what the environment variables passed to the subprocess mea and how the output should be formatted. The official reference documentation for the CGI protocol can be found on the World-Wide Web at `<URL:http://hoohoo.ncsa.uiuc.edu/cgi/overview.html>`. The `cgi` module was based on version 1.1 of the protocol and should also work with version 1.0.

The `cgi` module defines several classes that make it easy to access the information passed to the subprocess from a Python script; in particular, it knows how to parse the input sent by an HTML "form" using either a POST or a GET request (these are alternatives for submitting forms in the HTTP protocol).

The formatting of the output is so trivial that no additional support is needed. All you need to do is print a minimal set of MIME headers describing the output format, followed by a blank line and your actual output. E.g. if you want to generate HTML, your script could start as follows:

```
# Header -- one or more lines:
print "Content-type: text/html"
# Blank line separating header from body:
print
# Body, in HTML format:
print "<TITLE>The Amazing SPAM Homepage!</TITLE>"
# etc...
```

The server will add some header lines of its own, but it won't touch the output following the header.

The `cgi` module defines the following functions:

function of module cgi: **parse** *()*

Read and parse the form submitted to the script and return a dictionary containing the form's fields. This should be called at most once per script invocation, as it may consume standard input (if the form was submitted through a POST request). The keys in the resulting dictionary are the field names used in the submission; the values are *lists* of the field values (since field name may be used multiple times in a single form). `%' escapes in the values are translated to their single-character equivalent using `urllib.unquote()`. As a side effect, this function sets `environ['QUERY_STRING']` to the raw query string, if it isn't already set.

function of module cgi: **print_environ_usage** *()*

Print a piece of HTML listing the environment variables that may be set by the CGI protocol. This is mainly useful when learning about writing CGI scripts.

function of module cgi: **print_environ** *()*

Print a piece of HTML text showing the entire contents of the shell environment. This is mainly useful when debugging a CGI script.

function of module cgi: **print_form** *(form)*

Print a piece of HTML text showing the contents of the form (a dictionary, an instance of the `FormContentDict` class defined below, or a subclass thereof). This is mainly useful when debugging a CGI script.

function of module cgi: **escape** *(string)*

Convert special characters in string to HTML escapes. In particular, "&" is replaced with "`&`", "<" is replaced with "`<`", and ">" is replaced with "`>`". This is useful when printing (almost) arbitrary text in an HTML context. Note that for inclusion in quoted tag attributes (e.g.), some additional characters would have to be converted -- in particular the string quote. There is currently no function that does this.

The module defines the following classes. Since the base class initializes itself by calling `parse()`, at most one instance of at most one of these classes should be created per script invocation:

function of module cgi: **FormContentDict** *()*

This class behaves like a (read-only) dictionary and has the same keys and values as the dictionary returned by `parse()` (i.e. each field name maps to a list of values). Additionally, it initializes its data member `query_string` to the raw query sent from the server.

function of module cgi: **SvFormContentDict** *()*

This class, derived from `FormContentDict`, is a little more user-friendly when you are expecting that each field name is only used once in the form. When you access for a particular field (using `form[fieldname]`), it will return the string value of that item if it is unique, or raise `IndexError` if the field was specified more than once in the form. (If the field wasn't specified at all, `KeyError` is raised.) To access fields that are specified multiple times, use `form.getlist(fieldname)`. The `values()` and `items()` methods return mixed lists --- containing strings for singly-defined fields, and lists of strings for multiply-defined fields.

(It currently defines some more classes, but these are experimental and/or obsolescent, and are thus not documented -- see the source for more informations.)

The module defines the following variable:

data: module cgi **environ**

The shell environment, exactly as received from the http server. See the CGI documentation for a description of the various fields.

Example

This example assumes that you have a WWW server up and running, e.g. NCSA's `httpd`.

Place the following file in a convenient spot in the WWW server's directory tree. E.g., if you place it in the subdirectory `` `test' `` of the root directory and call it `` `test.html' ``, its URL will be `` `http://yourservername/test/test.html' ``.

```
<TITLE>Test Form Input</TITLE>
<H1>Test Form Input</H1>
<FORM METHOD="POST" ACTION="/cgi-bin/test.py">
<INPUT NAME=Name> (Name)<br>
<INPUT NAME=Address> (Address)<br>
<INPUT TYPE=SUBMIT>
</FORM>
```

Selecting this file's URL from a forms-capable browser such as Mosaic or Netscape will bring up a simple form with two text input fields and a "submit" button.

But wait. Before pressing "submit", a script that responds to the form must also be installed. The test file as shown assumes that the script is called `test.py' and lives in the server's cgi-bin directory. Here's the test script:

```
#!/usr/local/bin/python

import cgi

print "Content-type: text/html"
print                                   # End of headers!
print "<TITLE>Test Form Output</TITLE>"
print "<H1>Test Form Output</H1>"

form = cgi.SvFormContentDict()          # Load the form

name = addr = None                      # Default: no name and address

# Extract name and address from the form, if given

if form.has_key('Name'):
        name = form['Name']
if form.has_key('Address'):
        addr = form['Address']

# Print an unnumbered list of the name and address, if present

print "<UL>"
if name is not None:
        print "<LI>Name:", cgi.escape(name)
if addr is not None:
        print "<LI>Address:", cgi.escape(addr)
print "</UL>"
```

The script should be made executable (`chmod +x script'). If the Python interpreter is not located at `/usr/local/bin/python' but somewhere else, the first line of the script should be modified accordingly.

Now that everything is installed correctly, we can try out the form. Bring up the test form in your WWW browser, fill in a name and address in the form, and press the "submit" button. The script should now run and its output is sent back to your browser. This should roughly look as follows:

Test Form Output

- Name: the name you entered
- Address: the address you entered

If you didn't enter a name or address, the corresponding line will be missing (since the browser doesn't send empty form fields to the server).

Standard Module `urllib`

This module provides a high-level interface for fetching data across the World-Wide Web. In particular, the `urlopen` function is similar to the built-in function `open`, but accepts URLs (Universal Resource Locators) instead of filenames. Some restrictions apply -- it can only open URLs for reading, and no seek operations are available.

it defines the following public functions:

function of module urllib: **urlopen** *(url)*

Open a network object denoted by a URL for reading. If the URL does not have a scheme identifier, or if it has `file:' as its scheme identifier, this opens a local file; otherwise it opens a socket to a server somewhere on the network. If the connection cannot be made, or if the server returns an error code, the `IOError` exception is raised. If all went well, a file-like object is returned. This supports the following methods: `read()`, `readline()`, `readlines()`, `fileno()`, `close()` and `info()`. Except for the last one, these methods have the same interface as for file objects -- see the section on File Objects earlier in this manual. (It's not a built-in file object, however, so it can't be used at those few places where a true built-in file object is required.)

The `info()` method returns an instance of the class `rfc822.Message` containing the headers received from the server, if the protocol uses such headers (currently the only supported protocol that uses this is HTTP). See the description of the `rfc822` module.

function of module urllib: **urlretrieve** *(url)*

Copy a network object denoted by a URL to a local file, if necessary. If the URL points to a local file, or a valid cached copy of the object exists, the object is not copied. Return a tuple (filename, headers) where filename is the local file name under which the object can be found, and headers is either `None` (for a local object) or whatever the `info()` method of the object returned by `urlopen()` returned (for a remote object, possibly cached). Exceptions are the same as for `urlopen()`.

function of module urllib: **urlcleanup** *()*

Clear the cache that may have been built up by previous calls to `urlretrieve()`.

function of module urllib: **quote** *(string[, addsafe])*

Replace special characters in string using the `%xx` escape. Letters, digits, and the characters "`_,.-`" are never quoted. The optional addsafe parameter specifies additional characters that should not be quoted -- its default value is `'/'`.

Example: `quote('/~conolly/')` yields `'/%7econnolly/'`.

function of module urllib: **unquote** *(string)*

Replace `%xx' escapes by their single-character equivalent.

Example: `unquote('/%7Econnolly/')` yields `'/~connolly/'`.

Restrictions:

- Currently, only the following protocols are supported: HTTP, (versions 0.9 and 1.0), Gopher (but not Gopher-+), FTP, and local files.
- The caching feature of `urlretrieve()` has been disabled until I find the time to hack proper

processing of Expiration time headers.

- There should be a function to query whether a particular URL is in the cache.
- For backward compatibility, if a URL appears to point to a local file but the file can't be opened, the URL is re-interpreted using the FTP protocol. This can sometimes cause confusing error messages.
- The `urlopen()` and `urlretrieve()` functions can cause arbitrarily long delays while waiting for a network connection to be set up. This means that it is difficult to build an interactive web client using these functions without using threads.
- The data returned by `urlopen()` or `urlretrieve()` is the raw data returned by the server. This may be binary data (e.g. an image), plain text or (for example) HTML. The HTTP protocol provides type information in the reply header, which can be inspected by looking at the `Content-type` header. For the Gopher protocol, type information is encoded in the URL; there is currently no easy way to extract it. If the returned data is HTML, you can use the module `htmllib` to parse it.
- Although the `urllib` module contains (undocumented) routines to parse and unparse URL strings, the recommended interface for URL manipulation is in module `urlparse`.

Standard Module `httplib`

This module defines a class which implements the client side of the HTTP protocol. It is normally not used directly -- the module `urllib` uses it to handle URLs that use HTTP.

The module defines one class, `HTTP`. An `HTTP` instance represents one transaction with an HTTP server. It should be instantiated passing it a host and optional port number. If no port number is passed, the port is extracted from the host string if it has the form `host:port`, else the default HTTP port (80) is used. If no host is passed, no connection is made, and the `connect` method should be used to connect to a server. For example, the following calls all create instances that connect to the server at the same host and port:

```
>>> h1 = httplib.HTTP('www.cwi.nl')
>>> h2 = httplib.HTTP('www.cwi.nl:80')
>>> h3 = httplib.HTTP('www.cwi.nl', 80)
```

Once an `HTTP` instance has been connected to an HTTP server, it should be used as follows:

1. 1. Make exactly one call to the `putrequest()` method.
2. 2. Make zero or more calls to the `putheader()` method.
3. 3. Call the `endheaders()` method (this can be omitted if step 4 makes no calls).
4. 4. Optional calls to the `send()` method.
5. 5. Call the `getreply()` method.
6. 6. Call the `getfile()` method and read the data off the file object that it returns.

HTTP Objects

`HTTP` instances have the following methods:

Method: HTTP **set_debuglevel** *(level)*

Set the debugging level (the amount of debugging output printed). The default debug level is `0`, meaning no debugging output is printed.

Method: HTTP **connect** *(host[, port])*

Connect to the server given by host and port. See the intro for the default port. This should be called directly only if the instance was instantiated without passing a host.

Method: HTTP **send** *(data)*

Send data to the server. This should be used directly only after the `endheaders()` method has been called and before `getreply()` has been called.

Method: HTTP **putrequest** *(request, selector)*

This should be the first call after the connection to the server has been made. It sends a line to the server consisting of the request string, the selector string, and the HTTP version (`HTTP/1.0`).

Method: HTTP **putheader** *(header, argument[, ...])*

Send an RFC-822 style header to the server. It sends a line to the server consisting of the header, a colon and a space, and the first argument. If more arguments are given, continuation lines are sent, each consisting of a tab and an argument.

Method: HTTP **endheaders** *()*

Send a blank line to the server, signalling the end of the headers.

Method: HTTP **getreply** *()*

Complete the request by shutting down the sending end of the socket, read the reply from the server, and return a triple (replycode, message, headers). Here replycode is the integer reply code from the request (e.g. `200` if the request was handled properly); message is the message string corresponding to the reply code; and header is an instance of the class `rfc822.Message` containing the headers received from the server. See the description of the `rfc822` module.

Method: HTTP **getfile** *()*

Return a file object from which the data returned by the server can be read, using the `read()`, `readline()` or `readlines()` methods.

Example

Here is an example session:

```
>>> import httplib
>>> h = httplib.HTTP('www.cwi.nl')
>>> h.putrequest('GET', '/index.html')
>>> h.putheader('Accept', 'text/html')
>>> h.putheader('Accept', 'text/plain')
>>> h.endheaders()
>>> errcode, errmsg, headers = h.getreply()
>>> print errcode # Should be 200
>>> f = h.getfile()
>>> data f.read() # Get the raw HTML
>>> f.close()
```

>>>

Standard Module `ftplib`

This module defines the class `FTP` and a few related items. The `FTP` class implements the client side of the FTP protocol. You can use this to write Python programs that perform a variety of automated FTP jobs, such as mirroring other ftp servers. It is also used bu the module `urllib` to handle URLs that use FTP. For more information on FTP (File Transfer Protocol), see Internet RFC 959.

Here's a sample session using the `ftplib` module:

```
>>> from ftplib import FTP
>>> ftp = FTP('ftp.cwi.nl')   # connect to host, default port
>>> ftp.login()               # user anonymous, passwd user@hostname
>>> ftp.retrlines('LIST')     # list directory contents
total 24418
drwxrwsr-x   5 ftp-usr  pdmaint     1536 Mar 20 09:48 .
dr-xr-srwt 105 ftp-usr  pdmaint     1536 Mar 21 14:32 ..
-rw-r--r--   1 ftp-usr  pdmaint     5305 Mar 20 09:48 INDEX
 .
 .
 .
>>> ftp.quit()
```

The module defines the following items:

function of module ftplib: **FTP** *([host[, user, passwd, acct]])*

Return a new instance of the `FTP` class. When host is given, the method call `connect(host)` is made. When user is given, additionally the method call `login(user, passwd, acct)` is made (where passwd and acct default to the empty string when not given).

data: module ftplib **all_errors**

The set of all exceptions (as a tuple) that methods of `FTP` instances may raise as a result of problems with the FTP connection (as opposed to programming errors made by the caller). This set includes the four exceptions listed below as well as `socket.error` and `IOError`.

exception: module ftplib **error_reply**

Exception raised when an unexpected reply is received from the server.

exception: module ftplib **error_temp**

Exception raised when an error code in the range 400--499 is received.

exception: module ftplib **error_perm**

Exception raised when an error code in the range 500--599 is received.

exception: module ftplib **error_proto**

Exception raised when a reply is received from the server that does not begin with a digit in the range 1--5.

FTP Objects

FTP instances have the following methods:

Method: FTP object **set_debuglevel** *(level)*

Set the instance's debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the control connection.

Method: FTP object **connect** *(host[, port])*

Connect to the given host and port. The default port number is 21, as specified by the FTP protocol specification. It is rarely needed to specify a different port number. This function should be called only once for each instance; it should not be called at all if a host was given when the instance was created. All other methods can only be used after a connection has been made.

Method: FTP object **getwelcome** *()*

Return the welcome message sent by the server in reply to the initial connection. (This message sometimes contains disclaimers or help information that may be relevant to the user.)

Method: FTP object **login** *([user[, passwd[, acct]]])*

Log in as the given user. The passwd and acct parameters are optional and default to the empty string. If no user is specified, it defaults to `anonymous'. If user is `anonymous`, the default passwd is `realuser@host' where realuser is the real user name (glanced from the `LOGNAME' or `USER' environment variable) and host is the hostname as returned by `socket.gethostname()`. This function should be called only once for each instance, after a connection has been established; it should not be called at all if a host and user were given when the instance was created. Most FTP commands are only allowed after the client has logged in.

Method: FTP object **abort** *()*

Abort a file transfer that is in progress. Using this does not always work, but it's worth a try.

Method: FTP object **sendcmd** *(command)*

Send a simple command string to the server and return the response string.

Method: FTP object **voidcmd** *(command)*

Send a simple command string to the server and handle the response. Return nothing if a response code in the range 200--299 is received. Raise an exception otherwise.

Method: FTP object **retrbinary** *(command, callback, maxblocksize)*

Retrieve a file in binary transfer mode. command should be an appropriate `RETR' command, i.e. `"RETR filename"`. The callback function is called for each block of data received, with a single string argument giving the data block. The maxblocksize argument specifies the maximum block size (which may not be the actual size of the data blocks passed to callback).

Method: FTP object **retrlines** *(command[, callback])*

TOC

Retrieve a file or directory listing in ASCII transfer mode. var{command} should be an appropriate `RETR' command (see `retrbinary()` or a `LIST' command (usually just the string `"LIST"`). The callback function is called for each line, with the trailing CRLF stripped. The default callback prints the line to `sys.stdout`.

Method: FTP object **storbinary** *(command, file, blocksize)*

Store a file in binary transfer mode. command should be an appropriate `STOR' command, i.e. `"STOR filename"`. file is an open file object which is read until EOF using its `read()` method in blocks of size blocksize to provide the data to be stored.

Method: FTP object **storlines** *(command, file)*

Store a file in ASCII transfer mode. command should be an appropriate `STOR' command (see `storbinary()`). Lines are read until EOF from the open file object file using its `readline()` method to privide the data to be stored.

Method: FTP object **nlst** *(argument[, ...])*

Return a list of files as returned by the `NLST' command. The optional var{argument} is a directory to list (default is the current server directory). Multiple arguments can be used to pass non-standard options to the `NLST' command.

Method: FTP object **dir** *(argument[, ...])*

Return a directory listing as returned by the `LIST' command, as a list of lines. The optional var{argument} is a directory to list (default is the current server directory). Multiple arguments can be used to pass non-standard options to the `LIST' command. If the last argument is a function, it is used as a callback function as for `retrlines()`.

Method: FTP object **rename** *(fromname, toname)*

Rename file fromname on the server to toname.

Method: FTP object **cwd** *(pathname)*

Set the current directory on the server.

Method: FTP object **mkd** *(pathname)*

Create a new directory on the server.

Method: FTP object **pwd** *()*

Return the pathname of the current directory on the server.

Method: FTP object **quit** *()*

Send a `QUIT' command to the server and close the connection. This is the "polite" way to close a connection, but it may raise an exception of the server reponds with an error to the `QUIT` command.

Method: FTP object **close** *()*

Close the connection unilaterally. This should not be applied to an already closed connection (e.g. after a successful call to `quit()`.

Standard Module gopherlib

This module provides a minimal implementation of client side of the the Gopher protocol. It is used by the module `urllib` to handle URLs that use the Gopher protocol.

The module defines the following functions:

function of module gopherlib: **send_selector** *(selector, host[, port])*

Send a selector string to the gopher server at host and port (default 70). Return an open file object from which the returned document can be read.

function of module gopherlib: **send_query** *(selector, query, host[, port])*

Send a selector string and a query string to a gopher server at host and port (default 70). Return an open file object from which the returned document can be read.

Note that the data returned by the Gopher server can be of any type, depending on the first character of the selector string. If the data is text (first character of the selector is `0'), lines are terminated by CRLF, and the data is terminated by a line consisting of a single `.', and a leading `.' should be stripped from lines that begin with `..'. Directory listings (first charactger of the selector is `1') are transferred using the same protocol.

Standard Module nntplib

This module defines the class `NNTP` which implements the client side of the NNTP protocol. It can be used to implement a news reader or poster, or automated news processors. For more information on NNTP (Network News Transfer Protocol), see Internet RFC 977.

Here are two small examples of how it can be used. To list some statistics about a newsgroup and print the subjects of the last 10 articles:

@small{

```
>>> s = NNTP('news.cwi.nl')
>>> resp, count, first, last, name = s.group('comp.lang.python')
>>> print 'Group', name, 'has', count, 'articles, range', first, 'to', last
Group comp.lang.python has 59 articles, range 3742 to 3803
>>> resp, subs = s.xhdr('subject', first + '-' + last)
>>> for id, sub in subs[-10:]: print id, sub
...
3792 Re: Removing elements from a list while iterating...
3793 Re: Who likes Info files?
3794 Emacs and doc strings
3795 a few questions about the Mac implementation
3796 Re: executable python scripts
3797 Re: executable python scripts
3798 Re: a few questions about the Mac implementation
3799 Re: PROPOSAL: A Generic Python Object Interface for Python C Modules
3802 Re: executable python scripts
3803 Re: POSIX wait and SIGCHLD
```

```
>>> s.quit()
'205 news.cwi.nl closing connection.  Goodbye.'
>>>
```

}

To post an article from a file (this assumes that the article has valid headers):

```
>>> s = NNTP('news.cwi.nl')
>>> f = open('/tmp/article')
>>> s.post(f)
'240 Article posted successfully.'
>>> s.quit()
'205 news.cwi.nl closing connection.  Goodbye.'
>>>
```

The module itself defines the following items:

function of module nntplib: **NNTP** *(host[, port])*

Return a new instance of the `NNTP` class, representing a connection to the NNTP server running on host host, listening at port port. The default port is 119.

exception: module nntplib **error_reply**

Exception raised when an unexpected reply is received from the server.

exception: module nntplib **error_temp**

Exception raised when an error code in the range 400--499 is received.

exception: module nntplib **error_perm**

Exception raised when an error code in the range 500--599 is received.

exception: module nntplib **error_proto**

Exception raised when a reply is received from the server that does not begin with a digit in the range 1--5.

NNTP Objects

NNTP instances have the following methods. The response that is returned as the first item in the return tuple of almost all methods is the server's response: a string beginning with a three-digit code. If the server's response indicates an error, the method raises one of the above exceptions.

Method: NNTP object **getwelcome** *()*

Return the welcome message sent by the server in reply to the initial connection. (This message sometimes contains disclaimers or help information that may be relevant to the user.)

Method: NNTP object **set_debuglevel** *(level)*

Set the instance's debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request or response. A value of 2 or higher produces the maximum amount of debugging output,

logging each line sent and received on the connection (including message text).

Method: NNTP object **newgroups** *(date, time)*

Send a `NEWGROUPS' command. The date argument should be a string of the form `"yymmdd"` indicating the date, and time should be a string of the form `"hhmmss"` indicating the time. Return a pair `(response, groups)` where groups is a list of group names that are new since the given date and time.

Method: NNTP object **newnews** *(group, date, time)*

Send a `NEWNEWS' command. Here, group is a group name or `"*"`, and date and time have the same meaning as for `newgroups()`. Return a pair `(response, articles)` where articles is a list of article ids.

Method: NNTP object **list** *()*

Send a `LIST' command. Return a pair `(response, list)` where list is a list of tuples. Each tuple has the form `(group, last, first, flag)`, where group is a group name, last and first are the last and first article numbers (as strings), and flag is `'y'` if posting is allowed, `'n'` if not, and `'m'` if the newsgroup is moderated. (Note the ordering: last, first.)

Method: NNTP object **group** *(name)*

Send a `GROUP' command, where name is the group name. Return a tuple `(response, count, first, last, name)` where count is the (estimated) number of articles in the group, first is the first article number in the group, last is the last article number in the group, and name is the group name. The numbers are returned as strings.

Method: NNTP object **help** *()*

Send a `HELP' command. Return a pair `(response, list)` where list is a list of help strings.

Method: NNTP object **stat** *(id)*

Send a `STAT' command, where id is the message id (enclosed in `<' and `>') or an article number (as a string). Return a triple `(var{response`, number, id)} where number is the article number (as a string) and id is the article id (enclosed in `<' and `>').

Method: NNTP object **next** *()*

Send a `NEXT' command. Return as for `stat()`.

Method: NNTP object **last** *()*

Send a `LAST' command. Return as for `stat()`.

Method: NNTP object **head** *(id)*

Send a `HEAD' command, where id has the same meaning as for `stat()`. Return a pair `(response, list)` where list is a list of the article's headers (an uninterpreted list of lines, without trailing newlines).

Method: NNTP object **body** *(id)*

Send a `BODY' command, where id has the same meaning as for `stat()`. Return a pair `(response, list)` where list is a list of the article's body text (an uninterpreted list of lines, without trailing newlines).

Method: NNTP object **article** *(id)*

Send a `ARTICLE' command, where id has the same meaning as for `stat()`. Return a pair `(response, list)` where list is a list of the article's header and body text (an uninterpreted list of lines, without trailing newlines).

Method: NNTP object **slave** *()*

Send a `SLAVE' command. Return the server's response.

Method: NNTP object **xhdr** *(header, string)*

Send an `XHDR' command. This command is not defined in the RFC but is a common extension. The header argument is a header keyword, e.g. `"subject"`. The string argument should have the form `"first-last"` where first and last are the first and last article numbers to search. Return a pair `(response, list)`, where list is a list of pairs `(id, text)`, where id is an article id (as a string) and text is the text of the requested header for that article.

Method: NNTP object **post** *(file)*

Post an article using the `POST' command. The file argument is an open file object which is read until EOF using its `readline()` method. It should be a well-formed news article, including the required headers. The `post()` method automatically escapes lines beginning with `.'.

Method: NNTP object **ihave** *(id, file)*

Send an `IHAVE' command. If the response is not an error, treat file exactly as for the `post()` method.

Method: NNTP object **quit** *()*

Send a `QUIT' command and close the connection. Once this method has been called, no other methods of the NNTP object should be called.

Standard Module `urlparse`

This module defines a standard interface to break URL strings up in components (addessing scheme, network location, path etc.), to combine the components back into a URL string, and to convert a "relative URL" to an absolute URL given a "base URL".

The module has been designed to match the current Internet draft on Relative Uniform Resource Locators (and discovered a bug in an earlier draft!).

It defines the following functions:

function of module urlparse: **urlparse** *(urlstring[, default_scheme[, allow_fragments]])*

Parse a URL into 6 components, returning a 6-tuple: (addressing scheme, network location, path, parameters, query, fragment identifier). This corresponds to the general structure of a URL: `scheme://netloc/path;parameters?query#fragment`. Each tuple item is a string, possibly empty. The components are not broken up in smaller parts (e.g. the network location is a single string), and % escapes are not expanded. The delimiters as shown above are not part of the tuple items, except for a leading slash in the path component, which is retained if present.

Example:

```
urlparse('http://www.cwi.nl:80/%7Eguido/Python.html')
```

yields the tuple

```
('http', 'www.cwi.nl:80', '/%7Eguido/Python.html', '', '', '')
```

If the default_scheme argument is specified, it gives the default addressing scheme, to be used only if the URL string does not specify one. The default value for this argument is the empty string.

If the allow_fragments argument is zero, fragment identifiers are not allowed, even if the URL's addressing scheme normally does support them. The default value for this argument is `1`.

function of module urlparse: **urlunparse** *(tuple)*

Construct a URL string from a tuple as returned by `urlparse`. This may result in a slightly different, but equivalent URL, if the URL that was parsed originally had redundant delimiters, e.g. a ? with an empty query (the draft states that these are equivalent).

function of module urlparse: **urljoin** *(base, url[, allow_fragments])*

Construct a full ("absolute") URL by combining a "base URL" (base) with a "relative URL" (url). Informally, this uses components of the base URL, in particular the addressing scheme, the network location and (part of) the path, to provide missing components in the relative URL.

Example:

```
urljoin('http://www.cwi.nl/%7Eguido/Python.html', 'FAQ.html')
```

yields the string

```
'http://www.cwi.nl/%7Eguido/FAQ.html'
```

The allow_fragments argument has the same meaning as for `urlparse`.

Standard Module `htmllib`

This module defines a number of classes which can serve as a basis for parsing text files formatted in HTML (HyperText Mark-up Language). The classes are not directly concerned with I/O -- the have to be fed their input in string form, and will make calls to methods of a "formatter" object in order to produce output. The classes are designed to be used as base classes for other classes in order to add functionality, and allow most of their methods to be extended or overridden. In turn, the classes are derived from and extend the class `SGMLParser` defined in module `sgmllib`.

The following is a summary of the interface defined by `sgmllib.SGMLParser`:

- The interface to feed data to an instance is through the `feed()` method, which takes a string argument. This can be called with as little or as much text at a time as desired; `p.feed(a); p.feed(b)` has the same effect as `p.feed(a+b)`. When the data contains complete HTML elements, these are processed immediately; incomplete elements are saved in a buffer. To force processing of all unprocessed data, call the `close()` method.

  Example: to parse the entire contents of a file, do

`parser.feed(open(file).read()); parser.close()`.

- The interface to define semantics for HTML tags is very simple: derive a class and define methods called `start_tag()`, `end_tag()`, or `do_tag()`. The parser will call these at appropriate moments: `start_tag` or `do_tag` is called when an opening tag of the form `<tag ...>` is encountered; `end_tag` is called when a closing tag of the form `<tag>` is encountered. If an opening tag requires a corresponding closing tag, like `<H1>` ... `</H1>`, the class should define the `start_tag` method; if a tag requires no closing tag, like `<P>`, the class should define the `do_tag` method.

The module defines the following classes:

function of module htmllib: **HTMLParser** *()*

This is the most basic HTML parser class. It defines one additional entity name over the names defined by the `SGMLParser` base class, `&bullet;`. It also defines handlers for the following tags: `<LISTING>...</LISTING>`, `<XMP>...</XMP>`, and `<PLAINTEXT>` (the latter is terminated only by end of file).

function of module htmllib: **CollectingParser** *()*

This class, derived from `HTMLParser`, collects various useful bits of information from the HTML text. To this end it defines additional handlers for the following tags: `<A>...`, `<HEAD>...</HEAD>`, `<BODY>...</BODY>`, `<TITLE>...</TITLE>`, `<NEXTID>`, and `<ISINDEX>`.

function of module htmllib: **FormattingParser** *(formatter, stylesheet)*

This class, derived from `CollectingParser`, interprets a wide selection of HTML tags so it can produce formatted output from the parsed data. It is initialized with two objects, a formatter which should define a number of methods to format text into paragraphs, and a stylesheet which defines a number of static parameters for the formatting process. Formatters and style sheets are documented later in this section.

function of module htmllib: **AnchoringParser** *(formatter, stylesheet)*

This class, derived from `FormattingParser`, extends the handling of the `<A>...` tag pair to call the formatter's `bgn_anchor()` and `end_anchor()` methods. This allows the formatter to display the anchor in a different font or color, etc.

Instances of `CollectingParser` (and thus also instances of `FormattingParser` and `AnchoringParser`) have the following instance variables:

data: module htmllib **anchornames**

A list of the values of the `NAME` attributes of the `<A>` tags encountered.

data: module htmllib **anchors**

A list of the values of `HREF` attributes of the `<A>` tags encountered.

data: module htmllib **anchortypes**

A list of the values of the `TYPE` attributes of the `<A>` tags encountered.

data: module htmllib **inanchor**

Outside an `<A>...` tag pair, this is zero. Inside such a pair, it is a unique integer, which is positive if the anchor has a `HREF` attribute, negative if it hasn't. Its absolute value is one more than the index of the anchor in

the `anchors`, `anchornames` and `anchortypes` lists.

data: module htmllib **isindex**

True if the `<ISINDEX>` tag has been encountered.

data: module htmllib **nextid**

The attribute list of the last `<NEXTID>` tag encountered, or an empty list if none.

data: module htmllib **title**

The text inside the last `<TITLE>...</TITLE>` tag pair, or `''` if no title has been encountered yet.

The `anchors`, `anchornames` and `anchortypes` lists are "parallel arrays": items in these lists with the same index pertain to the same anchor. Missing attributes default to the empty string. Anchors with neither a `HREF` nor a `NAME` attribute are not entered in these lists at all.

The module also defines a number of style sheet classes. These should never be instantiated -- their class variables are the only behavior required. Note that style sheets are specifically designed for a particular formatter implementation. The currently defined style sheets are:

data: module htmllib **NullStylesheet**

A style sheet for use on a dumb output device such as an ASCII terminal.

data: module htmllib **X11Stylesheet**

A style sheet for use with an X11 server.

data: module htmllib **MacStylesheet**

A style sheet for use on Apple Macintosh computers.

data: module htmllib **StdwinStylesheet**

A style sheet for use with the `stdwin` module; it is an alias for either `X11Stylesheet` or `MacStylesheet`.

data: module htmllib **GLStylesheet**

A style sheet for use with the SGI Graphics Library and its font manager (the SGI-specific built-in modules `gl` and `fm`).

Style sheets have the following class variables:

data: module htmllib **stdfontset**

A list of up to four font definititions, respectively for the roman, italic, bold and constant-width variant of a font for normal text. If the list contains less than four font definitions, the last item is used as the default for missing items. The type of a font definition depends on the formatter in use; its only use is as a parameter to the formatter's `setfont()` method.

data: module htmllib **h1fontset**

data: module htmllib **h2fontset**

data: module htmllib **h3fontset**

The font set used for various headers (text inside `<H1>...</H1>` tag pairs etc.).

data: module htmllib **stdindent**

The indentation of normal text. This is measured in the "native" units of the formatter in use; for some formatters these are characters, for others (especially those that actually support variable-spacing fonts) in pixels or printer points.

data: module htmllib **ddindent**

The indentation used for the first level of `<DD>` tags.

data: module htmllib **ulindent**

The indentation used for the first level of `<UL>` tags.

data: module htmllib **h1indent**

The indentation used for level 1 headers.

data: module htmllib **h2indent**

The indentation used for level 2 headers.

data: module htmllib **literalindent**

The indentation used for literal text (text inside `<PRE>...</PRE>` and similar tag pairs).

Although no documented implementation of a formatter exists, the `FormattingParser` class assumes that formatters have a certain interface. This interface requires the following methods:

function of module htmllib: **setfont** *(fontspec)*

Set the font to be used subsequently. The fontspec argument is an item in a style sheet's font set.

function of module htmllib: **flush** *()*

Finish the current line, if not empty, and begin a new one.

function of module htmllib: **setleftindent** *(n)*

Set the left indentation of the following lines to n units.

function of module htmllib: **needvspace** *(n)*

Require at least n blank lines before the next line. Implies `flush()`.

function of module htmllib: **addword** *(word, space)*

Add a word to the current paragraph, followed by space spaces.

data: module htmllib **nospace**

If this instance variable is true, empty words should be ignored by `addword`. It should be set to false after a non-empty word has been added.

function of module htmllib: **setjust** *(justification)*

Set the justification of the current paragraph. The justification can be `'c'` (center), `'l'` (left justified), `'r'` (right justified) or `'lr'` (left and right justified).

function of module htmllib: **bgn_anchor** *(id)*

Begin an anchor. The id parameter is the value of the parser's `inanchor` attribute.

function of module htmllib: **end_anchor** *(id)*

End an anchor. The id parameter is the value of the parser's `inanchor` attribute.

A sample formatter implementation can be found in the module `fmt`, which in turn uses the module `Para`. These modules are not intended as standard library modules; they are available as an example of how to write a formatter.

Standard Module `sgmllib`

This module defines a class `SGMLParser` which serves as the basis for parsing text files formatted in SGML (Standard Generalized Mark-up Language). In fact, it does not provide a full SGML parser --- it only parses SGML insofar as it is used by HTML, and the module only exists as a basis for the `htmllib` module.

In particular, the parser is hardcoded to recognize the following elements:

- Opening and closing tags of the form "`<tag attr="value" ...>`" and "`</tag>`", respectively.
- Character references of the form "`&#name;`".
- Entity references of the form "`&name;`".
- SGML comments of the form "`<!--text>`".

The `SGMLParser` class must be instantiated without arguments. It has the following interface methods:

function of module sgmllib: **reset** *()*

Reset the instance. Loses all unprocessed data. This is called implicitly at instantiation time.

function of module sgmllib: **setnomoretags** *()*

Stop processing tags. Treat all following input as literal input (CDATA). (This is only provided so the HTML tag `<PLAINTEXT>` can be implemented.)

function of module sgmllib: **setliteral** *()*

Enter literal mode (CDATA mode).

function of module sgmllib: **feed** *(data)*

Feed some text to the parser. It is processed insofar as it consists of complete elements; incomplete data is buffered until more data is fed or `close()` is called.

function of module sgmllib: **close** *()*

Force processing of all buffered data as if it were followed by an end-of-file mark. This method may be redefined by a derived class to define additional processing at the end of the input, but the redefined version should always call `SGMLParser.close()`.

function of module sgmllib: **handle_charref** *(ref)*

This method is called to process a character reference of the form "`&#ref;`" where ref is a decimal number in the range 0-255. It translates the character to ASCII and calls the method `handle_data()` with the character as argument. If ref is invalid or out of range, the method `unknown_charref(ref)` is called instead.

function of module sgmllib: **handle_entityref** *(ref)*

This method is called to process an entity reference of the form "`&ref;`" where ref is an alphabetic entity reference. It looks for ref in the instance (or class) variable `entitydefs` which should give the entity's translation. If a translation is found, it calls the method `handle_data()` with the translation; otherwise, it calls the method `unknown_entityref(ref)`.

function of module sgmllib: **handle_data** *(data)*

This method is called to process arbitrary data. It is intended to be overridden by a derived class; the base class implementation does nothing.

function of module sgmllib: **unknown_starttag** *(tag, attributes)*

This method is called to process an unknown start tag. It is intended to be overridden by a derived class; the base class implementation does nothing. The attributes argument is a list of (name, value) pairs containing the attributes found inside the tag's <> brackets. The name has been translated to lower case and double quotes and backslashes in the value have been interpreted. For instance, for the tag , this method would be called as `unknown_starttag('a', [('href', 'http://www.cwi.nl/')])`.

function of module sgmllib: **unknown_endtag** *(tag)*

This method is called to process an unknown end tag. It is intended to be overridden by a derived class; the base class implementation does nothing.

function of module sgmllib: **unknown_charref** *(ref)*

This method is called to process an unknown character reference. It is intended to be overridden by a derived class; the base class implementation does nothing.

function of module sgmllib: **unknown_entityref** *(ref)*

This method is called to process an unknown entity reference. It is intended to be overridden by a derived class; the base class implementation does nothing.

Apart from overriding or extending the methods listed above, derived classes may also define methods of the following form to define processing of specific tags. Tag names in the input stream are case independent; the tag occurring in method names must be in lower case:

function of module sgmllib: **start_tag** *(attributes)*

This method is called to process an opening tag tag. It has preference over `do_tag()`. The attributes argument has the same meaning as described for `unknown_tag()` above.

function of module sgmllib: **do_tag** *(attributes)*

This method is called to process an opening tag tag that does not come with a matching closing tag. The attributes argument has the same meaning as described for `unknown_tag()` above.

function of module sgmllib: **end_tag** *()*

This method is called to process a closing tag tag.

Note that the parser maintains a stack of opening tags for which no matching closing tag has been found yet. Only tags processed by `start_tag()` are pushed on this stack. Definition of a `end_tag()` method is optional for these tags. For tags processed by `do_tag()` or by `unknown_tag()`, no `end_tag()` method must be defined.

Standard Module `rfc822`

This module defines a class, `Message`, which represents a collection of "email headers" as defined by the Internet standard RFC 822. It is used in various contexts, usually to read such headers from a file.

A `Message` instance is instantiated with an open file object as parameter. Instantiation reads headers from the file up to a blank line and stores them in the instance; after instantiation, the file is positioned directly after the blank line that terminates the headers.

Input lines as read from the file may either be terminated by CR-LF or by a single linefeed; a terminating CR-LF is replaced by a single linefeed before the line is stored.

All header matching is done independent of upper or lower case; e.g. `m['From']`, `m['from']` and `m['FROM']` all yield the same result.

Message Objects

A `Message` instance has the following methods:

function of module rfc822: **rewindbody** *()*

Seek to the start of the message body. This only works if the file object is seekable.

function of module rfc822: **getallmatchingheaders** *(name)*

Return a list of lines consisting of all headers matching name, if any. Each physical line, whether it is a continuation line or not, is a separate list item. Return the empty list if no header matches name.

function of module rfc822: **getfirstmatchingheader** *(name)*

Return a list of lines comprising the first header matching name, and its continuation line(s), if any. Return `None` if there is no header matching name.

function of module rfc822: **getrawheader** *(name)*

Return a single string consisting of the text after the colon in the first header matching name. This includes leading whitespace, the trailing linefeed, and internal linefeeds and whitespace if there any continuation line(s) were present. Return `None` if there is no header matching name.

function of module rfc822: **getheader** *(name)*

Like `getrawheader(name)`, but strip leading and trailing whitespace (but not internal whitespace).

function of module rfc822: **getaddr** *(name)*

Return a pair (full name, email address) parsed from the string returned by `getheader(name)`. If no he matching name exists, return `None, None`; otherwise both the full name and the address are (possibly em)strings.

Example: If `m`'s first `From` header contains the string `'jack@cwi.nl (Jack Jansen)'`, then `m.getaddr('From')` will yield the pair `('Jack Jansen', 'jack@cwi.nl')`. If the header contained `'Jack Jansen <jack@cwi.nl>'` instead, it would yield the exact same result.

function of module rfc822: **getaddrlist** *(name)*

This is similar to `getaddr(list)`, but parses a header containing a list of email addresses (e.g. a `To` header) and returns a list of (full name, email address) pairs (even if there was only one address in the header). If there is no header matching name, return an empty list.

XXX The current version of this function is not really correct. It yields bogus results if a full name contains a comma.

function of module rfc822: **getdate** *(name)*

Retrieve a header using `getheader` and parse it into a 9-tuple compatible with `time.mktime()`. If there is no header matching name, or it is unparsable, return `None`.

Date parsing appears to be a black art, and not all mailers adhere to the standard. While it has been tested and found correct on a large collection of email from many sources, it is still possible that this function may occasionally yield an incorrect result.

`Message` instances also support a read-only mapping interface. In particular: `m[name]` is the same as `m.getheader(name)`; and `len(m)`, `m.has_key(name)`, `m.keys()`, `m.values()` and `m.items()` act as expected (and consistently).

Finally, `Message` instances have two public instance variables:

data: module rfc822 **headers**

A list containing the entire set of header lines, in the order in which they were read. Each line contains a trailing newline. The blank line terminating the headers is not contained in the list.

data: module rfc822 **fp**

The file object passed at instantiation time.

Standard Module `mimetools`

This module defines a subclass of the class `rfc822.Message` and a number of utility functions that are useful for the manipulation for MIME style multipart or encoded message.

It defines the following items:

function of module mimetools: **Message** *(fp)*

Return a new instance of the `mimetools.Message` class. This is a subclass of the `rfc822.Message` class, with some additional methods (see below).

function of module mimetools: **choose_boundary** *()*

Return a unique string that has a high likelihood of being usable as a part boundary. The string has the form `"hostipaddr.uid.pid.timestamp.random"`.

function of module mimetools: **decode** *(input, output, encoding)*

Read data encoded using the allowed MIME encoding from open file object input and write the decoded data to open file object output. Valid values for encoding include `"base64"`, `"quoted-printable"` and `"uuencode"`.

function of module mimetools: **encode** *(input, output, encoding)*

Read data from open file object input and write it encoded using the allowed MIME encoding to open file object output. Valid values for encoding are the same as for `decode()`.

function of module mimetools: **copyliteral** *(input, output)*

Read lines until EOF from open file input and write them to open file output.

function of module mimetools: **copybinary** *(input, output)*

Read blocks until EOF from open file input and write them to open file output. The block size is currently fixed at 8192.

Additional Methods of Message objects

The `mimetools.Message` class defines the following methods in addition to the `rfc822.Message` class:

Method: mimetool.Message **getplist** *()*

Return the parameter list of the `Content-type` header. This is a list if strings. For parameters of the form `key=value', key is converted to lower case but value is not. For example, if the message contains the header `Content-type: text/html; spam=1; Spam=2; Spam' then `getplist()` will return the Python list `['spam=1', 'spam=2', 'Spam']`.

Method: mimetool.Message **getparam** *(name)*

Return the value of the first parameter (as returned by `getplist()` of the form `name=value' for the given name. If value is surrounded by quotes of the form <...> or "...", these are removed.

Method: mimetool.Message **getencoding** *()*

Return the encoding specified in the `Content-transfer-encoding' message header. If no such header exists, return `"7bit"`. The encoding is converted to lower case.

Method: mimetool.Message **gettype** *()*

Return the message type (of the form `type/var{subtype'}) as specified in the `Content-type' header. If no such header exists, return `"text/plain"`. The type is converted to lower case.

Method: mimetool.Message **getmaintype** *()*

Return the main type as specified in the `Content-type' header. If no such header exists, return `"text"`. The main type is converted to lower case.

Method: mimetool.Message **getsubtype** *()*

Return the subtype as specified in the `Content-type' header. If no such header exists, return `"plain"`. The subtype is converted to lower case.

Go to the previous, next section.

Go to the previous, next section.

Multimedia Services

The modules described in this chapter implement various algorithms or interfaces that are mainly useful for multimedia applications. They are available at the discretion of the installation. Here's an overview:

audioop
--- Manipulate raw audio data.

imageop
--- Manipulate raw image data.

aifc
--- Read and write audio files in AIFF or AIFC format.

jpeg
--- Read and write image files in compressed JPEG format.

rgbimg
--- Read and write image files in "SGI RGB" format (the module is *not* SGI specific though)!

Built-in Module `audioop`

The `audioop` module contains some useful operations on sound fragments. It operates on sound fragments consisting of signed integer samples 8, 16 or 32 bits wide, stored in Python strings. This is the same format as used by the `al` and `sunaudiodev` modules. All scalar items are integers, unless specified otherwise.

A few of the more complicated operations only take 16-bit samples, otherwise the sample size (in bytes) is always a parameter of the operation.

The module defines the following variables and functions:

exception: module audioop **error**

This exception is raised on all errors, such as unknown number of bytes per sample, etc.

function of module audioop: **add** *(fragment1, fragment2, width)*

Return a fragment which is the addition of the two samples passed as parameters. width is the sample width in bytes, either `1`, `2` or `4`. Both fragments should have the same length.

function of module audioop: **adpcm2lin** *(adpcmfragment, width, state)*

Decode an Intel/DVI ADPCM coded fragment to a linear fragment. See the description of `lin2adpcm` for details on ADPCM coding. Return a tuple `(sample, newstate)` where the sample has the width specified in width.

function of module audioop: **adpcm32lin** *(adpcmfragment, width, state)*

Decode an alternative 3-bit ADPCM code. See `lin2adpcm3` for details.

function of module audioop: **avg** *(fragment, width)*

Return the average over all samples in the fragment.

function of module audioop: **avgpp** *(fragment, width)*

Return the average peak-peak value over all samples in the fragment. No filtering is done, so the usefulness of this routine is questionable.

function of module audioop: **bias** *(fragment, width, bias)*

Return a fragment that is the original fragment with a bias added to each sample.

function of module audioop: **cross** *(fragment, width)*

Return the number of zero crossings in the fragment passed as an argument.

function of module audioop: **findfactor** *(fragment, reference)*

Return a factor F such that `rms(add(fragment, mul(reference, -F)))` is minimal, i.e., return the factor with which you should multiply reference to make it match as well as possible to fragment. The fragments should both contain 2-byte samples.

The time taken by this routine is proportional to `len(fragment)`.

function of module audioop: **findfit** *(fragment, reference)*

This routine (which only accepts 2-byte sample fragments)

Try to match reference as well as possible to a portion of fragment (which should be the longer fragment). This is (conceptually) done by taking slices out of fragment, using `findfactor` to compute the best match, and minimizing the result. The fragments should both contain 2-byte samples. Return a tuple `(offset, factor)` where offset is the (integer) offset into fragment where the optimal match started and factor is the (floating-point) factor as per `findfactor`.

function of module audioop: **findmax** *(fragment, length)*

Search fragment for a slice of length length samples (not bytes!) with maximum energy, i.e., return i for which `rms(fragment[i*2:(i+length)*2])` is maximal. The fragments should both contain 2-byte samples.

The routine takes time proportional to `len(fragment)`.

function of module audioop: **getsample** *(fragment, width, index)*

Return the value of sample index from the fragment.

function of module audioop: **lin2lin** *(fragment, width, newwidth)*

Convert samples between 1-, 2- and 4-byte formats.

function of module audioop: **lin2adpcm** *(fragment, width, state)*

Convert samples to 4 bit Intel/DVI ADPCM encoding. ADPCM coding is an adaptive coding scheme, whereby each 4 bit number is the difference between one sample and the next, divided by a (varying) s The Intel/DVI ADPCM algorithm has been selected for use by the IMA, so it may well become a standard.

`State` is a tuple containing the state of the coder. The coder returns a tuple `(adpcmfrag, newstate)`, and the newstate should be passed to the next call of lin2adpcm. In the initial call `None` can be passed as the state. adpcmfrag is the ADPCM coded fragment packed 2 4-bit values per byte.

function of module audioop: **lin2adpcm3** *(fragment, width, state)*

This is an alternative ADPCM coder that uses only 3 bits per sample. It is not compatible with the Intel/DVI ADPCM coder and its output is not packed (due to laziness on the side of the author). Its use is discouraged.

function of module audioop: **lin2ulaw** *(fragment, width)*

Convert samples in the audio fragment to U-LAW encoding and return this as a Python string. U-LAW is an audio encoding format whereby you get a dynamic range of about 14 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

function of module audioop: **minmax** *(fragment, width)*

Return a tuple consisting of the minimum and maximum values of all samples in the sound fragment.

function of module audioop: **max** *(fragment, width)*

Return the maximum of the *absolute value* of all samples in a fragment.

function of module audioop: **maxpp** *(fragment, width)*

Return the maximum peak-peak value in the sound fragment.

function of module audioop: **mul** *(fragment, width, factor)*

Return a fragment that has all samples in the original framgent multiplied by the floating-point value factor. Overflow is silently ignored.

function of module audioop: **reverse** *(fragment, width)*

Reverse the samples in a fragment and returns the modified fragment.

function of module audioop: **rms** *(fragment, width)*

Return the root-mean-square of the fragment, i.e. the square root of the quotient of the sum of all squared sample value, divided by the sumber of samples. This is a measure of the power in an audio signal.

function of module audioop: **tomono** *(fragment, width, lfactor, rfactor)*

Convert a stereo fragment to a mono fragment. The left channel is multiplied by lfactor and the right channel by rfactor before adding the two channels to give a mono signal.

function of module audioop: **tostereo** *(fragment, width, lfactor, rfactor)*

Generate a stereo fragment from a mono fragment. Each pair of samples in the stereo fragment are

computed from the mono sample, whereby left channel samples are multiplied by lfactor and right cha samples by rfactor.

function of module audioop: **ulaw2lin** *(fragment, width)*

Convert sound fragments in ULAW encoding to linearly encoded sound fragments. ULAW encoding always uses 8 bits samples, so width refers only to the sample width of the output fragment here.

Note that operations such as `mul` or `max` make no distinction between mono and stereo fragments, i.e. all samples are treated equal. If this is a problem the stereo fragment should be split into two mono fragments first and recombined later. Here is an example of how to do that:

```
def mul_stereo(sample, width, lfactor, rfactor):
    lsample = audioop.tomono(sample, width, 1, 0)
    rsample = audioop.tomono(sample, width, 0, 1)
    lsample = audioop.mul(sample, width, lfactor)
    rsample = audioop.mul(sample, width, rfactor)
    lsample = audioop.tostereo(lsample, width, 1, 0)
    rsample = audioop.tostereo(rsample, width, 0, 1)
    return audioop.add(lsample, rsample, width)
```

If you use the ADPCM coder to build network packets and you want your protocol to be stateless (i.e. to be able to tolerate packet loss) you should not only transmit the data but also the state. Note that you should send the initial state (the one you passed to `lin2adpcm`) along to the decoder, not the final state (as returned by the coder). If you want to use `struct` to store the state in binary you can code the first element (the predicted value) in 16 bits and the second (the delta index) in 8.

The ADPCM coders have never been tried against other ADPCM coders, only against themselves. It could well be that I misinterpreted the standards in which case they will not be interoperable with the respective standards.

The `find...` routines might look a bit funny at first sight. They are primarily meant to do echo cancellation. A reasonably fast way to do this is to pick the most energetic piece of the output sample, locate that in the input sample and subtract the whole output sample from the input sample:

```
def echocancel(outputdata, inputdata):
    pos = audioop.findmax(outputdata, 800)    # one tenth second
    out_test = outputdata[pos*2:]
    in_test = inputdata[pos*2:]
    ipos, factor = audioop.findfit(in_test, out_test)
    # Optional (for better cancellation):
    # factor = audioop.findfactor(in_test[ipos*2:ipos*2+len(out_test)],
    #             out_test)
    prefill = '\0'*(pos+ipos)*2
    postfill = '\0'*(len(inputdata)-len(prefill)-len(outputdata))
    outputdata = prefill + audioop.mul(outputdata,2,-factor) + postfill
    return audioop.add(inputdata, outputdata, 2)
```

Built-in Module `imageop`

The `imageop` module contains some useful operations on images. It operates on images consisting of 8 or 32 bit pixels stored in Python strings. This is the same format as used by `gl.lrectwrite` and the `imgfile` module.

The module defines the following variables and functions:

exception: module imageop **error**

This exception is raised on all errors, such as unknown number of bits per pixel, etc.

function of module imageop: **crop** *(image, psize, width, height, x0, y0, x1, y1)*

Return the selected part of image, which should by width by height in size and consist of pixels of psize bytes. x0, y0, x1 and y1 are like the `lrectread` parameters, i.e. the boundary is included in the new image. The new boundaries need not be inside the picture. Pixels that fall outside the old image will have their value set to zero. If x0 is bigger than x1 the new image is mirrored. The same holds for the y coordinates.

function of module imageop: **scale** *(image, psize, width, height, newwidth, newheight)*

Return image scaled to size newwidth by newheight. No interpolation is done, scaling is done by simple-minded pixel duplication or removal. Therefore, computer-generated images or dithered images will not look nice after scaling.

function of module imageop: **tovideo** *(image, psize, width, height)*

Run a vertical low-pass filter over an image. It does so by computing each destination pixel as the average of two vertically-aligned source pixels. The main use of this routine is to forestall excessive flicker if the image is displayed on a video device that uses interlacing, hence the name.

function of module imageop: **grey2mono** *(image, width, height, threshold)*

Convert a 8-bit deep greyscale image to a 1-bit deep image by tresholding all the pixels. The resulting image is tightly packed and is probably only useful as an argument to `mono2grey`.

function of module imageop: **dither2mono** *(image, width, height)*

Convert an 8-bit greyscale image to a 1-bit monochrome image using a (simple-minded) dithering algorithm.

function of module imageop: **mono2grey** *(image, width, height, p0, p1)*

Convert a 1-bit monochrome image to an 8 bit greyscale or color image. All pixels that are zero-valued on input get value p0 on output and all one-value input pixels get value p1 on output. To convert a monochrome black-and-white image to greyscale pass the values `0` and `255` respectively.

function of module imageop: **grey2grey4** *(image, width, height)*

Convert an 8-bit greyscale image to a 4-bit greyscale image without dithering.

function of module imageop: **grey2grey2** *(image, width, height)*

Convert an 8-bit greyscale image to a 2-bit greyscale image without dithering.

function of module imageop: **dither2grey2** *(image, width, height)*

Convert an 8-bit greyscale image to a 2-bit greyscale image with dithering. As for `dither2mono`, the dithering algorithm is currently very simple.

function of module imageop: **grey42grey** *(image, width, height)*

Convert a 4-bit greyscale image to an 8-bit greyscale image.

function of module imageop: **grey22grey** *(image, width, height)*

Convert a 2-bit greyscale image to an 8-bit greyscale image.

Standard Module `aifc`

This module provides support for reading and writing AIFF and AIFF-C files. AIFF is Audio Interchange File Format, a format for storing digital audio samples in a file. AIFF-C is a newer version of the format that includes the ability to compress the audio data.

Audio files have a number of parameters that describe the audio data. The sampling rate or frame rate is the number of times per second the sound is sampled. The number of channels indicate if the audio is mono, stereo, or quadro. Each frame consists of one sample per channel. The sample size is the size in bytes of each sample. Thus a frame consists of nchannels*samplesize bytes, and a second's worth of audio consists of nchannels*samplesize*framerate bytes.

For example, CD quality audio has a sample size of two bytes (16 bits), uses two channels (stereo) and has a frame rate of 44,100 frames/second. This gives a frame size of 4 bytes (2*2), and a second's worth occupies 2*2*44100 bytes, i.e. 176,400 bytes.

Module `aifc` defines the following function:

function of module aifc: **open** *(file, mode)*

Open an AIFF or AIFF-C file and return an object instance with methods that are described below. The argument file is either a string naming a file or a file object. The mode is either the string `'r'` when the file must be opened for reading, or `'w'` when the file must be opened for writing. When used for writing, the file object should be seekable, unless you know ahead of time how many samples you are going to write in total and use `writeframesraw()` and `setnframes()`.

Objects returned by `aifc.open()` when a file is opened for reading have the following methods:

Method: aifc object **getnchannels** *()*

Return the number of audio channels (1 for mono, 2 for stereo).

Method: aifc object **getsampwidth** *()*

Return the size in bytes of individual samples.

Method: aifc object **getframerate** *()*

Return the sampling rate (number of audio frames per second).

Method: aifc object **getnframes** *()*

Return the number of audio frames in the file.

Method: aifc object **getcomptype** *()*

Return a four-character string describing the type of compression used in the audio file. For AIFF files, the returned value is `'NONE'`.

Method: aifc object **getcompname** *()*

Return a human-readable description of the type of compression used in the audio file. For AIFF files, the returned value is `'not compressed'`.

Method: aifc object **getparams** *()*

Return a tuple consisting of all of the above values in the above order.

Method: aifc object **getmarkers** *()*

Return a list of markers in the audio file. A marker consists of a tuple of three elements. The first is the mark ID (an integer), the second is the mark position in frames from the beginning of the data (an integer), the third is the name of the mark (a string).

Method: aifc object **getmark** *(id)*

Return the tuple as described in `getmarkers` for the mark with the given id.

Method: aifc object **readframes** *(nframes)*

Read and return the next nframes frames from the audio file. The returned data is a string containing for each frame the uncompressed samples of all channels.

Method: aifc object **rewind** *()*

Rewind the read pointer. The next `readframes` will start from the beginning.

Method: aifc object **setpos** *(pos)*

Seek to the specified frame number.

Method: aifc object **tell** *()*

Return the current frame number.

Method: aifc object **close** *()*

Close the AIFF file. After calling this method, the object can no longer be used.

Objects returned by `aifc.open()` when a file is opened for writing have all the above methods, except for `readframes` and `setpos`. In addition the following methods exist. The `get` methods can only be

called after the corresponding `set` methods have been called. Before the first `writeframes` or `writeframesraw`, all parameters except for the number of frames must be filled in.

Method: aifc object **aiff** *()*

Create an AIFF file. The default is that an AIFF-C file is created, unless the name of the file ends in '.aiff' in which case the default is an AIFF file.

Method: aifc object **aifc** *()*

Create an AIFF-C file. The default is that an AIFF-C file is created, unless the name of the file ends in '.aiff' in which case the default is an AIFF file.

Method: aifc object **setnchannels** *(nchannels)*

Specify the number of channels in the audio file.

Method: aifc object **setsampwidth** *(width)*

Specify the size in bytes of audio samples.

Method: aifc object **setframerate** *(rate)*

Specify the sampling frequency in frames per second.

Method: aifc object **setnframes** *(nframes)*

Specify the number of frames that are to be written to the audio file. If this parameter is not set, or not set correctly, the file needs to support seeking.

Method: aifc object **setcomptype** *(type, name)*

Specify the compression type. If not specified, the audio data will not be compressed. In AIFF files, compression is not possible. The name parameter should be a human-readable description of the compression type, the type parameter should be a four-character string. Currently the following compression types are supported: NONE, ULAW, ALAW, G722.

Method: aifc object **setparams** *(nchannels, sampwidth, framerate, comptype, compname)*

Set all the above parameters at once. The argument is a tuple consisting of the various parameters. This means that it is possible to use the result of a `getparams` call as argument to `setparams`.

Method: aifc object **setmark** *(id, pos, name)*

Add a mark with the given id (larger than 0), and the given name at the given position. This method can be called at any time before `close`.

Method: aifc object **tell** *()*

Return the current write position in the output file. Useful in combination with `setmark`.

Method: aifc object **writeframes** *(data)*

Write data to the output file. This method can only be called after the audio file parameters have been set.

Method: aifc object **writeframesraw** *(data)*

Like `writeframes`, except that the header of the audio file is not updated.

Method: aifc object **close** *()*

Close the AIFF file. The header of the file is updated to reflect the actual size of the audio data. After calling this method, the object can no longer be used.

Built-in Module `jpeg`

The module `jpeg` provides access to the jpeg compressor and decompressor written by the Independent JPEG Group. JPEG is a (draft?) standard for compressing pictures. For details on jpeg or the Independent JPEG Group software refer to the JPEG standard or the documentation provided with the software.

The `jpeg` module defines these functions:

function of module jpeg: **compress** *(data, w, h, b)*

Treat data as a pixmap of width w and height h, with b bytes per pixel. The data is in SGI GL order, so the first pixel is in the lower-left corner. This means that `lrectread` return data can immediately be passed to compress. Currently only 1 byte and 4 byte pixels are allowed, the former being treated as greyscale and the latter as RGB color. Compress returns a string that contains the compressed picture, in JFIF format.

function of module jpeg: **decompress** *(data)*

Data is a string containing a picture in JFIF format. It returns a tuple `(data, width, height, bytesperpixel)`. Again, the data is suitable to pass to `lrectwrite`.

function of module jpeg: **setoption** *(name, value)*

Set various options. Subsequent compress and decompress calls will use these options. The following options are available:

`'forcegray'`

Force output to be grayscale, even if input is RGB.

`'quality'`

Set the quality of the compressed image to a value between `0` and `100` (default is `75`). Compress only.

`'optimize'`

Perform Huffman table optimization. Takes longer, but results in smaller compressed image. Compress only.

`'smooth'`

Perform inter-block smoothing on uncompressed image. Only useful for low-quality images. Decompress only.

Compress and uncompress raise the error `jpeg.error` in case of errors.

Built-in Module `rgbimg`

The rgbimg module allows python programs to access SGI imglib image files (also known as `.rgb' files). The module is far from complete, but is provided anyway since the functionality that there is is enough in some cases. Currently, colormap files are not supported.

The module defines the following variables and functions:

exception: module rgbimg **error**

This exception is raised on all errors, such as unsupported file type, etc.

function of module rgbimg: **sizeofimage** *(file)*

This function returns a tuple `(x, y)` where x and y are the size of the image in pixels. Only 4 byte RGBA pixels, 3 byte RGB pixels, and 1 byte greyscale pixels are currently supported.

function of module rgbimg: **longimagedata** *(file)*

This function reads and decodes the image on the specified file, and returns it as a Python string. The string has 4 byte RGBA pixels. The bottom left pixel is the first in the string. This format is suitable to pass to `gl.lrectwrite`, for instance.

function of module rgbimg: **longstoimage** *(data, x, y, z, file)*

This function writes the RGBA data in data to image file file. x and y give the size of the image. z is 1 if the saved image should be 1 byte greyscale, 3 if the saved image should be 3 byte RGB data, or 4 if the saved images should be 4 byte RGBA data. The input data always contains 4 bytes per pixel. These are the formats returned by `gl.lrectread`.

function of module rgbimg: **ttob** *(flag)*

This function sets a global flag which defines whether the scan lines of the image are read or written from bottom to top (flag is zero, compatible with SGI GL) or from top to bottom(flag is one, compatible with X).

Go to the previous, next section.

Go to the previous, next section.

Cryptographic Services

The modules described in this chapter implement various algorithms of a cryptographic nature. They are available at the discretion of the installation. Here's an overview:

md5

--- RSA's MD5 message digest algorithm.

mpz

--- Interface to the GNU MP library for arbitrary precision arithmetic.

rotor

--- Enigma-like encryption and decryption.

Hardcore cypherpunks will probably find the Python Cryptography Kit of further interest; the package adds built-in modules for DES and IDEA encryption, and provides a Python module for reading and decrypting PGP files. The Python Cryptography Kit is not distributed with Python but available separately. See the URL `http://www.cs.mcgill.ca/%7Efnord/crypt.html' for more information.

Built-in Module md5

This module implements the interface to RSA's MD5 message digest algorithm (see also Internet RFC 1321). Its use is quite straightforward: use the `md5.new()` to create an md5 object. You can now feed this object with arbitrary strings using the `update()` method, and at any point you can ask it for the digest (a strong kind of 128-bit checksum, a.k.a. "fingerprint") of the contatenation of the strings fed to it so far using the `digest()` method.

For example, to obtain the digest of the string `"Nobody inspects the spammish repetition"`:

```
>>> import md5
>>> m = md5.new()
>>> m.update("Nobody inspects")
>>> m.update(" the spammish repetition")
>>> m.digest()
'\273d\234\203\335\036\245\311\331\336\311\241\215\360\377\351'
```

More condensed:

```
>>> md5.new("Nobody inspects the spammish repetition").digest()
'\273d\234\203\335\036\245\311\331\336\311\241\215\360\377\351'
```

function of module md5: **new** *([arg])*

Return a new md5 object. If arg is present, the method call `update(arg)` is made.

function of module md5: **md5** *([arg])*

For backward compatibility reasons, this is an alternative name for the `new()` function.

An md5 object has the following methods:

Method: md5 **update** *(arg)*

Update the md5 object with the string arg. Repeated calls are equivalent to a single call with the concatenation of all the arguments, i.e. `m.update(a); m.update(b)` is equivalent to `m.update(a+b)`.

Method: md5 **digest** *()*

Return the digest of the strings passed to the `update()` method so far. This is an 8-byte string which may contain non-ASCII characters, including null bytes.

Method: md5 **copy** *()*

Return a copy ("clone") of the md5 object. This can be used to efficiently compute the digests of strings that share a common initial substring.

Built-in Module `mpz`

This module implements the interface to part of the GNU MP library. This library contains arbitrary precision integer and rational number arithmetic routines. Only the interfaces to the *integer* (`mpz_...') routines are provided. If not stated otherwise, the description in the GNU MP documentation can be applied.

In general, mpz-numbers can be used just like other standard Python numbers, e.g. you can use the built-in operators like `+`, `*`, etc., as well as the standard built-in functions like `abs`, `int`, ..., `divmod`, `pow`. **Please note:** the *bitwise-xor* operation has been implemented as a bunch of *and*s, *invert*s and *or*s, because the library lacks an `mpz_xor` function, and I didn't need one.

You create an mpz-number by calling the function called `mpz` (see below for an exact description). An mpz-number is printed like this: `mpz(value)`.

function of module mpz: **mpz** *(value)*

Create a new mpz-number. value can be an integer, a long, another mpz-number, or even a string. If it is a string, it is interpreted as an array of radix-256 digits, least significant digit first, resulting in a positive number. See also the `binary` method, described below.

A number of *extra* functions are defined in this module. Non mpz-arguments are converted to mpz-values first, and the functions return mpz-numbers.

function of module mpz: **powm** *(base, exponent, modulus)*

Return `pow(base, exponent) % modulus`. If `exponent == 0`, return `mpz(1)`. In contrast to

the C-library function, this version can handle negative exponents.

function of module mpz: **gcd** *(op1, op2)*

Return the greatest common divisor of op1 and op2.

function of module mpz: **gcdext** *(a, b)*

Return a tuple `(g, s, t)`, such that `a*s + b*t == g == gcd(a, b)`.

function of module mpz: **sqrt** *(op)*

Return the square root of op. The result is rounded towards zero.

function of module mpz: **sqrtrem** *(op)*

Return a tuple `(root, remainder)`, such that `root*root + remainder == op`.

function of module mpz: **divm** *(numerator, denominator, modulus)*

Returns a number q. such that `q * denominator % modulus == numerator`. One could also implement this function in Python, using `gcdext`.

An mpz-number has one method:

Method: mpz **binary** *()*

Convert this mpz-number to a binary string, where the number has been stored as an array of radix-256 digits, least significant digit first.

The mpz-number must have a value greater than or equal to zero, otherwise a `ValueError`-exception will be raised.

Built-in Module `rotor`

This module implements a rotor-based encryption algorithm, contributed by Lance Ellinghouse. The design is derived from the Enigma device, a machine used during World War II to encipher messages. A rotor is simply a permutation. For example, if the character `A' is the origin of the rotor, then a given rotor might map `A' to `L', `B' to `Z', `C' to `G', and so on. To encrypt, we choose several different rotors, and set the origins of the rotors to known positions; their initial position is the ciphering key. To encipher a character, we permute the original character by the first rotor, and then apply the second rotor's permutation to the result. We continue until we've applied all the rotors; the resulting character is our ciphertext. We then change the origin of the final rotor by one position, from `A' to `B'; if the final rotor has made a complete revolution, then we rotate the next-to-last rotor by one position, and apply the same procedure recursively. In other words, after enciphering one character, we advance the rotors in the same fashion as a car's odometer. Decoding works in the same way, except we reverse the permutations and apply them in the opposite order.

The available functions in this module are:

function of module rotor: **newrotor** *(key[, numrotors])*

Return a rotor object. key is a string containing the encryption key for the object; it can contain arbitrary binary data. The key will be used to randomly generate the rotor permutations and their initial positions. numrotors is the number of rotor permutations in the returned object; if it is omitted, a default value of 6 will be used.

Rotor objects have the following methods:

Method: rotor **setkey** *()*

Reset the rotor to its initial state.

Method: rotor **encrypt** *(plaintext)*

Reset the rotor object to its initial state and encrypt plaintext, returning a string containing the ciphertext. The ciphertext is always the same length as the original plaintext.

Method: rotor **encryptmore** *(plaintext)*

Encrypt plaintext without resetting the rotor object, and return a string containing the ciphertext.

Method: rotor **decrypt** *(ciphertext)*

Reset the rotor object to its initial state and decrypt ciphertext, returning a string containing the ciphertext. The plaintext string will always be the same length as the ciphertext.

Method: rotor **decryptmore** *(ciphertext)*

Decrypt ciphertext without resetting the rotor object, and return a string containing the ciphertext.

An example usage:

```
>>> import rotor
>>> rt = rotor.newrotor('key', 12)
>>> rt.encrypt('bar')
'\2534\363'
>>> rt.encryptmore('bar')
'\357\375$'
>>> rt.encrypt('bar')
'\2534\363'
>>> rt.decrypt('\2534\363')
'bar'
>>> rt.decryptmore('\357\375$')
'bar'
>>> rt.decrypt('\357\375$')
'l(\315'
>>> del rt
```

The module's code is not an exact simulation of the original Enigma device; it implements the rotor encryption scheme differently from the original. The most important difference is that in the original Enigma, there were only 5 or 6 different rotors in existence, and they were applied twice to each

character; the cipher key was the order in which they were placed in the machine. The Python rotor module uses the supplied key to initialize a random number generator; the rotor permutations and the initial positions are then randomly generated. The original device only enciphered the letters of the alphabet, while this module can handle any 8-bit binary data; it also produces binary output. This module can also operate with an arbitrary number of rotors.

The original Enigma cipher was broken in 1944. The version implemented here is probably a good deal more difficult to crack (especially if you use many rotors), but it won't be impossible for a truly skilful and determined attacker to break the cipher. So if you want to keep the NSA out of your files, this rotor cipher may well be unsafe, but for discouraging casual snooping through your files, it will probably be just fine, and may be somewhat safer than using the Unix `crypt' command.

Go to the previous, next section.

Go to the previous, next section.

Macintosh Specific Services

The modules in this chapter are available on the Apple Macintosh only.

Built-in Module `mac`

This module provides a subset of the operating system dependent functionality provided by the optional built-in module `posix`. It is best accessed through the more portable standard module `os`.

The following functions are available in this module: `chdir`, `getcwd`, `listdir`, `mkdir`, `rename`, `rmdir`, `stat`, `sync`, `unlink`, as well as the exception `error`.

Standard Module `macpath`

This module provides a subset of the pathname manipulation functions available from the optional standard module `posixpath`. It is best accessed through the more portable standard module `os`, as `os.path`.

The following functions are available in this module: `normcase`, `isabs`, `join`, `split`, `isdir`, `isfile`, `exists`.

Built-in Module `ctb`

This module provides a partial interface to the Macintosh Communications Toolbox. Currently, only Connection Manager tools are supported. It may not be available in all Mac Python versions.

data: module ctb **error**

The exception raised on errors.

data: module ctb **cmData**

data: module ctb **cmCntl**

data: module ctb **cmAttn**

Flags for the channel argument of the Read and Write methods.

data: module ctb **cmFlagsEOM**

End-of-message flag for Read and Write.

data: module ctb **choose***

Values returned by Choose.

data: module ctb **cmStatus***

Bits in the status as returned by Status.

function of module ctb: **available** *()*

Return 1 if the communication toolbox is available, zero otherwise.

function of module ctb: **CMNew** *(name, sizes)*

Create a connection object using the connection tool named name. sizes is a 6-tuple given buffer sizes for data in, data out, control in, control out, attention in and attention out. Alternatively, passing `None` will result in default buffer sizes.

connection object

For all connection methods that take a timeout argument, a value of `-1` is indefinite, meaning that the command runs to completion.

attribute: connection object **callback**

If this member is set to a value other than `None` it should point to a function accepting a single argument (the connection object). This will make all connection object methods work asynchronously, with the callback routine being called upon completion.

Note: for reasons beyond my understanding the callback routine is currently never called. You are advised against using asynchronous calls for the time being.

Method: connection object **Open** *(timeout)*

Open an outgoing connection, waiting at most timeout seconds for the connection to be established.

Method: connection object **Listen** *(timeout)*

Wait for an incoming connection. Stop waiting after timeout seconds. This call is only meaningful to some tools.

Method: connection object **accept** *(yesno)*

Accept (when yesno is non-zero) or reject an incoming call after Listen returned.

Method: connection object **Close** *(timeout, now)*

Close a connection. When now is zero, the close is orderly (i.e. outstanding output is flushed, etc.) with a timeout of timeout seconds. When now is non-zero the close is immediate, discarding output.

Method: connection object **Read** *(len, chan, timeout)*

Read len bytes, or until timeout seconds have passed, from the channel chan (which is one of cmData, cmCntl or cmAttn). Return a 2-tuple: the data read and the end-of-message flag.

Method: connection object **Write** *(buf, chan, timeout, eom)*

Write buf to channel chan, aborting after timeout seconds. When eom has the value cmFlagsEOM an end-of-message indicator will be written after the data (if this concept has a meaning for this communication tool). The method returns the number of bytes written.

Method: connection object **Status** *()*

Return connection status as the 2-tuple `(sizes, flags)`. sizes is a 6-tuple giving the actual buffer sizes used (see CMNew), flags is a set of bits describing the state of the connection.

Method: connection object **GetConfig** *()*

Return the configuration string of the communication tool. These configuration strings are tool-dependent, but usually easily parsed and modified.

Method: connection object **SetConfig** *(str)*

Set the configuration string for the tool. The strings are parsed left-to-right, with later values taking precedence. This means individual configuration parameters can be modified by simply appending something like `'baud 4800'` to the end of the string returned by GetConfig and passing that to this method. The method returns the number of characters actually parsed by the tool before it encountered an error (or completed successfully).

Method: connection object **Choose** *()*

Present the user with a dialog to choose a communication tool and configure it. If there is an outstanding connection some choices (like selecting a different tool) may cause the connection to be aborted. The return value (one of the choose* constants) will indicate this.

Method: connection object **Idle** *()*

Give the tool a chance to use the processor. You should call this method regularly.

Method: connection object **Abort** *()*

Abort an outstanding asynchronous Open or Listen.

Method: connection object **Reset** *()*

Reset a connection. Exact meaning depends on the tool.

Method: connection object **Break** *(length)*

Send a break. Whether this means anything, what it means and interpretation of the length parameter depend on the tool in use.

TOC

Built-in Module macconsole

This module is available on the Macintosh, provided Python has been built using the Think C compiler. It provides an interface to the Think console package, with which basic text windows can be created.

data: module macconsole **options**

An object allowing you to set various options when creating windows, see below.

data: module macconsole **C_ECHO**

data: module macconsole **C_NOECHO**

data: module macconsole **C_CBREAK**

data: module macconsole **C_RAW**

Options for the `setmode` method. C_ECHO and C_CBREAK enable character echo, the other two disable it, C_ECHO and C_NOECHO enable line-oriented input (erase/kill processing, etc).

function of module macconsole: **copen** *()*

Open a new console window. Return a console window object.

function of module macconsole: **fopen** *(fp)*

Return the console window object corresponding with the given file object. fp should be one of `sys.stdin`, `sys.stdout` or `sys.stderr`.

macconsole options object

These options are examined when a window is created:

option: macconsole **top**

option: macconsole **left**

The origin of the window.

option: macconsole **nrows**

option: macconsole **ncols**

The size of the window.

option: macconsole **txFont**

option: macconsole **txSize**

option: macconsole **txStyle**

The font, fontsize and fontstyle to be used in the window.

option: macconsole **title**

The title of the window.

option: macconsole **pause_atexit**

If set non-zero, the window will wait for user action before closing.

console window object

attribute: console window **file**

The file object corresponding to this console window. If the file is buffered, you should call `file.flush()` between `write()` and `read()` calls.

Method: console window **setmode** *(mode)*

Set the input mode of the console to C_ECHO, etc.

Method: console window **settabs** *(n)*

Set the tabsize to n spaces.

Method: console window **cleos** *()*

Clear to end-of-screen.

Method: console window **cleol** *()*

Clear to end-of-line.

Method: console window **inverse** *(onoff)*

Enable inverse-video mode: characters with the high bit set are displayed in inverse video (this disables the upper half of a non-ASCII character set).

Method: console window **gotoxy** *(x, y)*

Set the cursor to position `(x, y)`.

Method: console window **hide** *()*

Hide the window, remembering the contents.

Method: console window **show** *()*

Show the window again.

Method: console window **echo2printer** *()*

Copy everything written to the window to the printer as well.

Built-in Module macdnr

This module provides an interface to the Macintosh Domain Name Resolver. It is usually used in conjunction with the mactcp module, to map hostnames to IP-addresses. It may not be available in all Mac Python versions.

The `macdnr` module defines the following functions:

function of module macdnr: **Open** *([filename])*

Open the domain name resolver extension. If filename is given it should be the pathname of the extension, otherwise a default is used. Normally, this call is not needed since the other calls will open the extension automatically.

function of module macdnr: **Close** *()*

Close the resolver extension. Again, not needed for normal use.

function of module macdnr: **StrToAddr** *(hostname)*

Look up the IP address for hostname. This call returns a dnr result object of the "address" variation.

function of module macdnr: **AddrToName** *(addr)*

Do a reverse lookup on the 32-bit integer IP-address addr. Returns a dnr result object of the "address" variation.

function of module macdnr: **AddrToStr** *(addr)*

Convert the 32-bit integer IP-address addr to a dotted-decimal string. Returns the string.

function of module macdnr: **HInfo** *(hostname)*

Query the nameservers for a `HInfo` record for host hostname. These records contain hardware and software information about the machine in question (if they are available in the first place). Returns a dnr result object of the "hinfo" variety.

function of module macdnr: **MXInfo** *(domain)*

Query the nameservers for a mail exchanger for domain. This is the hostname of a host willing to accept SMTP mail for the given domain. Returns a dnr result object of the "mx" variety.

dnr result object

Since the DNR calls all execute asynchronously you do not get the results back immediately. Instead, you get a dnr result object. You can check this object to see whether the query is complete, and access its attributes to obtain the information when it is.

Alternatively, you can also reference the result attributes directly, this will result in an implicit wait for the query to complete.

The rtnCode and cname attributes are always available, the others depend on the type of query (addr, hinfo or mx).

Method: dnr result object **wait** *()*

Wait for the query to complete.

Method: dnr result object **isdone** *()*

Return 1 if the query is complete.

attribute: dnr result object **rtnCode**

The error code returned by the query.

attribute: dnr result object **cname**

The canonical name of the host that was queried.

attribute: dnr result object **ip0**

attribute: dnr result object **ip1**

attribute: dnr result object **ip2**

attribute: dnr result object **ip3**

At most four integer IP addresses for this host. Unused entries are zero. Valid only for address queries.

attribute: dnr result object **cpuType**

attribute: dnr result object **osType**

Textual strings giving the machine type an OS name. Valid for hinfo queries.

attribute: dnr result object **exchange**

The name of a mail-exchanger host. Valid for mx queries.

attribute: dnr result object **preference**

The preference of this mx record. Not too useful, since the Macintosh will only return a single mx record. Mx queries only.

The simplest way to use the module to convert names to dotted-decimal strings, without worrying about idle time, etc:

```
>>> def gethostname(name):
...     import macdnr
...     dnrr = macdnr.StrToAddr(name)
...     return macdnr.AddrToStr(dnrr.ip0)
```

Built-in Module `macfs`

This module provides access to macintosh FSSpec handling, the Alias Manager, finder aliases and the Standard File package.

Whenever a function or method expects a file argument, this argument can be one of three things: (1) a full or partial Macintosh pathname, (2) an FSSpec object or (3) a 3-tuple `(wdRefNum, parID, name)` as described in Inside Mac VI. and the standard file package can also be found there.

function of module macfs: **FSSpec** *(file)*

Create an FSSpec object for the specified file.

function of module macfs: **RawFSSpec** *(data)*

Create an FSSpec object given the raw data for the C structure for the FSSpec as a string. This is mainly useful if you have obtained an FSSpec structure over a network.

function of module macfs: **RawAlias** *(data)*

Create an Alias object given the raw data for the C structure for the alias as a string. This is mainly useful if you have obtained an FSSpec structure over a network.

function of module macfs: **ResolveAliasFile** *(file)*

Resolve an alias file. Returns a 3-tuple `(fsspec, isfolder, aliased)` where fsspec is the resulting FSSpec object, isfolder is true if fsspec points to a folder and aliased is true if the file was an alias in the first place (otherwise the FSSpec object for the file itself is returned).

function of module macfs: **StandardGetFile** *([type, ...])*

Present the user with a standard "open input file" dialog. Optionally, you can pass up to four 4-char file types to limit the files the user can choose from. The function returns an FSSpec object and a flag indicating that the user completed the dialog without cancelling.

function of module macfs: **StandardPutFile** *(prompt, [default])*

Present the user with a standard "open output file" dialog. prompt is the prompt string, and the optional default argument initializes the output file name. The function returns an FSSpec object and a flag indicating that the user completed the dialog without cancelling.

function of module macfs: **GetDirectory** *()*

Present the user with a non-standard "select a directory" dialog. Return an FSSpec object and a success-indicator.

FSSpec objects

attribute: FSSpec object **data**

The raw data from the FSSpec object, suitable for passing to other applications, for instance.

Method: FSSpec object **as_pathname** *()*

Return the full pathname of the file described by the FSSpec object.

Method: FSSpec object **as_tuple** *()*

Return the `(wdRefNum, parID, name)` tuple of the file described by the FSSpec object.

Method: FSSpec object **NewAlias** *([file])*

Create an Alias object pointing to the file described by this FSSpec. If the optional file parameter is present the alias will be relative to that file, otherwise it will be absolute.

Method: FSSpec object **NewAliasMinimal** *()*

Create a minimal alias pointing to this file.

Method: FSSpec object **GetCreatorType** *()*

Return the 4-char creator and type of the file.

Method: FSSpec object **SetCreatorType** *(creator, type)*

Set the 4-char creator and type of the file.

alias objects

attribute: alias object **data**

The raw data for the Alias record, suitable for storing in a resource or transmitting to other programs.

Method: alias object **Resolve** *([file])*

Resolve the alias. If the alias was created as a relative alias you should pass the file relative to which it is. Return the FSSpec for the file pointed to and a flag indicating whether the alias object itself was modified during the search process.

Method: alias object **GetInfo** *(num)*

An interface to the C routine `GetAliasInfo()`.

Method: alias object **Update** *(file, [file2])*

Update the alias to point to the file given. If file2 is present a relative alias will be created.

Note that it is currently not possible to directly manipulate a resource as an alias object. Hence, after calling Update or after Resolve indicates that the alias has changed the Python program is responsible for

getting the data from the alias object and modifying the resource.

Built-in Module `mactcp`

This module provides an interface to the Macintosh TCP/IP driver MacTCP.`macdnr` which provides an interface to the name-server (allowing you to translate hostnames to ip-addresses), a module `MACTCP` which has symbolic names for constants constants used by MacTCP and a wrapper module `socket` which mimics the UNIX socket interface (as far as possible). It may not be available in all Mac Python versions.

A complete description of the MacTCP interface can be found in the Apple MacTCP API documentation.

function of module mactcp: **MTU** *()*

Return the Maximum Transmit Unit (the packet size) of the network interface.

function of module mactcp: **IPAddr** *()*

Return the 32-bit integer IP address of the network interface.

function of module mactcp: **NetMask** *()*

Return the 32-bit integer network mask of the interface.

function of module mactcp: **TCPCreate** *(size)*

Create a TCP Stream object. size is the size of the receive buffer, `4096` is suggested by various sources.

function of module mactcp: **UDPCreate** *(size, port)*

Create a UDP stream object. size is the size of the receive buffer (and, hence, the size of the biggest datagram you can receive on this port). port is the UDP port number you want to receive datagrams on, a value of zero will make MacTCP select a free port.

TCP Stream Objects

attribute: TCP stream **asr**

When set to a value different than `None` this should point to a function with two integer parameters: an event code and a detail. This function will be called upon network-generated events such as urgent data arrival. In addition, it is called with eventcode `MACTCP.PassiveOpenDone` when a `PassiveOpen` completes. This is a Python addition to the MacTCP semantics. It is safe to do further calls from the `asr`.

Method: TCP stream **PassiveOpen** *(port)*

Wait for an incoming connection on TCP port port (zero makes the system pick a free port). The call returns immediately, and you should use wait to wait for completion. You should not issue any method calls other than `wait`, `isdone` or `GetSockName` before the call completes.

Method: TCP stream **wait** *()*

Wait for `PassiveOpen` to complete.

Method: TCP stream **isdone** *()*

Return 1 if a `PassiveOpen` has completed.

Method: TCP stream **GetSockName** *()*

Return the TCP address of this side of a connection as a 2-tuple `(host, port)`, both integers.

Method: TCP stream **ActiveOpen** *(lport, host, rport)*

Open an outgoing connection to TCP address `(host, rport)`. Use local port lport (zero makes the system pick a free port). This call blocks until the connection has been established.

Method: TCP stream **Send** *(buf, push, urgent)*

Send data buf over the connection. Push and urgent are flags as specified by the TCP standard.

Method: TCP stream **Rcv** *(timeout)*

Receive data. The call returns when timeout seconds have passed or when (according to the MacTCP documentation) "a reasonable amount of data has been received". The return value is a 3-tuple `(data, urgent, mark)`. If urgent data is outstanding `Rcv` will always return that before looking at any normal data. The first call returning urgent data will have the urgent flag set, the last will have the mark flag set.

Method: TCP stream **Close** *()*

Tell MacTCP that no more data will be transmitted on this connection. The call returns when all data has been acknowledged by the receiving side.

Method: TCP stream **Abort** *()*

Forcibly close both sides of a connection, ignoring outstanding data.

Method: TCP stream **Status** *()*

Return a TCP status object for this stream giving the current status (see below).

TCP Status Objects

This object has no methods, only some members holding information on the connection. A complete description of all fields in this objects can be found in the Apple documentation. The most interesting ones are:

attribute: TCP status **localHost**

attribute: TCP status **localPort**

attribute: TCP status **remoteHost**

attribute: TCP status **remotePort**

The integer IP-addresses and port numbers of both endpoints of the connection.

attribute: TCP status **sendWindow**

The current window size.

attribute: TCP status **amtUnackedData**

The number of bytes sent but not yet acknowledged. `sendWindow - amtUnackedData` is what you can pass to `Send` without blocking.

attribute: TCP status **amtUnreadData**

The number of bytes received but not yet read (what you can `Recv` without blocking).

UDP Stream Objects

Note that, unlike the name suggests, there is nothing stream-like about UDP.

attribute: UDP stream **asr**

The asynchronous service routine to be called on events such as datagram arrival without outstanding `Read` call. The `asr` has a single argument, the event code.

attribute: UDP stream **port**

A read-only member giving the port number of this UDP stream.

Method: UDP stream **Read** *(timeout)*

Read a datagram, waiting at most timeout seconds (is infinite). Return the data.

Method: UDP stream **Write** *(host, port, buf)*

Send buf as a datagram to IP-address host, port port.

Built-in Module `macspeech`

This module provides an interface to the Macintosh Speech Manager, allowing you to let the Macintosh utter phrases. You need a version of the speech manager extension (version 1 and 2 have been tested) in your `Extensions` folder for this to work. The module does not provide full access to all features of the Speech Manager yet. It may not be available in all Mac Python versions.

function of module macspeech: **Available** *()*

Test availability of the Speech Manager extension (and, on the PowerPC, the Speech Manager shared library). Return 0 or 1.

function of module macspeech: **Version** *()*

Return the (integer) version number of the Speech Manager.

function of module macspeech: **SpeakString** *(str)*

Utter the string str using the default voice, asynchronously. This aborts any speech that may still be active from prior `SpeakString` invocations.

function of module macspeech: **Busy** *()*

Return the number of speech channels busy, system-wide.

function of module macspeech: **CountVoices** *()*

Return the number of different voices available.

function of module macspeech: **GetIndVoice** *(num)*

Return a voice object for voice number num.

voice objects

Voice objects contain the description of a voice. It is currently not yet possible to access the parameters of a voice.

Method: voice object **GetGender** *()*

Return the gender of the voice: 0 for male, 1 for female and for neuter.

Method: voice object **NewChannel** *()*

Return a new speech channel object using this voice.

speech channel objects

A speech channel object allows you to speak strings with slightly more control than `SpeakString()`, and allows you to use multiple speakers at the same time. Please note that channel pitch and rate are interrelated in some way, so that to make your Macintosh sing you will have to adjust both.

Method: speech channel object **SpeakText** *(str)*

Start uttering the given string.

Method: speech channel object **Stop** *()*

Stop babbling.

Method: speech channel object **GetPitch** *()*

Return the current pitch of the channel, as a floating-point number.

Method: speech channel object **SetPitch** *(pitch)*

TOC

Set the pitch of the channel.

Method: speech channel object **GetRate** *()*

Get the speech rate (utterances per minute) of the channel as a floating point number.

Method: speech channel object **SetRate** *(rate)*

Set the speech rate of the channel.

Go to the previous, next section.

Go to the previous, next section.

Standard Windowing Interface

The modules in this chapter are available only on those systems where the STDWIN library is available. STDWIN runs on UNIX under X11 and on the Macintosh. See CWI report CS-R8817.

Warning: Using STDWIN is not recommended for new applications. It has never been ported to Microsoft Windows or Windows NT, and for X11 or the Macintosh it lacks important functionality -- in particular, it has no tools for the construction of dialogs. For most platforms, alternative, native solutions exist (though none are currently documented in this manual): Tkinter for UNIX under X11, native Xt with Motif or Athena widgets for UNIX under X11, Win32 for Windows and Windows NT, and a collection of native toolkit interfaces for the Macintosh.

Built-in Module `stdwin`

This module defines several new object types and functions that provide access to the functionality of STDWIN.

On Unix running X11, it can only be used if the `DISPLAY` environment variable is set or an explicit `-display displayname' argument is passed to the Python interpreter.

Functions have names that usually resemble their C STDWIN counterparts with the initial `w' dropped. Points are represented by pairs of integers; rectangles by pairs of points. For a complete description of STDWIN please refer to the documentation of STDWIN for C programmers (aforementioned CWI report).

Functions Defined in Module `stdwin`

The following functions are defined in the `stdwin` module:

function of module stdwin: **open** *(title)*

Open a new window whose initial title is given by the string argument. Return a window object; window object methods are described below.(16)

function of module stdwin: **getevent** *()*

Wait for and return the next event. An event is returned as a triple: the first element is the event type, a small integer; the second element is the window object to which the event applies, or `None` if it applies to no window in particular; the third element is type-dependent. Names for event types and command codes are defined in the standard module `stdwinevent`.

function of module stdwin: **pollevent** *()*

Return the next event, if one is immediately available. If no event is available, return `()`.

function of module stdwin: **getactive** *()*

Return the window that is currently active, or `None` if no window is currently active. (This can be emulated by monitoring WE_ACTIVATE and WE_DEACTIVATE events.)

function of module stdwin: **listfontnames** *(pattern)*

Return the list of font names in the system that match the pattern (a string). The pattern should normally be `'*'`; returns all available fonts. If the underlying window system is X11, other patterns follow the standard X11 font selection syntax (as used e.g. in resource definitions), i.e. the wildcard character `'*'` matches any sequence of characters (including none) and `'?'` matches any single character. On the Macintosh this function currently returns an empty list.

function of module stdwin: **setdefscrollbars** *(hflag, vflag)*

Set the flags controlling whether subsequently opened windows will have horizontal and/or vertical scroll bars.

function of module stdwin: **setdefwinpos** *(h, v)*

Set the default window position for windows opened subsequently.

function of module stdwin: **setdefwinsize** *(width, height)*

Set the default window size for windows opened subsequently.

function of module stdwin: **getdefscrollbars** *()*

Return the flags controlling whether subsequently opened windows will have horizontal and/or vertical scroll bars.

function of module stdwin: **getdefwinpos** *()*

Return the default window position for windows opened subsequently.

function of module stdwin: **getdefwinsize** *()*

Return the default window size for windows opened subsequently.

function of module stdwin: **getscrsize** *()*

Return the screen size in pixels.

function of module stdwin: **getscrmm** *()*

Return the screen size in millimeters.

function of module stdwin: **fetchcolor** *(colorname)*

Return the pixel value corresponding to the given color name. Return the default foreground color for unknown color names. Hint: the following code tests whether you are on a machine that supports more than two colors:

```
if stdwin.fetchcolor('black') <> \
          stdwin.fetchcolor('red') <> \
          stdwin.fetchcolor('white'):
    print 'color machine'
else:
    print 'monochrome machine'
```

function of module stdwin: **setfgcolor** *(pixel)*

Set the default foreground color. This will become the default foreground color of windows opened subsequently, including dialogs.

function of module stdwin: **setbgcolor** *(pixel)*

Set the default background color. This will become the default background color of windows opened subsequently, including dialogs.

function of module stdwin: **getfgcolor** *()*

Return the pixel value of the current default foreground color.

function of module stdwin: **getbgcolor** *()*

Return the pixel value of the current default background color.

function of module stdwin: **setfont** *(fontname)*

Set the current default font. This will become the default font for windows opened subsequently, and is also used by the text measuring functions `textwidth`, `textbreak`, `lineheight` and `baseline` below. This accepts two more optional parameters, size and style: Size is the font size (in `points'). Style is a single character specifying the style, as follows: `'b'` = bold, `'i'` = italic, `'o'` = bold + italic, `'u'` = underline; default style is roman. Size and style are ignored under X11 but used on the Macintosh. (Sorry for all this complexity -- a more uniform interface is being designed.)

function of module stdwin: **menucreate** *(title)*

Create a menu object referring to a global menu (a menu that appears in all windows). Methods of menu objects are described below. Note: normally, menus are created locally; see the window method `menucreate` below. **Warning:** the menu only appears in a window as long as the object returned by this call exists.

function of module stdwin: **newbitmap** *(width, height)*

Create a new bitmap object of the given dimensions. Methods of bitmap objects are described below. Not available on the Macintosh.

function of module stdwin: **fleep** *()*

Cause a beep or bell (or perhaps a `visual bell' or flash, hence the name).

function of module stdwin: **message** *(string)*

Display a dialog box containing the string. The user must click OK before the function returns.

function of module stdwin: **askync** *(prompt, default)*

Display a dialog that prompts the user to answer a question with yes or no. Return 0 for no, 1 for yes. If the user hits the Return key, the default (which must be 0 or 1) is returned. If the user cancels the dialog, the `KeyboardInterrupt` exception is raised.

function of module stdwin: **askstr** *(prompt, default)*

Display a dialog that prompts the user for a string. If the user hits the Return key, the default string is returned. If the user cancels the dialog, the `KeyboardInterrupt` exception is raised.

function of module stdwin: **askfile** *(prompt, default, new)*

Ask the user to specify a filename. If new is zero it must be an existing file; otherwise, it must be a new file. If the user cancels the dialog, the `KeyboardInterrupt` exception is raised.

function of module stdwin: **setcutbuffer** *(i, string)*

Store the string in the system's cut buffer number i, where it can be found (for pasting) by other applications. On X11, there are 8 cut buffers (numbered 0..7). Cut buffer number 0 is the `clipboard' on the Macintosh.

function of module stdwin: **getcutbuffer** *(i)*

Return the contents of the system's cut buffer number i.

function of module stdwin: **rotatecutbuffers** *(n)*

On X11, rotate the 8 cut buffers by n. Ignored on the Macintosh.

function of module stdwin: **getselection** *(i)*

Return X11 selection number i. Selections are not cut buffers. Selection numbers are defined in module `stdwinevents`. Selection `WS_PRIMARY` is the primary selection (used by xterm, for instance); selection `WS_SECONDARY` is the secondary selection; selection `WS_CLIPBOARD` is the clipboard selection (used by xclipboard). On the Macintosh, this always returns an empty string.

function of module stdwin: **resetselection** *(i)*

Reset selection number i, if this process owns it. (See window method `setselection()`).

function of module stdwin: **baseline** *()*

Return the baseline of the current font (defined by STDWIN as the vertical distance between the baseline and the top of the characters).

function of module stdwin: **lineheight** *()*

Return the total line height of the current font.

function of module stdwin: **textbreak** *(str, width)*

Return the number of characters of the string that fit into a space of width bits wide when drawn in th curent font.

function of module stdwin: **textwidth** *(str)*

Return the width in bits of the string when drawn in the current font.

function of module stdwin: **connectionnumber** *()*

function of module stdwin: **fileno** *()*

(X11 under UNIX only) Return the "connection number" used by the underlying X11 implementation. (This is normally the file number of the socket.) Both functions return the same value; `connectionnumber()` is named after the corresponding function in X11 and STDWIN, while `fileno()` makes it possible to use the `stdwin` module as a "file" object parameter to `select.select()`. Note that if `select()` implies that input is possible on `stdwin`, this does not guarantee that an event is ready -- it may be some internal communication going on between the X server and the client library. Thus, you should call `stdwin.pollevent()` until it returns `None` to check for events if you don't want your program to block. Because of internal buffering in X11, it is also possible that `stdwin.pollevent()` returns an event while `select()` does not find `stdwin` to be ready, so you should read any pending events with `stdwin.pollevent()` until it returns `None` before entering a blocking `select()` call.

Window Objects

Window objects are created by `stdwin.open()`. They are closed by their `close()` method or when they are garbage-collected. Window objects have the following methods:

Method: window **begindrawing** *()*

Return a drawing object, whose methods (described below) allow drawing in the window.

Method: window **change** *(rect)*

Invalidate the given rectangle; this may cause a draw event.

Method: window **gettitle** *()*

Returns the window's title string.

Method: window **getdocsize** *()*

Return a pair of integers giving the size of the document as set by `setdocsize()`.

Method: window **getorigin** *()*

Return a pair of integers giving the origin of the window with respect to the document.

Method: window **gettitle** *()*

Return the window's title string.

Method: window **getwinsize** *()*

Return a pair of integers giving the size of the window.

Method: window **getwinpos** *()*

Return a pair of integers giving the position of the window's upper left corner (relative to the upper left corner of the screen).

Method: window **menucreate** *(title)*

Create a menu object referring to a local menu (a menu that appears only in this window). Methods of menu objects are described below. **Warning:** the menu only appears as long as the object returned by this call exists.

Method: window **scroll** *(rect, point)*

Scroll the given rectangle by the vector given by the point.

Method: window **setdocsize** *(point)*

Set the size of the drawing document.

Method: window **setorigin** *(point)*

Move the origin of the window (its upper left corner) to the given point in the document.

Method: window **setselection** *(i, str)*

Attempt to set X11 selection number i to the string str. (See stdwin method `getselection()` for the meaning of i.) Return true if it succeeds. If succeeds, the window "owns" the selection until (a) another application takes ownership of the selection; or (b) the window is deleted; or (c) the application clears ownership by calling `stdwin.resetselection(i)`. When another application takes ownership of the selection, a `WE_LOST_SEL` event is received for no particular window and with the selection number as detail. Ignored on the Macintosh.

Method: window **settimer** *(dsecs)*

Schedule a timer event for the window in `dsecs/10` seconds.

Method: window **settitle** *(title)*

Set the window's title string.

Method: window **setwincursor** *(name)*

Set the window cursor to a cursor of the given name. It raises the `RuntimeError` exception if no cursor of the given name exists. Suitable names include `'ibeam'`, `'arrow'`, `'cross'`, `'watch'` and `'plus'`. On X11, there are many more (see `` `<X11/cursorfont.h>' ``).

Method: window **setwinpos** *(h, v)*

Set the the position of the window's upper left corner (relative to the upper left corner of the screen).

Method: window **setwinsize** *(width, height)*

Set the window's size.

Method: window **show** *(rect)*

Try to ensure that the given rectangle of the document is visible in the window.

Method: window **textcreate** *(rect)*

Create a text-edit object in the document at the given rectangle. Methods of text-edit objects are described below.

Method: window **setactive** *()*

Attempt to make this window the active window. If successful, this will generate a WE_ACTIVATE event (and a WE_DEACTIVATE event in case another window in this application became inactive).

Method: window **close** *()*

Discard the window object. It should not be used again.

Drawing Objects

Drawing objects are created exclusively by the window method `begindrawing()`. Only one drawing object can exist at any given time; the drawing object must be deleted to finish drawing. No drawing object may exist when `stdwin.getevent()` is called. Drawing objects have the following methods:

Method: drawing **box** *(rect)*

Draw a box just inside a rectangle.

Method: drawing **circle** *(center, radius)*

Draw a circle with given center point and radius.

Method: drawing **elarc** *(center, (rh, rv), (a1, a2))*

Draw an elliptical arc with given center point. `(rh, rv)` gives the half sizes of the horizontal and vertical radii. `(a1, a2)` gives the angles (in degrees) of the begin and end points. 0 degrees is at 3 o'clock, 90 degrees is at 12 o'clock.

Method: drawing **erase** *(rect)*

Erase a rectangle.

Method: drawing **fillcircle** *(center, radius)*

Draw a filled circle with given center point and radius.

Method: drawing **fillelarc** *(center, (rh, rv), (a1, a2))*

Draw a filled elliptical arc; arguments as for `elarc`.

Method: drawing **fillpoly** *(points)*

Draw a filled polygon given by a list (or tuple) of points.

Method: drawing **invert** *(rect)*

Invert a rectangle.

Method: drawing **line** *(p1, p2)*

Draw a line from point p1 to p2.

Method: drawing **paint** *(rect)*

Fill a rectangle.

Method: drawing **poly** *(points)*

Draw the lines connecting the given list (or tuple) of points.

Method: drawing **shade** *(rect, percent)*

Fill a rectangle with a shading pattern that is about percent percent filled.

Method: drawing **text** *(p, str)*

Draw a string starting at point p (the point specifies the top left coordinate of the string).

Method: drawing **xorcircle** *(center, radius)*

Method: drawing **xorelarc** *(center, (rh, rv), (a1, a2))*

Method: drawing **xorline** *(p1, p2)*

Method: drawing **xorpoly** *(points)*

Draw a circle, an elliptical arc, a line or a polygon, respectively, in XOR mode.

Method: drawing **setfgcolor** *()*

Method: drawing **setbgcolor** *()*

Method: drawing **getfgcolor** *()*

Method: drawing **getbgcolor** *()*

These functions are similar to the corresponding functions described above for the `stdwin` module, but affect or return the colors currently used for drawing instead of the global default colors. When a drawing object is created, its colors are set to the window's default colors, which are in turn initialized from the global default colors when the window is created.

Method: drawing **setfont** *()*

Method: drawing **baseline** *()*

Method: drawing **lineheight** *()*

Method: drawing **textbreak** *()*

Method: drawing **textwidth** *()*

These functions are similar to the corresponding functions described above for the `stdwin` module, but affect or use the current drawing font instead of the global default font. When a drawing object is created, its font is set to the window's default font, which is in turn initialized from the global default font when the window is created.

Method: drawing **bitmap** *(point, bitmap, mask)*

Draw the bitmap with its top left corner at point. If the optional mask argument is present, it should be either the same object as bitmap, to draw only those bits that are set in the bitmap, in the foreground color, or `None`, to draw all bits (ones are drawn in the foreground color, zeros in the background color). Not available on the Macintosh.

Method: drawing **cliprect** *(rect)*

Set the "clipping region" to a rectangle. The clipping region limits the effect of all drawing operations, until it is changed again or until the drawing object is closed. When a drawing object is created the clipping region is set to the entire window. When an object to be drawn falls partly outside the clipping region, the set of pixels drawn is the intersection of the clipping region and the set of pixels that would be drawn by the same operation in the absence of a clipping region.

Method: drawing **noclip** *()*

Reset the clipping region to the entire window.

Method: drawing **close** *()*

Method: drawing **enddrawing** *()*

Discard the drawing object. It should not be used again.

Menu Objects

A menu object represents a menu. The menu is destroyed when the menu object is deleted. The following methods are defined:

Method: menu **additem** *(text, shortcut)*

Add a menu item with given text. The shortcut must be a string of length 1, or omitted (to specify no shortcut).

Method: menu **setitem** *(i, text)*

Set the text of item number i.

Method: menu **enable** *(i, flag)*

Enable or disables item i.

Method: menu **check** *(i, flag)*

Set or clear the check mark for item i.

Method: menu **close** *()*

Discard the menu object. It should not be used again.

Bitmap Objects

A bitmap represents a rectangular array of bits. The top left bit has coordinate (0, 0). A bitmap can be drawn with the `bitmap` method of a drawing object. Bitmaps are currently not available on the Macintosh.

The following methods are defined:

Method: bitmap **getsize** *()*

Return a tuple representing the width and height of the bitmap. (This returns the values that have been passed to the `newbitmap` function.)

Method: bitmap **setbit** *(point, bit)*

Set the value of the bit indicated by point to bit.

Method: bitmap **getbit** *(point)*

Return the value of the bit indicated by point.

Method: bitmap **close** *()*

Discard the bitmap object. It should not be used again.

Text-edit Objects

A text-edit object represents a text-edit block. For semantics, see the STDWIN documentation for C programmers. The following methods exist:

Method: text-edit **arrow** *(code)*

Pass an arrow event to the text-edit block. The code must be one of `WC_LEFT`, `WC_RIGHT`, `WC_UP` or `WC_DOWN` (see module `stdwinevents`).

Method: text-edit **draw** *(rect)*

Pass a draw event to the text-edit block. The rectangle specifies the redraw area.

Method: text-edit **event** *(type, window, detail)*

Pass an event gotten from `stdwin.getevent()` to the text-edit block. Return true if the event was

handled.

Method: text-edit **getfocus** *()*

Return 2 integers representing the start and end positions of the focus, usable as slice indices on the string returned by `gettext()`.

Method: text-edit **getfocustext** *()*

Return the text in the focus.

Method: text-edit **getrect** *()*

Return a rectangle giving the actual position of the text-edit block. (The bottom coordinate may differ from the initial position because the block automatically shrinks or grows to fit.)

Method: text-edit **gettext** *()*

Return the entire text buffer.

Method: text-edit **move** *(rect)*

Specify a new position for the text-edit block in the document.

Method: text-edit **replace** *(str)*

Replace the text in the focus by the given string. The new focus is an insert point at the end of the string.

Method: text-edit **setfocus** *(i, j)*

Specify the new focus. Out-of-bounds values are silently clipped.

Method: text-edit **settext** *(str)*

Replace the entire text buffer by the given string and set the focus to `(0, 0)`.

Method: text-edit **setview** *(rect)*

Set the view rectangle to rect. If rect is `None`, viewing mode is reset. In viewing mode, all output from the text-edit object is clipped to the viewing rectangle. This may be useful to implement your own scrolling text subwindow.

Method: text-edit **close** *()*

Discard the text-edit object. It should not be used again.

Example

Here is a minimal example of using STDWIN in Python. It creates a window and draws the string "Hello world" in the top left corner of the window. The window will be correctly redrawn when covered and re-exposed. The program quits when the close icon or menu item is requested.

```
import stdwin
```

```
from stdwinevents import *

def main():
    mywin = stdwin.open('Hello')
    #
    while 1:
        (type, win, detail) = stdwin.getevent()
        if type == WE_DRAW:
            draw = win.begindrawing()
            draw.text((0, 0), 'Hello, world')
            del draw
        elif type == WE_CLOSE:
            break

main()
```

Standard Module `stdwinevents`

This module defines constants used by STDWIN for event types (`WE_ACTIVATE` etc.), command codes (`WC_LEFT` etc.) and selection types (`WS_PRIMARY` etc.). Read the file for details. Suggested usage is

```
>>> from stdwinevents import *
>>>
```

Standard Module `rect`

This module contains useful operations on rectangles. A rectangle is defined as in module `stdwin`: a pair of points, where a point is a pair of integers. For example, the rectangle

```
(10, 20), (90, 80)
```

is a rectangle whose left, top, right and bottom edges are 10, 20, 90 and 80, respectively. Note that the positive vertical axis points down (as in `stdwin`).

The module defines the following objects:

exception: module rect **error**

The exception raised by functions in this module when they detect an error. The exception argument is a string describing the problem in more detail.

data: module rect **empty**

The rectangle returned when some operations return an empty result. This makes it possible to quickly check whether a result is empty:

```
>>> import rect
>>> r1 = (10, 20), (90, 80)
>>> r2 = (0, 0), (10, 20)
>>> r3 = rect.intersect([r1, r2])
>>> if r3 is rect.empty: print 'Empty intersection'
Empty intersection
>>>
```

function of module rect: **is_empty** *(r)*

Returns true if the given rectangle is empty. A rectangle `(left, top), (right, bottom)` is empty if `left >= right` or `top => bottom`.

function of module rect: **intersect** *(list)*

Returns the intersection of all rectangles in the list argument. It may also be called with a tuple argument. Raises `rect.error` if the list is empty. Returns `rect.empty` if the intersection of the rectangles is empty.

function of module rect: **union** *(list)*

Returns the smallest rectangle that contains all non-empty rectangles in the list argument. It may also be called with a tuple argument or with two or more rectangles as arguments. Returns `rect.empty` if the list is empty or all its rectangles are empty.

function of module rect: **pointinrect** *(point, rect)*

Returns true if the point is inside the rectangle. By definition, a point `(h, v)` is inside a rectangle `(left, top), (right, bottom)` if `left <= h < right` and `top <= v < bottom`.

function of module rect: **inset** *(rect, (dh, dv))*

Returns a rectangle that lies inside the `rect` argument by dh pixels horizontally and dv pixels vertically. If dh or dv is negative, the result lies outside rect.

function of module rect: **rect2geom** *(rect)*

Converts a rectangle to geometry representation: `(left, top), (width, height)`.

function of module rect: **geom2rect** *(geom)*

Converts a rectangle given in geometry representation back to the standard rectangle representation `(left, top), (right, bottom)`.

Go to the previous, next section.

SGI IRIX Specific Services

The modules described in this chapter provide interfaces to features that are unique to SGI's IRIX operating system (versions 4 and 5).

Built-in Module `al`

This module provides access to the audio facilities of the SGI Indy and Indigo workstations. See section 3A of the IRIX man pages for details. You'll need to read those man pages to understand what these functions do! Some of the functions are not available in IRIX releases before 4.0.5. Again, see the manual to check whether a specific function is available on your platform.

All functions and methods defined in this module are equivalent to the C functions with `AL' prefixed to their name.

Symbolic constants from the C header file `` `<audio.h>' `` are defined in the standard module `AL`, see below.

Warning: the current version of the audio library may dump core when bad argument values are passed rather than returning an error status. Unfortunately, since the precise circumstances under which this may happen are undocumented and hard to check, the Python interface can provide no protection against this kind of problems. (One example is specifying an excessive queue size -- there is no documented upper limit.)

The module defines the following functions:

function of module al: **openport** *(name, direction[, config])*

The name and direction arguments are strings. The optional config argument is a configuration object as returned by `al.newconfig()`. The return value is an port object; methods of port objects are described below.

function of module al: **newconfig** *()*

The return value is a new configuration object; methods of configuration objects are described below.

function of module al: **queryparams** *(device)*

The device argument is an integer. The return value is a list of integers containing the data returned by ALqueryparams().

function of module al: **getparams** *(device, list)*

The device argument is an integer. The list argument is a list such as returned by `queryparams`; it is modified in place (!).

function of module al: **setparams** *(device, list)*

The device argument is an integer. The list argument is a list such as returned by `al.queryparams`.

Configuration Objects

Configuration objects (returned by `al.newconfig()` have the following methods:

Method: audio configuration object **getqueuesize** *()*

Return the queue size.

Method: audio configuration object **setqueuesize** *(size)*

Set the queue size.

Method: audio configuration object **getwidth** *()*

Get the sample width.

Method: audio configuration object **setwidth** *(width)*

Set the sample width.

Method: audio configuration object **getchannels** *()*

Get the channel count.

Method: audio configuration object **setchannels** *(nchannels)*

Set the channel count.

Method: audio configuration object **getsampfmt** *()*

Get the sample format.

Method: audio configuration object **setsampfmt** *(sampfmt)*

Set the sample format.

Method: audio configuration object **getfloatmax** *()*

Get the maximum value for floating sample formats.

Method: audio configuration object **setfloatmax** *(floatmax)*

Set the maximum value for floating sample formats.

Port Objects

Port objects (returned by `al.openport()` have the following methods:

Method: audio port object **closeport** *()*

Close the port.

Method: audio port object **getfd** *()*

Return the file descriptor as an int.

Method: audio port object **getfilled** *()*

Return the number of filled samples.

Method: audio port object **getfillable** *()*

Return the number of fillable samples.

Method: audio port object **readsamps** *(nsamples)*

Read a number of samples from the queue, blocking if necessary. Return the data as a string containing the raw data, (e.g., 2 bytes per sample in big-endian byte order (high byte, low byte) if you have set the sample width to 2 bytes).

Method: audio port object **writesamps** *(samples)*

Write samples into the queue, blocking if necessary. The samples are encoded as described for the `readsamps` return value.

Method: audio port object **getfillpoint** *()*

Return the `fill point'.

Method: audio port object **setfillpoint** *(fillpoint)*

Set the `fill point'.

Method: audio port object **getconfig** *()*

Return a configuration object containing the current configuration of the port.

Method: audio port object **setconfig** *(config)*

Set the configuration from the argument, a configuration object.

Method: audio port object **getstatus** *(list)*

Get status information on last error.

Standard Module AL

This module defines symbolic constants needed to use the built-in module `al` (see above); they are equivalent to those defined in the C header file `` `<audio.h>' `` except that the name prefix `AL_' is omitted. Read the module source for a complete list of the defined names. Suggested use:

```
import al
```

```
from AL import *
```

Built-in Module cd

This module provides an interface to the Silicon Graphics CD library. It is available only on Silicon Graphics systems.

The way the library works is as follows. A program opens the CD-ROM device with `cd.open()` and creates a parser to parse the data from the CD with `cd.createparser()`. The object returned by `cd.open()` can be used to read data from the CD, but also to get status information for the CD-ROM device, and to get information about the CD, such as the table of contents. Data from the CD is passed to the parser, which parses the frames, and calls any callback functions that have previously been added.

An audio CD is divided into tracks or programs (the terms are used interchangeably). Tracks can be subdivided into indices. An audio CD contains a table of contents which gives the starts of the tracks on the CD. Index 0 is usually the pause before the start of a track. The start of the track as given by the table of contents is normally the start of index 1.

Positions on a CD can be represented in two ways. Either a frame number or a tuple of three values, minutes, seconds and frames. Most functions use the latter representation. Positions can be both relative to the beginning of the CD, and to the beginning of the track.

Module `cd` defines the following functions and constants:

function of module cd: **createparser** *()*

Create and return an opaque parser object. The methods of the parser object are described below.

function of module cd: **msftoframe** *(min, sec, frame)*

Converts a `(minutes, seconds, frames)` triple representing time in absolute time code into the corresponding CD frame number.

function of module cd: **open** *([device[, mode]])*

Open the CD-ROM device. The return value is an opaque player object; methods of the player object are described below. The device is the name of the SCSI device file, e.g. /dev/scsi/sc0d4l0, or `None`. If omited or `None`, the hardware inventory is consulted to locate a CD-ROM drive. The `mode`, if not omited, should be the string 'r'.

The module defines the following variables:

data: module cd **error**

Exception raised on various errors.

data: module cd **DATASIZE**

The size of one frame's worth of audio data. This is the size of the audio data as passed to the callback of type `audio`.

data: module cd **BLOCKSIZE**

The size of one uninterpreted frame of audio data.

The following variables are states as returned by `getstatus`:

data: module cd **READY**

The drive is ready for operation loaded with an audio CD.

data: module cd **NODISC**

The drive does not have a CD loaded.

data: module cd **CDROM**

The drive is loaded with a CD-ROM. Subsequent play or read operations will return I/O errors.

data: module cd **ERROR**

An error aoocurred while trying to read the disc or its table of contents.

data: module cd **PLAYING**

The drive is in CD player mode playing an audio CD through its audio jacks.

data: module cd **PAUSED**

The drive is in CD layer mode with play paused.

data: module cd **STILL**

The equivalent of `PAUSED` on older (non 3301) model Toshiba CD-ROM drives. Such drives have never been shipped by SGI.

data: module cd **audio**

data: module cd **pnum**

data: module cd **index**

data: module cd **ptime**

data: module cd **atime**

data: module cd **catalog**

data: module cd **ident**

data: module cd **control**

Integer constants describing the various types of parser callbacks that can be set by the `addcallback()` method of CD parser objects (see below).

Player objects (returned by `cd.open()`) have the following methods:

Method: CD player object **allowremoval** *()*

Unlocks the eject button on the CD-ROM drive permitting the user to eject the caddy if desired.

Method: CD player object **bestreadsize** *()*

Returns the best value to use for the `num_frames` parameter of the `readda` method. Best is defined as the value that permits a continuous flow of data from the CD-ROM drive.

Method: CD player object **close** *()*

Frees the resources associated with the player object. After calling `close`, the methods of the object should no longer be used.

Method: CD player object **eject** *()*

Ejects the caddy from the CD-ROM drive.

Method: CD player object **getstatus** *()*

Returns information pertaining to the current state of the CD-ROM drive. The returned information is a tuple with the following values: `state`, `track`, `rtime`, `atime`, `ttime`, `first`, `last`, `scsi_audio`, `cur_block`. `rtime` is the time relative to the start of the current track; `atime` is the time relative to the beginning of the disc; `ttime` is the total time on the disc. For more information on the meaning of the values, see the manual for CDgetstatus. The value of `state` is one of the following: `cd.ERROR`, `cd.NODISC`, `cd.READY`, `cd.PLAYING`, `cd.PAUSED`, `cd.STILL`, or `cd.CDROM`.

Method: CD player object **gettrackinfo** *(track)*

Returns information about the specified track. The returned information is a tuple consisting of two elements, the start time of the track and the duration of the track.

Method: CD player object **msftoblock** *(min, sec, frame)*

Converts a minutes, seconds, frames triple representing a time in absolute time code into the corresponding logical block number for the given CD-ROM drive. You should use `cd.msftoframe()` rather than `msftoblock()` for comparing times. The logical block number differs from the frame number by an offset required by certain CD-ROM drives.

Method: CD player object **play** *(start, play)*

Starts playback of an audio CD in the CD-ROM drive at the specified track. The audio output appears on the CD-ROM drive's headphone and audio jacks (if fitted). Play stops at the end of the disc. `start` is the number of the track at which to start playing the CD; if `play` is 0, the CD will be set to an initial paused state. The method `togglepause()` can then be used to commence play.

Method: CD player object **playabs** *(min, sec, frame, play)*

Like `play()`, except that the start is given in minutes, seconds, frames instead of a track number.

Method: CD player object **playtrack** *(start, play)*

Like `play()`, except that playing stops at the end of the track.

Method: CD player object **playtrackabs** *(track, min, sec, frame, play)*

Like `play()`, except that playing begins at the spcified absolute time and ends at the end of the specified track.

Method: CD player object **preventremoval** *()*

Locks the eject button on the CD-ROM drive thus preventing the user from arbitrarily ejecting the caddy.

Method: CD player object **readda** *(num_frames)*

Reads the specified number of frames from an audio CD mounted in the CD-ROM drive. The return value is a string representing the audio frames. This string can be passed unaltered to the `parseframe` method of the parser object.

Method: CD player object **seek** *(min, sec, frame)*

Sets the pointer that indicates the starting point of the next read of digital audio data from a CD-ROM. The pointer is set to an absolute time code location specified in minutes, seconds, and frames. The return value is the logical block number to which the pointer has been set.

Method: CD player object **seekblock** *(block)*

Sets the pointer that indicates the starting point of the next read of digital audio data from a CD-ROM. The pointer is set to the specified logical block number. The return value is the logical block number to which the pointer has been set.

Method: CD player object **seektrack** *(track)*

Sets the pointer that indicates the starting point of the next read of digital audio data from a CD-ROM. The pointer is set to the specified track. The return value is the logical block number to which the pointer has been set.

Method: CD player object **stop** *()*

Stops the current playing operation.

Method: CD player object **togglepause** *()*

Pauses the CD if it is playing, and makes it play if it is paused.

Parser objects (returned by `cd.createparser()`) have the following methods:

Method: CD parser object **addcallback** *(type, func, arg)*

Adds a callback for the parser. The parser has callbacks for eight different types of data in the digital audio data stream. Constants for these types are defined at the `cd` module level (see above). The callback is called as follows: `func(arg, type, data)`, where `arg` is the user supplied argument, `type` is the particular type of callback, and `data` is the data returned for this `type` of callback. The type of the data depends on the `type` of callback as follows:

`cd.audio`:

The argument is a string which can be passed unmodified to `al.writesamps()`.

`cd.pnum`:

The argument is an integer giving the program (track) number.

`cd.index`:

The argument is an integer giving the index number.

`cd.ptime`:

The argument is a tuple consisting of the program time in minutes, seconds, and frames.

`cd.atime`:

The argument is a tuple consisting of the absolute time in minutes, seconds, and frames.

`cd.catalog`:

The argument is a string of 13 characters, giving the catalog number of the CD.

`cd.ident`:

The argument is a string of 12 characters, giving the ISRC identification number of the recording. The string consists of two characters country code, three characters owner code, two characters giving the year, and five characters giving a serial number.

`cd.control`:

The argument is an integer giving the control bits from the CD subcode data.

Method: CD parser object **deleteparser** *()*

Deletes the parser and frees the memory it was using. The object should not be used after this call. This call is done automatically when the last reference to the object is removed.

Method: CD parser object **parseframe** *(frame)*

Parses one or more frames of digital audio data from a CD such as returned by `readda`. It determines which subcodes are present in the data. If these subcodes have changed since the last frame, then `parseframe` executes a callback of the appropriate type passing to it the subcode data found in the frame. Unlike the C function, more than one frame of digital audio data can be passed to this method.

Method: CD parser object **removecallback** *(type)*

Removes the callback for the given `type`.

Method: CD parser object **resetparser** *()*

Resets the fields of the parser used for tracking subcodes to an initial state. `resetparser` should be called after the disc has been changed.

Built-in Module `fl`

This module provides an interface to the FORMS Library by Mark Overmars. The source for the library can be retrieved by anonymous ftp from host `ftp.cs.ruu.nl', directory `SGI/FORMS'. It was last tested with version 2.0b.

Most functions are literal translations of their C equivalents, dropping the initial `fl_' from their name. Constants used by the library are defined in module `FL` described below.

The creation of objects is a little different in Python than in C: instead of the `current form' maintained by the library to which new FORMS objects are added, all functions that add a FORMS object to a form are methods of the Python object representing the form. Consequently, there are no Python equivalents for the C functions `fl_addto_form` and `fl_end_form`, and the equivalent of `fl_bgn_form` is called `fl.make_form`.

Watch out for the somewhat confusing terminology: FORMS uses the word object for the buttons, sliders etc. that you can place in a form. In Python, `object' means any value. The Python interface to FORMS introduces two new Python object types: form objects (representing an entire form) and FORMS objects (representing one button, slider etc.). Hopefully this isn't too confusing...

There are no `free objects' in the Python interface to FORMS, nor is there an easy way to add object classes written in Python. The FORMS interface to GL event handling is available, though, so you can mix FORMS with pure GL windows.

Please note: importing `fl` implies a call to the GL function `foreground()` and to the FORMS routine `fl_init()`.

Functions Defined in Module `fl`

Module `fl` defines the following functions. For more information about what they do, see the description of the equivalent C function in the FORMS documentation:

function of module fl: **make_form** *(type, width, height)*

Create a form with given type, width and height. This returns a form object, whose methods are described below.

function of module fl: **do_forms** *()*

The standard FORMS main loop. Returns a Python object representing the FORMS object needing interaction, or the special value `FL.EVENT`.

function of module fl: **check_forms** *()*

Check for FORMS events. Returns what `do_forms` above returns, or `None` if there is no event that immediately needs interaction.

function of module fl: **set_event_call_back** *(function)*

Set the event callback function.

function of module fl: **set_graphics_mode** *(rgbmode, doublebuffering)*

Set the graphics modes.

function of module fl: **get_rgbmode** *()*

Return the current rgb mode. This is the value of the C global variable `fl_rgbmode`.

function of module fl: **show_message** *(str1, str2, str3)*

Show a dialog box with a three-line message and an OK button.

function of module fl: **show_question** *(str1, str2, str3)*

Show a dialog box with a three-line message and YES and NO buttons. It returns `1` if the user pressed YES, `0` if NO.

function of module fl: **show_choice** *(str1, str2, str3, but1[, but2, but3])*

Show a dialog box with a three-line message and up to three buttons. It returns the number of the button clicked by the user (`1`, `2` or `3`).

function of module fl: **show_input** *(prompt, default)*

Show a dialog box with a one-line prompt message and text field in which the user can enter a string. The second argument is the default input string. It returns the string value as edited by the user.

function of module fl: **show_file_selector** *(message, directory, pattern, default)*

Show a dialog box in which the user can select a file. It returns the absolute filename selected by the user, or `None` if the user presses Cancel.

function of module fl: **get_directory** *()*

function of module fl: **get_pattern** *()*

function of module fl: **get_filename** *()*

These functions return the directory, pattern and filename (the tail part only) selected by the user in the last `show_file_selector` call.

function of module fl: **qdevice** *(dev)*

function of module fl: **unqdevice** *(dev)*

function of module fl: **isqueued** *(dev)*

function of module fl: **qtest** *()*

function of module fl: **qread** *()*

function of module fl: **qreset** *()*

function of module fl: **qenter** *(dev, val)*

function of module fl: **get_mouse** *()*

function of module fl: **tie** *(button, valuator1, valuator2)*

These functions are the FORMS interfaces to the corresponding GL functions. Use these if you want to

handle some GL events yourself when using `fl.do_events`. When a GL event is detected that FORMS cannot handle, `fl.do_forms()` returns the special value `FL.EVENT` and you should cal `fl.qread()` to read the event from the queue. Don't use the equivalent GL functions!

function of module fl: **color** *()*

function of module fl: **mapcolor** *()*

function of module fl: **getmcolor** *()*

See the description in the FORMS documentation of `fl_color`, `fl_mapcolor` and `fl_getmcolor`.

Form Objects

Form objects (returned by `fl.make_form()` above) have the following methods. Each method corresponds to a C function whose name is prefixed with `fl_'; and whose first argument is a form pointer; please refer to the official FORMS documentation for descriptions.

All the `add_...' functions return a Python object representing the FORMS object. Methods of FORMS objects are described below. Most kinds of FORMS object also have some methods specific to that kind; these methods are listed here.

Method: form object **show_form** *(placement, bordertype, name)*

Show the form.

Method: form object **hide_form** *()*

Hide the form.

Method: form object **redraw_form** *()*

Redraw the form.

Method: form object **set_form_position** *(x, y)*

Set the form's position.

Method: form object **freeze_form** *()*

Freeze the form.

Method: form object **unfreeze_form** *()*

Unfreeze the form.

Method: form object **activate_form** *()*

Activate the form.

Method: form object **deactivate_form** *()*

Deactivate the form.

Method: form object **bgn_group** *()*

Begin a new group of objects; return a group object.

Method: form object **end_group** *()*

End the current group of objects.

Method: form object **find_first** *()*

Find the first object in the form.

Method: form object **find_last** *()*

Find the last object in the form.

Method: form object **add_box** *(type, x, y, w, h, name)*

Add a box object to the form. No extra methods.

Method: form object **add_text** *(type, x, y, w, h, name)*

Add a text object to the form. No extra methods.

Method: form object **add_clock** *(type, x, y, w, h, name)*

Add a clock object to the form.
Method: `get_clock`.

Method: form object **add_button** *(type, x, y, w, h, name)*

Add a button object to the form.
Methods: `get_button`, `set_button`.

Method: form object **add_lightbutton** *(type, x, y, w, h, name)*

Add a lightbutton object to the form.
Methods: `get_button`, `set_button`.

Method: form object **add_roundbutton** *(type, x, y, w, h, name)*

Add a roundbutton object to the form.
Methods: `get_button`, `set_button`.

Method: form object **add_slider** *(type, x, y, w, h, name)*

Add a slider object to the form.
Methods: `set_slider_value`, `get_slider_value`, `set_slider_bounds`, `get_slider_bounds`, `set_slider_return`, `set_slider_size`, `set_slider_precision`, `set_slider_step`.

Method: form object **add_valslider** *(type, x, y, w, h, name)*

Add a valslider object to the form.
Methods: `set_slider_value`, `get_slider_value`, `set_slider_bounds`, `get_slider_bounds`, `set_slider_return`, `set_slider_size`, `set_slider_precision`, `set_slider_step`.

Method: form object **add_dial** *(type, x, y, w, h, name)*

Add a dial object to the form.
Methods: `set_dial_value`, `get_dial_value`, `set_dial_bounds`, `get_dial_bounds`.

Method: form object **add_positioner** *(type, x, y, w, h, name)*

Add a positioner object to the form.
Methods: `set_positioner_xvalue`, `set_positioner_yvalue`, `set_positioner_xbounds`, `set_positioner_ybounds`, `get_positioner_xvalue`, `get_positioner_yvalue`, `get_positioner_xbounds`, `get_positioner_ybounds`.

Method: form object **add_counter** *(type, x, y, w, h, name)*

Add a counter object to the form.
Methods: `set_counter_value`, `get_counter_value`, `set_counter_bounds`, `set_counter_step`, `set_counter_precision`, `set_counter_return`.

Method: form object **add_input** *(type, x, y, w, h, name)*

Add a input object to the form.
Methods: `set_input`, `get_input`, `set_input_color`, `set_input_return`.

Method: form object **add_menu** *(type, x, y, w, h, name)*

Add a menu object to the form.
Methods: `set_menu`, `get_menu`, `addto_menu`.

Method: form object **add_choice** *(type, x, y, w, h, name)*

Add a choice object to the form.
Methods: `set_choice`, `get_choice`, `clear_choice`, `addto_choice`, `replace_choice`, `delete_choice`, `get_choice_text`, `set_choice_fontsize`, `set_choice_fontstyle`.

Method: form object **add_browser** *(type, x, y, w, h, name)*

Add a browser object to the form.
Methods: `set_browser_topline`, `clear_browser`, `add_browser_line`, `addto_browser`, `insert_browser_line`, `delete_browser_line`, `replace_browser_line`, `get_browser_line`, `load_browser`, `get_browser_maxline`, `select_browser_line`, `deselect_browser_line`, `deselect_browser`, `isselected_browser_line`, `get_browser`, `set_browser_fontsize`, `set_browser_fontstyle`, `set_browser_specialkey`.

Method: form object **add_timer** *(type, x, y, w, h, name)*

Add a timer object to the form.
Methods: `set_timer`, `get_timer`.

Form objects have the following data attributes; see the FORMS documentation:

Name

Type -- *Meaning*

`window`

int (read-only) -- GL window id

`w`

float -- form width

`h`

float -- form height

`x`

float -- form x origin

`y`

float -- form y origin

`deactivated`

int -- nonzero if form is deactivated

`visible`

int -- nonzero if form is visible

`frozen`

int -- nonzero if form is frozen

`doublebuf`

int -- nonzero if double buffering on

FORMS Objects

Besides methods specific to particular kinds of FORMS objects, all FORMS objects also have the following methods:

Method: FORMS object **set_call_back** *(function, argument)*

Set the object's callback function and argument. When the object needs interaction, the callback function will be called with two arguments: the object, and the callback argument. (FORMS objects without a callback function are returned by `fl.do_forms()` or `fl.check_forms()` when they need interaction.) Call this method without arguments to remove the callback function.

Method: FORMS object **delete_object** *()*

Delete the object.

Method: FORMS object **show_object** *()*

Show the object.

Method: FORMS object **hide_object** *()*

Hide the object.

Method: FORMS object **redraw_object** *()*

Redraw the object.

Method: FORMS object **freeze_object** *()*

Freeze the object.

Method: FORMS object **unfreeze_object** *()*

Unfreeze the object.

FORMS objects have these data attributes; see the FORMS documentation:

Name

Type -- *Meaning*

`objclass`

int (read-only) -- object class

`type`

int (read-only) -- object type

`boxtype`

int -- box type

`x`

float -- x origin

`y`

float -- y origin

`w`

float -- width

`h`

float -- height

`col1`

int -- primary color

`col2`

int -- secondary color

`align`

int -- alignment

`lcol`

int -- label color

`lsize`
: float -- label font size

`label`
: string -- label string

`lstyle`
: int -- label style

`pushed`
: int (read-only) -- (see FORMS docs)

`focus`
: int (read-only) -- (see FORMS docs)

`belowmouse`
: int (read-only) -- (see FORMS docs)

`frozen`
: int (read-only) -- (see FORMS docs)

`active`
: int (read-only) -- (see FORMS docs)

`input`
: int (read-only) -- (see FORMS docs)

`visible`
: int (read-only) -- (see FORMS docs)

`radio`
: int (read-only) -- (see FORMS docs)

`automatic`
: int (read-only) -- (see FORMS docs)

Standard Module `FL`

This module defines symbolic constants needed to use the built-in module `fl` (see above); they are equivalent to those defined in the C header file `` `<forms.h>' `` except that the name prefix `FL_' is omitted. Read the module source for a complete list of the defined names. Suggested use:

```
import fl
from FL import *
```

Standard Module `flp`

This module defines functions that can read form definitions created by the `form designer' (`fdesign`) program that comes with the FORMS library (see module `fl` above).

For now, see the file `` `flp.doc' `` in the Python library source directory for a description.

XXX A complete description should be inserted here!

Built-in Module `fm`

This module provides access to the IRIS *Font Manager* library. It is available only on Silicon Graphics machines. See also: 4Sight User's Guide, Section 1, Chapter 5: Using the IRIS Font Manager.

This is not yet a full interface to the IRIS Font Manager. Among the unsupported features are: matrix operations; cache operations; character operations (use string operations instead); some details of font info; individual glyph metrics; and printer matching.

It supports the following operations:

function of module fm: **init** *()*

Initialization function. Calls `fminit()`. It is normally not necessary to call this function, since it is called automatically the first time the `fm` module is imported.

function of module fm: **findfont** *(fontname)*

Return a font handle object. Calls `fmfindfont(fontname)`.

function of module fm: **enumerate** *()*

Returns a list of available font names. This is an interface to `fmenumerate()`.

function of module fm: **prstr** *(string)*

Render a string using the current font (see the `setfont()` font handle method below). Calls `fmprstr(string)`.

function of module fm: **setpath** *(string)*

Sets the font search path. Calls `fmsetpath(string)`. (XXX Does not work!?!)

function of module fm: **fontpath** *()*

Returns the current font search path.

Font handle objects support the following operations:

Method: font handle **scalefont** *(factor)*

Returns a handle for a scaled version of this font. Calls `fmscalefont(fh, factor)`.

Method: font handle **setfont** *()*

Makes this font the current font. Note: the effect is undone silently when the font handle object is deleted. Calls `fmsetfont(fh)`.

Method: font handle **getfontname** *()*

Returns this font's name. Calls `fmgetfontname(fh)`.

Method: font handle **getcomment** *()*

Returns the comment string associated with this font. Raises an exception if there is none. Calls `fmgetcomment(fh)`.

Method: font handle **getfontinfo** *()*

Returns a tuple giving some pertinent data about this font. This is an interface to `fmgetfontinfo()`. The returned tuple contains the following numbers: `(printermatched, fixed_width, xorig, yorig, xsize, ysize, height, nglyphs)`.

Method: font handle **getstrwidth** *(string)*

Returns the width, in pixels, of the string when drawn in this font. Calls `fmgetstrwidth(fh, string)`.

Built-in Module `gl`

This module provides access to the Silicon Graphics *Graphics Library*. It is available only on Silicon Graphics machines.

Warning: Some illegal calls to the GL library cause the Python interpreter to dump core. In particular, the use of most GL calls is unsafe before the first window is opened.

The module is too large to document here in its entirety, but the following should help you to get started. The parameter conventions for the C functions are translated to Python as follows:

- All (short, long, unsigned) int values are represented by Python integers.
- All float and double values are represented by Python floating point numbers. In most cases, Python integers are also allowed.
- All arrays are represented by one-dimensional Python lists. In most cases, tuples are also allowed.
- All string and character arguments are represented by Python strings, for instance, `winopen('Hi There!')` and `rotate(900, 'z')`.
- All (short, long, unsigned) integer arguments or return values that are only used to specify the length of an array argument are omitted. For example, the C call

  ```
  lmdef(deftype, index, np, props)
  ```

  is translated to Python as

```
lmdef(deftype, index, props)
```

- Output arguments are omitted from the argument list; they are transmitted as function return values instead. If more than one value must be returned, the return value is a tuple. If the C function has both a regular return value (that is not omitted because of the previous rule) and an output argument, the return value comes first in the tuple. Examples: the C call

  ```
  getmcolor(i, &red, &green, &blue)
  ```

  is translated to Python as

  ```
  red, green, blue = getmcolor(i)
  ```

The following functions are non-standard or have special argument conventions:

function of module gl: **varray** *(argument)*

Equivalent to but faster than a number of `v3d()` calls. The argument is a list (or tuple) of points. Each point must be a tuple of coordinates `(x, y, z)` or `(x, y)`. The points may be 2- or 3-dimensional but must all have the same dimension. Float and int values may be mixed however. The points are always converted to 3D double precision points by assuming `z = 0.0` if necessary (as indicated in the man page), and for each point `v3d()` is called.

function of module gl: **nvarray** *()*

Equivalent to but faster than a number of `n3f` and `v3f` calls. The argument is an array (list or tuple) of pairs of normals and points. Each pair is a tuple of a point and a normal for that point. Each point or normal must be a tuple of coordinates `(x, y, z)`. Three coordinates must be given. Float and int values may be mixed. For each pair, `n3f()` is called for the normal, and then `v3f()` is called for the point.

function of module gl: **vnarray** *()*

Similar to `nvarray()` but the pairs have the point first and the normal second.

function of module gl: **nurbssurface** *(s_k, t_k, ctl, s_ord, t_ord, type)*

Defines a nurbs surface. The dimensions of `ctl[][]` are computed as follows: `[len(s_k) - s_ord]`, `[len(t_k) - t_ord]`.

function of module gl: **nurbscurve** *(knots, ctlpoints, order, type)*

Defines a nurbs curve. The length of ctlpoints is `len(knots) - order`.

function of module gl: **pwlcurve** *(points, type)*

Defines a piecewise-linear curve. points is a list of points. type must be `N_ST`.

function of module gl: **pick** *(n)*

function of module gl: **select** *(n)*

The only argument to these functions specifies the desired size of the pick or select buffer.

function of module gl: **endpick** *()*

function of module gl: **endselect** *()*

These functions have no arguments. They return a list of integers representing the used part of the pick/select buffer. No method is provided to detect buffer overrun.

Here is a tiny but complete example GL program in Python:

```
import gl, GL, time

def main():
    gl.foreground()
    gl.prefposition(500, 900, 500, 900)
    w = gl.winopen('CrissCross')
    gl.ortho2(0.0, 400.0, 0.0, 400.0)
    gl.color(GL.WHITE)
    gl.clear()
    gl.color(GL.RED)
    gl.bgnline()
    gl.v2f(0.0, 0.0)
    gl.v2f(400.0, 400.0)
    gl.endline()
    gl.bgnline()
    gl.v2f(400.0, 0.0)
    gl.v2f(0.0, 400.0)
    gl.endline()
    time.sleep(5)

main()
```

Standard Modules `GL` and `DEVICE`

These modules define the constants used by the Silicon Graphics *Graphics Library* that C programmers find in the header files `` `<gl/gl.h>' `` and `` `<gl/device.h>' ``. Read the module source files for details.

Built-in Module `imgfile`

The imgfile module allows python programs to access SGI imglib image files (also known as `` `.rgb' `` files). The module is far from complete, but is provided anyway since the functionality that there is is enough in some cases. Currently, colormap files are not supported.

The module defines the following variables and functions:

exception: module imgfile **error**

This exception is raised on all errors, such as unsupported file type, etc.

function of module imgfile: **getsizes** *(file)*

This function returns a tuple `(x, y, z)` where x and y are the size of the image in pixels and z is the number of bytes per pixel. Only 3 byte RGB pixels and 1 byte greyscale pixels are currently supported.

function of module imgfile: **read** *(file)*

This function reads and decodes the image on the specified file, and returns it as a python string. The string has either 1 byte greyscale pixels or 4 byte RGBA pixels. The bottom left pixel is the first in the string. This format is suitable to pass to `gl.lrectwrite`, for instance.

function of module imgfile: **readscaled** *(file, x, y, filter[, blur])*

This function is identical to read but it returns an image that is scaled to the given x and y sizes. If the filter and blur parameters are omitted scaling is done by simply dropping or duplicating pixels, so the result will be less than perfect, especially for computer-generated images.

Alternatively, you can specify a filter to use to smoothen the image after scaling. The filter forms supported are `'impulse'`, `'box'`, `'triangle'`, `'quadratic'` and `'gaussian'`. If a filter is specified blur is an optional parameter specifying the blurriness of the filter. It defaults to `1.0`.

`readscaled` makes no attempt to keep the aspect ratio correct, so that is the users' responsibility.

function of module imgfile: **ttob** *(flag)*

This function sets a global flag which defines whether the scan lines of the image are read or written from bottom to top (flag is zero, compatible with SGI GL) or from top to bottom(flag is one, compatible with X). The default is zero.

function of module imgfile: **write** *(file, data, x, y, z)*

This function writes the RGB or greyscale data in data to image file file. x and y give the size of the image, z is 1 for 1 byte greyscale images or 3 for RGB images (which are stored as 4 byte values of which only the lower three bytes are used). These are the formats returned by `gl.lrectread`.

SunOS Specific Services

The modules described in this chapter provide interfaces to features that are unique to the SunOS operating system (versions 4 and 5; the latter is also known as Solaris version 2).

Built-in Module sunaudiodev

This module allows you to access the sun audio interface. The sun audio hardware is capable of recording and playing back audio data in U-LAW format with a sample rate of 8K per second. A full description can be gotten with `man audio'.

The module defines the following variables and functions:

exception: module sunaudiodev **error**

This exception is raised on all errors. The argument is a string describing what went wrong.

function of module sunaudiodev: **open** *(mode)*

This function opens the audio device and returns a sun audio device object. This object can then be used to do I/O on. The mode parameter is one of `'r'` for record-only access, `'w'` for play-only access, `'rw'` for both and `'control'` for access to the control device. Since only one process is allowed to have the recorder or player open at the same time it is a good idea to open the device only for the activity needed. See the audio manpage for details.

Audio Device Objects

The audio device objects are returned by `open` define the following methods (except `control` objects which only provide getinfo, setinfo and drain):

Method: audio device **close** *()*

This method explicitly closes the device. It is useful in situations where deleting the object does not immediately close it since there are other references to it. A closed device should not be used again.

Method: audio device **drain** *()*

This method waits until all pending output is processed and then returns. Calling this method is often not necessary: destroying the object will automatically close the audio device and this will do an implicit drain.

Method: audio device **flush** *()*

This method discards all pending output. It can be used avoid the slow response to a user's stop request (due to buffering of up to one second of sound).

Method: audio device **getinfo** *()*

This method retrieves status information like input and output volume, etc. and returns it in the form of an audio status object. This object has no methods but it contains a number of attributes describing the current device status. The names and meanings of the attributes are described in `/usr/include/sun/audioio.h' and in the audio man page. Member names are slightly different from their C counterparts: a status object is only a single structure. Members of the `play` substructure have `o_' prepended to their name and members of the `record` structure have `i_'. So, the C member `play.sample_rate` is accessed as `o_sample_rate`, `record.gain` as `i_gain` and `monitor_gain` plainly as `monitor_gain`.

Method: audio device **ibufcount** *()*

This method returns the number of samples that are buffered on the recording side, i.e. the program will not block on a `read` call of so many samples.

Method: audio device **obufcount** *()*

This method returns the number of samples buffered on the playback side. Unfortunately, this number cannot be used to determine a number of samples that can be written without blocking since the kernel output queue length seems to be variable.

Method: audio device **read** *(size)*

This method reads size samples from the audio input and returns them as a python string. The function blocks until enough data is available.

Method: audio device **setinfo** *(status)*

This method sets the audio device status parameters. The status parameter is an device status object as returned by `getinfo` and possibly modified by the program.

Method: audio device **write** *(samples)*

Write is passed a python string containing audio samples to be played. If there is enough buffer space free it will immediately return, otherwise it will block.

There is a companion module, `SUNAUDIODEV`, which defines useful symbolic constants like `MIN_GAIN`, `MAX_GAIN`, `SPEAKER`, etc. The names of the constants are the same names as used in the C include file `<sun/audioio.h>', with the leading string `AUDIO_' stripped.

Useability of the control device is limited at the moment, since there is no way to use the "wait for something to happen" feature the device provides.

Python library reference

(1)

Most descriptions sorely lack explanations of the exceptions that may be raised -- this will be fixed in a future version of this manual.

(2)

As a consequence, the list `[1, 2]` is considered equal to `[1.0, 2.0]`, and similar for tuples.

(3)

They must have since the parser can't tell the type of the operands.

(4)

A tuple object in this case should be a singleton.

(5)

These numbers are fairly arbitrary. They are intended to avoid printing endless strings of meaningless digits without hampering correct use and without having to know the exact precision of floating point values on a particular machine.

(6)

The advantage of leaving the newline on is that an empty string can be returned to mean EOF without being ambiguous. Another advantage is that (in cases where it might matter, e.g. if you want to make an exact copy of a file while scanning its lines) you can tell whether the last line of a file ended in a newline or not (yes this happens!).

(7)

It is used relatively rarely so does not warrant being made into a statement.

(8)

This is ugly -- the language definition should require truncation towards zero.

(9)

Specifying a buffer size currently has no effect on systems that don't have `setvbuf()`. The interface to specify the buffer size is not done using a method that calls `setvbuf()`, because that may dump core when called after any I/O has been performed, and there's no reliable way to determine whether this is the case.

(10)

In the current implementation, local variable bindings cannot normally be affected this way, but variables retrieved from other scopes (e.g. modules) can be. This may change.

(11)

The name of this module stems from a bit of terminology used by the designers of Modula-3 (amongst others), who use the term "marshalling" for shipping of data around in a self-contained form. Strictly speaking, "to marshal" means to convert some data from internal to external form (in an RPC buffer for instance) and "unmarshalling" for the reverse process.

(12)

A solution would be to refuse such literals in the parser, since they are inherently non-portable. Another solution would be to let the `marshal` module raise an exception when an integer value would be truncated. At least one of these solutions will be implemented in a future version.

(13)

The problem with automatically passing on `environ` is that there is no portable way of changing the environment.

(14)

Updated and converted to LaTeX by Guido van Rossum. The references to the old profiler are left in the text, although it no longer exists.

(15)

This was once necessary, when Python would print any unused expression result that was not `None`. The method is still defined for backward compatibility.

(16)

The Python version of STDWIN does not support draw procedures; all drawing requests are reported as draw events.

GNU Readline Library

Edition 2.0, for `Readline Library` Version 2.0.

July 1994

Brian Fox, Free Software Foundation Chet Ramey, Case Western Reserve University

Go to the next section.

This document describes the GNU Readline Library, a utility which aids in the consistency of user interface across discrete programs that need to provide a command line interface.

Published by the Free Software Foundation

Cambridge, MA 02139 USA

Command Line Editing

This chapter describes the basic features of the GNU command line editing interface.

Introduction to Line Editing

The following paragraphs describe the notation used to represent keystrokes.

The text C-k is read as `Control-K' and describes the character produced when the Control key is depressed and the k key is struck.

The text M-k is read as `Meta-K' and describes the character produced when the meta key (if you have one) is depressed, and the k key is struck. If you do not have a meta key, the identical keystroke can be generated by typing ESC *first*, and then typing k. Either process is known as metafying the k key.

The text M-C-k is read as `Meta-Control-k' and describes the character produced by metafying C-k.

In addition, several keys have their own names. Specifically, DEL, ESC, LFD, SPC, RET, and TAB all stand for themselves when seen in this text, or in an init file (see section Readline Init File, for more info).

Readline Interaction

Often during an interactive session you type in a long line of text, only to notice that the first word on the line is misspelled. The Readline library gives you a set of commands for manipulating the text as you type it in, allowing you to just fix your typo, and not forcing you to retype the majority of the line. Using these editing commands, you move the cursor to the place that needs correction, and delete or insert the text of the corrections. Then, when you are satisfied with the line, you simply press RETURN. You do not have to be at the end of the line to press RETURN; the entire line is accepted regardless of the location of the cursor within the line.

Readline Bare Essentials

In order to enter characters into the line, simply type them. The typed character appears where the cursor was, and then the cursor moves one space to the right. If you mistype a character, you can use your erase character to back up and delete the mistyped character.

Sometimes you may miss typing a character that you wanted to type, and not notice your error until you have typed several other characters. In that case, you can type C-b to move the cursor to the left, and then correct your mistake. Afterwards, you can move the cursor to the right with C-f.

When you add text in the middle of a line, you will notice that characters to the right of the cursor are `pushed over' to make room for the text that you have inserted. Likewise, when you delete text behind the cursor, characters to the right of the cursor are `pulled back' to fill in the blank space created by the removal of the text. A list of the basic bare essentials for editing the text of an input line follows.

C-b
: Move back one character.

C-f
: Move forward one character.

DEL
: Delete the character to the left of the cursor.

C-d
: Delete the character underneath the cursor.

Printing characters
: Insert the character into the line at the cursor.

C-_
: Undo the last thing that you did. You can undo all the way back to an empty line.

Readline Movement Commands

The above table describes the most basic possible keystrokes that you need in order to do editing of the input line. For your convenience, many other commands have been added in addition to C-b, C-f, C-d, and DEL. Here are some commands for moving more rapidly about the line.

C-a

Move to the start of the line.

C-e

Move to the end of the line.

M-f

Move forward a word.

M-b

Move backward a word.

C-l

Clear the screen, reprinting the current line at the top.

Notice how C-f moves forward a character, while M-f moves forward a word. It is a loose convention that control keystrokes operate on characters while meta keystrokes operate on words.

Readline Killing Commands

Killing text means to delete the text from the line, but to save it away for later use, usually by yanking (re-inserting) it back into the line. If the description for a command says that it `kills' text, then you can be sure that you can get the text back in a different (or the same) place later.

When you use a kill command, the text is saved in a kill-ring. Any number of consecutive kills save all of the killed text together, so that when you yank it back, you get it all. The kill ring is not line specific; the text that you killed on a previously typed line is available to be yanked back later, when you are typing another line.

Here is the list of commands for killing text.

C-k

Kill the text from the current cursor position to the end of the line.

M-d

Kill from the cursor to the end of the current word, or if between words, to the end of the next word.

M-DEL

Kill from the cursor the start of the previous word, or if between words, to the start of the previous word.

C-w

Kill from the cursor to the previous whitespace. This is different than M-DEL because the word boundaries differ.

And, here is how to yank the text back into the line. Yanking means to copy the most-recently-killed text from the kill buffer.

C-y

Yank the most recently killed text back into the buffer at the cursor.

M-y

Rotate the kill-ring, and yank the new top. You can only do this if the prior command is C-y or M-y.

Readline Arguments

You can pass numeric arguments to Readline commands. Sometimes the argument acts as a repeat count, other times it is the *sign* of the argument that is significant. If you pass a negative argument to a command which normally acts in a forward direction, that command will act in a backward direction. For example, to kill text back to the start of the line, you might type M-- C-k.

The general way to pass numeric arguments to a command is to type meta digits before the command. If the first `digit' you type is a minus sign (-), then the sign of the argument will be negative. Once you have typed one meta digit to get the argument started, you can type the remainder of the digits, and then the command. For example, to give the C-d command an argument of 10, you could type M-1 0 C-d.

Readline Init File

Although the Readline library comes with a set of Emacs-like keybindings installed by default, it is possible that you would like to use a different set of keybindings. You can customize programs that use Readline by putting commands in an init file in your home directory. The name of this file is taken from the value of the environment variable `INPUTRC`. If that variable is unset, the default is `` `~/.inputrc' ``.

When a program which uses the Readline library starts up, the init file is read, and the key bindings are set.

In addition, the `C-x C-r` command re-reads this init file, thus incorporating any changes that you might have made to it.

Readline Init Syntax

There are only a few basic constructs allowed in the Readline init file. Blank lines are ignored. Lines beginning with a # are comments. Lines beginning with a $ indicate conditional constructs (see section Conditional Init Constructs). Other lines denote variable settings and key bindings.

Variable Settings

You can change the state of a few variables in Readline by using the `set` command within the init file. Here is how you would specify that you wish to use `vi` line editing commands:

```
set editing-mode vi
```

Right now, there are only a few variables which can be set; so few, in fact, that we just list them here:

`editing-mode`

The `editing-mode` variable controls which editing mode you are using. By default, Readline starts up in Emacs editing mode, where the keystrokes are most similar to Ema This variable can be set to either `emacs` or `vi`.

`horizontal-scroll-mode`

This variable can be set to either `On` or `Off`. Setting it to `On` means that the text of the lines that you edit will scroll horizontally on a single screen line when they are longer than the width of the screen, instead of wrapping onto a new screen line. By default, this variable is set to `Off`.

`mark-modified-lines`

This variable, when set to `On`, says to display an asterisk (`*') at the start of history lines which have been modified. This variable is `off` by default.

`bell-style`

Controls what happens when Readline wants to ring the terminal bell. If set to `none`, Readline never rings the bell. If set to `visible`, Readline uses a visible bell if one is available. If set to `audible` (the default), Readline attempts to ring the terminal's bell.

`comment-begin`

The string to insert at the beginning of the line when the `vi-comment` command is executed. The default value is `"#"`.

`meta-flag`

If set to `on`, Readline will enable eight-bit input (it will not strip the eighth bit from the characters it reads), regardless of what the terminal claims it can support. The default value is `off`.

`convert-meta`

If set to `on`, Readline will convert characters with the eigth bit set to an ASCII key sequence by stripping the eigth bit and prepending an ESC character, converting them to a meta-prefixed key sequence. The default value is `on`.

`output-meta`

If set to `on`, Readline will display characters with the eighth bit set directly rather than as a meta-prefixed escape sequence. The default is `off`.

`completion-query-items`

The number of possible completions that determines when the user is asked whether he wants to see the list of possibilities. If the number of possible completions is greater than this value, Readline will ask the user whether or not he wishes to view them; otherwise, they are simply listed. The default limit is `100`.

`keymap`

Sets Readline's idea of the current keymap for key binding commands. Acceptable `keymap` names are `emacs`, `emacs-standard`, `emacs-meta`, `emacs-ctlx`, `vi`, `vi-move`, `vi-command`, and `vi-insert`. `vi` is equivalent to `vi-command`; `emacs` is equivalent to `emacs-standard`. The default value is `emacs`. The value of the `editing-mode` variable also affects the default keymap.

`show-all-if-ambiguous`

This alters the default behavior of the completion functions. If set to `on`, words which h more than one possible completion cause the matches to be listed immediately instead o ringing the bell. The default value is `off`.

`expand-tilde`

If set to `on`, tilde expansion is performed when Readline attempts word completion. The default is `off`.

- Key Bindings The syntax for controlling key bindings in the init file is simple. First you have to know the name of the command that you want to change. The following pages contain tables of the command name, the default keybinding, and a short description of what the command does.

Once you know the name of the command, simply place the name of the key you wish to bind the command to, a colon, and then the name of the command on a line in the init file. The name of the key can be expressed in different ways, depending on which is most comfortable for you.

keyname: function-name or macro

keyname is the name of a key spelled out in English. For example:

```
Control-u: universal-argument
Meta-Rubout: backward-kill-word
Control-o: ">&output"
```

In the above example, `C-u' is bound to the function `universal-argument`, and `C-o' is bound to run the macro expressed on the right hand side (that is, to insert the text `>&output' into the line).

"keyseq": function-name or macro

keyseq differs from keyname above in that strings denoting an entire key sequence can be specified, by placing the key sequence in double quotes. Some GNU Emacs style key escapes can be used, as in the following example, but the special character names are not recognized.

```
"\C-u": universal-argument
"\C-x\C-r": re-read-init-file
"\e[11~": "Function Key 1"
```

In the above example, `C-u' is bound to the function `universal-argument` (just as it was in the first example), `C-x C-r' is bound to the function `re-read-init-file`, and `ESC [ 1 1 ~' is bound to insert the text `Function Key 1'. The following escape sequences are available when specifying key sequences:

`\C-`

control prefix

`\M-`

meta prefix

`\e`

an escape character

`\\`
: backslash

`\"`
: "

`\'`
: '

When entering the text of a macro, single or double quotes should be used to indicate a macro definition. Unquoted text is assumed to be a function name. Backslash will quote any character in the macro text, including " and '. For example, the following binding will make C-x \ insert a single \ into the line:

```
"\C-x\\": "\\"
```

Conditional Init Constructs

Readline implements a facility similar in spirit to the conditional compilation features of the C preprocessor which allows key bindings and variable settings to be performed as the result of tests. There are three parser directives used.

`$if`
: The `$if` construct allows bindings to be made based on the editing mode, the terminal being used, or the application using Readline. The text of the test extends to the end of the line; no characters are required to isolate it.

  `mode`
  : The `mode=` form of the `$if` directive is used to test whether Readline is in `emacs` or `vi` mode. This may be used in conjunction with the `set keymap' command, for instance, to set bindings in the `emacs-standard` and `emacs-ctlx` keymaps only if Readline is starting out in `emacs` mode.

  `term`
  : The `term=` form may be used to include terminal-specific key bindings, perhaps to bind the key sequences output by the terminal's function keys. The word on the right side of the `=' is tested against the full name of the terminal and the portion of the terminal name before the first `-'. This allows sun to match both sun and sun-cmd, for instance.

  `application`
  : The application construct is used to include application-specific settings. Each program using the Readline library sets the application name, and you can test for it. This could be used to bind key sequences to functions useful for a specific program. For instance, the following command adds a key sequence that quotes the current or previous word in Bash:

```
$if bash
# Quote the current or previous word
"\C-xq": "\eb\"\ef\""
```

```
$endif
```

- $endif This command, as you saw in the previous example, terminates an `$if` command.
- $else Commands in this branch of the `$if` directive are executed if the test fails.

Bindable Readline Commands

Commands For Moving

`beginning-of-line (C-a)`
Move to the start of the current line.

`end-of-line (C-e)`
Move to the end of the line.

`forward-char (C-f)`
Move forward a character.

`backward-char (C-b)`
Move back a character.

`forward-word (M-f)`
Move forward to the end of the next word. Words are composed of letters and digits.

`backward-word (M-b)`
Move back to the start of this, or the previous, word. Words are composed of letters and digits.

`clear-screen (C-l)`
Clear the screen and redraw the current line, leaving the current line at the top of the screen.

`redraw-current-line ()`
Refresh the current line. By default, this is unbound.

Commands For Manipulating The History

`accept-line (Newline, Return)`
Accept the line regardless of where the cursor is. If this line is non-empty, add it to the history list. If this line was a history line, then restore the history line to its original state.

`previous-history (C-p)`
Move `up' through the history list.

`next-history (C-n)`
Move `down' through the history list.

`beginning-of-history (M-<)`
Move to the first line in the history.

`end-of-history (M->)`
Move to the end of the input history, i.e., the line you are entering.

`reverse-search-history (C-r)`

Search backward starting at the current line and moving `up' through the history as necessary. This is an incremental search.

`forward-search-history (C-s)`

Search forward starting at the current line and moving `down' through the the history as necessary. This is an incremental search.

`non-incremental-reverse-search-history (M-p)`

Search backward starting at the current line and moving `up' through the history as necessary using a non-incremental search for a string supplied by the user.

`non-incremental-forward-search-history (M-n)`

Search forward starting at the current line and moving `down' through the the history as necessary using a non-incremental search for a string supplied by the user.

`history-search-forward ()`

Search forward through the history for the string of characters between the start of the current line and the current point. This is a non-incremental search. By default, this command is unbound.

`history-search-backward ()`

Search backward through the history for the string of characters between the start of the current line and the current point. This is a non-incremental search. By default, this command is unbound.

`yank-nth-arg (M-C-y)`

Insert the first argument to the previous command (usually the second word on the previous line). With an argument n, insert the nth word from the previous command (the words in the previous command begin with word 0). A negative argument inserts the nth word from the end of the previous command.

`yank-last-arg (M-., M-_)`

Insert last argument to the previous command (the last word on the previous line). With an argument, behave exactly like `yank-nth-arg`.

Commands For Changing Text

`delete-char (C-d)`

Delete the character under the cursor. If the cursor is at the beginning of the line, there are no characters in the line, and the last character typed was not C-d, then return EOF.

`backward-delete-char (Rubout)`

Delete the character behind the cursor. A numeric arg says to kill the characters instead of deleting them.

`quoted-insert (C-q, C-v)`

Add the next character that you type to the line verbatim. This is how to insert key sequences like C-q, for example.

`tab-insert (M-TAB)`

Insert a tab character.

`self-insert (a, b, A, 1, !, ...)`

Insert yourself.

`transpose-chars (C-t)`

Drag the character before the cursor forward over the character at the cursor, moving the cursor forward as well. If the insertion point is at the end of the line, then this transposes the last two characters of the line. Negative argumentss don't work.

`transpose-words (M-t)`

Drag the word behind the cursor past the word in front of the cursor moving the cursor over that word as well.

`upcase-word (M-u)`

Uppercase the current (or following) word. With a negative argument, do the previous word, but do not move the cursor.

`downcase-word (M-l)`

Lowercase the current (or following) word. With a negative argument, do the previous word, but do not move the cursor.

`capitalize-word (M-c)`

Capitalize the current (or following) word. With a negative argument, do the previous word, but do not move the cursor.

Killing And Yanking

`kill-line (C-k)`

Kill the text from the current cursor position to the end of the line.

`backward-kill-line (C-x Rubout)`

Kill backward to the beginning of the line.

`unix-line-discard (C-u)`

Kill backward from the cursor to the beginning of the current line. Save the killed text on the kill-ring.

`kill-whole-line ()`

Kill all characters on the current line, no matter where the cursor is. By default, this is unbound.

`kill-word (M-d)`

Kill from the cursor to the end of the current word, or if between words, to the end of the next word. Word boundaries are the same as `forward-word`.

`backward-kill-word (M-DEL)`

Kill the word behind the cursor. Word boundaries are the same as `backward-word`.

`unix-word-rubout (C-w)`

Kill the word behind the cursor, using white space as a word boundary. The killed text is saved on the kill-ring.

`delete-horizontal-space ()`

Delete all spaces and tabs around point. By default, this is unbound.

`yank (C-y)`

Yank the top of the kill ring into the buffer at the current cursor position.

`yank-pop (M-y)`

Rotate the kill-ring, and yank the new top. You can only do this if the prior command is yank or yank-pop.

Specifying Numeric Arguments

`digit-argument (M-0, M-1, ... M--)`

Add this digit to the argument already accumulating, or start a new argument. M-- starts a negative argument.

`universal-argument ()`

Each time this is executed, the argument count is multiplied by four. The argument count is initially one, so executing this function the first time makes the argument count four. By default, this is not bound to a key.

Letting Readline Type For You

`complete (TAB)`

Attempt to do completion on the text before the cursor. This is application-specific. Generally, if you are typing a filename argument, you can do filename completion; if you are typing a command, you can do command completion, if you are typing in a symbol to GDB, you can do symbol name completion, if you are typing in a variable to Bash, you can do variable name completion, and so on.

`possible-completions (M-?)`

List the possible completions of the text before the cursor.

`insert-completions ()`

Insert all completions of the text before point that would have been generated by `possible-completions`. By default, this is not bound to a key.

Keyboard Macros

`start-kbd-macro (C-x ()`

Begin saving the characters typed into the current keyboard macro.

`end-kbd-macro (C-x ))`

Stop saving the characters typed into the current keyboard macro and save the definition.

`call-last-kbd-macro (C-x e)`

Re-execute the last keyboard macro defined, by making the characters in the macro appear as if typed at the keyboard.

Some Miscellaneous Commands

`re-read-init-file (C-x C-r)`

Read in the contents of your init file, and incorporate any bindings or variable assignments found there.

`abort (C-g)`

Abort the current editing command and ring the terminal's bell (subject to the setting of `bell-style`).

`do-uppercase-version (M-a, M-b, ...)`

Run the command that is bound to the corresoponding uppercase character.

`prefix-meta (ESC)`

Make the next character that you type be metafied. This is for people without a meta key. Typing `ESC f' is equivalent to typing `M-f'.

`undo (C-_, C-x C-u)`

Incremental undo, separately remembered for each line.

`revert-line (M-r)`

Undo all changes made to this line. This is like typing the `undo` command enough times to get back to the beginning.

`tilde-expand (M-~)`

Perform tilde expansion on the current word.

`dump-functions ()`

Print all of the functions and their key bindings to the readline output stream. If a numeric argument is supplied, the output is formatted in such a way that it can be made part of an inputrc file.

Readline vi Mode

While the Readline library does not have a full set of `vi` editing functions, it does contain enough to allow simple editing of the line. The Readline `vi` mode behaves as specified in the Posix 1003.2 standard.

In order to switch interactively between `Emacs` and `Vi` editing modes, use the command M-C-j (toggle-editing-mode). The Readline default is `emacs` mode.

When you enter a line in `vi` mode, you are already placed in `insertion' mode, as if you had typed an `i'. Pressing ESC switches you into `command' mode, where you can edit the text of the line with the standard `vi` movement keys, move to previous history lines with `k', and following lines with `j', and so forth.

Go to the next section.

Go to the previous, next section.

Programming with GNU Readline

This chapter describes the interface between the GNU Readline Library and other programs. If you are a programmer, and you wish to include the features found in GNU Readline such as completion, line editing, and interactive history manipulation in your own programs, this section is for you.

Basic Behavior

Many programs provide a command line interface, such as `mail`, `ftp`, and `sh`. For such programs, the default behaviour of Readline is sufficient. This section describes how to use Readline in the simplest way possible, perhaps to replace calls in your code to `gets()` or `fgets ()`.

The function `readline ()` prints a prompt and then reads and returns a single line of text from the user. The line `readline` returns is allocated with `malloc ()`; you should `free ()` the line when you are done with it. The declaration for `readline` in ANSI C is

```
char *readline (char *prompt);
```

So, one might say

```
char *line = readline ("Enter a line: ");
```

in order to read a line of text from the user. The line returned has the final newline removed, so only the text remains.

If `readline` encounters an `EOF` while reading the line, and the line is empty at that point, then `(char *)NULL` is returned. Otherwise, the line is ended just as if a newline had been typed.

If you want the user to be able to get at the line later, (with C-p for example), you must call `add_history ()` to save the line away in a history list of such lines.

```
add_history (line);
```

For full details on the GNU History Library, see the associated manual.

It is preferable to avoid saving empty lines on the history list, since users rarely have a burning need to reuse a blank line. Here is a function which usefully replaces the standard `gets ()` library function, and has the advantage of no static buffer to overflow:

```
/* A static variable for holding the line. */
static char *line_read = (char *)NULL;

/* Read a string, and return a pointer to it.  Returns NULL on EOF. */
char *
rl_gets ()
{
  /* If the buffer has already been allocated, return the memory
```

```
    to the free pool. */
  if (line_read)
    {
      free (line_read);
      line_read = (char *)NULL;
    }

  /* Get a line from the user. */
  line_read = readline ("");

  /* If the line has any text in it, save it on the history. */
  if (line_read && *line_read)
    add_history (line_read);

  return (line_read);
}
```

This function gives the user the default behaviour of TAB completion: completion on file names. If you do not want Readline to complete on filenames, you can change the binding of the TAB key with `rl_bind_key ()`.

```
int rl_bind_key (int key, int (*function)());
```

`rl_bind_key ()` takes two arguments: key is the character that you want to bind, and function is the address of the function to call when key is pressed. Binding TAB to `rl_insert ()` makes TAB insert itself. `rl_bind_key ()` returns non-zero if key is not a valid ASCII character code (between 0 and 255).

Thus, to disable the default TAB behavior, the following suffices:

```
rl_bind_key ('\t', rl_insert);
```

This code should be executed once at the start of your program; you might write a function called `initialize_readline ()` which performs this and other desired initializations, such as installing custom completers (see section Custom Completers).

Custom Functions

Readline provides many functions for manipulating the text of the line, but it isn't possible to anticipate the needs of all programs. This section describes the various functions and variables defined within the Readline library which allow a user program to add customized functionality to Readline.

The Function Type

For readabilty, we declare a new type of object, called Function. A `Function` is a C function which returns an `int`. The type declaration for `Function` is:

```
typedef int Function ();
```

The reason for declaring this new type is to make it easier to write code describing pointers to C functions. Let us say we had a variable called func which was a pointer to a function. Instead of the classic C declaration

```
int (*)()func;
```

we may write

```
Function *func;
```

Similarly, there are

```
typedef void VFunction ();
typedef char *CPFunction (); and
typedef char **CPPFunction ();
```

for functions returning no value, `pointer to char`, and `pointer to pointer to char`, respectively.

Writing a New Function

In order to write new functions for Readline, you need to know the calling conventions for keyboard-invoked functions, and the names of the variables that describe the current state of the line read so far.

The calling sequence for a command `foo` looks like

```
foo (int count, int key)
```

where count is the numeric argument (or 1 if defaulted) and key is the key that invoked this function.

It is completely up to the function as to what should be done with the numeric argument. Some functions use it as a repeat count, some as a flag, and others to choose alternate behavior (refreshing the current line as opposed to refreshing the screen, for example). Some choose to ignore it. In general, if a function uses the numeric argument as a repeat count, it should be able to do something useful with both negative and positive arguments. At the very least, it should be aware that it can be passed a negative argument.

Variable: char * **rl_line_buffer**

This is the line gathered so far. You are welcome to modify the contents of the line, but see section Allowing Undoing.

Variable: int **rl_point**

The offset of the current cursor position in `rl_line_buffer` (the *point*).

Variable: int **rl_end**

The number of characters present in `rl_line_buffer`. When `rl_point` is at the end of the line, `rl_point` and `rl_end` are equal.

Variable: int **rl_mark**

The mark (saved position) in the current line. If set, the mark and point define a *region*.

Variable: int **rl_done**

Setting this to a non-zero value causes Readline to return the current line immediately.

Variable: int **rl_pending_input**

Setting this to a value makes it the next keystroke read. This is a way to stuff a single character into the input stream.

Variable: char * **rl_prompt**

The prompt Readline uses. This is set from the argument to `readline ()`, and should not be assigned to directly.

Variable: char * **rl_terminal_name**

The terminal type, used for initialization.

Variable: char * **rl_readline_name**

This variable is set to a unique name by each application using Readline. The value allows conditional parsing of the inputrc file (see section Conditional Init Constructs).

Variable: FILE * **rl_instream**

The stdio stream from which Readline reads input.

Variable: FILE * **rl_outstream**

The stdio stream to which Readline performs output.

Variable: Function * **rl_startup_hook**

If non-zero, this is the address of a function to call just before `readline` prints the first prompt.

Readline Convenience Functions

Naming a Function

The user can dynamically change the bindings of keys while using Readline. This is done by representing the function with a descriptive name. The user is able to type the descriptive name when referring to the function. Thus, in an init file, one might find

```
Meta-Rubout:    backward-kill-word
```

This binds the keystroke Meta-Rubout to the function *descriptively* named `backward-kill-word`. You, as the programmer, should bind the functions you write to descriptive names as well. Readline provides a function for doing that:

Function: int **rl_add_defun** *(char *name, Function *function, int key)*

Add name to the list of named functions. Make function be the function that gets called. If key is not -1, then bind it to function using `rl_bind_key ()`.

Using this function alone is sufficient for most applications. It is the recommended way to add a few functions to the default functions that Readline has built in. If you need to do something other than adding a function to Readline, you may need to use the underlying functions described below.

Selecting a Keymap

Key bindings take place on a keymap. The keymap is the association between the keys that the user types and the functions that get run. You can make your own keymaps, copy existing keymaps, and tell Readline which keymap to use.

Function: Keymap **rl_make_bare_keymap** *()*

Returns a new, empty keymap. The space for the keymap is allocated with `malloc ()`; you should `free ()` it when you are done.

Function: Keymap **rl_copy_keymap** *(Keymap map)*

Return a new keymap which is a copy of map.

Function: Keymap **rl_make_keymap** *()*

Return a new keymap with the printing characters bound to rl_insert, the lowercase Meta characters bound to run their equivalents, and the Meta digits bound to produce numeric arguments.

Function: void **rl_discard_keymap** *(Keymap keymap)*

Free the storage associated with keymap.

Readline has several internal keymaps. These functions allow you to change which keymap is active.

Function: Keymap **rl_get_keymap** *()*

Returns the currently active keymap.

Function: void **rl_set_keymap** *(Keymap keymap)*

Makes keymap the currently active keymap.

Function: Keymap **rl_get_keymap_by_name** *(char *name)*

Return the keymap matching name. name is one which would be supplied in a `set keymap` inputrc line (see section Readline Init File).

Binding Keys

You associate keys with functions through the keymap. Readline has several internal keymaps: `emacs_standard_keymap`, `emacs_meta_keymap`, `emacs_ctlx_keymap`, `vi_movement_keymap`, and `vi_insertion_keymap`. `emacs_standard_keymap` is the default, and the examples in this manual assume that.

These functions manage key bindings.

Function: int **rl_bind_key** *(int key, Function *function)*

Binds key to function in the currently active keymap. Returns non-zero in the case of an invalid key.

Function: int **rl_bind_key_in_map** *(int key, Function *function, Keymap map)*

Bind key to function in map. Returns non-zero in the case of an invalid key.

Function: int **rl_unbind_key** *(int key)*

Bind key to the null function in the currently active keymap. Returns non-zero in case of error.

Function: int **rl_unbind_key_in_map** *(int key, Keymap map)*

Bind key to the null function in map. Returns non-zero in case of error.

Function: int **rl_generic_bind** *(int type, char *keyseq, char *data, Keymap map)*

Bind the key sequence represented by the string keyseq to the arbitrary pointer data. type says what kind of data is pointed to by data; this can be a function (`ISFUNC`), a macro (`ISMACR`), or a keymap (`ISKMAP`). This makes new keymaps as necessary. The initial keymap in which to do bindings is map.

Function: int **rl_parse_and_bind** *(char *line)*

Parse line as if it had been read from the `inputrc` file and perform any key bindings and variable assignments found (see section Readline Init File).

Associating Function Names and Bindings

These functions allow you to find out what keys invoke named functions and the functions invoked by a particular key sequence.

Function: Function * **rl_named_function** *(char *name)*

Return the function with name name.

Function: Function * **rl_function_of_keyseq** *(char *keyseq, Keymap map, int *type)*

Return the function invoked by keyseq in keymap map. If map is NULL, the current keymap is used. If type is not NULL, the type of the object is returned in it (one of `ISFUNC`, `ISKMAP`, or `ISMACR`).

Function: char ** **rl_invoking_keyseqs** *(Function *function)*

Return an array of strings representing the key sequences used to invoke function in the current keymap.

Function: char ** **rl_invoking_keyseqs_in_map** *(Function *function, Keymap map)*

Return an array of strings representing the key sequences used to invoke function in the keymap map.

Allowing Undoing

Supporting the undo command is a painless thing, and makes your functions much more useful. It is certainly easy to try something if you know you can undo it. I could use an undo function for the stock market.

If your function simply inserts text once, or deletes text once, and uses `rl_insert_text ()` or `rl_delete_text ()` to do it, then undoing is already done for you automatically.

If you do multiple insertions or multiple deletions, or any combination of these operations, you should group them together into one operation. This is done with `rl_begin_undo_group ()` and `rl_end_undo_group ()`.

The types of events that can be undone are:

```
enum undo_code { UNDO_DELETE, UNDO_INSERT, UNDO_BEGIN, UNDO_END };
```

Notice that `UNDO_DELETE` means to insert some text, and `UNDO_INSERT` means to delete some text. That is, the undo code tells undo what to undo, not how to undo it. `UNDO_BEGIN` and `UNDO_END` are tags added by `rl_begin_undo_group ()` and `rl_end_undo_group ()`.

Function: int **rl_begin_undo_group** *()*

Begins saving undo information in a group construct. The undo information usually comes from calls to

`rl_insert_text ()` and `rl_delete_text ()`, but could be the result of calls to `rl_add_undo ()`.

Function: int **rl_end_undo_group** *()*

Closes the current undo group started with `rl_begin_undo_group ()`. There should be one call to `rl_end_undo_group ()` for each call to `rl_begin_undo_group ()`.

Function: void **rl_add_undo** *(enum undo_code what, int start, int end, char *text)*

Remember how to undo an event (according to what). The affected text runs from start to end, and encompasses text.

Function: void **free_undo_list** *()*

Free the existing undo list.

Function: int **rl_do_undo** *()*

Undo the first thing on the undo list. Returns `0` if there was nothing to undo, non-zero if something was undone.

Finally, if you neither insert nor delete text, but directly modify the existing text (e.g., change its case), call `rl_modifying ()` once, just before you modify the text. You must supply the indices of the text range that you are going to modify.

Function: int **rl_modifying** *(int start, int end)*

Tell Readline to save the text between start and end as a single undo unit. It is assumed that you will subsequently modify that text.

Redisplay

Function: int **rl_redisplay** *()*

Change what's displayed on the screen to reflect the current contents of `rl_line_buffer`.

Function: int **rl_forced_update_display** *()*

Force the line to be updated and redisplayed, whether or not Readline thinks the screen display is correct.

Function: int **rl_on_new_line** *()*

Tell the update routines that we have moved onto a new (empty) line, usually after ouputting a newline.

Function: int **rl_reset_line_state** *()*

Reset the display state to a clean state and redisplay the current line starting on a new line.

Function: int **rl_message** *(va_alist)*

The arguments are a string as would be supplied to `printf`. The resulting string is displayed in the echo area. The echo area is also used to display numeric arguments and search strings.

Function: int **rl_clear_message** *()*

Clear the message in the echo area.

Modifying Text

Function: int **rl_insert_text** *(char *text)*

Insert text into the line at the current cursor position.

Function: int **rl_delete_text** *(int start, int end)*

Delete the text between start and end in the current line.

Function: char * **rl_copy_text** *(int start, int end)*

Return a copy of the text between start and end in the current line.

Function: int **rl_kill_text** *(int start, int end)*

Copy the text between start and end in the current line to the kill ring, appending or prepending to the last kill if the last command was a kill command. The text is deleted. If start is less than end, the text is appended, otherwise prepended. If the last command was not a kill, a new kill ring slot is used.

Utility Functions

Function: int **rl_reset_terminal** *(char *terminal_name)*

Reinitialize Readline's idea of the terminal settings using terminal_name as the terminal type (e.g., `vt100`).

Function: int **alphabetic** *(int c)*

Return 1 if c is an alphabetic character.

Function: int **numeric** *(int c)*

Return 1 if c is a numeric character.

Function: int **ding** *()*

Ring the terminal bell, obeying the setting of `bell-style`.

The following are implemented as macros, defined in `chartypes.h`.

Function: int **uppercase_p** *(int c)*

Return 1 if c is an uppercase alphabetic character.

Function: int **lowercase_p** *(int c)*

Return 1 if c is a lowercase alphabetic character.

Function: int **digit_p** *(int c)*

Return 1 if c is a numeric character. Function:

Function: int **to_upper** *(int c)*

If c is a lowercase alphabetic character, return the corresponding uppercase character.

Function: int **to_lower** *(int c)*

If c is an uppercase alphabetic character, return the corresponding lowercase character.

Function: int **digit_value** *(int c)*

If c is a number, return the value it represents.

An Example

Here is a function which changes lowercase characters to their uppercase equivalents, and uppercase characters to lowercase. If this function was bound to `M-c', then typing `M-c' would change the case of the character under point. Typing `M-1 0 M-c' would change the case of the following 10 characters, leaving the cursor on the last character changed.

```
/* Invert the case of the COUNT following characters. */
int
invert_case_line (count, key)
     int count, key;
{
  register int start, end, i;

  start = rl_point;

  if (rl_point >= rl_end)
    return (0);

  if (count < 0)
    {
      direction = -1;
      count = -count;
    }
  else
    direction = 1;

  /* Find the end of the range to modify. */
  end = start + (count * direction);

  /* Force it to be within range. */
  if (end > rl_end)
    end = rl_end;
  else if (end < 0)
    end = 0;

  if (start == end)
    return (0);

  if (start > end)
    {
      int temp = start;
      start = end;
      end = temp;
    }
```

```
  /* Tell readline that we are modifying the line, so it will save
     the undo information. */
  rl_modifying (start, end);

  for (i = start; i != end; i++)
    {
      if (uppercase_p (rl_line_buffer[i]))
        rl_line_buffer[i] = to_lower (rl_line_buffer[i]);
      else if (lowercase_p (rl_line_buffer[i]))
        rl_line_buffer[i] = to_upper (rl_line_buffer[i]);
    }
  /* Move point to on top of the last character changed. */
  rl_point = (direction == 1) ? end - 1 : start;
  return (0);
}
```

Custom Completers

Typically, a program that reads commands from the user has a way of disambiguating commands and data. If your program is one of these, then it can provide completion for commands, data, or both. The following sections describe how your program and Readline cooperate to provide this service.

How Completing Works

In order to complete some text, the full list of possible completions must be available. That is, it is not possible to accurately expand a partial word without knowing all of the possible words which make sense in that context. The Readline library provides the user interface to completion, and two of the most common completion functions: filename and username. For completing other types of text, you must write your own completion function. This section describes exactly what such functions must do, and provides an example.

There are three major functions used to perform completion:

1. The user-interface function `rl_complete ()`. This function is called with the same arguments as other Readline functions intended for interactive use: count and invoking_key. It isolates the word to be completed and calls `completion_matches ()` to generate a list of possible completions. It then either lists the possible completions, inserts the possible completions, or actually performs the completion, depending on which behavior is desired.
2. The internal function `completion_matches ()` uses your generator function to generate the list of possible matches, and then returns the array of these matches. You should place the address of your generator function in `rl_completion_entry_function`.
3. The generator function is called repeatedly from `completion_matches ()`, returning a string each time. The arguments to the generator function are text and state. text is the partial word to be completed. state is zero the first time the function is called, allowing the generator to perform any necessary initialization, and a positive non-zero integer for each subsequent call. When the generator function returns `(char *)NULL` this signals `completion_matches ()` that there are no more possibilities left. Usually the generator function computes the list of possible completions when state is zero, and returns them one at a time on subsequent calls. Each string the generator function returns as a match must be allocated with `malloc()`; Readline frees the strings when it has finished with them.

Function: int **rl_complete** *(int ignore, int invoking_key)*

Complete the word at or before point. You have supplied the function that does the initial simple matching selection algorithm (see `completion_matches ()`). The default is to do filename completion.

Variable: Function * **rl_completion_entry_function**

This is a pointer to the generator function for `completion_matches ()`. If the value of `rl_completion_entry_function` is `(Function *)NULL` then the default filename generator function, `filename_entry_function ()`, is used.

Completion Functions

Here is the complete list of callable completion functions present in Readline.

Function: int **rl_complete_internal** *(int what_to_do)*

Complete the word at or before point. what_to_do says what to do with the completion. A value of `?' means list the possible completions. `TAB' means do standard completion. `*' means insert all of the possible completions. `!' means to display all of the possible completions, if there is more than one, as well as performing partial completion.

Function: int **rl_complete** *(int ignore, int invoking_key)*

Complete the word at or before point. You have supplied the function that does the initial simple matching selection algorithm (see `completion_matches ()` and `rl_completion_entry_function`). The default is to do filename completion. This calls `rl_complete_internal ()` with an argument depending on invoking_key.

Function: int **rl_possible_completions** *(int count, int invoking_key))*

List the possible completions. See description of `rl_complete ()`. This calls `rl_complete_internal ()` with an argument of `?'.

Function: int **rl_insert_completions** *(int count, int invoking_key))*

Insert the list of possible completions into the line, deleting the partially-completed word. See description of `rl_complete ()`. This calls `rl_complete_internal ()` with an argument of `*'.

Function: char ** **completion_matches** *(char *text, CPFunction *entry_func)*

Returns an array of `(char *)` which is a list of completions for text. If there are no completions, returns `(char **)NULL`. The first entry in the returned array is the substitution for text. The remaining entries are the possible completions. The array is terminated with a `NULL` pointer.

entry_func is a function of two args, and returns a `(char *)`. The first argument is text. The second is a state argument; it is zero on the first call, and non-zero on subsequent calls. entry_func returns a `NULL` pointer to the caller when there are no more matches.

Function: char * **filename_completion_function** *(char *text, int state)*

A generator function for filename completion in the general case. Note that completion in Bash is a little different because of all the pathnames that must be followed when looking up completions for a command. The Bash source is a useful reference for writing custom completion functions.

Function: char * **username_completion_function** *(char *text, int state)*

A completion generator for usernames. text contains a partial username preceded by a random character (usua
`~'). As with all completion generators, state is zero on the first call and non-zero for subsequent calls.

Completion Variables

Variable: Function * **rl_completion_entry_function**

A pointer to the generator function for `completion_matches ()`. `NULL` means to use `filename_entry_function ()`, the default filename completer.

Variable: CPPFunction * **rl_attempted_completion_function**

A pointer to an alternative function to create matches. The function is called with text, start, and end. start and end are indices in `rl_line_buffer` saying what the boundaries of text are. If this function exists and returns `NULL`, or if this variable is set to `NULL`, then `rl_complete ()` will call the value of `rl_completion_entry_function` to generate matches, otherwise the array of strings returned will be used.

Variable: int **rl_completion_query_items**

Up to this many items will be displayed in response to a possible-completions call. After that, we ask the user if she is sure she wants to see them all. The default value is 100.

Variable: char * **rl_basic_word_break_characters**

The basic list of characters that signal a break between words for the completer routine. The default value of this variable is the characters which break words for completion in Bash, i.e., `" \t\n\"\\'`@$><=;|&{(`".

Variable: char * **rl_completer_word_break_characters**

The list of characters that signal a break between words for `rl_complete_internal ()`. The default list is the value of `rl_basic_word_break_characters`.

Variable: char * **rl_special_prefixes**

The list of characters that are word break characters, but should be left in text when it is passed to the completion function. Programs can use this to help determine what kind of completing to do. For instance, Bash sets this variable to "$@" so that it can complete shell variables and hostnames.

Variable: int **rl_ignore_completion_duplicates**

If non-zero, then disallow duplicates in the matches. Default is 1.

Variable: int **rl_filename_completion_desired**

Non-zero means that the results of the matches are to be treated as filenames. This is *always* zero on entry, and can only be changed within a completion entry generator function. If it is set to a non-zero value, directory names have a slash appended and Readline attempts to quote completed filenames if they contain any embedded word break characters.

Variable: int **rl_filename_quoting_desired**

Non-zero means that the results of the matches are to be quoted using double quotes (or an application-specific quoting mechanism) if the completed filename contains any characters in `rl_completer_word_break_chars`. This is *always* non-zero on entry, and can only be changed within a completion entry generator function.

Variable: Function * **rl_ignore_some_completions_function**

This function, if defined, is called by the completer when real filename completion is done, after all the matching names have been generated. It is passed a `NULL` terminated array of matches. The first element (`matches[0]`) is the maximal substring common to all matches. This function can re-arrange the list of matches as required, but each element deleted from the array must be freed.

Variable: char * **rl_completer_quote_characters**

List of characters which can be used to quote a substring of the line. Completion occurs on the entire substring, and within the substring `rl_completer_word_break_characters` are treated as any other character, unless they also appear within this list.

A Short Completion Example

Here is a small application demonstrating the use of the GNU Readline library. It is called `fileman`, and the source code resides in `` `examples/fileman.c' ``. This sample application provides completion of command names, line editing features, and access to the history list.

```
/* fileman.c -- A tiny application which demonstrates how to use the
   GNU Readline library.  This application interactively allows users
   to manipulate files and their modes. */

#include <stdio.h>
#include <sys/types.h>
#include <sys/file.h>
#include <sys/stat.h>
#include <sys/errno.h>

#include <readline/readline.h>
#include <readline/history.h>

extern char *getwd ();
extern char *xmalloc ();

/* The names of functions that actually do the manipulation. */
int com_list (), com_view (), com_rename (), com_stat (), com_pwd ();
int com_delete (), com_help (), com_cd (), com_quit ();

/* A structure which contains information on the commands this program
   can understand. */

typedef struct {
  char *name;                   /* User printable name of the function. */
  Function *func;               /* Function to call to do the job. */
  char *doc;                    /* Documentation for this function.  */
} COMMAND;

COMMAND commands[] = {
  { "cd", com_cd, "Change to directory DIR" },
```

```
  { "delete", com_delete, "Delete FILE" },
  { "help", com_help, "Display this text" },
  { "?", com_help, "Synonym for `help'" },
  { "list", com_list, "List files in DIR" },
  { "ls", com_list, "Synonym for `list'" },
  { "pwd", com_pwd, "Print the current working directory" },
  { "quit", com_quit, "Quit using Fileman" },
  { "rename", com_rename, "Rename FILE to NEWNAME" },
  { "stat", com_stat, "Print out statistics on FILE" },
  { "view", com_view, "View the contents of FILE" },
  { (char *)NULL, (Function *)NULL, (char *)NULL }
};

/* Forward declarations. */
char *stripwhite ();
COMMAND *find_command ();

/* The name of this program, as taken from argv[0]. */

Texinfo

The GNU Documentation Format

Edition 2.18, for Texinfo Version Two

March 1993

by Robert J. Chassell and Richard M. Stallman

Go to the next section.

This is the second edition of the Texinfo documentation,
and is consistent with version 2 of `texinfo.tex'.

Published by the Free Software Foundation
675 Massachusetts Avenue,
Cambridge, MA 02139 USA
Printed copies are available for $15 each.
ISBN-1882114-12-4

Cover art by Etienne Suvasa.

Texinfo Copying Conditions

The programs currently being distributed that relate to Texinfo include portions of GNU Emacs, plus other separate programs (including `makeinfo`, `info`, `texindex`, and `texinfo.tex`). These programs are free; this means that everyone is free to use them and free to redistribute them on a free basis. The Texinfo-related programs are not in the public domain; they are copyrighted and there are restrictions on their distribution, but these restrictions are designed to permit everything that a good cooperating citizen would want to do. What is not allowed is to try to prevent others from further sharing any version of these programs that they might get from you.

Specifically, we want to make sure that you have the right to give away copies of the programs that relate to Texinfo, that you receive source code or else can get it if you want it, that you can change these programs or use pieces of them in new free programs, and that you know you can do these things.

To make sure that everyone has such rights, we have to forbid you to deprive anyone else of these rights. For example, if you distribute copies of the Texinfo related programs, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must tell them their rights.

Also, for our own protection, we must make certain that everyone finds out that there is no warranty for the programs that relate to Texinfo. If these programs are modified by someone else and passed on, we want their recipients to know that what they have is not what we distributed, so that any problems

introduced by others will not reflect on our reputation.

The precise conditions of the licenses for the programs currently being distributed that relate to Texinfo are found in the General Public Licenses that accompany them.

Go to the next section.

Go to the previous, next section.

Overview of Texinfo

Texinfo(1) is a documentation system that uses a single source file to produce both on-line information and printed output. This means that instead of writing two different documents, one for the on-line help or other on-line information and the other for a typeset manual or other printed work, you need write only one document. When the work is revised, you need revise only one document. (You can read the on-line information, known as an Info file, with an Info documentation-reading program.)

Using Texinfo, you can create a printed document with the normal features of a book, including chapters, sections, cross references, and indices. From the same Texinfo source file, you can create a menu-driven, on-line Info file with nodes, menus, cross references, and indices. You can, if you wish, make the chapters and sections of the printed document correspond to the nodes of the on-line information; and you use the same cross references and indices for both the Info file and the printed work. The GNU Emacs Manual is a good example of a Texinfo file, as is this manual.

To make a printed document, you process a Texinfo source file with the TeX typesetting program. This creates a DVI file that you can typeset and print as a book or report. (Note that the Texinfo language is completely different from TeX's usual language, PlainTeX, which Texinfo replaces.) If you do not have TeX, but do have `troff` or `nroff`, you can use the `texi2roff` program instead.

To make an Info file, you process a Texinfo source file with the `makeinfo` utility or Emacs's `texinfo-format-buffer` command; this creates an Info file that you can install on-line.

TeX and `texi2roff` work with many types of printer; similarly, Info works with almost every type of computer terminal. This power makes Texinfo a general purpose system, but brings with it a constraint, which is that a Texinfo file may contain only the customary "typewriter" characters (letters, numbers, spaces, and punctuation marks) but no special graphics.

A Texinfo file is a plain ASCII file containing text and @-commands (words preceded by an `@') that tell the typesetting and formatting programs what to do. You may edit a Texinfo file with any text editor; but it is especially convenient to use GNU Emacs since that editor has a special mode, called Texinfo mode, that provides various Texinfo-related features. (See section Using Texinfo Mode.)

Before writing a Texinfo source file, you should become familiar with the Info documentation reading program and learn about nodes, menus, cross references, and the rest. (@inforef{Top, info, info}, for more information.)

You can use Texinfo to create both on-line help and printed manuals; moreover, Texinfo is freely redistributable. For these reasons, Texinfo is the format in which documentation for GNU utilities and libraries is written.

Info files

An Info file is a Texinfo file formatted so that the Info documentation reading program can operate on it. (`makeinfo` and `texinfo-format-buffer` are two commands that convert a Texinfo file into an Info file.)

Info files are divided into pieces called nodes, each of which contains the discussion of one topic. Each node has a name, and contains both text for the user to read and pointers to other nodes, which are identified by their names. The Info program displays one node at a time, and provides commands with which the user can move to other related nodes.

Each node of an Info file may have any number of child nodes that describe subtopics of the node's topic. The names of child nodes are listed in a menu within the parent node; this allows you to use certain Info commands to move to one of the child nodes. Generally, an Info file is organized like a book. If a node is at the logical level of a chapter, its child nodes are at the level of sections; likewise, the child nodes of sections are at the level of subsections. All the children of any one parent are linked together in a bidirectional chain of `Next' and `Previous' pointers. The `Next' pointer provides a link to the next section, and the `Previous' pointer provides a link to the previous section. This means that all the nodes that are at the level of sections within a chapter are linked together. Normally the order in this chain is the same as the order of the children in the parent's menu. Each child node records the parent node name as its `Up' pointer. The last child has no `Next' pointer, and the first child has the parent both as its `Previous' and as its `Up' pointer.(2)

The book-like structuring of an Info file into nodes that correspond to chapters, sections, and the like is a matter of convention, not a requirement. The `Up', `Previous', and `Next' pointers of a node can point to any other nodes, and a menu can contain any other nodes. Thus, the node structure can be any directed graph. But it is usually more comprehensible to follow a structure that corresponds to the structure of chapters and sections in a printed book or report.

In addition to menus and to `Next', `Previous', and `Up' pointers, Info provides pointers of another kind, called references, that can be sprinkled throughout the text. This is usually the best way to represent links that do not fit a hierarchical structure.

Usually, you will design a document so that its nodes match the structure of chapters and sections in the printed output. But there are times when this is not right for the material being discussed. Therefore, Texinfo uses separate commands to specify the node structure for the Info file and the section structure for the printed output.

Generally, you enter an Info file through a node that by convention is called `Top'. This node normally contains just a brief summary of the file's purpose, and a large menu through which the rest of the file is reached. From this node, you can either traverse the file systematically by going from node to node, or you can go to a specific node listed in the main menu, or you can search the index menus and then go directly to the node that has the information you want.

If you want to read through an Info file in sequence, as if it were a printed manual, you can get the whole file with the advanced Info command g* RET. (@inforef{Expert, Advanced Info commands, info}.)

The `dir' file in the `info' directory serves as the departure point for the whole Info system. From

it, you can reach the `Top' nodes of each of the documents in a complete Info system.

Printed Books

A Texinfo file can be formatted and typeset as a printed book or manual. To do this, you need TeX, a powerful, sophisticated typesetting program written by Donald Knuth.(3)

A Texinfo-based book is similar to any other typeset, printed work: it can have a title page, copyright page, table of contents, and preface, as well as chapters, numbered or unnumbered sections and subsections, page headers, cross references, footnotes, and indices.

You can use Texinfo to write a book without ever having the intention of converting it into on-line information. You can use Texinfo for writing a printed novel, and even to write a printed memo, although this latter application is not recommended since electronic mail is so much easier.

TeX is a general purpose typesetting program. Texinfo provides a file called `texinfo.tex' that contains information (definitions or macros) that TeX uses when it typesets a Texinfo file. (`texinfo.tex' tells TeX how to convert the Texinfo @-commands to TeX commands, which TeX can then process to create the typeset document.) `texinfo.tex' contains the specifications for printing a document.

Most often, documents are printed on 8.5 inch by 11 inch pages (216mm by 280mm; this is the default size), but you can also print for 7 inch by 9.25 inch pages (178mm by 235mm; the `@smallbook` size) or on European A4 size paper (`@afourpaper`). (See section Printing "Small" Books. Also, see section Printing on A4 Paper.)

By changing the parameters in `texinfo.tex', you can change the size of the printed document. In addition, you can change the style in which the printed document is formatted; for example, you can change the sizes and fonts used, the amount of indentation for each paragraph, the degree to which words are hyphenated, and the like. By changing the specifications, you can make a book look dignified, old and serious, or light-hearted, young and cheery.

TeX is freely distributable. It is written in a dialect of Pascal called WEB and can be compiled either in Pascal or (by using a conversion program that comes with the TeX distribution) in C. (See section 'TeX Mode' in The GNU Emacs Manual, for information about TeX.)

TeX is very powerful and has a great many features. Because a Texinfo file must be able to present information both on a character-only terminal in Info form and in a typeset book, the formatting commands that Texinfo supports are necessarily limited.

See section How to Obtain TeX.

@-commands

In a Texinfo file, the commands that tell TeX how to typeset the printed manual and tell `makeinfo` and `texinfo-format-buffer` how to create an Info file are preceded by `@'; they are called

@-commands. For example, `@node` is the command to indicate a node and `@chapter` is the comm to indicate the start of a chapter.

> **Please note:** All the @-commands, with the exception of the `@TeX{}` command, must be written entirely in lower case.

The Texinfo @-commands are a strictly limited set of constructs. The strict limits make it possible for Texinfo files to be understood both by TeX and by the code that converts them into Info files. You can display Info files on any terminal that displays alphabetic and numeric characters. Similarly, you can print the output generated by TeX on a wide variety of printers.

Depending on what they do or what arguments(4) they take, you need to write @-commands on lines of their own or as part of sentences:

- Write a command such as `@noindent` at the beginning of a line as the only text on the line. (`@noindent` prevents the beginning of the next line from being indented as the beginning of a paragraph.)
- Write a command such as `@chapter` at the beginning of a line followed by the command's arguments, in this case the chapter title, on the rest of the line. (`@chapter` creates chapter titles.)
- Write a command such as `@dots{}` wherever you wish but usually within a sentence. (`@dots{}` creates dots ...)
- Write a command such as `@code{sample-code}` wherever you wish (but usually within a sentence) with its argument, sample-code in this example, between the braces. (`@code` marks text as being code.)
- Write a command such as `@example` at the beginning of a line of its own; write the body-text on following lines; and write the matching `@end` command, `@end example` in this case, at the beginning of a line of its own after the body-text. (`@example` ... `@end example` indents and typesets body-text as an example.)

As a general rule, a command requires braces if it mingles among other text; but it does not need braces if it starts a line of its own. The non-alphabetic commands, such as `@:`, are exceptions to the rule; they do not need braces.

As you gain experience with Texinfo, you will rapidly learn how to write the different commands: the different ways to write commands make it easier to write and read Texinfo files than if all commands followed exactly the same syntax. (For details about @-command syntax, see section @-Command Syntax.)

General Syntactic Conventions

All ASCII printing characters except `@', `{' and `}' can appear in a Texinfo file and stand for themselves. `@' is the escape character which introduces commands. `{' and `}' should be used only to surround arguments to certain commands. To put one of these special characters into the document, put an `@' character in front of it, like this: `@@', `@{', and `@}'.

It is customary in TeX to use doubled single-quote characters to begin and end quotations: @tt{ '' } and @w{@tt{ '' }}. This convention should be followed in Texinfo files. TeX converts doubled single-quote

characters to left- and right-hand doubled quotation marks, "like this", and Info converts doubled single-quote characters to ASCII double-quotes: @tt{ " } and @tt{ " } to @w{@tt{ " }}.

Use three hyphens in a row, `---', for a dash--like this. In TeX, a single or even a double hyphen produces a printed dash that is shorter than the usual typeset dash. Info reduces three hyphens to two for display on the screen.

To prevent a paragraph from being indented in the printed manual, put the command `@noindent` on a line by itself before the paragraph.

If you mark off a region of the Texinfo file with the `@iftex` and `@end iftex` commands, that region will appear only in the printed copy; in that region, you can use certain commands borrowed from PlainTeX that you cannot use in Info. Likewise, if you mark off a region with the `@ifinfo` and `@end ifinfo` commands, that region will appear only in the Info file; in that region, you can use Info commands that you cannot use in TeX. (See section Conditionally Visible Text.)

> **Caution:** Do not use tabs in a Texinfo file! TeX uses variable-width fonts, which means that it cannot predefine a tab to work in all circumstances. Consequently, TeX treats tabs like single spaces, and that is not what they look like.
>
> To avoid this problem, Texinfo mode causes GNU Emacs to insert multiple spaces when you press the TAB key.
>
> Also, you can run `untabify` in Emacs to convert tabs in a region to multiple spaces.

Comments

You can write comments in a Texinfo file that will not appear in either the Info file or the printed manual by using the `@comment` command (which may be abbreviated to `@c`). Such comments are for the person who reads the Texinfo file. All the text on a line that follows either `@comment` or `@c` is a comment; the rest of the line does not appear in either the Info file or the printed manual. (Often, you can write the `@comment` or `@c` in the middle of a line, and only the text that follows after the `@comment` or `@c` command does not appear; but some commands, such as `@settitle` and `@setfilename`, work on a whole line. You cannot use `@comment` or `@c` in a line beginning with such a command.)

You can write long stretches of text that will not appear in either the Info file or the printed manual by using the `@ignore` and `@end ignore` commands. Write each of these commands on a line of its own, starting each command at the beginning of the line. Text between these two commands does not appear in the processed output. You can use `@ignore` and `@end ignore` for writing comments. Often, `@ignore` and `@end ignore` is used to enclose a part of the copying permissions that applies to the Texinfo source file of a document, but not to the Info or printed version of the document.

What a Texinfo File Must Have

By convention, the names of Texinfo files end with one of the extensions `.texinfo', `.texi', or `.tex'. The longer extension is preferred since it describes more clearly to a human reader the nature of the file. The shorter extensions are for operating systems that cannot handle long file names.

In order to be made into a printed manual and an Info file, a Texinfo file **must** begin with lines like this:

```
\input texinfo
@setfilename info-file-name
@settitle name-of-manual
```

The contents of the file follow this beginning, and then you **must** end a Texinfo file with a line like this:

```
@bye
```

The `\input texinfo' line tells TeX to use the `texinfo.tex' file, which tells TeX how to translate the Texinfo @-commands into TeX typesetting commands. (Note the use of the backslash, `\'; this is correct for TeX.) The `@setfilename' line provides a name for the Info file and the `@settitle' line specifies a title for the page headers (or footers) of the printed manual.

The `@bye' line at the end of the file on a line of its own tells the formatters that the file is ended and to stop formatting.

Usually, you will not use quite such a spare format, but will include mode setting and start-of-header and end-of-header lines at the beginning of a Texinfo file, like this:

```
\input texinfo   @c -*-texinfo-*-
@c %**start of header
@setfilename info-file-name
@settitle name-of-manual
@c %**end of header
```

In the first line, `-*-texinfo-*-' causes Emacs to switch into Texinfo mode when you edit the file.

The `@c' lines which surround the `@setfilename' and `@settitle' lines are optional, but you need them in order to run TeX or Info on just part of the file. (See section Start of Header, for more information.)

Furthermore, you will usually provide a Texinfo file with a title page, indices, and the like. But the minimum, which can be useful for short documents, is just the three lines at the beginning and the one line at the end.

Six Parts of a Texinfo File

Generally, a Texinfo file contains more than the minimal beginning and end--it usually contains six parts:

1. Header

   The Header names the file, tells TeX which definitions' file to use, and performs other "housekeeping" tasks.

2. Summary Description and Copyright

   The Summary Description and Copyright segment describes the document and contains the copyright notice and copying permissions for the Info file. The segment must be enclosed between

`@ifinfo` and `@end ifinfo` commands so that the formatters place it only in the Info file.

3. Title and Copyright

   The Title and Copyright segment contains the title and copyright pages and copying permissions for the printed manual. The segment must be enclosed between `@titlepage` and `@end titlepage` commands. The title and copyright page appear only in the printed manual.

4. `Top' Node and Master Menu

   The Master Menu contains a complete menu of all the nodes in the whole Info file. It appears only in the Info file, in the `Top' node.

5. Body

   The Body of the document may be structured like a traditional book or encyclopedia or it may be free form.

6. End

   The End contains commands for printing indices and generating the table of contents, and the `@bye` command on a line of its own.

A Short Sample Texinfo File

Here is a complete but very short Texinfo file, in 6 parts. The first three parts of the file, from `\input texinfo' through to `@end titlepage', look more intimidating than they are. Most of the material is standard boilerplate; when you write a manual, simply insert the names for your own manual in this segment. (See section Beginning a Texinfo File.)

In the following, the sample text is *indented*; comments on it are not. The complete file, without any comments, is shown in section A Sample Texinfo File.

Part 1: Header

The header does not appear in either the Info file or the printed output. It sets various parameters, including the name of the Info file and the title used in the header.

```
\input texinfo   @c -*-texinfo-*-
@c %**start of header
@setfilename sample.info
@settitle Sample Document
@c %**end of header

@setchapternewpage odd
```

Part 2: Summary Description and Copyright

The summary description and copyright segment does not
appear in the printed document.

```
@ifinfo
This is a short example of a complete Texinfo file.

Copyright @copyright{} 1990 Free Software Foundation, Inc.
@end ifinfo
```

Part 3: Titlepage and Copyright

The titlepage segment does not appear in the Info file.

```
@titlepage
@sp 10
@comment The title is printed in a large font.
@center @titlefont{Sample Title}

@c The following two commands start the copyright page.
@page
@vskip 0pt plus 1filll
Copyright @copyright{} 1990 Free Software Foundation, Inc.
@end titlepage
```

Part 4: `Top' Node and Master Menu

The `Top' node contains the master menu for the Info file.
Since a printed manual uses a table of contents rather than
a menu, the master menu appears only in the Info file.

```
@node    Top,       First Chapter, (dir),    (dir)
@comment node-name, next,          previous, up

@menu
* First Chapter::    The first chapter is the
                     only chapter in this sample.
* Concept Index::    This index has two entries.
@end menu
```

Part 5: The Body of the Document

The body segment contains all the text of the document, but not the indices or table of contents. This example illustrates a node and a chapter containing an enumerated list.

```
@node    First Chapter, Concept Index, Top,      Top
@comment node-name,     next,          previous, up
@chapter First Chapter
@cindex Sample index entry

This is the contents of the first chapter.
@cindex Another sample index entry

Here is a numbered list.

@enumerate
@item
This is the first item.

@item
This is the second item.
@end enumerate

The @code{makeinfo} and @code{texinfo-format-buffer}
commands transform a Texinfo file such as this into
an Info file; and @TeX{} typesets it for a printed
manual.
```

Part 6: The End of the Document

The end segment contains commands both for generating an index in a node and unnumbered chapter of its own and for generating the table of contents; and it contains the `@bye` command that marks the end of the document.

```
@node    Concept Index,    ,  First Chapter, Top
@comment node-name,    next,  previous,      up
@unnumbered Concept Index

@printindex cp

@contents
@bye
```

The Results

Here is what the contents of the first chapter of the sample look like:

> This is the contents of the first chapter.
>
> Here is a numbered list.
>
> 1. This is the first item.
> 2. This is the second item.
>
> The `makeinfo` and `texinfo-format-buffer` commands transform a Texinfo file such as this into an Info file; and TeX typesets it for a printed manual.

Acknowledgements

Richard M. Stallman wrote Edition 1.0 of this manual. Robert J. Chassell revised and extended it, starting with Edition 1.1.

Our thanks go out to all who helped improve this work, particularly to Francois Pinard and David D. Zuhn, who tirelessly recorded and reported mistakes and obscurities; our special thanks go to Melissa Weisshaus for her frequent and often tedious reviews of nearly similar editions. Our mistakes are our own.

TOC

Using Texinfo Mode

You may edit a Texinfo file with any text editor you choose. A Texinfo file is no different from any other ASCII file. However, GNU Emacs comes with a special mode, called Texinfo mode, that provides Emacs commands and tools to help ease your work.

This chapter describes features of GNU Emacs' Texinfo mode but not any features of the Texinfo formatting language. If you are reading this manual straight through from the beginning, you may want to skim through this chapter briefly and come back to it after reading succeeding chapters which describe the Texinfo formatting language in detail.

Texinfo mode provides special features for working with Texinfo files:

- Insert frequently used @commands.
- Automatically create `@node` lines.
- Show the structure of a Texinfo source file.
- Automatically create or update the `Next', `Previous', and `Up' pointers of a node.
- Automatically create or update menus.
- Automatically create a master menu.
- Format a part or all of a file for Info.
- Typeset and print part or all of a file.

Perhaps the two most helpful features are those for inserting frequently used @-commands and for creating node pointers and menus.

The Usual GNU Emacs Editing Commands

In most cases, the usual Text mode commands work the same in Texinfo mode as they do in Text mode. Texinfo mode adds new editing commands and tools to GNU Emacs' general purpose editing features. The major difference concerns filling. In Texinfo mode, the paragraph separation variable and syntax table are redefined so that Texinfo commands that should be on lines of their own are not inadvertently included in paragraphs. Thus, the M-q (`fill-paragraph`) command will refill a paragraph but not mix an indexing command on a line adjacent to it into the paragraph.

In addition, Texinfo mode sets the `page-delimiter` variable to the value of `texinfo-chapter-level-regexp`; by default, this is a regular expression matching the commands for chapters and their equivalents, such as appendices. With this value for the page delimiter, you can jump from chapter title to chapter title with the C-x] (`forward-page`) and C-x [(`backward-page`) commands and narrow to a chapter with the C-x p (`narrow-to-page`) command. (See section 'Pages' in The GNU Emacs Manual, for details about the page commands.)

You may name a Texinfo file however you wish, but the convention is to end a Texinfo file name wi one of the three extensions `.texinfo', `.texi', or `.tex'. A longer extension is preferred, since it is explicit, but a shorter extension may be necessary for operating systems that limit the length of file names. GNU Emacs automatically enters Texinfo mode when you visit a file with a `.texinfo' or `.texi' extension. Also, Emacs switches to Texinfo mode when you visit a file that has `-*-texinfo-*-' in its first line. If ever you are in another mode and wish to switch to Texinfo mode, type `M-x texinfo-mode'.

Like all other Emacs features, you can customize or enhance Texinfo mode as you wish. In particular, the keybindings are very easy to change. The keybindings described here are the default or standard ones.

Inserting Frequently Used Commands

Texinfo mode provides commands to insert various frequently used @-commands into the buffer. You can use these commands to save keystrokes.

The insert commands are invoked by typing C-c twice and then the first letter of the @-command:

C-c C-c c

M-x texinfo-insert-@code

> Insert `@code{}` and put the cursor between the braces.

C-c C-c d

M-x texinfo-insert-@dfn

> Insert `@dfn{}` and put the cursor between the braces.

C-c C-c e

M-x texinfo-insert-@end

> Insert `@end` and attempt to insert the correct following word, such as `example' or `table'. (This command does not handle nested lists correctly, but inserts the word appropriate to the immediately preceding list.)

C-c C-c i

M-x texinfo-insert-@item

> Insert `@item` and put the cursor at the beginning of the next line.

C-c C-c k

M-x texinfo-insert-@kbd

> Insert `@kbd{}` and put the cursor between the braces.

C-c C-c n

M-x texinfo-insert-@node

> Insert `@node` and a comment line listing the sequence for the `Next', `Previous', and `Up' nodes. Leave point after the `@node`.

C-c C-c o

M-x texinfo-insert-@noindent

Insert `@noindent` and put the cursor at the beginning of the next line.

C-c C-c s

M-x texinfo-insert-@samp

Insert `@samp{}` and put the cursor between the braces.

C-c C-c t

M-x texinfo-insert-@table

Insert `@table` followed by a SPC and leave the cursor after the SPC.

C-c C-c v

M-x texinfo-insert-@var

Insert `@var{}` and put the cursor between the braces.

C-c C-c x

M-x texinfo-insert-@example

Insert `@example` and put the cursor at the beginning of the next line.

C-c C-c {

M-x texinfo-insert-braces

Insert `{}` and put the cursor between the braces.

C-c C-c }

C-c C-c]

M-x up-list

Move from between a pair of braces forward past the closing brace. Typing C-c C-c] is easier than typing C-c C-c }, which is, however, more mnemonic; hence the two keybindings. (Also, you can move out from between braces by typing C-f.)

To put a command such as `@code{...}` around an *existing* word, position the cursor in front of the word and type C-u 1 C-c C-c c. This makes it easy to edit existing plain text. The value of the prefix argument tells Emacs how many words following point to include between braces--1 for one word, 2 for two words, and so on. Use a negative argument to enclose the previous word or words. If you do not specify a prefix argument, Emacs inserts the @-command string and positions the cursor between the braces. This feature works only for those @-commands that operate on a word or words within one line, such as `@kbd` and `@var`.

This set of insert commands was created after analyzing the frequency with which different @-commands are used in the GNU Emacs Manual and the GDB Manual. If you wish to add your own insert commands, you can bind a keyboard macro to a key, use abbreviations, or extend the code in `` `texinfo.el' ``.

C-c C-c C-d (`texinfo-start-menu-description`) is an insert command that works differently from the other insert commands. It inserts a node's section or chapter title in the space for the description in a menu entry line. (A menu entry has three parts, the entry name, the node name, and the description. Only the node name is required, but a description helps explain what the node is about. See section The Parts of a Menu.)

To use `texinfo-start-menu-description`, position point in a menu entry line and type C-c C-d. The command looks for and copies the title that goes with the node name, and inserts the title as a description; it positions point at beginning of the inserted text so you can edit it. The function does not insert the title if the menu entry line already contains a description.

This command is only an aid to writing descriptions; it does not do the whole job. You must edit the inserted text since a title tends to use the same words as a node name but a useful description uses different words.

Showing the Section Structure of a File

You can show the section structure of a Texinfo file by using the C-c C-s command (`texinfo-show-structure`). This command shows the section structure of a Texinfo file by listing the lines that begin with the @-commands for `@chapter`, `@section`, and the like. It constructs what amounts to a table of contents. These lines are displayed in another buffer called the `*Occur*' buffer. In that buffer, you can position the cursor over one of the lines and use the C-c C-c command (`occur-mode-goto-occurrence`), to jump to the corresponding spot in the Texinfo file.

C-c C-s

M-x texinfo-show-structure

> Show the `@chapter`, `@section`, and such lines of a Texinfo file.

C-c C-c

M-x occur-mode-goto-occurrence

> Go to the line in the Texinfo file corresponding to the line under the cursor in the `*Occur*' buffer.

If you call `texinfo-show-structure` with a prefix argument by typing C-u C-c C-s, it will list not only those lines with the @-commands for `@chapter`, `@section`, and the like, but also the `@node` lines. (This is how the `texinfo-show-structure` command worked without an argument in the first version of Texinfo. It was changed because `@node` lines clutter up the `*Occur*' buffer and are usually not needed.) You can use `texinfo-show-structure` with a prefix argument to check whether the `Next', `Previous', and `Up' pointers of an `@node` line are correct.

Often, when you are working on a manual, you will be interested only in the structure of the current chapter. In this case, you can mark off the region of the buffer that you are interested in with the C-x n (`narrow-to-region`) command and `texinfo-show-structure` will work on only that region. To see the whole buffer again, use C-x w (`widen`). (See section 'Narrowing' in The GNU Emacs Manual, for more information about the narrowing commands.)

In addition to providing the `texinfo-show-structure` command, Texinfo mode sets the value of the page delimiter variable to match the chapter-level @-commands. This enables you to use the C-x] (`forward-page`) and C-x [(`backward-page`) commands to move forward and backward by chapter, and to use the C-x p (`narrow-to-page`) command to narrow to a chapter. See section 'Pages' in The GNU Emacs Manual, for more information about the page commands.

Updating Nodes and Menus

Texinfo mode provides commands for automatically creating or updating menus and node pointers. The commands are called "update" commands because their most frequent use is for updating a Texinfo file after you have worked on it; but you can use them to insert the `Next', `Previous', and `Up' pointers into an `@node` line that has none and to create menus in a file that has none.

If you do not use the updating commands, you need to write menus and node pointers by hand, which is a tedious task.

You can use the updating commands

- to insert or update the `Next', `Previous', and `Up' pointers of a node,
- to insert or update the menu for a section, and
- to create a master menu for a Texinfo source file.

You can also use the commands to update all the nodes and menus in a region or in a whole Texinfo file.

The updating commands work only with conventional Texinfo files, which are structured hierarchically like books. In such files, a structuring command line must follow closely after each `@node` line, except for the `Top' `@node` line. (A structuring command line is a line beginning with `@chapter`, `@section`, or other similar command.)

You can write the structuring command line on the line that follows immediately after an `@node` line or else on the line that follows after a single `@comment` line or a single `@ifinfo` line. You cannot interpose more than one line between the `@node` line and the structuring command line; and you may interpose only an `@comment` line or an `@ifinfo` line.

Commands which work on a whole buffer require that the `Top' node be followed by a node with an `@chapter` or equivalent-level command. Note that the menu updating commands will not create a main or master menu for a Texinfo file that has only `@chapter`-level nodes! The menu updating commands only create menus *within* nodes for lower level nodes. To create a menu of chapters, you must provide a `Top' node.

The menu updating commands remove menu entries that refer to other Info files since they do not refer to nodes within the current buffer. This is a deficiency. Rather than use menu entries, you can use cross references to refer to other Info files. None of the updating commands affect cross references.

Texinfo mode has five updating commands that are used most often: two are for updating the node pointers or menu of a single node (or a region); two are for updating every node pointer and menu in a file; and one, the `texinfo-master-menu` command, is for creating a master menu for a complete file, and optionally, for updating every node and menu in the whole Texinfo file.

The `texinfo-master-menu` command is the primary command:

C-c C-u m

M-x texinfo-master-menu

> Create or update a master menu that includes all the other menus (incorporating the descriptions from pre-existing menus, if any).

With an argument (prefix argument, C-u, if interactive), first create or update all the nodes and the regular menus in the buffer before constructing the master menu. (See section The `Top' Node and Master Menu, for more about a master menu.)

For `texinfo-master-menu` to work, the Texinfo file must have a `Top' node and at least one subsequent node.

After extensively editing a Texinfo file, you can type the following:

```
C-u M-x texinfo-master-menu
or
C-u C-c C-u m
```

This updates all the nodes and menus completely and all at once.

The other major updating commands do smaller jobs and are designed for the person who updates nodes and menus as he or she writes a Texinfo file.

The commands are:

C-c C-u C-n

M-x texinfo-update-node

Insert the `Next', `Previous', and `Up' pointers for the node that point is within (i.e., for the `@node` line preceding point). If the `@node` line has pre-existing `Next', `Previous', or `Up' pointers in it, the old pointers are removed and new ones inserted. With an argument (prefix argument, C-u, if interactive), this command updates all `@node` lines in the region (which is the text between point and mark).

C-c C-u C-m

M-x texinfo-make-menu

Create or update the menu in the node that point is within. With an argument (C-u as prefix argument, if interactive), the command makes or updates menus for the nodes which are either within or a part of the region.

Whenever `texinfo-make-menu` updates an existing menu, the descriptions from that menu are incorporated into the new menu. This is done by copying descriptions from the existing menu to the entries in the new menu that have the same node names. If the node names are different, the descriptions are not copied to the new menu.

C-c C-u C-e

M-x texinfo-every-node-update

Insert or update the `Next', `Previous', and `Up' pointers for every node in the buffer.

C-c C-u C-a

M-x texinfo-all-menus-update

Create or update all the menus in the buffer. With an argument (C-u as prefix argument, if interactive), first insert or update all the node pointers before working on the menus.

If a master menu exists, the `texinfo-all-menus-update` command updates it; but the command does not create a new master menu if none already exists. (Use the `texinfo-master-menu` command for that.)

When working on a document that does not merit a master menu, you can type the following:

```
C-u C-c C-u C-a
or
C-u M-x texinfo-all-menus-update
```

This updates all the nodes and menus.

The `texinfo-column-for-description` variable specifies the column to which menu descriptions are indented. By default, the value is 32 although it is often useful to reduce it to as low as 24. You can set the variable with the M-x edit-options command (see section 'Editing Variable Values' in The GNU Emacs Manual) or with the M-x set-variable command (see section 'Examining and Setting Variables' in The GNU Emacs Manual).

Also, the `texinfo-indent-menu-description` command may be used to indent existing menu descriptions to a specified column. Finally, if you wish, you can use the `texinfo-insert-node-lines` command to insert missing `@node` lines into a file. (See section Other Updating Commands, for more information.)

Updating Requirements

To use the updating commands, you must organize the Texinfo file hierarchically with chapters, sections, subsections, and the like. When you construct the hierarchy of the manual, do not `jump down' more than one level at a time: you can follow the `Top' node with a chapter, but not with a section; you can follow a chapter with a section, but not with a subsection. However, you may `jump up' any number of levels at one time--for example, from a subsection to a chapter.

Each `@node` line, with the exception of the line for the `Top' node, must be followed by a line with a structuring command such as `@chapter`, `@section`, or `@unnumberedsubsec`.

Each `@node` line/structuring-command line combination must look either like this:

```
@node     Comments,  Minimum, Conventions, Overview
@comment  node-name, next,    previous,    up
@section Comments
```

or like this (without the `@comment` line):

```
@node Comments, Minimum, Conventions, Overview
@section Comments
```

In this example, `Comments' is the name of both the node and the section. The next node is called `Minimum' and the previous node is called `Conventions'. The `Comments' section is within the

`Overview' node, which is specified by the `Up' pointer. (Instead of an `@comment` line, you can wri
`@ifinfo` line.)

If a file has a `Top' node, it must be called `top' or `Top' and be the first node in the file.

The menu updating commands create a menu of sections within a chapter, a menu of subsections within a section, and so on. This means that you must have a `Top' node if you want a menu of chapters.

Incidentally, the `makeinfo` command will create an Info file for a hierarchically organized Texinfo file that lacks `Next', `Previous' and `Up' pointers. Thus, if you can be sure that your Texinfo file will be formatted with `makeinfo`, you have no need for the `update node' commands. (See section Creating an Info File, for more information about `makeinfo`.) However, both `makeinfo` and the `texinfo-format-...` commands require that you insert menus in the file.

Other Updating Commands

In addition to the five major updating commands, Texinfo mode possesses several less frequently used updating commands:

M-x texinfo-insert-node-lines

> Insert `@node` lines before the `@chapter`, `@section`, and other sectioning commands wherever they are missing throughout a region in a Texinfo file.
>
> With an argument (C-u as prefix argument, if interactive), the `texinfo-insert-node-lines` command not only inserts `@node` lines but also inserts the chapter or section titles as the names of the corresponding nodes. In addition, it inserts the titles as node names in pre-existing `@node` lines that lack names. Since node names should be more concise than section or chapter titles, you must manually edit node names so inserted.
>
> For example, the following marks a whole buffer as a region and inserts `@node` lines and titles throughout:
>
> ```
> C-x h C-u M-x texinfo-insert-node-lines
> ```
>
> (Note that this command inserts titles as node names in `@node` lines; the `texinfo-start-menu-description` command (see section Inserting Frequently Used Commands) inserts titles as descriptions in menu entries, a different action. However, in both cases, you need to edit the inserted text.)

M-x texinfo-multiple-files-update

> Update nodes and menus in a document built from several separate files. With C-u as a prefix argument, create and insert a master menu in the outer file. With a numeric prefix argument, such as C-u 2, first update all the menus and all the `Next', `Previous', and `Up' pointers of all the included files before creating and inserting a master menu in the outer file. The `texinfo-multiple-files-update` command is described in the appendix on `@include` files. See section `texinfo-multiple-files-update`}.

M-x texinfo-indent-menu-description

Indent every description in the menu following point to the specified column. You can use this command to give yourself more space for descriptions. With an argument (C-u as prefix argument, if interactive), the `texinfo-indent-menu-description` command indents every description in every menu in the region. However, this command does not indent the second and subsequent lines of a multi-line description.

M-x texinfo-sequential-node-update

Insert the names of the nodes immediately following and preceding the current node as the `Next' or `Previous' pointers regardless of those nodes' hierarchical level. This means that the `Next' node of a subsection may well be the next chapter. Sequentially ordered nodes are useful for novels and other documents that you read through sequentially. (However, in Info, the `g* RET` command lets you look through the file sequentially, so sequentially ordered nodes are not strictly necessary.) With an argument (prefix argument, if interactive), the `texinfo-sequential-node-update` command sequentially updates all the nodes in the region.

Formatting for Info

Texinfo mode provides several commands for formatting part or all of a Texinfo file for Info. Often, when you are writing a document, you want to format only part of a file--that is, a region.

You can use either the `texinfo-format-region` or the `makeinfo-region` command to format a region:

C-c C-e C-r

M-x texinfo-format-region

C-c C-m C-r

M-x makeinfo-region

Format the current region for Info.

You can use either the `texinfo-format-buffer` or the `makeinfo-buffer` command to format a whole buffer:

C-c C-e C-b

M-x texinfo-format-buffer

C-c C-m C-b

M-x makeinfo-buffer

Format the current buffer for Info.

For example, after writing a Texinfo file, you can type the following:

```
C-u C-c C-u m
or
C-u M-x texinfo-master-menu
```

This updates all the nodes and menus. Then type the following to create an Info file:

```
C-c C-m C-b
or
M-x makeinfo-buffer
```

For the Info formatting commands to work, the file *must* include a line that has `@setfilename` in its header.

Not all systems support the `makeinfo`-based formatting commands.

See section Creating an Info File, for details about Info formatting.

Formatting and Printing

Typesetting and printing a Texinfo file is a multi-step process in which you first create a file for printing (called a DVI file), and then print the file. Optionally, you may also create indices. To do this, you must run the `texindex` command after first running the `tex` typesetting command; and then you must run the `tex` command again.

Often, when you are writing a document, you want to typeset and print only part of a file to see what it will look like. You can use the `texinfo-tex-region` and related commands for this purpose. Use the `texinfo-tex-buffer` command to format all of a buffer.

C-c C-t C-r

M-x texinfo-tex-region

> Run TeX on the region.

C-c C-t C-b

M-x texinfo-tex-buffer

> Run TeX on the buffer.

C-c C-t C-i

M-x texinfo-texindex

> Run `texindex` to sort the indices of a Texinfo file formatted with `texinfo-tex-region` or `texinfo-tex-buffer`. You must run the `tex` command a second time after sorting the raw index files.

C-c C-t C-p

M-x texinfo-tex-print

> Print the file (or the part of the file) previously formatted with `texinfo-tex-buffer` or `texinfo-tex-region`.

For `texinfo-tex-region` or `texinfo-tex-buffer` to work, the file *must* start with a `\input texinfo' line and must include an `@settitle` line. The file must end with `@bye` on a line by itself. (When you use `texinfo-tex-region`, you must surround the `@settitle` line with start-of-header and end-of-header lines.)

See section Format and Print Hardcopy, for a description of the other TeX related commands, such as

`tex-show-print-queue`.

Texinfo Mode Summary

In Texinfo mode, each set of commands has default keybindings that begin with the same keys. All the commands that are custom-created for Texinfo mode begin with C-c. The keys are somewhat mnemonic.

Insert Commands

The insert commands are invoked by typing C-c twice and then the first letter of the @-command to be inserted. (It might make more sense mnemonically to use C-c C-i, for `custom insert', but C-c C-c is quick to type.)

```
C-c C-c c       Insert `@code'.
C-c C-c d       Insert `@dfn'.
C-c C-c e       Insert `@end'.
C-c C-c i       Insert `@item'.
C-c C-c n       Insert `@node'.
C-c C-c s       Insert `@samp'.
C-c C-c v       Insert `@var'.
C-c C-c {       Insert braces.
C-c C-c ]
C-c C-c }       Move out of enclosing braces.

C-c C-c C-d     Insert a node's section title
                in the space for the description
                in a menu entry line.
```

Show Structure

The `texinfo-show-structure` command is often used within a narrowed region.

```
C-c C-s         List all the headings.
```

The Master Update Command

The `texinfo-master-menu` command creates a master menu; and can be used to update every node and menu in a file as well.

```
C-c C-u m
M-x texinfo-master-menu
                Create or update a master menu.

C-u C-c C-u m   With C-u as a prefix argument, first
```

```
                create or update all nodes and regular
                menus, and then create a master menu.
```

Update Pointers

The update pointer commands are invoked by typing C-c C-u and then either typing C-n for `texinfo-update-node` or typing C-e for `texinfo-every-node-update`.

```
C-c C-u C-n     Update a node.
C-c C-u C-e     Update every node in the buffer.
```

Update Menus

Invoke the update menu commands by typing C-c C-u and then either C-m for `texinfo-make-menu` or C-a for `texinfo-all-menus-update`. To update both nodes and menus at the same time, precede C-c C-u C-a with C-u.

```
C-c C-u C-m     Make or update a menu.

C-c C-u C-a     Make or update all
                menus in a buffer.

C-u C-c C-u C-a With C-u as a prefix argument,
                first create or update all nodes and
                then create or update all menus.
```

Format for Info

The Info formatting commands that are written in Emacs Lisp are invoked by typing C-c C-e and then either C-r for a region or C-b for the whole buffer.

The Info formatting commands that are written in C and based on the `makeinfo` program are invoked by typing C-c C-m and then either C-r for a region or C-b for the whole buffer.

Use the `texinfo-format...` commands:

```
C-c C-e C-r     Format the region.
C-c C-e C-b     Format the buffer.
```

Use `makeinfo`:

```
C-c C-m C-r     Format the region.
C-c C-m C-b     Format the buffer.
C-c C-m C-l     Recenter the makeinfo output buffer.
C-c C-m C-k     Kill the makeinfo formatting job.
```

Typeset and Print

The TeX typesetting and printing commands are invoked by typing C-c C-t and then another control command: C-r for `texinfo-tex-region`, C-b for `texinfo-tex-buffer`, and so on.

```
C-c C-t C-r     Run TeX on the region.
C-c C-t C-b     Run TeX on the buffer.
C-c C-t C-i     Run texindex.
C-c C-t C-p     Print the DVI file.
C-c C-t C-q     Show the print queue.
C-c C-t C-d     Delete a job from the print queue.
C-c C-t C-k     Kill the current TeX formatting job.
C-c C-t C-x     Quit a currently stopped TeX formatting job.
C-c C-t C-l     Recenter the output buffer.
```

Other Updating Commands

The `other updating commands' do not have standard keybindings because they are rarely used.

```
M-x texinfo-insert-node-lines
                Insert missing @node lines in region.
                With C-u as a prefix argument,
                use section titles as node names.

M-x texinfo-multiple-files-update
                Update a multi-file document.
                With C-u 2 as a prefix argument,
                create or update all nodes and menus
                in all included files first.

M-x texinfo-indent-menu-description
                Indent descriptions.

M-x texinfo-sequential-node-update
                Insert node pointers in strict sequence.
```

Go to the previous, next section.

TOC

Beginning a Texinfo File

Certain pieces of information must be provided at the beginning of a Texinfo file, such as the name of the file and the title of the document.

Generally, the beginning of a Texinfo file has four parts:

1. The header, delimited by special comment lines, that includes the commands for naming the Texinfo file and telling TeX what definitions' file to use when processing the Texinfo file.
2. A short statement of what the file is about, with a copyright notice and copying permissions. This is enclosed in `@ifinfo` and `@end ifinfo` commands so that the formatters place it only in the Info file.
3. A title page and copyright page, with a copyright notice and copying permissions. This is enclosed between `@titlepage` and `@end titlepage` commands. The title and copyright page appear only in the printed manual.
4. The `Top' node that contains a menu for the whole Info file. The contents of this node appear only in the Info file.

Also, optionally, you may include the copying conditions for a program and a warranty disclaimer. The copying section will be followed by an introduction or else by the first chapter of the manual.

Since the copyright notice and copying permissions for the Texinfo document (in contrast to the copying permissions for a program) are in parts that appear only in the Info file or only in the printed manual, this information must be given twice.

Sample Texinfo File Beginning

The following sample shows what is needed.

```
\input texinfo   @c -*-texinfo-*-
@c %**start of header
@setfilename name-of-info-file
@settitle name-of-manual
@setchapternewpage odd
@c %**end of header

@ifinfo
This file documents ...

Copyright year copyright-owner

Permission is granted to ...
```

```
@end ifinfo

@c  This title page illustrates only one of the
@c  two methods of forming a title page.

@titlepage
@title name-of-manual-when-printed
@subtitle subtitle-if-any
@subtitle second-subtitle
@author author

@c  The following two commands
@c  start the copyright page.
@page
@vskip 0pt plus 1filll
Copyright @copyright{} year copyright-owner

Published by ...

Permission is granted to ...
@end titlepage

@node Top, Overview, (dir), (dir)

@ifinfo
This document describes ...

This document applies to version ...
of the program named ...
@end ifinfo

@menu
* Copying::          Your rights and freedoms.
* First Chapter::    Getting started ...
* Second Chapter::             ...
  ...
  ...
@end menu

@node    First Chapter, Second Chapter, top,      top
@comment node-name,     next,           previous, up
@chapter First Chapter
@cindex Index entry for First Chapter
```

The Texinfo File Header

Texinfo files start with at least three lines that provide Info and TeX with necessary information. These are the `\input texinfo` line, the `@settitle` line, and the `@setfilename` line. If you want to run TeX on just a part of the Texinfo File, you must write the `@settitle` and `@setfilename` lines between start-of-header and end-of-header lines.

Thus, the beginning of a Texinfo file looks like this:

```
\input texinfo   @c -*-texinfo-*-
@setfilename sample.info
@settitle Sample Document
```

or else like this:

```
\input texinfo   @c -*-texinfo-*-
@c %**start of header
@setfilename sample.info
@settitle Sample Document
@c %**end of header
```

The First Line of a Texinfo File

Every Texinfo file that is to be the top-level input to TeX must begin with a line that looks like this:

```
\input texinfo   @c -*-texinfo-*-
```

This line serves two functions:

1. When the file is processed by TeX, the `\input texinfo` command tells TeX to load the macros needed for processing a Texinfo file. These are in a file called `` `texinfo.tex' ``, which is usually located in the `` `/usr/lib/tex/macros' `` directory. TeX uses the backslash, `\', to mark the beginning of a command, just as Texinfo uses @. The `` `texinfo.tex' `` file causes the switch from `\' to `@'; before the switch occurs, TeX requires `\', which is why it appears at the beginning of the file.
2. When the file is edited in GNU Emacs, the `-*-texinfo-*-' mode specification tells Emacs to use Texinfo mode.

Start of Header

Write a start-of-header line on the second line of a Texinfo file. Follow the start-of-header line with `@setfilename` and `@settitle` lines and, optionally, with other command lines, such as `@smallbook` or `@footnotestyle`; and then by an end-of-header line (see section End of Header).

With these lines, you can format part of a Texinfo file for Info or typeset part for printing.

A start-of-header line looks like this:

```
@c %**start of header
```

The odd string of characters, `%**', is to ensure that no other comment is accidentally taken for a start-of-header line.

@setfilename

In order to be made into an Info file, a Texinfo file must contain a line that looks like this:

```
@setfilename info-file-name
```

Write the `@setfilename` command at the beginning of a line and follow it on the same line by the Info file name. Do not write anything else on the line; anything on the line after the command is considered part of the file name, including a comment.

The `@setfilename` line specifies the name of the Info file to be generated. This name should be different from the name of the Texinfo file. The convention is to write a name with a `.info' extension, to produce an Info file name such as `` `texinfo.info' ``.

Some operating systems cannot handle long file names. You can run into a problem even when the file name you specify is itself short enough. This occurs because the Info formatters split a long Info file into short indirect subfiles, and name them by appending `-1', `-2', ..., `-10', `-11', and so on, to the original file name. (See section Tag Files and Split Files.) The subfile name `` `texinfo.info-10' ``, for example, is too long for some systems; so the Info file name for this document is actually `` `texinfo' `` rather than `` `texinfo.info' ``.

The Info formatting commands ignore everything written before the `@setfilename` line, which is why the very first line of the file (the `\input` line) does not need to be commented out. The `@setfilename` line is ignored when you typeset a printed manual.

@settitle

In order to be made into a printed manual, a Texinfo file must contain a line that looks like this:

```
@settitle title
```

Write the `@settitle` command at the beginning of a line and follow it on the same line by the title. This tells TeX the title to use in a header or footer. Do not write anything else on the line; anything on the line after the command is considered part of the title, including a comment.

Conventionally, TeX formats a Texinfo file for double-sided output so as to print the title in the left-hand (even-numbered) page headings and the current chapter titles in the right-hand (odd-numbered) page headings. (TeX learns the title of each chapter from each `@chapter` command.) Page footers are not printed.

Even if you are printing in a single-sided style, TeX looks for an `@settitle` command line, in case you include the manual title in the heading.

The `@settitle` command should precede everything that generates actual output in TeX.

Although the title in the `@settitle` command is usually the same as the title on the title page, it does not affect the title as it appears on the title page. Thus, the two do not need not match exactly; and the title in the `@settitle` command can be a shortened or expanded version of the title as it appears on the title page. (See section `@titlepage`.)

TeX prints page headings only for that text that comes after the `@end titlepage` command in the Texinfo file, or that comes after an `@headings` command that turns on headings. (See section The `@headings` Command, for more information.)

You may, if you wish, create your own, customized headings and footings. See section Page Headings, for a detailed discussion of this process.

`@setchapternewpage`

In a book or a manual, text is usually printed on both sides of the paper, chapters start on right-hand pages, and right-hand pages have odd numbers. But in short reports, text often is printed only on one side of the paper. Also in short reports, chapters sometimes do not start on new pages, but are printed on the same page as the end of the preceding chapter, after a small amount of vertical whitespace.

You can use the `@setchapternewpage` command with various arguments to specify how TeX should start chapters and whether it should typeset pages for printing on one or both sides of the paper (single-sided or double-sided printing).

Write the `@setchapternewpage` command at the beginning of a line followed by its argument.

For example, you would write the following to cause each chapter to start on a fresh odd-numbered page:

```
@setchapternewpage odd
```

You can specify one of three alternatives with the `@setchapternewpage` command:

`@setchapternewpage off`

> Cause TeX to typeset a new chapter on the same page as the last chapter, after skipping some vertical whitespace. Also, cause TeX to format page headers for single-sided printing. (You can override the headers format with the `@headings double` command; see section The `@headings` Command.)

`@setchapternewpage on`

> Cause TeX to start new chapters on new pages and to typeset page headers for single-sided printing. This is the form most often used for short reports.
>
> This alternative is the default.

`@setchapternewpage odd`

Cause TeX to start new chapters on new, odd-numbered pages (right-handed pages) and to typ
for double-sided printing. This is the form most often used for books and manuals.

Texinfo does not have an `@setchapternewpage even` command.

(You can countermand or modify an `@setchapternewpage` command with an `@headings` command. See section The `@headings` Command Command}.)

At the beginning of a manual or book, pages are not numbered--for example, the title and copyright pages of a book are not numbered. By convention, table of contents pages are numbered with roman numerals and not in sequence with the rest of the document.

Since an Info file does not have pages, the `@setchapternewpage` command has no effect on it.

Usually, you do not write an `@setchapternewpage` command for single-sided printing, but accept the default which is to typeset for single-sided printing and to start new chapters on new pages. Usually, you write an `@setchapternewpage odd` command for double-sided printing.

Paragraph Indenting

The Info formatting commands may insert spaces at the beginning of the first line of each paragraph, thereby indenting that paragraph. You can use the `@paragraphindent` command to specify the indentation. Write an `@paragraphindent` command at the beginning of a line followed by either `asis' or a number. The template is:

```
@paragraphindent indent
```

The Info formatting commands indent according to the value of indent:

- If the value of indent is `asis', the Info formatting commands do not change the existing indentation.
- If the value of indent is 0, the Info formatting commands delete existing indentation.
- If the value of indent is greater than 0, the Info formatting commands indent the paragraph by that number of spaces.

The default value of indent is `asis'.

Write the `@paragraphindent` command before or shortly after the end-of-header line at the beginning of a Texinfo file. (If you write the command between the start-of-header and end-of-header lines, the region formatting commands indent paragraphs as specified.)

A peculiarity of `texinfo-format-buffer` and `texinfo-format-region` is that they do not indent (nor fill) paragraphs that contain `@w` or `@*` commands. See section Refilling Paragraphs, for a detailed description of what goes on.

End of Header

Follow the header lines with an end-of-header line. An end-of-header line looks like this:

```
@c %**end of header
```

If you include the `@setchapternewpage` command between the start-of-header and end-of-header lines, TeX will typeset a region as that command specifies. Similarly, if you include an `@smallbook` command between the start-of-header and end-of-header lines, TeX will typeset a region in the "small" book format.

See section Start of Header.

Summary and Copying Permissions for Info

The title page and the copyright page appear only in the printed copy of the manual; therefore, the same information must be inserted in a section that appears only in the Info file. This section usually contains a brief description of the contents of the Info file, a copyright notice, and copying permissions.

The copyright notice should read:

```
Copyright year copyright-owner
```

and be put on a line by itself.

Standard text for the copyright permissions is contained in an appendix to this manual; see section `ifinfo' Copying Permissions, for the complete text.

The permissions text appears in an Info file *before* the first node. This mean that a reader does *not* see this text when reading the file using Info, except when using the advanced Info command g *.

The Title and Copyright Pages

A manual's name and author are usually printed on a title page. Sometimes copyright information is printed on the title page as well; more often, copyright information is printed on the back of the title page.

The title and copyright pages appear in the printed manual, but not in the Info file. Because of this, it is possible to use several slightly obscure TeX typesetting commands that cannot be used in an Info file. In addition, this part of the beginning of a Texinfo file contains the text of the copying permissions that will appear in the printed manual.

See section Titlepage Copying Permissions, for the standard text for the copyright permissions.

@titlepage

Start the material for the title page and following copyright page with `@titlepage` on a line by itself and end it with `@end titlepage` on a line by itself.

The `@end titlepage` command starts a new page and turns on page numbering. (See section Page Headings, for details about how to generate of page headings.) All the material that you want to appear on unnumbered pages should be put between the `@titlepage` and `@end titlepage` commands. By using the `@page` command you can force a page break within the region delineated by the `@titlepage` and `@end titlepage` commands and thereby create more than one unnumbered page. This is how the copyright page is produced. (The `@titlepage` command might perhaps have been better named the `@titleandadditionalpages` command, but that would have been rather long!)

When you write a manual about a computer program, you should write the version of the program to which the manual applies on the title page. If the manual changes more frequently than the program or is independent of it, you should also include an edition number(5) for the manual. This helps readers keep track of which manual is for which version of the program. (The `Top' node should also contain this information; see section `@top'.)

Texinfo provides two methods for creating a title page. One method uses the `@titlefont`, `@sp`, and `@center` commands to generate a title page in which the words on the page are centered.

The second method uses the `@title`, `@subtitle`, and `@author` commands to create a title page with black rules under the title and author lines and the subtitle text set flush to the right hand side of the page. With this method, you do not specify any of the actual formatting of the title page. You specify the text you want, and Texinfo does the formatting. You may use either method.

@titlefont, @center, and @sp

You can use the `@titlefont`, `@sp`, and `@center` commands to create a title page for a printed document. (This is the first of the two methods for creating a title page in Texinfo.)

Use the `@titlefont` command to select a large font suitable for the title itself.

For example:

```
@titlefont{Texinfo}
```

Use the `@center` command at the beginning of a line to center the remaining text on that line. Thus,

```
@center @titlefont{Texinfo}
```

centers the title, which in this example is "Texinfo" printed in the title font.

Use the `@sp` command to insert vertical space. For example:

```
@sp 2
```

This inserts two blank lines on the printed page. (See section @sp n: Insert Blank Lines}, for more information about the @sp command.)

A template for this method looks like this:

```
@titlepage
@sp 10
@center @titlefont{name-of-manual-when-printed}
@sp 2
@center subtitle-if-any
@sp 2
@center author
...
@end titlepage
```

The spacing of the example fits an 8 1/2 by 11 inch manual.

@title, @subtitle, and @author

You can use the @title, @subtitle, and @author commands to create a title page in which the vertical and horizontal spacing is done for you automatically. This contrasts with the method described in the previous section, in which the @sp command is needed to adjust vertical spacing.

Write the @title, @subtitle, or @author commands at the beginning of a line followed by the title, subtitle, or author.

The @title command produces a line in which the title is set flush to the left-hand side of the page in a larger than normal font. The title is underlined with a black rule.

The @subtitle command sets subtitles in a normal-sized font flush to the right-hand side of the page.

The @author command sets the names of the author or authors in a middle-sized font flush to the left-hand side of the page on a line near the bottom of the title page. The names are underlined with a black rule that is thinner than the rule that underlines the title. (The black rule only occurs if the @author command line is followed by an @page command line.)

There are two ways to use the @author command: you can write the name or names on the remaining part of the line that starts with an @author command:

```
@author by Jane Smith and John Doe
```

or you can write the names one above each other by using two (or more) @author commands:

```
@author Jane Smith
@author John Doe
```

(Only the bottom name is underlined with a black rule.)

A template for this method looks like this:

```
@titlepage
@title name-of-manual-when-printed
@subtitle subtitle-if-any
@subtitle second-subtitle
@author author
@page
...
@end titlepage
```

Copyright Page and Permissions

By international treaty, the copyright notice for a book should be either on the title page or on the back of the title page. The copyright notice should include the year followed by the name of the organization or person who owns the copyright.

When the copyright notice is on the back of the title page, that page is customarily not numbered. Therefore, in Texinfo, the information on the copyright page should be within `@titlepage` and `@end titlepage` commands.

Use the `@page` command to cause a page break. To push the copyright notice and the other text on the copyright page towards the bottom of the page, you can write a somewhat mysterious line after the `@page` command that reads like this:

```
@vskip 0pt plus 1filll
```

This is a TeX command that is not supported by the Info formatting commands. The `@vskip` command inserts whitespace. The `0pt plus 1filll' means to put in zero points of mandatory whitespace, and as much optional whitespace as needed to push the following text to the bottom of the page. Note the use of three `l's in the word `filll'; this is the correct usage in TeX.

In a printed manual, the `@copyright{}` command generates a `c' inside a circle. (In Info, it generates `(C)'.) The copyright notice itself has the following legally defined sequence:

```
Copyright (C) year copyright-owner
```

It is customary to put information on how to get a manual after the copyright notice, followed by the copying permissions for the manual.

Note that permissions must be given here as well as in the summary segment within `@ifinfo` and `@end ifinfo` that immediately follows the header since this text appears only in the printed manual and the `ifinfo' text appears only in the Info file.

See section Sample Permissions, for the standard text.

Heading Generation

An `@end titlepage` command on a line by itself not only marks the end of the title and copyright pages, but also causes TeX to start generating page headings and page numbers.

To repeat what is said elsewhere, Texinfo has two standard page heading formats, one for documents which are printed on one side of each sheet of paper (single-sided printing), and the other for documents which are printed on both sides of each sheet (double-sided printing). (See section `@setchapternewpage`.) You can specify these formats in different ways:

- The conventional way is to write an `@setchapternewpage` command before the title page commands, and then have the `@end titlepage` command start generating page headings in the manner desired. (See section `@setchapternewpage`.)
- Alternatively, you can use the `@headings` command to prevent page headings from being generated or to start them for either single or double-sided printing. (Write an `@headings` command immediately after the `@end titlepage` command. See section The `@headings` Command Command}, for more information.)
- Or, you may specify your own page heading and footing format. See section Page Headings, for detailed information about page headings and footings.

Most documents are formatted with the standard single-sided or double-sided format, using `@setchapternewpage odd` for double-sided printing and no `@setchapternewpage` command for single-sided printing.

The `@headings` Command

The `@headings` command is rarely used. It specifies what kind of page headings and footings to print on each page. Usually, this is controlled by the `@setchapternewpage` command. You need the `@headings` command only if the `@setchapternewpage` command does not do what you want, or if you want to turn off pre-defined page headings prior to defining your own. Write an `@headings` command immediately after the `@end titlepage` command.

There are four ways to use the `@headings` command:

`@headings off`

: Turn off printing of page headings.

`@headings single`

: Turn on page headings appropriate for single-sided printing.

`@headings double`

`@headings on`

: Turn on page headings appropriate for double-sided printing. The two commands, `@headings on` and `@headings double`, are synonymous.

For example, suppose you write `@setchapternewpage off` before the `@titlepage` command to tell TeX to start a new chapter on the same page as the end of the last chapter. This command also causes

TeX to typeset page headers for single-sided printing. To cause TeX to typeset for double sided print, write `@headings double` after the `@end titlepage` command.

You can stop TeX from generating any page headings at all by writing `@headings off` on a line of its own immediately after the line containing the `@end titlepage` command, like this:

```
@end titlepage
@headings off
```

The `@headings off` command overrides the `@end titlepage` command, which would otherwise cause TeX to print page headings.

You can also specify your own style of page heading and footing. See section Page Headings, for more information.

The `Top' Node and Master Menu

The `Top' node is the node from which you enter an Info file.

A `Top' node should contain a brief description of the Info file and an extensive, master menu for the whole Info file. This helps the reader understand what the Info file is about. Also, you should write the version number of the program to which the Info file applies; or, at least, the edition number.

The contents of the `Top' node should appear only in the Info file; none of it should appear in printed output, so enclose it between `@ifinfo` and `@end ifinfo` commands. (TeX does not print either an `@node` line or a menu; they appear only in Info; strictly speaking, you are not required to enclose these parts between `@ifinfo` and `@end ifinfo`, but it is simplest to do so. See section Conditionally Visible Text.)

Sometimes, you will want to place an `@top` sectioning command line containing the title of the document immediately after the `@node Top` line (see section The `@top` Sectioning Command, for more information).

For example, the beginning of the Top node of this manual contains an `@top` sectioning command, a short description, and edition and version information. It looks like this:

```
...
@end titlepage

@ifinfo
@node Top, Copying, (dir), (dir)
@top Texinfo

Texinfo is a documentation system...

This is edition...
```

```
...
@end ifinfo

@menu
* Copying::                Texinfo is freely
                             redistributable.
* Overview::               What is Texinfo?
...
@end menu
```

In a `Top' node, the `Previous', and `Up' nodes usually refer to the top level directory of the whole Info system, which is called `(dir)'. The `Next' node refers to the first node that follows the main or master menu, which is usually the copying permissions, introduction, or first chapter.

Parts of a Master Menu

A master menu is a detailed main menu listing all the nodes in a file.

A master menu is enclosed in `@menu` and `@end menu` commands and does not appear in the printed document.

Generally, a master menu is divided into parts.

- The first part contains the major nodes in the Texinfo file: the nodes for the chapters, chapter-like sections, and the appendices.
- The second part contains nodes for the indices.
- The third and subsequent parts contain a listing of the other, lower level nodes, often ordered by chapter. This way, rather than go through an intermediary menu, an inquirer can go directly to a particular node when searching for specific information. These menu items are not required; add them if you think they are a convenience.

Each section in the menu can be introduced by a descriptive line. So long as the line does not begin with an asterisk, it will not be treated as a menu entry. (See section Writing a Menu, for more information.)

For example, the master menu for this manual looks like the following (but has many more entries):

```
@menu
* Copying::              Texinfo is freely
                           redistributable.
* Overview::             What is Texinfo?
* Texinfo Mode::         Special features in GNU Emacs.
...
...
* Command and Variable Index::
                        An entry for each @-command.
* Concept Index::        An entry for each concept.
```

```
 -- The Detailed Node Listing ---

Overview of Texinfo

* Info Files::           What is an Info file?
* Printed Manuals::      Characteristics of
                           a printed manual.

@end menu
```

Software Copying Permissions

If the Texinfo file has a section containing the "General Public License" and the distribution information and a warranty disclaimer for the software that is documented, this section usually follows the `Top' node. The General Public License is very important to Project GNU software. It ensures that you and others will continue to have a right to use and share the software.

The copying and distribution information and the disclaimer are followed by an introduction or else by the first chapter of the manual.

Although an introduction is not a required part of a Texinfo file, it is very helpful. Ideally, it should state clearly and concisely what the file is about and who would be interested in reading it. In general, an introduction would follow the licensing and distribution information, although sometimes people put it earlier in the document. Usually, an introduction is put in an `@unnumbered` section. (See section `@unnumbered`, `@appendix` Commands}.)

Go to the previous, next section.

Go to the previous, next section.

Ending a Texinfo File

The end of a Texinfo file should include the commands that create indices and generate detailed and summary tables of contents. And it must include the `@bye` command that marks the last line processed by TeX.

For example:

```
@node    Concept Index,     , Variables Index, Top
@c        node-name,    next, previous,        up
@unnumbered Concept Index

@printindex cp

@contents
@bye
```

Index Menus and Printing an Index

To print an index means to include it as part of a manual or Info file. This does not happen automatically just because you use `@cindex` or other index-entry generating commands in the Texinfo file; those just cause the raw data for the index to be accumulated. To generate an index, you must include the `@printindex` command at the place in the document where you want the index to appear. Also, as part of the process of creating a printed manual, you must run a program called `texindex` (see section Format and Print Hardcopy) to sort the raw data to produce a sorted index file. The sorted index file is what is actually used to print the index.

Texinfo offers six different types of predefined index: the concept index, the function index, the variables index, the keystroke index, the program index, and the data type index (see section Predefined Indices). Each index type has a two-letter name: `cp', `fn', `vr', `ky', `pg', and `tp'. You may merge indices, or put them into separate sections (see section Combining Indices); or you may define your own indices (see section Defining New Indices).

The `@printindex` command takes a two-letter index name, reads the corresponding sorted index file and formats it appropriately into an index.

The `@printindex` command does not generate a chapter heading for the index. Consequently, you should precede the `@printindex` command with a suitable section or chapter command (usually `@unnumbered`) to supply the chapter heading and put the index into the table of contents. Precede the `@unnumbered` command with an `@node` line.

For example:

```
@node Variable Index, Concept Index, Function Index, Top
@comment    node-name,         next,       previous, up
@unnumbered Variable Index

@printindex vr

@node     Concept Index,     , Variable Index, Top
@comment      node-name, next,       previous, up
@unnumbered Concept Index

@printindex cp

@summarycontents
@contents
@bye
```

(Readers often prefer that the concept index come last in a book, since that makes it easiest to find.)

Generating a Table of Contents

The `@chapter`, `@section`, and other structuring commands supply the information to make up a table of contents, but they do not cause an actual table to appear in the manual. To do this, you must use the `@contents` and `@summarycontents` commands:

`@contents`

> Generate a table of contents in a printed manual, including all chapters, sections, subsections, etc., as well as appendices and unnumbered chapters. (Headings generated by the `@heading` series of commands do not appear in the table of contents.) The `@contents` command should be written on a line by itself.

`@shortcontents`

`@summarycontents`

> (`@summarycontents` is a synonym for `@shortcontents`; the two commands are exactly the same.)
>
> Generate a short or summary table of contents that lists only the chapters (and appendices and unnumbered chapters). Omit sections, subsections and subsubsections. Only a long manual needs a short table of contents in addition to the full table of contents.
>
> Write the `@shortcontents` command on a line by itself right *before* the `@contents` command.

The table of contents commands automatically generate a chapter-like heading at the top of the first table of contents page. Write the table of contents commands at the very end of a Texinfo file, just before the `@bye` command, following any index sections--anything in the Texinfo file after the table of contents commands will be omitted from the table of contents.

When you print a manual with a table of contents, the table of contents are printed last and numbered with roman numerals. You need to place those pages in their proper place, after the title page, yourself. (This is the only collating you need to do for a printed manual. The table of contents is printed last because it is generated after the rest of the manual is typeset.)

Here is an example of where to write table of contents commands:

```
indices...
@shortcontents
@contents
@bye
```

Since an Info file uses menus instead of tables of contents, the Info formatting commands ignore the `@contents` and `@shortcontents` commands.

@bye File Ending

An `@bye` command terminates TeX or Info formatting. None of the formatting commands see any of the file following `@bye`. The `@bye` command should be on a line by itself.

If you wish, you may follow the `@bye` line with notes. These notes will not be formatted and will not appear in either Info or a printed manual; it is as if text after `@bye` were within `@ignore` ... `@end ignore`. Also, you may follow the `@bye` line with a local variables list. See section Using the Local Variables List, for more information.

Go to the previous, next section.

Go to the previous, next section.

Chapter Structuring

The chapter structuring commands divide a document into a hierarchy of chapters, sections, subsections, and subsubsections. These commands generate large headings; they also provide information for the table of contents of a printed manual (see section Generating a Table of Contents).

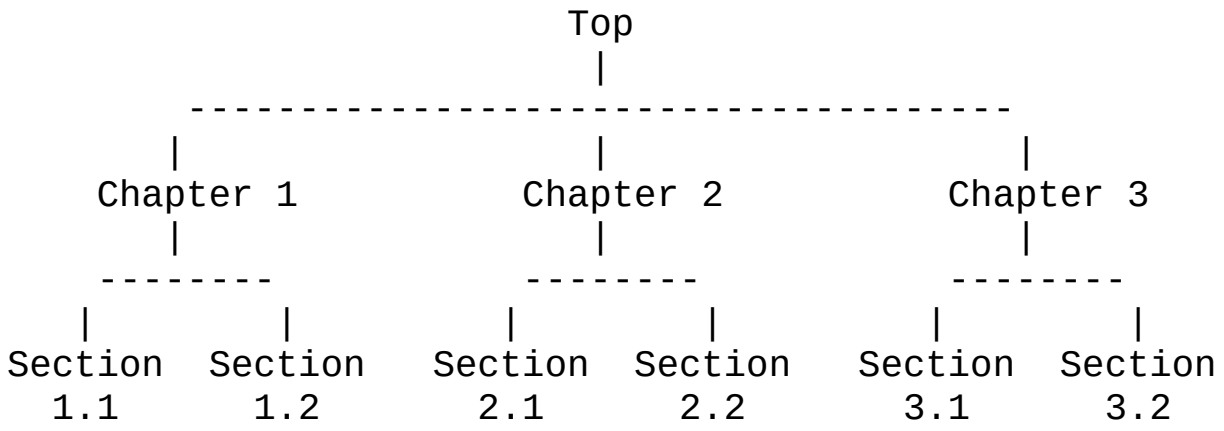
The chapter structuring commands do not create an Info node structure, so normally you should put an `@node` command immediately before each chapter structuring command (see section Nodes). The only time you are likely to use the chapter structuring commands without using the node structuring commands is if you are writing a document that contains no cross references and will never be transformed into Info format.

It is unlikely that you will ever write a Texinfo file that is intended only as an Info file and not as a printable document. If you do, you might still use chapter structuring commands to create a heading at the top of each node--but you don't need to.

Tree Structure of Sections

A Texinfo file is usually structured like a book with chapters, sections, subsections, and the like. This structure can be visualized as a tree (or rather as an upside-down tree) with the root at the top and the levels corresponding to chapters, sections, subsection, and subsubsections.

Here is a diagram that shows a Texinfo file with three chapters, each of which has two sections.



In a Texinfo file that has this structure, the beginning of Chapter 2 looks like this:

```
@node    Chapter 2,  Chapter 3, Chapter 1, top
@chapter Chapter 2
```

The chapter structuring commands are described in the sections that follow; the `@node` and `@menu`

commands are described in following chapters. (See section Nodes, and see section Menus.)

Types of Structuring Command

The chapter structuring commands fall into four groups or series, each of which contains structuring commands corresponding to the hierarchical levels of chapters, sections, subsections, and subsubsections.

The four groups are the `@chapter` series, the `@unnumbered` series, the `@appendix` series, and the `@heading` series.

Each command produces titles that have a different appearance on the printed page or Info file; only some of the commands produce titles that are listed in the table of contents of a printed book or manual.

- The `@chapter` and `@appendix` series of commands produce numbered or lettered entries both in the body of a printed work and in its table of contents.
- The `@unnumbered` series of commands produce unnumbered entries both in the body of a printed work and in its table of contents. The `@top` command, which has a special use, is a member of this series (see section `@top`).
- The `@heading` series of commands produce unnumbered headings that do not appear in a table of contents. The heading commands never start a new page.
- The `@majorheading` command produces results similar to using the `@chapheading` command but generates a larger vertical whitespace before the heading.
- When an `@setchapternewpage` command says to do so, the `@chapter`, `@unnumbered`, and `@appendix` commands start new pages in the printed manual; the `@heading` commands do not.

Here are the four groups of chapter structuring commands:

@top

The `@top` command is a special sectioning command that you use only after an `@node Top` line at the beginning of a Texinfo file. The `@top` command tells the `makeinfo` formatter which node is the `Top' node. It has the same typesetting effect as `@unnumbered` (see section `@unnumbered, @appendix`). For detailed information, see section The `@top` Sectioning Command.

@chapter

`@chapter` identifies a chapter in the document. Write the command at the beginning of a line and follow it on the same line by the title of the chapter.

For example, this chapter in this manual is entitled "Chapter Structuring"; the `@chapter` line looks like this:

`@chapter Chapter Structuring`

In TeX, the `@chapter` command creates a chapter in the document, specifying the chapter title. The chapter is numbered automatically.

In Info, the `@chapter` command causes the title to appear on a line by itself, with a line of asterisks inserted underneath. Thus, in Info, the above example produces the following output:

```
Chapter Structuring
*******************
```

@unnumbered, @appendix

Use the `@unnumbered` command to create a chapter that appears in a printed manual without chapter numbers of any kind. Use the `@appendix` command to create an appendix in a printed manual that is labelled by letter instead of by number.

For Info file output, the `@unnumbered` and `@appendix` commands are equivalent to `@chapter`: the title is printed on a line by itself with a line of asterisks underneath. (See section `@chapter`}.)

To create an appendix or an unnumbered chapter, write an `@appendix` or `@unnumbered` command at the beginning of a line and follow it on the same line by the title, as you would if you were creating a chapter.

@majorheading, @chapheading

The `@majorheading` and `@chapheading` commands put chapter-like headings in the body of a document.

However, neither command causes TeX to produce a numbered heading or an entry in the table of contents; and neither command causes TeX to start a new page in a printed manual.

In TeX, an `@majorheading` command generates a larger vertical whitespace before the heading than an `@chapheading` command but is otherwise the same.

In Info, the `@majorheading` and `@chapheading` commands are equivalent to `@chapter`: the title is printed on a line by itself with a line of asterisks underneath. (See section `@chapter`.)

@section

In a printed manual, an `@section` command identifies a numbered section within a chapter. The section title appears in the table of contents. In Info, an `@section` command provides a title for a segment of text, underlined with `=`'.

This section is headed with an `@section` command and looks like this in the Texinfo file:

`@section @code{@@section}`

To create a section, write the `@section` command at the beginning of a line and follow it on the same line by the section title.

Thus,

```
@section This is a section
```

produces

```
This is a section
==================
```

in Info.

@unnumberedsec, @appendixsec, @heading

The `@unnumberedsec`, `@appendixsec`, and `@heading` commands are, respectively, the unnumbered, appendix-like, and heading-like equivalents of the `@section` command. (See section `@section`.)

`@unnumberedsec`

> The `@unnumberedsec` command may be used within an unnumbered chapter or within a regular chapter or appendix to provide an unnumbered section.

`@appendixsec`

`@appendixsection`

> `@appendixsection` is a longer spelling of the `@appendixsec` command; the two are synonymous.
>
> Conventionally, the `@appendixsec` or `@appendixsection` command is used only within appendices.

`@heading`

> You may use the `@heading` command anywhere you wish for a section-style heading that will not appear in the table of contents.

The @subsection Command

Subsections are to sections as sections are to chapters. (See section `@section`.) In Info, subsection titles are underlined with `-'. For example,

```
@subsection This is a subsection
```

produces

```
This is a subsection
--------------------
```

In a printed manual, subsections are listed in the table of contents and are numbered three levels deep.

The `@subsection`-like Commands

The `@unnumberedsubsec`, `@appendixsubsec`, and `@subheading` commands are, respectively, the unnumbered, appendix-like, and heading-like equivalents of the `@subsection` command. (See section The `@subsection` Command.)

In Info, the `@subsection`-like commands generate a title underlined with hyphens. In a printed manual, an `@subheading` command produces a heading like that of a subsection except that it is not numbered and does not appear in the table of contents. Similarly, an `@unnumberedsubsec` command produces an unnumbered heading like that of a subsection and an `@appendixsubsec` command produces a subsection-like heading labelled with a letter and numbers; both of these commands produce headings that appear in the table of contents.

The `subsub' Commands

The fourth and lowest level sectioning commands in Texinfo are the `subsub' commands. They are:

`@subsubsection`

Subsubsections are to subsections as subsections are to sections. (See section The `@subsection` Command.) In a printed manual, subsubsection titles appear in the table of contents and are numbered four levels deep.

`@unnumberedsubsubsec`

Unnumbered subsubsection titles appear in the table of contents of a printed manual, but lack numbers. Otherwise, unnumbered subsubsections are the same as subsubsections. In Info, unnumbered subsubsections look exactly like ordinary subsubsections.

`@appendixsubsubsec`

Conventionally, appendix commands are used only for appendices and are lettered and numbered appropriately in a printed manual. They also appear in the table of contents. In Info, appendix subsubsections look exactly like ordinary subsubsections.

`@subsubheading`

The `@subsubheading` command may be used anywhere that you need a small heading that will not appear in the table of contents. In Info, subsubheadings look exactly like ordinary subsubsection headings.

In Info, `subsub' titles are underlined with periods. For example,

```
@subsubsection This is a subsubsection
```

produces

```
This is a subsubsection
.......................
```

Go to the previous, next section.

Go to the previous, next section.

Nodes

Nodes are the primary segments of a Texinfo file. They do not themselves impose a hierarchic or any other kind of structure on a file. Nodes contain node pointers that name other nodes, and can contain menus which are lists of nodes. In Info, the movement commands can carry you to a pointed-to node or to a node listed in a menu. Node pointers and menus provide structure for Info files just as chapters, sections, subsections, and the like, provide structure for printed books.

The node and menu commands and the chapter structuring commands are independent of each other:

- In Info, node and menu commands provide structure. The chapter structuring commands generate headings with different kinds of underlining--asterisks for chapters, hyphens for sections, and so on; they do nothing else.
- In TeX, the chapter structuring commands generate chapter and section numbers and tables of contents. The node and menu commands provide information for cross references; they do nothing else.

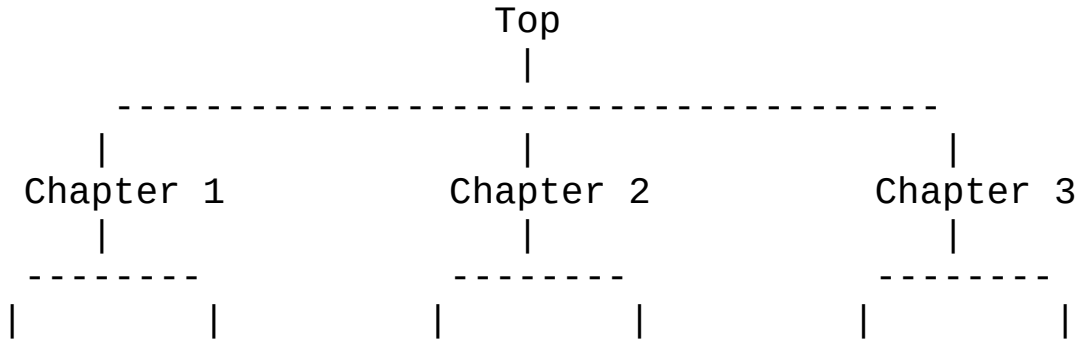
You can use node pointers and menus to structure an Info file any way you want; and you can write a Texinfo file so that its Info output has a different structure than its printed output. However, most Texinfo files are written such that the structure for the Info output corresponds to the structure for the printed output. It is not convenient to do otherwise.

Generally, printed output is structured in a tree-like hierarchy in which the chapters are the major limbs from which the sections branch out. Similarly, node pointers and menus are organized to create a matching structure in the Info output.

Node and Menu Illustration

Here is a copy of the diagram shown earlier that illustrates a Texinfo file with three chapters, each of which contains two sections.

Note that the "root" is at the top of the diagram and the "leaves" are at the bottom. This is how such a diagram is drawn conventionally; it illustrates an upside-down tree. For this reason, the root node is called the `Top' node, and `Up' node pointers carry you closer to the root.



```
 Section  Section   Section  Section   Section  Section
   1.1      1.2       2.1      2.2       3.1      3.2
```

Write the beginning of the node for Chapter 2 like this:

```
@node     Chapter 2,  Chapter 3, Chapter 1, top
@comment  node-name,  next,      previous,  up
```

This `@node` line says that the name of this node is "Chapter 2", the name of the `Next' node is "Chapter 3", the name of the `Previous' node is "Chapter 1", and the name of the `Up' node is "Top".

> **Please Note:** `Next' refers to the next node at the same hierarchical level in the manual, not necessarily to the next node within the Texinfo file. In the Texinfo file, the subsequent node may be at a lower level--a section-level node may follow a chapter-level node, and a subsection-level node may follow a section-level node. `Next' and `Previous' refer to nodes at the *same* hierarchical level. (The `Top' node contains the exception to this rule. Since the `Top' node is the only node at that level, `Next' refers to the first following node, which is almost always a chapter or chapter-level node.)

To go to Sections 2.1 and 2.2 using Info, you need a menu inside Chapter 2. (See section Menus.) You would write the menu just before the beginning of Section 2.1, like this:

```
@menu
* Sect. 2.1::    Description of this section.
* Sect. 2.2::
@end menu
```

Write the node for Sect. 2.1 like this:

```
@node     Sect. 2.1, Sect. 2.2, Chapter 2, Chapter 2
@comment  node-name, next,      previous,  up
```

In Info format, the `Next' and `Previous' pointers of a node usually lead to other nodes at the same level--from chapter to chapter or from section to section (sometimes, as shown, the `Previous' pointer points up); an `Up' pointer usually leads to a node at the level above (closer to the `Top' node); and a `Menu' leads to nodes at a level below (closer to `leaves'). (A cross reference can point to a node at any level; see section Cross References.)

Usually, an `@node` command and a chapter structuring command are used in sequence, along with indexing commands. (You may follow the `@node` line with a comment line that reminds you which pointer is which.)

Here is the beginning of the chapter in this manual called "Ending a Texinfo File". This shows an `@node` line followed by a comment line, an `@chapter` line, and then by indexing lines.

```
@node    Ending a File, Structuring, Beginning a File, Top
@comment node-name,     next,        previous,         up
```

```
@chapter Ending a Texinfo File
@cindex Ending a Texinfo file
@cindex Texinfo file ending
@cindex File ending
```

The @node Command

A node is a segment of text that begins at an `@node` command and continues until the next `@node` command. The definition of node is different from that for chapter or section. A chapter may contain sections and a section may contain subsections; but a node cannot contain subnodes; the text of a node continues only until the next `@node` command in the file. A node usually contains only one chapter structuring command, the one that follows the `@node` line. On the other hand, in printed output nodes are used only for cross references, so a chapter or section may contain any number of nodes. Indeed, a chapter usually contains several nodes, one for each section, subsection, and subsubsection.

To create a node, write an `@node` command at the beginning of a line, and follow it with four arguments, separated by commas, on the rest of the same line. These arguments are the name of the node, and the names of the `Next', `Previous', and `Up' pointers, in that order. You may insert spaces before each pointer if you wish; the spaces are ignored. You must write the name of the node, and the names of the `Next', `Previous', and `Up' pointers, all on the same line. Otherwise, the formatters fail. (@inforef{Top, info, info}, for more information about nodes in Info.)

Usually, you write one of the chapter-structuring command lines immediately after an `@node` line--for example, an `@section` or `@subsection` line. (See section Types of Structuring Command.)

> **Please note:** The GNU Emacs Texinfo mode updating commands work only with Texinfo files in which `@node` lines are followed by chapter structuring lines. See section Updating Requirements.

TeX uses `@node` lines to identify the names to use for cross references. For this reason, you must write `@node` lines in a Texinfo file that you intend to format for printing, even if you do not intend to format it for Info. (Cross references, such as the one at the end of this sentence, are made with `@xref` and its related commands; see section Cross References.)

The name of a node identifies the node. The pointers enable you to reach other nodes and consist of the names of those nodes.

Normally, a node's `Up' pointer contains the name of the node whose menu mentions that node. The node's `Next' pointer contains the name of the node that follows that node in that menu and its `Previous' pointer contains the name of the node that precedes it in that menu. When a node's `Previous' node is the same as its `Up' node, both node pointers name the same node.

Usually, the first node of a Texinfo file is the `Top' node, and its `Up' and `Previous' pointers point to the `dir' file, which contains the main menu for all of Info.

The `Top' node itself contains the main or master menu for the manual. Also, it is helpful to include a brief description of the manual in the `Top' node. See section The First Node, for information on how to

write the first node of a Texinfo file.

How to Write an @node Line

The easiest way to write an `@node` line is to write `@node` at the beginning of a line and then the name of the node, like this:

```
@node node-name
```

If you are using GNU Emacs, you can use the update node commands provided by Texinfo mode to insert the names of the pointers; or you can leave the pointers out of the Texinfo file and let `makeinfo` insert node pointers into the Info file it creates. (See section Using Texinfo Mode, and section Creating Pointers with `makeinfo`.)

Alternatively, you can insert the `Next', `Previous', and `Up' pointers yourself. If you do this, you may find it helpful to use the Texinfo mode keyboard command C-c C-c n. This command inserts `@node' and a comment line listing the names of the pointers in their proper order. The comment line helps you keep track of which arguments are for which pointers. This comment line is especially useful if you are not familiar with Texinfo.

The template for a node line with `Next', `Previous', and `Up' pointers looks like this:

```
@node node-name, next, previous, up
```

If you wish, you can ignore `@node` lines altogether in your first draft and then use the `texinfo-insert-node-lines` command to create `@node` lines for you. However, we do not recommend this practice. It is better to name the node itself at the same time that you write a segment so you can easily make cross references. A large number of cross references are an especially important feature of a good Info file.

After you have inserted an `@node` line, you should immediately write an @-command for the chapter or section and insert its name. Next (and this is important!), put in several index entries. Usually, you will find at least two and often as many as four or five ways of referring to the node in the index. Use them all. This will make it much easier for people to find the node.

@node Line Tips

Here are three suggestions:

- Try to pick node names that are informative but short.

  In the Info file, the file name, node name, and pointer names are all inserted on one line, which may run into the right edge of the window. (This does not cause a problem with Info, but is ugly.)
- Try to pick node names that differ from each other near the beginnings of their names. This way, it is easy to use automatic name completion in Info.
- By convention, node names are capitalized just as they would be for section or chapter titles--initial and significant words are capitalized; others are not.

@node Line Requirements

Here are several requirements for `@node` lines:

- All the node names for a single Info file must be unique.

  Duplicates confuse the Info movement commands. This means, for example, that if you end every chapter with a summary, you must name each summary node differently. You cannot just call each one "Summary". You may, however, duplicate the titles of chapters, sections, and the like. Thus you can end each chapter in a book with a section called "Summary", so long as the node names for those sections are all different.
- A pointer name must be the name of a node.

  The node to which a pointer points may come before or after the node containing the pointer.
- You cannot use any of the Texinfo @-commands in a node name; @-commands confuse Info.

  Thus, the beginning of the section called `@chapter` looks like this:

```
@node  chapter, unnumbered & appendix, makeinfo top, Structuring
@comment  node-name,  next,  previous,  up
@section @code{@@chapter}
@findex chapter
```

- You cannot use commas, colons, or apostrophes within a node name; these confuse TeX or the Info formatters.

  For example, the following is a section title:

```
@code{@@unnumberedsec}, @code{@@appendixsec}, @code{@@heading}
```

  The corresponding node name is:

```
unnumberedsec appendixsec heading
```

- Case is significant.

The First Node

The first node of a Texinfo file is the `Top' node, except in an included file (see section Include Files).

The `Top' node (which must be named `top' or `Top') should have as its `Up' and `Previous' nodes the name of a node in another file, where there is a menu that leads to this file. Specify the file name in parentheses. If the file is to be installed directly in the Info directory file, use `(dir)' as the parent of the `Top' node; this is short for `(dir)top', and specifies the `Top' node in the `dir' file, which contains the main menu for Info. For example, the `@node Top` line of this manual looks like this:

```
@node Top, Overview, (dir), (dir)
```

(You may use the Texinfo updating commands or the `makeinfo` utility to insert these `Next' and `(pointers automatically.)

See section Installing an Info File, for more information about installing an Info file in the `info' directory.

The `Top' node contains the main or master menu for the document.

The `@top` Sectioning Command

A special sectioning command, `@top`, has been created for use with the `@node Top` line. The `@top` sectioning command tells `makeinfo` that it marks the `Top' node in the file. It provides the information that `makeinfo` needs to insert node pointers automatically. Write the `@top` command at the beginning of the line immediately following the `@node Top` line. Write the title on the remaining part of the same line as the `@top` command.

In Info, the `@top` sectioning command causes the title to appear on a line by itself, with a line of asterisks inserted underneath.

In TeX and `texinfo-format-buffer`, the `@top` sectioning command is merely a synonym for `@unnumbered`. Neither of these formatters require an `@top` command, and do nothing special with it. You can use `@chapter` or `@unnumbered` after the `@node Top` line when you use these formatters. Also, you can use `@chapter` or `@unnumbered` when you use the Texinfo updating commands to create or update pointers and menus.

Whatever sectioning command follows an `@node Top` line, whether it be `@top` or `@chapter`, the `@node Top` line and the immediately following line and any additional text must be enclosed between `@ifinfo` and `@end ifinfo` commands. (See section Conditionally Visible Text.) This prevents the title and the accompanying text from appearing in printed output. Write the `@ifinfo` command before the `@node` line and write the `@end ifinfo` command after the `@top` or other sectioning command and after any additional text. (You can write the `@end ifinfo` command after the `@end menu` command if you like.)

The `Top' Node Summary

You can help readers by writing a summary in the `Top' node, after the `@top` line, before the main or master menu. The summary should briefly describe the Info file. You should also write the version number of the program to which the manual applies in this section. This helps the reader keep track of which manual is for which version of the program. If the manual changes more frequently than the program or is independent of it, you should also include an edition number for the manual. (The title page should also contain this information: see section `@titlepage`.)

Put the whole of the `Top' node, including the `@top` sectioning command line if you have one, between `@ifinfo` and `@end ifinfo` so none of the text appears in the printed output (see section Conditionally Visible Text). (You may want to repeat the brief description from the `Top' node within `@iftex` ... `@end iftex` at the beginning of the first chapter, for those who read the printed manual.)

Creating Pointers with `makeinfo`

The `makeinfo` program has a feature for automatically creating node pointers for a hierarchically organized file that lacks them.

When you take advantage of this feature, you do not need to write the `Next', `Previous', and `Up' pointers after the name of a node. However, you must write a sectioning command, such as `@chapter` or `@section`, on the line immediately following each truncated `@node` line. You cannot write a comment line after a node line; the section line must follow it immediately.

In addition, you must follow the `Top' `@node` line with a line beginning with `@top` to mark the `Top' node in the file. See section `@top`}.

Finally, you must write the name of each node (except for the `Top' node) in a menu that is one or more hierarchical levels above the node's hierarchical level.

This node pointer insertion feature in `makeinfo` is an alternative to the menu and pointer creation and update commands in Texinfo mode. (See section Updating Nodes and Menus.) It is especially helpful to people who do not use GNU Emacs for writing Texinfo documents.

Go to the previous, next section.

Go to the previous, next section.

Menus

Menus contain pointers to subordinate nodes.(6) In Info, you use menus to go to such nodes. Menus have no effect in printed manuals and do not appear in them.

By convention, a menu is put at the end of a node since a reader who uses the menu may not see text that follows it.

A node that has a menu should not contain much text. If you have a lot of text and a menu, move most of the text into a new subnode--all but a few lines. Otherwise, a reader with a terminal that displays only a few lines may miss the menu and its associated text. As a practical matter, you should locate a menu within 20 lines of the beginning of the node.

The short text before a menu may look awkward in a printed manual. To avoid this, you can write a menu near the beginning of its node and follow the menu by an `@node` line, and then an `@heading` line located within `@ifinfo` and `@end ifinfo`. This way, the menu, `@node` line, and title appear only in the Info file, not the printed document.

For example, the preceding two paragraphs follow an Info-only menu, `@node` line, and heading, and look like this:

```
@menu
* Menu Location::              Put a menu in a short node.
* Writing a Menu::             What is a menu?
* Menu Parts::                 A menu entry has three parts.
* Less Cluttered Menu Entry:: Two part menu entry.
* Menu Example::               Two and three part entries.
* Other Info Files::           How to refer to a different
                                 Info file.
@end menu

@node Menu Location, Writing a Menu,  , Menus
@ifinfo
@heading Menus Need Short Nodes
@end ifinfo
```

The Texinfo file for this document contains more than a dozen examples of this procedure. One is at the beginning of this chapter; another is at the beginning of the "Cross References" chapter.

Writing a Menu

A menu consists of an `@menu` command on a line by itself followed by menu entry lines or menu comment lines and then by an `@end menu` command on a line by itself.

A menu looks like this:

```
@menu
Larger Units of Text

* Files::                      All about handling files.
* Multiples: Buffers.          Multiple buffers; editing
                                 several files at once.
@end menu
```

In a menu, every line that begins with an `* ' is a menu entry. (Note the space after the asterisk.) A line that does not start with an `* ' may also appear in a menu. Such a line is not a menu entry but is a menu comment line that appears in the Info file. In the example above, the line `Larger Units of Text' is a menu comment line; the two lines starting with `* ' are menu entries.

The Parts of a Menu

A menu entry has three parts, only the second of which is required:

1. The menu entry name.
2. The name of the node (required).
3. A description of the item.

The template for a menu entry looks like this:

```
* menu-entry-name: node-name.   description
```

Follow the menu entry name with a single colon and follow the node name with tab, comma, period, or newline.

In Info, a user selects a node with the m (`Info-menu`) command. The menu entry name is what the user types after the m command.

The third part of a menu entry is a descriptive phrase or sentence. Menu entry names and node names are often short; the description explains to the reader what the node is about. The description, which is optional, can spread over two or more lines. A useful description complements the node name rather than repeats it.

Less Cluttered Menu Entry

When the menu entry name and node name are the same, you can write the name immediately after the asterisk and space at the beginning of the line and follow the name with two colons.

For example, write

```
* Name::                                  description
```

instead of

```
* Name: Name.                             description
```

You should use the node name for the menu entry name whenever possible, since it reduces visual clutter in the menu.

A Menu Example

A menu looks like this in Texinfo:

```
@menu
* menu entry name: Node name.   A short description.
* Node name::                   This form is preferred.
@end menu
```

This produces:

```
* menu:

* menu entry name: Node name.   A short description.
* Node name::                   This form is preferred.
```

Here is an example as you might see it in a Texinfo file:

```
@menu
Larger Units of Text

* Files::                       All about handling files.
* Multiples: Buffers.           Multiple buffers; editing
                                  several files at once.
@end menu
```

This produces:

```
* menu:
```

```
Larger Units of Text

* Files::                      All about handling files.
* Multiples: Buffers.          Multiple buffers; editing
                                 several files at once.
```

In this example, the menu has two entries. `Files' is both a menu entry name and the name of the node referred to by that name. `Multiples' is the menu entry name; it refers to the node named `Buffers'. The line `Larger Units of Text' is a comment; it appears in the menu, but is not an entry.

Since no file name is specified with either `Files' or `Buffers', they must be the names of nodes in the same Info file (see section Referring to Other Info Files).

Referring to Other Info Files

You can create a menu entry that enables a reader in Info to go to a node in another Info file by writing the file name in parentheses just before the node name. In this case, you should use the three-part menu entry format, which saves the reader from having to type the file name.

The format looks like this:

```
@menu
* first-entry-name:(filename)nodename.     description
* second-entry-name:(filename)second-node. description
@end menu
```

For example, to refer directly to the `Outlining' and `Rebinding' nodes in the Emacs Manual, you would write a menu like this:

```
@menu
* Outlining: (emacs)Outline Mode. The major mode for
                                  editing outlines.
* Rebinding: (emacs)Rebinding.    How to redefine the
                                  meaning of a key.
@end menu
```

If you do not list the node name, but only name the file, then Info presumes that you are referring to the `Top' node.

The `dir' file that contains the main menu for Info has menu entries that list only file names. These take you directly to the `Top' nodes of each Info document. (See section Installing an Info File.)

For example:

```
* Info: (info).          Documentation browsing system.
* Emacs: (emacs).        The extensible, self-documenting
```

```
text editor.
```

(The `dir' top level directory for the Info system is an Info file, not a Texinfo file, but a menu entry looks the same in both types of file.)

Note that the GNU Emacs Texinfo mode menu updating commands only work with nodes within the current buffer, so you cannot use them to create menus that refer to other files. You must write such menus by hand.

Go to the previous, next section.

Go to the previous, next section.

Cross References

Cross references are used to refer the reader to other parts of the same or different Texinfo files. In Texinfo, nodes are the places to which cross references can refer.

Often, but not always, a printed document should be designed so that it can be read sequentially. People tire of flipping back and forth to find information that should be presented to them as they need it.

However, in any document, some information will be too detailed for the current context, or incidental to it; use cross references to provide access to such information. Also, an on-line help system or a reference manual is not like a novel; few read such documents in sequence from beginning to end. Instead, people look up what they need. For this reason, such creations should contain many cross references to help readers find other information that they may not have read.

In a printed manual, a cross reference results in a page reference, unless it is to another manual altogether, in which case the cross reference names that manual.

In Info, a cross reference results in an entry that you can follow using the Info `f' command. (@inforef{Help-Adv, Some advanced Info commands, info}.)

The various cross reference commands use nodes to define cross reference locations. This is evident in Info, in which a cross reference takes you to the specified node. TeX also uses nodes to define cross reference locations, but the action is less obvious. When TeX generates a DVI file, it records nodes' page numbers and uses the page numbers in making references. Thus, if you are writing a manual that will only be printed, and will not be used on-line, you must nonetheless write `@node` lines to name the places to which you make cross references.

Different Cross Reference Commands

There are four different cross reference commands:

`@xref`

: Used to start a sentence in the printed manual saying `See ...' or an entry in the Info file saying `*Note ...'.

`@ref`

: Used within or, more often, at the end of a sentence; same as `@xref` for Info; produces just the reference in the printed manual without a preceding `See'.

`@pxref`

: Used within parentheses to make a reference that suits both an Info file and a printed book. Starts with a lower case `see' within the printed manual. (`p' is for `parenthesis'.)

`@inforef`

: Used to make a reference to an Info file for which there is no printed manual.

(The `@cite` command is used to make references to books and manuals for which there is no corresponding Info file and, therefore, no node to which to point. See section `@cite`{reference}.)

Parts of a Cross Reference

A cross reference command requires only one argument, which is the name of the node to which it refers. But a cross reference command may contain up to four additional arguments. By using these arguments, you can provide a cross reference name for Info, a topic description or section title for the printed output, the name of a different Info file, and the name of a different printed manual.

Here is a simple cross reference example:

```
@xref{Node name}.
```

which produces

```
*Note Node name::.
```

and

> See Section nnn [Node name], page ppp.

Here is an example of a full five-part cross reference:

```
@xref{Node name, Cross Reference Name, Particular Topic,
info-file-name, A Printed Manual}, for details.
```

which produces

```
*Note Cross Reference Name: (info-file-name)Node name,
for details.
```

in Info and

> See section "Particular Topic" in *A Printed Manual*, for details.

in a printed book.

The five possible arguments for a cross reference are:

1. The node name (required). This is the node to which the cross reference takes you. In a printed document, the location of the node provides the page reference only for references within the same document.
2. The cross reference name for the Info reference, if it is to be different from the node name. If you include this argument, it argument becomes the first part of the cross reference. It is usually omitted.
3. A topic description or section name. Often, this is the title of the section. This is used as the name of the reference in the printed manual. If omitted, the node name is used.

4. The name of the Info file in which the reference is located, if it is different from the current fil
5. The name of a printed manual from a different Texinfo file.

The template for a full five argument cross reference looks like this:

```
@xref{node-name, cross-reference-name, title-or-topic,
info-file-name, printed-manual-title}.
```

Cross references with one, two, three, four, and five arguments are described separately following the description of `@xref`.

Write a node name in a cross reference in exactly the same way as in the `@node` line, including the same capitalization; otherwise, the formatters may not find the reference.

You can write cross reference commands within a paragraph, but note how Info and TeX format the output of each of the various commands: write `@xref` at the beginning of a sentence; write `@pxref` only within parentheses, and so on.

@xref

The `@xref` command generates a cross reference for the beginning of a sentence. The Info formatting commands convert it into an Info cross reference, which the Info `f' command can use to bring you directly to another node. The TeX typesetting commands convert it into a page reference, or a reference to another book or manual.

Most often, an Info cross reference looks like this:

```
*Note node-name::.
```

or like this

```
*Note cross-reference-name: node-name.
```

In TeX, a cross reference looks like this:

```
See Section section-number [node-name], page page.
```

or like this

```
See Section section-number [title-or-topic], page page.
```

The `@xref` command does not generate a period or comma to end the cross reference in either the Info file or the printed output. You must write that period or comma yourself; otherwise, Info will not recognize the end of the reference. (The `@pxref` command works differently. See section `@pxref`.)

> **Please note:** A period or comma **must** follow the closing brace of an `@xref`. It is required to terminate the cross reference. This period or comma will appear in the output, both in the

Info file and in the printed manual.

`@xref` must refer to an Info node by name. Use `@node` to define the node (see section How to Write an `@node` Line).

`@xref` is followed by several arguments inside braces, separated by commas. Whitespace before and after these commas is ignored.

A cross reference requires only the name of a node; but it may contain up to four additional arguments. Each of these variations produces a cross reference that looks somewhat different.

> **Please note:** Commas separate arguments in a cross reference; avoid including them in the title or other part lest the formatters mistake them for separators.

`@xref` with One Argument

The simplest form of `@xref` takes one argument, the name of another node in the same Info file. The Info formatters produce output that the Info readers can use to jump to the reference; TeX produces output that specifies the page and section number for you.

For example,

```
@xref{Tropical Storms}.
```

produces

```
*Note Tropical Storms::.
```

and

> See Section 3.1 [Tropical Storms], page 24.

(Note that in the preceding example the closing brace is followed by a period.)

You can write a clause after the cross reference, like this:

```
@xref{Tropical Storms}, for more info.
```

which produces

```
*Note Tropical Storms::, for more info.
```

> See Section 3.1 [Tropical Storms], page 24, for more info.

(Note that in the preceding example the closing brace is followed by a comma, and then by the clause, which is followed by a period.)

@xref with Two Arguments

With two arguments, the second is used as the name of the Info cross reference, while the first is still the name of the node to which the cross reference points.

The template is like this:

```
@xref{node-name, cross-reference-name}.
```

For example,

```
@xref{Electrical Effects, Lightning}.
```

produces:

```
*Note Lightning: Electrical Effects.
```

and

> See Section 5.2 [Electrical Effects], page 57.

(Note that in the preceding example the closing brace is followed by a period; and that the node name is printed, not the cross reference name.)

You can write a clause after the cross reference, like this:

```
@xref{Electrical Effects, Lightning}, for more info.
```

which produces

```
*Note Lightning: Electrical Effects, for more info.
```

and

> See Section 5.2 [Electrical Effects], page 57, for more info.

(Note that in the preceding example the closing brace is followed by a comma, and then by the clause, which is followed by a period.)

@xref with Three Arguments

A third argument replaces the node name in the TeX output. The third argument should be the name of the section in the printed output, or else state the topic discussed by that section. Often, you will want to use initial upper case letters so it will be easier to read when the reference is printed. Use a third argument when the node name is unsuitable because of syntax or meaning.

Remember to avoid placing a comma within the title or topic section of a cross reference, or within any other section. The formatters divide cross references into arguments according to the commas; a comma within a title or other section will divide it into two arguments. In a reference, you need to write a title

such as "Clouds, Mist, and Fog" without the commas.

Also, remember to write a comma or period after the closing brace of a `@xref` to terminate the cross reference. In the following examples, a clause follows a terminating comma.

The template is like this:

```
@xref{node-name, cross-reference-name, title-or-topic}.
```

For example,

```
@xref{Electrical Effects, Lightning, Thunder and Lightning},
for details.
```

produces

```
*Note Lightning: Electrical Effects, for details.
```

and

> See Section 5.2 [Thunder and Lightning], page 57, for details.

If a third argument is given and the second one is empty, then the third argument serves both. (Note how two commas, side by side, mark the empty second argument.)

```
@xref{Electrical Effects, , Thunder and Lightning},
for details.
```

produces

```
*Note Thunder and Lightning: Electrical Effects, for details.
```

and

> See Section 5.2 [Thunder and Lightning], page 57, for details.

As a practical matter, it is often best to write cross references with just the first argument if the node name and the section title are the same, and with the first and third arguments if the node name and title are different.

Here are several examples from The GAWK Manual:

```
@xref{Sample Program}.
@xref{Glossary}.
@xref{Case-sensitivity, ,Case-sensitivity in Matching}.
@xref{Close Output, , Closing Output Files and Pipes},
   for more information.
@xref{Regexp, , Regular Expressions as Patterns}.
```

@xref with Four and Five Arguments

In a cross reference, a fourth argument specifies the name of another Info file, different from the file in which the reference appears, and a fifth argument specifies its title as a printed manual.

Remember that a comma or period must follow the closing brace of an `@xref` command to terminate the cross reference. In the following examples, a clause follows a terminating comma.

The template is:

```
@xref{node-name, cross-reference-name, title-or-topic,
info-file-name, printed-manual-title}.
```

For example,

```
@xref{Electrical Effects, Lightning, Thunder and Lightning,
weather, An Introduction to Meteorology}, for details.
```

produces

```
*Note Lightning: (weather)Electrical Effects, for details.
```

The name of the Info file is enclosed in parentheses and precedes the name of the node.

In a printed manual, the reference looks like this:

> See section "Thunder and Lightning" in *An Introduction to Meteorology*, for details.

The title of the printed manual is typeset in italics; and the reference lacks a page number since TeX cannot know to which page a reference refers when that reference is to another manual.

Often, you will leave out the second argument when you use the long version of `@xref`. In this case, the third argument, the topic description, will be used as the cross reference name in Info.

The template looks like this:

```
@xref{node-name, , title-or-topic, info-file-name,
printed-manual-title}, for details.
```

which produces

```
*Note title-or-topic: (info-file-name)node-name, for details.
```

and

> See section title-or-topic in printed-manual-title, for details.

For example,

```
@xref{Electrical Effects, , Thunder and Lightning,
```

```
weather, An Introduction to Meteorology}, for details.
```

produces

```
*Note Thunder and Lightning: (weather)Electrical Effects,
for details.
```

and

> See section "Thunder and Lightning" in *An Introduction to Meteorology*, for details.

On rare occasions, you may want to refer to another Info file that is within a single printed manual--when multiple Texinfo files are incorporated into the same TeX run but make separate Info files. In this case, you need to specify only the fourth argument, and not the fifth.

Naming a `Top' Node

In a cross reference, you must always name a node. This means that in order to refer to a whole manual, you must identify the `Top' node by writing it as the first argument to the `@xref` command. (This is different from the way you write a menu entry; see section Referring to Other Info Files.) At the same time, to provide a meaningful section topic or title in the printed cross reference (instead of the word `Top'), you must write an appropriate entry for the third argument to the `@xref` command.

Thus, to make a cross reference to The GNU Make Manual, write:

```
@xref{Top, , Overview, make, The GNU Make Manual}.
```

which produces

```
*Note Overview: (make)Top.
```

and

> See section "Overview" in *The GNU Make Manual*.

In this example, `Top' is the name of the first node, and `Overview' is the name of the first section of the manual.

@ref

`@ref` is nearly the same as `@xref` except that it does not generate a `See' in the printed output, just the reference itself. This makes it useful as the last part of a sentence.

For example,

```
For more information, see @ref{Hurricanes}.
```

produces

```
For more information, see *Note Hurricanes.
```

and

> For more information, see Section 8.2 [Hurricanes], page 123.

The `@ref` command sometimes leads writers to express themselves in a manner that is suitable for a printed manual but looks awkward in the Info format. Bear in mind that your audience will be using both the printed and the Info format.

For example,

```
Sea surges are described in @ref{Hurricanes}.
```

produces

> Sea surges are described in Section 6.7 [Hurricanes], page 72.

in a printed document, and the following in Info:

```
Sea surges are described in *Note Hurricanes::.
```

> **Caution:** You *must* write a period or comma immediately after an `@ref` command with two or more arguments. Otherwise, Info will not find the end of the cross reference entry and its attempt to follow the cross reference will fail. As a general rule, you should write a period or comma after every `@ref` command. This looks best in both the printed and the Info output.

@pxref

The parenthetical reference command, `@pxref`, is nearly the same as `@xref`, but you use it *only* inside parentheses and you do *not* type a comma or period after the command's closing brace. The command differs from `@xref` in two ways:

1. TeX typesets the reference for the printed manual with a lower case `see' rather than an upper case `See'.
2. The Info formatting commands automatically end the reference with a closing colon or period.

Because one type of formatting automatically inserts closing punctuation and the other does not, you should use `@pxref` *only* inside parentheses as part of another sentence. Also, you yourself should not insert punctuation after the reference, as you do with `@xref`.

`@pxref` is designed so that the output looks right and works right between parentheses both in printed output and in an Info file. In a printed manual, a closing comma or period should not follow a cross reference within parentheses; such punctuation is wrong. But in an Info file, suitable closing punctuation must follow the cross reference so Info can recognize its end. `@pxref` spares you the need to use complicated methods to put a terminator into one form of the output and not the other.

With one argument, a parenthetical cross reference looks like this:

```
... storms cause flooding (@pxref{Hurricanes}) ...
```

which produces

```
... storms cause flooding (*Note Hurricanes::) ...
```

and

> ... storms cause flooding (see Section 6.7 [Hurricanes], page 72) ...

With two arguments, a parenthetical cross reference has this template:

```
... (@pxref{node-name, cross-reference-name}) ...
```

which produces

```
... (*Note cross-reference-name: node-name.) ...
```

and

> ... (see Section nnn [node-name], page ppp) ...

`@pxref` can be used with up to five arguments just like `@xref` (see section `@xref`).

> **Please note:** Use `@pxref` only as a parenthetical reference. Do not try to use `@pxref` as a clause in a sentence. It will look bad in either the Info file, the printed output, or both.
>
> Also, parenthetical cross references look best at the ends of sentences. Although you may write them in the middle of a sentence, that location breaks up the flow of text.

`@inforef`

`@inforef` is used for cross references to Info files for which there are no printed manuals. Even in a printed manual, `@inforef` generates a reference directing the user to look in an Info file.

The command takes either two or three arguments, in the following order:

1. The node name.
2. The cross reference name (optional).
3. The Info file name.

Separate the arguments with commas, as with `@xref`. Also, you must terminate the reference with a comma or period after the `}', as you do with `@xref`.

The template is:

```
@inforef{node-name, cross-reference-name, info-file-name},
```

Thus,

```
@inforef{Expert, Advanced Info commands, info},
for more information.
```

produces

```
*Note Advanced Info commands: (info)Expert,
for more information.
```

and

> See Info file `info', node `Expert', for more information.

Similarly,

```
@inforef{Expert, , info}, for more information.
```

produces

```
*Note (info)Expert::, for more information.
```

and

> See Info file `info', node `Expert', for more information.

The converse of `@inforef` is `@cite`, which is used to refer to printed works for which no Info form exists. See section `@cite{reference}`.

Marking Words and Phrases

In Texinfo, you can mark words and phrases in a variety of ways. The Texinfo formatters use this information to determine how to highlight the text. You can specify, for example, whether a word or phrase is a defining occurrence, a metasyntactic variable, or a symbol used in a program. Also, you can emphasize text.

Indicating Definitions, Commands, etc.

Texinfo has commands for indicating just what kind of object a piece of text refers to. For example, metasyntactic variables are marked by `@var`, and code by `@code`. Since the pieces of text are labelled by commands that tell what kind of object they are, it is easy to change the way the Texinfo formatters prepare such text. (Texinfo is an *intentional* formatting language rather than a *typesetting* formatting language.)

For example, in a printed manual, code is usually illustrated in a typewriter font; `@code` tells TeX to typeset this text in this font. But it would be easy to change the way TeX highlights code to use another font, and this change would not effect how keystroke examples are highlighted. If straight typesetting commands were used in the body of the file and you wanted to make a change, you would need to check every single occurrence to make sure that you were changing code and not something else that should not be changed.

The highlighting commands can be used to generate useful information from the file, such as lists of functions or file names. It is possible, for example, to write a program in Emacs Lisp (or a keyboard macro) to insert an index entry after every paragraph that contains words or phrases marked by a specified command. You could do this to construct an index of functions if you had not already made the entries.

The commands serve a variety of purposes:

`@code{sample-code}`
: Indicate text that is a literal example of a piece of a program.

`@kbd{keyboard-characters}`
: Indicate keyboard input.

`@key{key-name}`
: Indicate the conventional name for a key on a keyboard.

`@samp{text}`
: Indicate text that is a literal example of a sequence of characters.

`@var{metasyntactic-variable}`
: Indicate a metasyntactic variable.

`@file{file-name}`

Indicate the name of a file.

`@dfn{term}`

Indicate the introductory or defining use of a term.

`@cite{reference}`

Indicate the name of a book.

@code{sample-code}

Use the `@code` command to indicate text that is a piece of a program and which consists of entire syntactic tokens. Enclose the text in braces.

Thus, you should use `@code` for an expression in a program, for the name of a variable or function used in a program, or for a keyword. Also, you should use `@code` for the name of a program, such as `diff`, that is a name used in the machine. (You should write the name of a program in the ordinary text font if you regard it as a new English word, such as `Emacs' or `Bison'.)

Use `@code` for environment variables such as `TEXINPUTS`, and other variables.

Use `@code` for command names in command languages that resemble programming languages, such as Texinfo or the shell. For example, `@code` and `@samp` are produced by writing `@code{@@code}' and `@code{@@samp}' in the Texinfo source, respectively.

Note, however, that you should not use `@code` for shell options such as `-c' when such options stand alone. (Use `@samp`.) Also, an entire shell command often looks better if written using `@samp` rather than `@code`. In this case, the rule is to choose the more pleasing format.

It is incorrect to alter the case of a word inside an `@code` command when it appears at the beginning of a sentence. Most computer languages are case sensitive. In C, for example, `Printf` is different from the identifier `printf`, and most likely is a misspelling of it. Even in languages which are not case sensitive, it is confusing to a human reader to see identifiers spelled in different ways. Pick one spelling and always use that. If you do not want to start a sentence with a command written all in lower case, you should rearrange the sentence.

Do not use the `@code` command for a string of characters shorter than a syntactic token. If you are writing about `TEXINPU', which is just a part of the name for the `TEXINPUTS` environment variable, you should use `@samp`.

In particular, you should not use the `@code` command when writing about the characters used in a token; do not, for example, use `@code` when you are explaining what letters or printable symbols can be used in the names of functions. (Use `@samp`.) Also, you should not use `@code` to mark text that is considered input to programs unless the input is written in a language that is like a programming language. For example, you should not use `@code` for the keystroke commands of GNU Emacs (use `@kbd` instead) although you may use `@code` for the names of the Emacs Lisp functions that the keystroke commands invoke.

In the printed manual, `@code` causes TeX to typeset the argument in a typewriter face. In the Info file, it causes the Info formatting commands to use single quotation marks around the text.

For example,

```
Use @code{diff} to compare two files.
```

produces this in the printed manual:

> Use `diff` to compare two files.

and this in the Info file:

```
Use `diff' to compare two files.
```

@kbd{keyboard-characters}

Use the `@kbd` command for characters of input to be typed by users. For example, to refer to the characters M-a, write

```
@kbd{M-a}
```

and to refer to the characters M-x shell, write

```
@kbd{M-x shell}
```

The `@kbd` command has the same effect as `@code` in Info, but may produce a different font in a printed manual.

You can embed another @-command inside the braces of an `@kbd` command. Here, for example, is the way to describe a command that would be described more verbosely as "press an `r' and then press the RET key":

```
@kbd{r @key{RET}}
```

This produces: r RET

You also use the `@kbd` command if you are spelling out the letters you type; for example:

```
To give the @code{logout} command,
type the characters @kbd{l o g o u t @key{RET}}.
```

This produces:

> To give the `logout` command, type the characters l o g o u t RET.

(Also, this example shows that you can add spaces for clarity. If you really want to mention a space character as one of the characters of input, write @key{SPC} for it.)

@key{key-name}

Use the `@key` command for the conventional name for a key on a keyboard, as in:

```
@key{RET}
```

You can use the `@key` command within the argument of an `@kbd` command when the sequence of characters to be typed includes one or more keys that are described by name.

For example, to produce C-x ESC you would type:

```
@kbd{C-x @key{ESC}}
```

Here is a list of the recommended names for keys; they are all in upper case:

`SPC`
: Space

`RET`
: Return

`LFD`
: Linefeed

`TAB`
: Tab

`BS`
: Backspace

`ESC`
: Escape

`DEL`
: Delete

`SFT`
: Shift

`CTL`
: Control

`META`
: Meta

There are subtleties to handling words like `meta' or `ctl' that are names of shift keys. When mentioning a character in which the shift key is used, such as Meta-a, use the `@kbd` command alone; do not use the `@key` command; but when you are referring to the shift key in isolation, use the `@key` command. For example, write `@kbd{Meta-a}' to produce Meta-a and `@key{META}' to produce META. This is because Meta-a refers to keys that you press on a keyboard, but META refers to a key without implying that you press it. In short, use `@kbd` for what you do, and use `@key` for what you talk about: "Press

`@kbd{M-a}` to move point to the beginning of the sentence. The `@key{META}` key is often in the lower left of the keyboard."

@samp{text}

Use the `@samp` command to indicate text that is a literal example or `sample' of a sequence of characters in a file, string, pattern, etc. Enclose the text in braces. The argument appears within single quotation marks in both the Info file and the printed manual; in addition, it is printed in a fixed-width font.

```
To match @samp{foo} at the end of the line,
use the regexp @samp{foo$}.
```

produces

> To match `foo' at the end of the line, use the regexp `foo$'.

Any time you are referring to single characters, you should use `@samp` unless `@kbd` is more appropriate. Use `@samp` for the names of command-line options. Also, you may use `@samp` for entire statements in C and for entire shell commands--in this case, `@samp` often looks better than `@code`. Basically, `@samp` is a catchall for whatever is not covered by `@code`, `@kbd`, or `@key`.

Only include punctuation marks within braces if they are part of the string you are specifying. Write punctuation marks outside the braces if those punctuation marks are part of the English text that surrounds the string. In the following sentence, for example, the commas and period are outside of the braces:

```
In English, the vowels are @samp{a}, @samp{e},
@samp{i}, @samp{o}, @samp{u}, and sometimes
@samp{y}.
```

This produces:

> In English, the vowels are `a', `e', `i', `o', `u', and sometimes `y'.

@var{metasyntactic-variable}

Use the `@var` command to indicate metasyntactic variables. A metasyntactic variable is something that stands for another piece of text. For example, you should use a metasyntactic variable in the documentation of a function to describe the arguments that are passed to that function.

Do not use `@var` for the names of particular variables in programming languages. These are specific names from a program, so `@code` is correct for them. For example, the Lisp variable `texinfo-tex-command` is not a metasyntactic variable; it is properly formatted using `@code`.

The effect of `@var` in the Info file is to change the case of the argument to all upper case; in the printed manual, to italicize it.

For example,

```
To delete file @var{filename},
type @code{rm @var{filename}}.
```

produces

> To delete file filename, type `rm filename`.

(Note that `@var` may appear inside `@code`, `@samp`, `@file`, etc.)

Write a metasyntactic variable all in lower case without spaces, and use hyphens to make it more readable. Thus, the Texinfo source for the illustration of how to begin a Texinfo manual looks like this:

```
\input texinfo
@@setfilename @var{info-file-name}
@@settitle @var{name-of-manual}
```

This produces:

```
\input texinfo
@setfilename info-file-name
@settitle name-of-manual
```

In some documentation styles, metasyntactic variables are shown with angle brackets, for example:

```
..., type rm <filename>
```

However, that is not the style that Texinfo uses. (You can, of course, modify the sources to TeX and the Info formatting commands to output the `<...>` format if you wish.)

@file{file-name}

Use the `@file` command to indicate text that is the name of a file, buffer, or directory, or is the name of a node in Info. You can also use the command for file name suffixes. Do not use `@file` for symbols in a programming language; use `@code`.

Currently, `@file` is equivalent to `@samp` in its effects. For example,

```
The @file{.el} files are in
the @file{/usr/local/emacs/lisp} directory.
```

produces

> The `.el' files are in the `/usr/local/emacs/lisp' directory.

@dfn{term}

Use the `@dfn` command to identify the introductory or defining use of a technical term. Use the command only in passages whose purpose is to introduce a term which will be used again or which the reader ought to know. Mere passing mention of a term for the first time does not deserve `@dfn`. The

command generates italics in the printed manual, and double quotation marks in the Info file. For example:

```
Getting rid of a file is called @dfn{deleting} it.
```

produces

> Getting rid of a file is called deleting it.

As a general rule, a sentence containing the defining occurrence of a term should be a definition of the term. The sentence does not need to say explicitly that it is a definition, but it should contain the information of a definition--it should make the meaning clear.

@cite{reference}

Use the `@cite` command for the name of a book that lacks a companion Info file. The command produces italics in the printed manual, and quotation marks in the Info file.

(If a book is written in Texinfo, it is better to use a cross reference command since a reader can easily follow such a reference in Info. See section `@xref`.)

Emphasizing Text

Usually, Texinfo changes the font to mark words in the text according to what category the words belong to; an example is the `@code` command. Most often, this is the best way to mark words. However, sometimes you will want to emphasize text without indicating a category. Texinfo has two commands to do this. Also, Texinfo has several commands that specify the font in which TeX will typeset text. These commands have no affect on Info and only one of them, the `@r` command, has any regular use.

@emph{text} and @strong{text}

The `@emph` and `@strong` commands are for emphasis; `@strong` is stronger. In printed output, `@emph` produces *italics* and `@strong` produces **bold**.

For example,

```
@quotation
@strong{Caution:} @code{rm * .[^.]*} removes @emph{all}
files in the directory.
@end quotation
```

produces the following in printed output:

> **Caution**: `rm * .[^.]*` removes *all* files in the directory.

and the following in Info:

```
*Caution*: `rm * .[^.]*' removes *all*
files in the directory.
```

The `@strong` command is seldom used except to mark what is, in effect, a typographical element, such as the word `Caution' in the preceding example.

In the Info file, both `@emph` and `@strong` put asterisks around the text.

> **Caution:** Do not use `@emph` or `@strong` with the word `Note'; Info will mistake the combination for a cross reference. Use a phrase such as **Please note** or **Caution** instead.

@sc{text}: The Small Caps Font

Use the `@sc' command to set text in the printed output in A SMALL CAPS FONT and set text in the Info file in upper case letters.

Write the text between braces in lower case, like this:

```
The @sc{acm} and @sc{ieee} are technical societies.
```

This produces:

```
The ACM and IEEE are technical societies.
```

TeX typesets the small caps font in a manner that prevents the letters from `jumping out at you on the page'. This makes small caps text easier to read than text in all upper case. The Info formatting commands set all small caps text in upper case.

If the text between the braces of an `@sc` command is upper case, TeX typesets in FULL-SIZE CAPITALS. Use full-size capitals sparingly.

You may also use the small caps font for a jargon word such as ATO (a NASA word meaning `abort to orbit').

There are subtleties to using the small caps font with a jargon word such as CDR, a word used in Lisp programming. In this case, you should use the small caps font when the word refers to the second and subsequent elements of a list (the CDR of the list), but you should use `@code' when the word refers to the Lisp function of the same spelling.

Fonts for Printing, Not Info

Texinfo provides four font commands that specify font changes in the printed manual but have no effect in the Info file. `@i` requests *italic* font (in some versions of TeX, a slanted font is used), `@b` requests **bold** face, `@t` requests the `fixed-width`, typewriter-style font used by `@code`, and `@r` requests a roman font, which is the usual font in which text is printed. All four commands apply to an argument that follows, surrounded by braces.

Only the `@r` command has much use: in example programs, you can use the `@r` command to convert code comments from the fixed-width font to a roman font. This looks better in printed output.

For example,

```
@lisp
(+ 2 2)    ; @r{Add two plus two.}
@end lisp
```

produces

```
(+ 2 2)    ; Add two plus two.
```

If possible, you should avoid using the other three font commands. If you need to use one, it probably indicates a gap in the Texinfo language.

Go to the previous, next section.

Go to the previous, next section.

Quotations and Examples

Quotations and examples are blocks of text consisting of one or more whole paragraphs that are set off from the bulk of the text and treated differently. They are usually indented.

In Texinfo, you always begin a quotation or example by writing an @-command at the beginning of a line by itself, and end it by writing an `@end` command that is also at the beginning of a line by itself. For instance, you begin an example by writing `@example` by itself at the beginning of a line and end the example by writing `@end example` on a line by itself, at the beginning of that line.

The Block Enclosing Commands

Here are commands for quotations and examples:

`@quotation`

Indicate text that is quoted. The text is filled, indented, and printed in a roman font by default.

`@example`

Illustrate code, commands, and the like. The text is printed in a fixed-width font, and indented but not filled.

`@lisp`

Illustrate Lisp code. The text is printed in a fixed-width font, and indented but not filled.

`@smallexample`

Illustrate code, commands, and the like. Similar to `@example`, except that in TeX this command typesets text in a smaller font for the smaller `@smallbook` format than for the 8.5 by 11 inch format.

`@smalllisp`

Illustrate Lisp code. Similar to `@lisp`, except that in TeX this command typesets text in a smaller font for the smaller `@smallbook` format than for the 8.5 by 11 inch format.

`@display`

Display illustrative text. The text is indented but not filled, and no font is specified (so, by default, the font is roman).

`@format`

Print illustrative text. The text is not indented and not filled and no font is specified (so, by default, the font is roman).

The `@exdent` command is used within the above constructs to undo the indentation of a line.

The `@flushleft` and `@flushright` commands are used to line up the left or right margins of unfilled text.

The `@noindent` command may be used after one of the above constructs to prevent the following t from being indented as a new paragraph.

You can use the `@cartouche` command within one of the above constructs to highlight the example or quotation by drawing a box with rounded corners around it. (The `@cartouche` command affects only the printed manual; it has no effect in the Info file; see section Drawing Cartouches Around Examples.)

@quotation

The text of a quotation is processed normally except that:

- the margins are closer to the center of the page, so the whole of the quotation is indented;
- the first lines of paragraphs are indented no more than other lines;
- in the printed output, interparagraph spacing is reduced.

  This is an example of text written between an `@quotation` command and an `@end quotation` command. An `@quotation` command is most often used to indicate text that is excerpted from another (real or hypothetical) printed work.

Write an `@quotation` command as text on a line by itself. This line will disappear from the output. Mark the end of the quotation with a line beginning with and containing only `@end quotation`. The `@end quotation` line will likewise disappear from the output. Thus, the following,

```
@quotation
This is
a foo.
@end quotation
```

produces

> This is a foo.

@example

The `@example` command is used to indicate an example that is not part of the running text, such as computer input or output.

```
This is an example of text written between an
@example command
and an @end example command.
The text is indented but not filled.

In the printed manual, the text is typeset in a
fixed-width font, and extra spaces and blank lines are
significant.  In the Info file, an analogous result is
obtained by indenting each line with five spaces.
```

Write an `@example` command at the beginning of a line by itself. This line will disappear from the output. Mark the end of the example with an `@end example` command, also written at the beginning of a line by itself. The `@end example` will disappear from the output.

For example,

```
@example
mv foo bar
@end example
```

produces

```
mv foo bar
```

Since the lines containing `@example` and `@end example` will disappear, you should put a blank line before the `@example` and another blank line after the `@end example`. (Remember that blank lines between the beginning `@example` and the ending `@end example` will appear in the output.)

> **Caution:** Do not use tabs in the lines of an example (or anywhere else in Texinfo, for that matter)! TeX treats tabs as single spaces, and that is not what they look like. This is a problem with TeX. (If necessary, in Emacs, you can use M-x untabify to convert tabs in a region to multiple spaces.)

Examples are often, logically speaking, "in the middle" of a paragraph, and the text continues after an example should not be indented. The `@noindent` command prevents a piece of text from being indented as if it were a new paragraph.

(The `@code` command is used for examples of code that are embedded within sentences, not set off from preceding and following text. See section `@code{sample-code}`.)

`@noindent`

An example or other inclusion can break a paragraph into segments. Ordinarily, the formatters indent text that follows an example as a new paragraph. However, you can prevent this by writing `@noindent` at the beginning of a line by itself preceding the continuation text.

For example:

```
@example
This is an example
@end example

@noindent
This line is not indented.  As you can see, the
beginning of the line is fully flush left with the line
that follows after it.  (This whole example is between
@code{@@display} and @code{@@end display}.)
```

produces

```
This is an example
```

```
This line is not indented.  As you can see, the
beginning of the line is fully flush left with the line
that follows after it.  (This whole example is between
@display and @end display.)
```

To adjust the number of blank lines properly in the Info file output, remember that the line containing `@noindent` does not generate a blank line, and neither does the `@end example` line.

In the Texinfo source file for this manual, each line that says `produces' is preceded by a line containing `@noindent`.

Do not put braces after an `@noindent` command; they are not necessary, since `@noindent` is a command used outside of paragraphs (see section @-Command Syntax).

@lisp

The `@lisp` command is used for Lisp code. It is synonymous with the `@example` command.

```
This is an example of text written between an
@lisp command and an @end lisp command.
```

Use `@lisp` instead of `@example` so as to preserve information regarding the nature of the example. This is useful, for example, if you write a function that evaluates only and all the Lisp code in a Texinfo file. Then you can use the Texinfo file as a Lisp library.(7)

Mark the end of `@lisp` with `@end lisp` on a line by itself.

@smallexample and @smalllisp

In addition to the regular `@example` and `@lisp` commands, Texinfo has two other "example-style" commands. These are the `@smallexample` and `@smalllisp` commands. Both these commands are designed for use with the `@smallbook` command that causes TeX to produce a printed manual in a 7 by 9.25 inch format rather than the regular 8.5 by 11 inch format.

In TeX, the `@smallexample` and `@smalllisp` commands typeset text in a smaller font for the smaller `@smallbook` format than for the 8.5 by 11 inch format. Consequently, many examples containing long lines fit in a narrower, `@smallbook` page without needing to be shortened. Both commands typeset in the normal font size when you format for the 8.5 by 11 inch size; indeed, in this

situation, the `@smallexample` and `@smalllisp` commands are defined to be the `@example` and `@lisp` commands.

In Info, the `@smallexample` and `@smalllisp` commands are equivalent to the `@example` and `@lisp` commands, and work exactly the same.

Mark the end of `@smallexample` or `@smalllisp` with `@end smallexample` or `@end smalllisp`, respectively.

Here is an example written in the small font used by the `@smallexample` and `@smalllisp` commands:

The `@smallexample` and `@smalllisp` commands make it easier to prepare smaller format manuals without forcing you to edit examples by hand to fit them onto narrower pages.

As a general rule, a printed document looks better if you write all the examples in a chapter consistently in `@example` or in `@smallexample`. Only occasionally should you mix the two formats.

See section Printing "Small" Books, for more information about the `@smallbook` command.

@display

The `@display` command begins a kind of example. It is like the `@example` command except that, in a printed manual, `@display` does not select the fixed-width font. In fact, it does not specify the font at all, so that the text appears in the same font it would have appeared in without the `@display` command.

```
This is an example of text written between an @display command
and an @end display command.  The @display command
indents the text, but does not fill it.
```

@format

The `@format` command is similar to `@example` except that, in the printed manual, `@format` does not select the fixed-width font and does not narrow the margins.

```
This is an example of text written between an @format command
and an @end format command.  As you can see
from this example,
the @format command does not fill the text.
```

@exdent: Undoing a Line's Indentation

The `@exdent` command removes any indentation a line might have. The command is written at the beginning of a line and applies only to the text that follows the command that is on the same line. Do not use braces around the text. In a printed manual, the text on an `@exdent` line is printed in the roman font.

`@exdent` is usually used within examples. Thus,

```
@example
This line follows an @@example command.
@exdent This line is exdented.
This line follows the exdented line.
The @@end example comes on the next line.
@end group
```

produces

```
This line follows an @example command.
This line is exdented.
This line follows the exdented line.
The @end example comes on the next line.
```

In practice, the `@exdent` command is rarely used. Usually, you un-indent text by ending the example and returning the page to its normal width.

@flushleft and @flushright

The `@flushleft` and `@flushright` commands line up the ends of lines on the left and right margins of a page, but do not fill the text. The commands are written on lines of their own, without braces. The `@flushleft` and `@flushright` commands are ended by `@end flushleft` and `@end flushright` commands on lines of their own.

For example,

```
@flushleft
This text is
written flushleft.
@end flushleft
```

produces

```
This text is
written flushleft.
```

Flushright produces the type of indentation often used in the return address of letters.

For example,

```
@flushright
Here is an example of text written
flushright.  The @code{@flushright} command
right justifies every line but leaves the
left end ragged.
@end flushright
```

produces

```
Here is an example of text written
flushright.  The @flushright command
right justifies every line but leaves the
left end ragged.
```

Drawing Cartouches Around Examples

In a printed manual, the `@cartouche` command draws a box with rounded corners around its contents. You can use this command to further highlight an example or quotation. For instance, you could write a manual in which one type of example is surrounded by a cartouche for emphasis.

The `@cartouche` command affects only the printed manual; it has no effect in the Info file.

For example,

```
@example
@cartouche
% pwd
/usr/local/lib/emacs/info
@end cartouche
@end example
```

surrounds the two-line example with a box with rounded corners, in the printed manual.

In a printed manual, the example looks like this:

```
% pwd
/usr/local/lib/emacs/info
```

Go to the previous, next section.

Go to the previous, next section.

Making Lists and Tables

Texinfo has several ways of making lists and two-column tables. Lists can be bulleted or numbered, while two-column tables can highlight the items in the first column.

Texinfo automatically indents the text in lists or tables, and numbers an enumerated list. This last feature is useful if you modify the list, since you do not need to renumber it yourself.

Numbered lists and tables begin with the appropriate @-command at the beginning of a line, and end with the corresponding `@end` command on a line by itself. The table and itemized-list commands also require that you write formatting information on the same line as the beginning @-command.

Begin an enumerated list, for example, with an `@enumerate` command and end the list with an `@end enumerate` command. Begin an itemized list with an `@itemize` command, followed on the same line by a formatting command such as `@bullet`, and end the list with an `@end itemize` command.

Precede each element of a list with an `@item` or `@itemx` command.

Here is an itemized list of the different kinds of table and lists:

- Itemized lists with and without bullets.
- Enumerated lists, using numbers or letters.
- Two-column tables with highlighting.

Here is an enumerated list with the same items:

1. Itemized lists with and without bullets.
2. Enumerated lists, using numbers or letters.
3. Two-column tables with highlighting.

And here is a two-column table with the same items and their @-commands:

`@itemize`
: Itemized lists with and without bullets.

`@enumerate`
: Enumerated lists, using numbers or letters.

`@table`
`@ftable`
`@vtable`
: Two-column tables with highlighting.

Making an Itemized List

The `@itemize` command produces sequences of indented paragraphs, with a bullet or other mark inside the left margin at the beginning of each paragraph for which such a mark is desired.

Begin an itemized list by writing `@itemize` at the beginning of a line. Follow the command, on the same line, with a character or a Texinfo command that generates a mark. Usually, you will write `@bullet` after `@itemize`, but you can use `@minus`, or any character or any special symbol that results in a single character in the Info file. (When you write `@bullet` or `@minus` after an `@itemize` command, you may omit the `{}'.)

Write the text of the indented paragraphs themselves after the `@itemize`, up to another line that says `@end itemize`.

Before each paragraph for which a mark in the margin is desired, write a line that says just `@item`. Do not write any other text on this line.

Usually, you should put a blank line before an `@item`. This puts a blank line in the Info file. (TeX inserts the proper interline whitespace in either case.) Except when the entries are very brief, these blank lines make the list look better.

Here is an example of the use of `@itemize`, followed by the output it produces. Note that `@bullet` produces an `*' in Info and a round dot in TeX.

```
@itemize @bullet
@item
Some text for foo.

@item
Some text
for bar.
@end itemize
```

This produces:

- Some text for foo.
- Some text for bar.

Itemized lists may be embedded within other itemized lists. Here is a list marked with dashes embedded in a list marked with bullets:

```
@itemize @bullet
@item
First item.

@itemize @minus
@item
```

```
Inner item.

@item
Second inner item.
@end itemize

@item
Second outer item.
@end itemize
```

This produces:

- First item.
  - Inner item.
  - Second inner item.
- Second outer item.

Making a Numbered or Lettered List

`@enumerate` is like `@itemize` except that the marks in the left margin contain successive integers or letters. (See section Making an Itemized List.)

Write the `@enumerate` command at the beginning of a line. The command does not require an argument, but accepts either a number or a letter as an option. Without an argument, `@enumerate` starts the list with the number 1. With a numeric argument, such as 3, the command starts the list with that number. With an upper or lower case letter, such as a or A, the command starts the list with that letter.

Write the text of the enumerated list in the same way you write an itemized list: put `@item` on a line of its own before the start of each paragraph that you want enumerated. Do not write any other text on the line beginning with `@item`.

You should put a blank line between entries in the list. This generally makes it easier to read the Info file.

Here is an example of `@enumerate` without an argument:

```
@enumerate
@item
Underlying causes.

@item
Proximate causes.
@end enumerate
```

This produces:

1. Underlying causes.

2. Proximate causes.

Here is an example with an argument of 3:

```
@enumerate 3
@item
Predisposing causes.

@item
Precipitating causes.

@item
Perpetuating causes.
@end enumerate
```

This produces:

1. Predisposing causes.
2. Precipitating causes.
3. Perpetuating causes.

Here is a brief summary of the alternatives. The summary is constructed using `@enumerate` with an argument of a.

1. `@enumerate`

   Without an argument, produce a numbered list, starting with the number 1.
2. `@enumerate positive-integer`

   With a (positive) numeric argument, start a numbered list with that number. You can use this to continue a list that you interrupted with other text.
3. `@enumerate upper-case-letter`

   With an upper case letter as argument, start a list in which each item is marked by a letter, beginning with that upper case letter.
4. `@enumerate lower-case-letter`

   With a lower case letter as argument, start a list in which each item is marked by a letter, beginning with that lower case letter.

You can also nest enumerated lists, as in an outline.

Making a Two-column Table

`@table` is similar to `@itemize`, but the command allows you to specify a name or heading line for each item. (See section Making an Itemized List}.) The `@table` command is used to produce two-column tables, and is especially useful for glossaries and explanatory exhibits.

Write the `@table` command at the beginning of a line and follow it on the same line with an argument that is a Texinfo command such as `@code`, `@samp`, `@var`, or `@kbd`. Although these commands are usually followed by arguments in braces, in this case you use the command name without an argument because `@item` will supply the argument. This command will be applied to the text that goes into the first column of each item and determines how it will be highlighted. For example, `@samp` will cause the text in the first column to be highlighted with an `@samp` command.

You may also choose to use the `@asis` command as an argument to `@table`. `@asis` is a command that does nothing; if you use this command after `@table`, TeX and the Info formatting commands output the first column entries without added highlighting (`as is').

(The `@table` command may work with other commands besides those listed here. However, you can only use commands that normally take arguments in braces.)

Begin each table entry with an `@item` command at the beginning of a line. Write the first column text on the same line as the `@item` command. Write the second column text on the line following the `@item` line and on subsequent lines. (You do not need to type anything for an empty second column entry.) You may write as many lines of supporting text as you wish, even several paragraphs. But only text on the same line as the `@item` will be placed in the first column.

Normally, you should put a blank line before an `@item` line. This puts a blank like in the Info file. Except when the entries are very brief, a blank line looks better.

The following table, for example, highlights the text in the first column with an `@samp` command:

```
@table @samp
@item foo
This is the text for
@samp{foo}.

@item bar
Text for @samp{bar}.
@end table
```

This produces:

`foo'
: This is the text for `foo'.

`bar'
: Text for `bar'.

If you want to list two or more named items with a single block of text, use the `@itemx` command. (See section @itemx.)

@ftable and @vtable

The `@ftable` and `@vtable` commands are the same as the `@table` command except that `@ftable` automatically enters each of the items in the first column of the table into the index of functions and `@vtable` automatically enters each of the items in the first column of the table into the index of variables. This simplifies the task of creating indices. Only the items on the same line as the `@item` commands are indexed, and they are indexed in exactly the form that they appear on that line. See section Creating Indices, for more information about indices.

Begin a two-column table using `@ftable` or `@vtable` by writing the @-command at the beginning of a line, followed on the same line by an argument that is a Texinfo command such as `@code`, exactly as you would for an `@table` command; and end the table with an `@end ftable` or `@end vtable` command on a line by itself.

@itemx

Use the `@itemx` command inside a table when you have two or more first column entries for the same item, each of which should appear on a line of its own. Use `@itemx` for all but the first entry. The `@itemx` command works exactly like `@item` except that it does not generate extra vertical space above the first column text.

For example,

```
@table @code
@item upcase
@itemx downcase
These two functions accept a character or a string as
argument, and return the corresponding upper case (lower
case) character or string.
@end table
```

This produces:

`upcase`

`downcase`

> These two functions accept a character or a string as argument, and return the corresponding upper case (lower case) character or string.

(Note also that this example illustrates multi-line supporting text in a two-column table.)

Go to the previous, next section.

Go to the previous, next section.

Creating Indices

Using Texinfo, you can generate indices without having to sort and collate entries manually. In an index, the entries are listed in alphabetical order, together with information on how to find the discussion of each entry. In a printed manual, this information consists of page numbers. In an Info file, this information is a menu entry leading to the first node referenced.

Texinfo provides several predefined kinds of index: an index for functions, an index for variables, an index for concepts, and so on. You can combine indices or use them for other than their canonical purpose. If you wish, you can define your own indices.

Making Index Entries

When you are making index entries, it is good practice to think of the different ways people may look for something. Different people *do not* think of the same words when they look something up. A helpful index will have items indexed under all the different words that people may use. For example, one reader may think it obvious that the two-letter names for indices should be listed under "Indices, two-letter names", since the word "Index" is the general concept. But another reader may remember the specific concept of two-letter names and search for the entry listed as "Two letter names for indices". A good index will have both entries and will help both readers.

Like typesetting, the construction of an index is a highly skilled, professional art, the subtleties of which are not appreciated until you need to do it yourself.

See section Index Menus and Printing an Index, for information about printing an index at the end of a book or creating an index menu in an Info file.

Predefined Indices

Texinfo provides six predefined indices:

- A concept index listing concepts that are discussed.
- A function index listing functions (such as entry points of libraries).
- A variables index listing variables (such as global variables of libraries).
- A keystroke index listing keyboard commands.
- A program index listing names of programs.
- A data type index listing data types (such as structures defined in header files).

Not every manual needs all of these, and most manuals use two or three of them. This manual has two indices: a concept index and an @-command index (that is actually the function index but is called a command index in the chapter heading). Two or more indices can be combined into one using the

`@synindex` or `@syncodeindex` commands. See section Combining Indices.

Defining the Entries of an Index

The data to make an index come from many individual indexing commands scattered throughout the Texinfo source file. Each command says to add one entry to a particular index; after formatting, the index will give the current page number or node name as the reference.

An index entry consists of an indexing command at the beginning of a line followed, on the rest of the line, by the entry.

For example, this section begins with the following five entries for the concept index:

```
@cindex Defining indexing entries
@cindex Index entries
@cindex Entries for an index
@cindex Specifying index entries
@cindex Creating index entries
```

Each predefined index has its own indexing command---`@cindex` for the concept index, `@findex` for the function index, and so on.

The usual convention is to capitalize the first word of each index entry, unless that word is the name of a function, variable, or other such entity that should not be capitalized. Thus, if you are documenting Emacs Lisp, you should usually capitalize entries in the concept index, but not those in the function index. However, if your concept index entries are consistently short (one or two words each) it may look better for each regular entry to start with a lower case letter. Whichever convention you adapt, please be consistent!

By default, entries for a concept index are printed in a small roman font and entries for the other indices are printed in a small `@code` font. You may change the way part of an entry is printed with the usual Texinfo commands, such as `@file` for file names and `@emph` for emphasis (see section Marking Words and Phrases).

The six indexing commands for predefined indices are:

`@cindex concept`
: Make an entry in the concept index for concept.

`@findex function`
: Make an entry in the function index for function.

`@vindex variable`
: Make an entry in the variable index for variable.

`@kindex keystroke`
: Make an entry in the key index for keystroke.

`@pindex program`

Make an entry in the program index for program.

`@tindex data type`

Make an entry in the data type index for data type.

Caution: Do not use a colon in an index entry. In Info, a colon separates the menu entry name from the node name. An extra colon confuses Info. See section The Parts of a Menu, for more information about the structure of a menu entry.

If you write several identical index entries in different places in a Texinfo file, the index in the printed manual will list all the pages to which those entries refer. However, the index in the Info file will list **only** the node that references the **first** of those index entries. Therefore, it is best to write indices in which each entry refers to only one place in the Texinfo file. Fortunately, this constraint is a feature rather than a loss since it means that the index will be easy to use. Otherwise, you could create an index that lists several pages for one entry and your reader would not know to which page to turn. If you have two identical entries for one topic, change the topics slightly, or qualify them to indicate the difference.

You are not actually required to use the predefined indices for their canonical purposes. For example, suppose you wish to index some C preprocessor macros. You could put them in the function index along with actual functions, just by writing `@findex` commands for them; then, when you print the "Function Index" as an unnumbered chapter, you could give it the title `Function and Macro Index' and all will be consistent for the reader. Or you could put the macros in with the data types by writing `@tindex` commands for them, and give that index a suitable title so the reader will understand. (See section Index Menus and Printing an Index.)

Combining Indices

Sometimes you will want to combine two disparate indices such as functions and concepts, perhaps because you have few enough of one of them that a separate index for them would look silly.

You could put functions into the concept index by writing `@cindex` commands for them instead of `@findex` commands, and produce a consistent manual by printing the concept index with the title `Function and Concept Index' and not printing the `Function Index' at all; but this is not a robust procedure. It works only if your document is never included as part of another document that is designed to have a separate function index; if your document were to be included with such a document, the functions from your document and those from the other would not end up together. Also, to make your function names appear in the right font in the concept index, you would need to enclose every one of them between the braces of `@code`.

`@syncodeindex`

When you want to combine functions and concepts into one index, you should index the functions with `@findex` and index the concepts with `@cindex`, and use the `@syncodeindex` command to redirect the function index entries into the concept index.

The `@syncodeindex` command takes two arguments; they are the name of the index to redirect, and the name of the index to redirect it to. The template looks like this:

```
@syncodeindex from to
```

For this purpose, the indices are given two-letter names:

`cp'
: concept index

`fn'
: function index

`vr'
: variable index

`ky'
: key index

`pg'
: program index

`tp'
: data type index

Write an `@syncodeindex` command before or shortly after the end-of-header line at the beginning of a Texinfo file. For example, to merge a function index with a concept index, write the following:

```
@syncodeindex fn cp
```

This will cause all entries designated for the function index to merge in with the concept index instead.

To merge both a variables index and a function index into a concept index, write the following:

```
@syncodeindex vr cp
@syncodeindex fn cp
```

The `@syncodeindex` command puts all the entries from the `from' index (the redirected index) into the `@code` font, overriding whatever default font is used by the index to which the entries are now directed. This way, if you direct function names from a function index into a concept index, all the function names are printed in the `@code` font as you would expect.

`@synindex`

The `@synindex` command is nearly the same as the `@syncodeindex` command, except that it does not put the `from' index entries into the `@code` font; rather it puts them in the roman font. Thus, you use `@synindex` when you merge a concept index into a function index.

See section Index Menus and Printing an Index, for information about printing an index at the end of a book or creating an index menu in an Info file.

Defining New Indices

In addition to the predefined indices, you may use the `@defindex` and `@defcodeindex` commands to define new indices. These commands create new indexing @-commands with which you mark index entries. The `@defindex` command is used like this:

```
@defindex name
```

The name of an index should be a two letter word, such as `au'. For example:

```
@defindex au
```

This defines a new index, called the `au' index. At the same time, it creates a new indexing command, `@auindex`, that you can use to make index entries. Use the new indexing command just as you would use a predefined indexing command.

For example, here is a section heading followed by a concept index entry and two `au' index entries.

```
@section Cognitive Semantics
@cindex kinesthetic image schemas
@auindex Johnson, Mark
@auindex Lakoff, George
```

(Evidently, `au' serves here as an abbreviation for "author".) Texinfo constructs the new indexing command by concatenating the name of the index with `index'; thus, defining an `au' index leads to the automatic creation of an `@auindex` command.

Use the `@printindex` command to print the index, as you do with the predefined indices. For example:

```
@node Author Index, Subject Index, , Top
@unnumbered Author Index

@printindex au
```

The `@defcodeindex` is like the `@defindex` command, except that, in the printed output, it prints entries in an `@code` font instead of a roman font. Thus, it parallels the `@findex` command rather than the `@cindex` command.

You should define new indices within or right after the end-of-header line of a Texinfo file, before any `@synindex` or `@syncodeindex` commands (see section The Texinfo File Header).

Go to the previous, next section.

Go to the previous, next section.

Special Insertions

Texinfo provides several commands for formatting dimensions, for inserting single characters that have special meaning in Texinfo, such as braces, and for inserting special graphic symbols that do not correspond to characters, such as dots and bullets.

These are:

- Braces, `@' and periods.
- Format a dimension, such as `12pt'.
- Dots and bullets.
- The TeX logo and the copyright symbol.
- A minus sign.

Inserting `@', Braces, and Periods

`@' and curly braces are special characters in Texinfo. To insert these characters so they appear in text, you must put an `@' in front of these characters to prevent Texinfo from misinterpreting them.

Periods are also special. Depending on whether the period is inside or at the end of a sentence, less or more space is inserted after a period in a typeset manual. Since it is not always possible for Texinfo to determine when a period ends a sentence and when it is used in an abbreviation, special commands are needed in some circumstances. (Usually, Texinfo can guess how to handle periods, so you do not need to use the special commands; you just enter a period as you would if you were using a typewriter, which means you put two spaces after the period, question mark, or exclamation mark that ends a sentence.)

Do not put braces after any of these commands; they are not necessary.

Inserting `@' with @@

@@ stands for a single `@' in either printed or Info output.

Do not put braces after an @@ command.

Inserting `{' and `}'with @{ and @}

@{ stands for a single `{' in either printed or Info output.

@} stands for a single `}' in either printed or Info output.

Do not put braces after either an @{ or an @} command.

TOC

Spacing After Colons and Periods

Use the `@:` command after a period, question mark, exclamation mark, or colon that should not be followed by extra space. For example, use `@:` after periods that end abbreviations which are not at the ends of sentences. `@:` has no effect on the Info file output.

For example,

```
The s.o.p.@: has three parts ...
The s.o.p. has three parts ...
```

produces the following. If you look carefully at this printed output, you will see a little more whitespace after `s.o.p.' in the second line.

> The s.o.p. has three parts ...
> The s.o.p. has three parts ...

@: has no effect on the Info output. (`s.o.p' is an acronym for "Standard Operating Procedure".)

Use `@.` instead of a period at the end of a sentence that ends with a single capital letter. Otherwise, TeX will think the letter is an abbreviation and will not insert the correct end-of-sentence spacing. Here is an example:

```
Give it to M.I.B. and to M.E.W@.  Also, give it to R.J.C@.
Give it to M.I.B. and to M.E.W.  Also, give it to R.J.C.
```

produces the following. If you look carefully at this printed output, you will see a little more whitespace after the `W' in the first line.

> Give it to M.I.B. and to M.E.W. Also, give it to R.J.C.
> Give it to M.I.B. and to M.E.W. Also, give it to R.J.C.

In the Info file output, `@.` is equivalent to a simple `.'.

The meanings of `@:` and `@.` in Texinfo are designed to work well with the Emacs sentence motion commands. This made it necessary for them to be incompatible with some other formatting systems that use @-commands.

Do not put braces after either an `@:` or an `@.` command.

@dmn{dimension}: Format a Dimension

At times, you may want to write `12pt' or `8.5in' with little or no space between the number and the abbreviation for the dimension. You can use the `@dmn` command to do this. On seeing the command, TeX inserts just enough space for proper typesetting; the Info formatting commands insert no space at all, since the Info file does not require it.

To use the `@dmn` command, write the number and then follow it immediately, with no intervening space, by `@dmn`, and then by the dimension within braces.

For example,

```
A4 paper is 8.27@dmn{in} wide.
```

produces

> A4 paper is 8.27in wide.

Not everyone uses this style. Instead of writing `8.27@dmn{in}' in the Texinfo file, you may write `8.27 in.' or `8.27 inches'. (In these cases, the formatters may insert a line break between the number and the dimension. Also, if you write a period after an abbreviation within a sentence, you should write `@:' after the period to prevent TeX from inserting extra whitespace. See section Spacing After Colons and Periods.)

Inserting Ellipsis, Dots, and Bullets

An ellipsis (a line of dots) is not typeset as a string of periods, so a special command is used for ellipsis in Texinfo. The `@bullet` command is special, too. Each of these commands is followed by a pair of braces, `{}', without any whitespace between the name of the command and the braces. (You need to use braces with these commands because you can use them next to other text; without the braces, the formatters would be confused. See section @-Command Syntax, for further information.)

@dots{}

Use the `@dots{}` command to generate an ellipsis, which is three dots in a row, appropriately spaced, like this: `...'. Do not simply write three periods in the input file; that would work for the Info file output, but would produce the wrong amount of space between the periods in the printed manual.

Here is an ellipsis: ...

Here are three periods in a row: ...

In printed output, the three periods in a row are closer together than the dots in the ellipsis.

@bullet{}

Use the `@bullet{}` command to generate a large round dot, or the closest possible thing to one. In Info, an asterisk is used.

Here is a bullet: *

When you use `@bullet` in `@itemize`, you do not need to type the braces, because `@itemize` supplies them. See section Making an Itemized List.

Inserting TeX and the Copyright Symbol

The logo `TeX' is typeset in a special fashion and it needs an @-command. The copyright symbol, `(C)', is also special. Each of these commands is followed by a pair of braces, `{}', without any whitespace between the name of the command and the braces.

@TeX{}

Use the `@TeX{}` command to generate `TeX'. In a printed manual, this is a special logo that is different from three ordinary letters. In Info, it just looks like `TeX'. The `@TeX{}` command is unique among Texinfo commands in that the T and the X are in upper case.

@copyright{}

Use the `@copyright{}` command to generate `(C)'. In a printed manual, this is a `c' inside a circle, and in Info, this is `(C)'.

@minus{}: Inserting a Minus Sign

Use the `@minus{}` command to generate a minus sign. In a fixed-width font, this is a single hyphen, but in a proportional font, the symbol is the customary length for a minus sign--a little longer than a hyphen.

You can compare the two forms:

```
`-' is a minus sign generated with `@minus{}',

`-' is a hyphen generated with the character `-'.
```

In the fixed-width font used by Info, `@minus{}` is the same as a hyphen.

You should not use `@minus{}` inside `@code` or `@example` because the width distinction is not made in the fixed-width font they use.

When you use `@minus` to specify the mark beginning each entry in an itemized list, you do not need to type the braces (see section Making an Itemized List).

Go to the previous, next section.

Go to the previous, next section.

Glyphs for Examples

In Texinfo, code is often illustrated in examples that are delimited by `@example` and `@end example`, or by `@lisp` and `@end lisp`. In such examples, you can indicate the results of evaluation or an expansion using `=>' or `==>'. Likewise, there are commands to insert glyphs to indicate printed output, error messages, equivalence of expressions, and the location of point.

The glyph-insertion commands do not need to be used within an example, but most often they are. Every glyph-insertion command is followed by a pair of left- and right-hand braces.

=>
: `@result{}` points to the result of an expression.

==>
: `@expansion{}` shows the results of a macro expansion.

-|
: `@print{}` indicates printed output.

error-->
: `@error{}` indicates that the following text is an error message.

==
: `@equiv{}` indicates the exact equivalence of two forms.

-!-
: `@point{}` shows the location of point.

=>: Indicating Evaluation

Use the `@result{}` command to indicate the result of evaluating an expression.

The `@result{}` command is displayed as `=>' in Info and as `=>' in the printed output.

Thus, the following,

```
(cdr '(1 2 3))
     => (2 3)
```

may be read as "`(cdr '(1 2 3))` evaluates to `(2 3)`".

==>: Indicating an Expansion

When an expression is a macro call, it expands into a new expression. You can indicate the result of the expansion with the `@expansion{}` command.

The `@expansion{}` command is displayed as `==>' in Info and as `==>' in the printed output.

For example, the following

```
@lisp
(third '(a b c))
     @expansion{} (car (cdr (cdr '(a b c))))
     @result{} c
@end lisp
```

produces

```
(third '(a b c))
     ==> (car (cdr (cdr '(a b c))))
     => c
```

which may be read as:

> `(third '(a b c))` expands to `(car (cdr (cdr '(a b c))))`; the result of evaluating the expression is `c`.

Often, as in this case, an example looks better if the `@expansion{}` and `@result{}` commands are indented five spaces.

-|: Indicating Printed Output

Sometimes an expression will print output during its execution. You can indicate the printed output with the `@print{}` command.

The `@print{}` command is displayed as `-|' in Info and as `-|' in the printed output.

In the following example, the printed text is indicated with `-|', and the value of the expression follows on the last line.

```
(progn (print 'foo) (print 'bar))
     -| foo
     -| bar
     => bar
```

In a Texinfo source file, this example is written as follows:

```
@lisp
```

```
(progn (print 'foo) (print 'bar))
     @print{} foo
     @print{} bar
     @result{} bar
@end lisp
```

error-->: Indicating an Error Message

A piece of code may cause an error when you evaluate it. You can designate the error message with the `@error{}` command.

The `@error{}` command is displayed as `error-->' in Info and as `error-->' in the printed output.

Thus,

```
@lisp
(+ 23 'x)
@error{} Wrong type argument: integer-or-marker-p, x
@end lisp
```

produces

```
(+ 23 'x)
error--> Wrong type argument: integer-or-marker-p, x
```

This indicates that the following error message is printed when you evaluate the expression:

```
Wrong type argument: integer-or-marker-p, x
```

Note that `error-->' itself is not part of the error message.

==: Indicating Equivalence

Sometimes two expressions produce identical results. You can indicate the exact equivalence of two forms with the `@equiv{}` command.

The `@equiv{}` command is displayed as `==' in Info and as `==' in the printed output.

Thus,

```
@lisp
(make-sparse-keymap) @equiv{} (list 'keymap)
@end lisp
```

produces

```
(make-sparse-keymap) == (list 'keymap)
```

This indicates that evaluating `(make-sparse-keymap)` produces identical results to evaluating `(list 'keymap)`.

Indicating Point in a Buffer

Sometimes you need to show an example of text in an Emacs buffer. In such examples, the convention is to include the entire contents of the buffer in question between two lines of dashes containing the buffer name.

You can use the `@point{}' command to show the location of point in the text in the buffer. (The symbol for point, of course, is not part of the text in the buffer; it indicates the place *between* two characters where point is located.)

The `@point{}` command is displayed as `-!-' in Info and as `-!-' in the printed output.

The following example shows the contents of buffer `` `foo' `` before and after evaluating a Lisp command to insert the word `changed`.

```
---------- Buffer: foo ----------
This is the -!-contents of foo.
---------- Buffer: foo ----------

(insert "changed ")
     => nil
---------- Buffer: foo ----------
This is the changed -!-contents of foo.
---------- Buffer: foo ----------
```

In a Texinfo source file, the example is written like this:

```
@example
---------- Buffer: foo ----------
This is the @point{}contents of foo.
---------- Buffer: foo ----------

(insert "changed ")
     @result{} nil
---------- Buffer: foo ----------
This is the changed @point{}contents of foo.
---------- Buffer: foo ----------
@end example
```

TOC

Making and Preventing Breaks

Usually, a Texinfo file is processed both by TeX and by one of the Info formatting commands. Line, paragraph, or page breaks sometimes occur in the `wrong' place in one or other form of output. You must ensure that text looks right both in the printed manual and in the Info file.

For example, in a printed manual, page breaks may occur awkwardly in the middle of an example; to prevent this, you can hold text together using a grouping command that keeps the text from being split across two pages. Conversely, you may want to force a page break where none would occur normally. Fortunately, problems like these do not often arise. When they do, use the break, break prevention, or pagination commands.

The break commands create line and paragraph breaks:

`@*`
: Force a line break.

`@sp n`
: Skip n blank lines.

The line-break-prevention command holds text together all on one line:

`@w{text}`
: Prevent text from being split and hyphenated across two lines.

The pagination commands apply only to printed output, since Info files do not have pages.

`@page`
: Start a new page in the printed manual.

`@group`
: Hold text together that must appear on one printed page.

`@need mils`
: Start a new printed page if not enough space on this one.

@*: Generate Line Breaks

The `@*` command forces a line break in both the printed manual and in Info.

For example,

```
This line @* is broken @*in two places.
```

produces

```
This line
 is broken
in two places.
```

(Note that the space after the first `@*` command is faithfully carried down to the next line.)

The `@*` command is often used in a file's copyright page:

```
This is edition 2.0 of the Texinfo documentation,@*
and is for ...
```

In this case, the `@*` command keeps TeX from stretching the line across the whole page in an ugly manner.

> **Please note:** Do not write braces after an `@*` command; they are not needed.
>
> Do not write an `@refill` command at the end of a paragraph containing an `@*` command; it will cause the paragraph to be refilled after the line break occurs, negating the effect of the line break.

@w{text}: Prevent Line Breaks

`@w{text}` outputs text and prohibits line breaks within text.

You can use the `@w` command to prevent TeX from automatically hyphenating a long name or phrase that accidentally falls near the end of a line.

```
You can copy GNU software from @w{@file{prep.ai.mit.edu}}.
```

produces

> You can copy GNU software from `` `prep.ai.mit.edu' ``.

In the Texinfo file, you must write the `@w` command and its argument (all the affected text) all on one line.

> **Caution:** Do not write an `@refill` command at the end of a paragraph containing an `@w` command; it will cause the paragraph to be refilled and may thereby negate the effect of the `@w` command.

@sp n: Insert Blank Lines

A line beginning with and containing only `@sp n` generates n blank lines of space in both the printed manual and the Info file. `@sp` also forces a paragraph break. For example,

```
@sp 2
```

generates two blank lines.

The `@sp` command is most often used in the title page.

`@page`: Start a New Page

A line containing only `@page` starts a new page in a printed manual. The command has no effect on Info files since they are not paginated. An `@page` command is often used in the `@titlepage` section of a Texinfo file to start the copyright page.

`@group`: Prevent Page Breaks

The `@group` command (on a line by itself) is used inside an `@example` or similar construct to begin an unsplittable vertical group, which will appear entirely on one page in the printed output. The group is terminated by a line containing only `@end group`. These two lines produce no output of their own, and in the Info file output they have no effect at all.

Although `@group` would make sense conceptually in a wide variety of contexts, its current implementation works reliably only within `@example` and variants, and within `@display`, `@format`, `@flushleft` and `@flushright`. See section Quotations and Examples. (What all these commands have in common is that each line of input produces a line of output.) In other contexts, `@group` can cause anomalous vertical spacing.

This formatting requirement means that you should write:

```
@example
@group
...
@end group
@end example
```

with the `@group` and `@end group` commands inside the `@example` and `@end example` commands.

The `@group` command is most often used to hold an example together on one page. In this Texinfo manual, more than 100 examples contain text that is enclosed between `@group` and `@end group`.

If you forget to end a group, you may get strange and unfathomable error messages when you run TeX. This is because TeX keeps trying to put the rest of the Texinfo file onto the one page and does not start to generate error messages until it has processed considerable text. It is a good rule of thumb to look for a missing `@end group` if you get incomprehensible error messages in TeX.

`@need mils`: Prevent Page Breaks

A line containing only `@need n` starts a new page in a printed manual if fewer than n mils (thousandths of an inch) remain on the current page. Do not use braces around the argument n. The `@need` command has no effect on Info files since they are not paginated.

This paragraph is preceded by an `@need` command that tells TeX to start a new page if fewer than 8 mils (eight-tenths inch) remain on the page. It looks like this:

```
@need 800
This paragraph is preceded by ...
```

The `@need` command is useful for preventing orphans (single lines at the bottoms of printed pages).

Go to the previous, next section.

Go to the previous, next section.

Definition Commands

The `@deffn` command and the other definition commands enable you to describe functions, variables, macros, commands, user options, special forms and other such artifacts in a uniform format.

In the Info file, a definition causes the entity category---`Function', `Variable', or whatever--to appear at the beginning of the first line of the definition, followed by the entity's name and arguments. In the printed manual, the command causes TeX to print the entity's name and its arguments on the left margin and print the category next to the right margin. In both output formats, the body of the definition is indented. Also, the name of the entity is entered into the appropriate index: `@deffn` enters the name into the index of functions, `@defvr` enters it into the index of variables, and so on.

A manual need not and should not contain more than one definition for a given name. An appendix containing a summary should use `@table` rather than the definition commands.

The Template for a Definition

The `@deffn` command is used for definitions of entities that resemble functions. To write a definition using the `@deffn` command, write the `@deffn` command at the beginning of a line and follow it on the same line by the category of the entity, the name of the entity itself, and its arguments (if any). Then write the body of the definition on succeeding lines. (You may embed examples in the body.) Finally, end the definition with an `@end deffn` command written on a line of its own. (The other definition commands follow the same format.)

The template for a definition looks like this:

```
@deffn category name arguments...
body-of-definition
@end deffn
```

For example,

```
@deffn Command forward-word count
This command moves point forward @var{count} words
(or backward if @var{count} is negative). ...
@end deffn
```

produces

> Command: **forward-word** *count*
>
> This function moves point forward count words (or backward if count is negative). ...

Capitalize the category name like a title. If the name of the category contains spaces, as in the phrase

`Interactive Command', write braces around it. For example:

```
@deffn {Interactive Command} isearch-forward
...
@end deffn
```

Otherwise, the second word will be mistaken for the name of the entity.

Some of the definition commands are more general than others. The `@deffn` command, for example, is the general definition command for functions and the like--for entities that may take arguments. When you use this command, you specify the category to which the entity belongs. The `@deffn` command possesses three predefined, specialized variations, `@defun`, `@defmac`, and `@defspec`, that specify the category for you: "Function", "Macro", and "Special Form" respectively. The `@defvr` command also is accompanied by several predefined, specialized variations for describing particular kinds of variables.

The template for a specialized definition, such as `@defun`, is similar to the template for a generalized definition, except that you do not need to specify the category:

```
@defun name arguments...
body-of-definition
@end defun
```

Thus,

```
@defun buffer-end flag
This function returns @code{(point-min)} if @var{flag}
is less than 1, @code{(point-max)} otherwise.
...
@end defun
```

produces

> Function: **buffer-end** *flag*
>
> This function returns `(point-min)` if flag is less than 1, `(point-max)` otherwise. ...

See section A Sample Function Definition, for a more detailed example of a function definition, including the use of `@example` inside the definition.

The other specialized commands work like `@defun`.

Optional and Repeated Arguments

Some entities take optional or repeated arguments, which may be specified by a distinctive glyph that uses square brackets and ellipses. For example, a special form often breaks its argument list into separate arguments in more complicated ways than a straightforward function.

An argument enclosed within square brackets is optional. Thus, the phrase `[optional-arg]' means

that optional-arg is optional. An argument followed by an ellipsis is optional and may be repeated more than once. Thus, `repeated-args...' stands for zero or more arguments. Parentheses are used when several arguments are grouped into additional levels of list structure in Lisp.

Here is the `@defspec` line of an example of an imaginary special form:

> Special Form: **foobar** *(var [from to [inc]]) body...*

In this example, the arguments from and to are optional, but must both be present or both absent. If they are present, inc may optionally be specified as well. These arguments are grouped with the argument var into a list, to distinguish them from body, which includes all remaining elements of the form.

In a Texinfo source file, this `@defspec` line is written like this (except it would not be split over two lines, as it is in this example).

```
@defspec foobar (@var{var} [@var{from} @var{to}
     [@var{inc}]]) @var{body}@dots{}
```

The function is listed in the Command and Variable Index under `foobar'.

Two or More `First' Lines

To create two or more `first' or header lines for a definition, follow the first `@deffn` line by a line beginning with `@deffnx`. The `@deffnx` command works exactly like `@deffn` except that it does not generate extra vertical white space between it and the preceding line.

For example,

```
@deffn {Interactive Command} isearch-forward
@deffnx {Interactive Command} isearch-backward
These two search commands are similar except ...
@end deffn
```

produces

Interactive Command: **isearch-forward**

Interactive Command: **isearch-backward**

These two search commands are similar except ...

Each of the other definition commands has an `x' form: `@defunx`, `@defvrx`, `@deftypefunx`, etc.

The `x' forms work just like `@itemx`; see section `@itemx`.

The Definition Commands

Texinfo provides more than a dozen definition commands, all of which are described in this section.

The definition commands automatically enter the name of the entity in the appropriate index: for example, `@deffn`, `@defun`, and `@defmac` enter function names in the index of functions; `@defvr` and `@defvar` enter variable names in the index of variables.

Although the examples that follow mostly illustrate Lisp, the commands can be used for other programming languages.

Functions and Similar Entities

This section describes the commands for describing functions and similar entities:

`@deffn category name arguments...`

The `@deffn` command is the general definition command for functions, interactive commands, and similar entities that may take arguments. You must choose a term to describe the category of entity being defined; for example, "Function" could be used if the entity is a function. The `@deffn` command is written at the beginning of a line and is followed on the same line by the category of entity being described, the name of this particular entity, and its arguments, if any. Terminate the definition with `@end deffn` on a line of its own.

For example, here is a definition:

```
@deffn Command forward-char nchars
Move point forward @var{nchars} characters.
@end deffn
```

This shows a rather terse definition for a "command" named `forward-char` with one argument, nchars.

`@deffn` prints argument names such as nchars in italics or upper case, as if `@var` had been used, because we think of these names as metasyntactic variables--they stand for the actual argument values. Within the text of the description, write an argument name explicitly with `@var` to refer to the value of the argument. In the example above, we used `@var{nchars}' in this way.

The template for `@deffn` is:

```
@deffn category name arguments...
body-of-definition
@end deffn
```

`@defun name arguments...`

The `@defun` command is the definition command for functions. `@defun` is equivalent to `@deffn Function ...'.

For example,

```
@defun set symbol new-value
Change the value of the symbol @var{symbol}
to @var{new-value}.
@end defun
```

shows a rather terse definition for a function `set` whose arguments are symbol and new-value. The argument names on the `@defun` line automatically appear in italics or upper case as if they were enclosed in `@var`. Terminate the definition with `@end defun` on a line of its own.

The template is:

```
@defun function-name arguments...
body-of-definition
@end defun
```

`@defun` creates an entry in the index of functions.

`@defmac name arguments...`

The `@defmac` command is the definition command for macros. `@defmac` is equivalent to `@deffn Macro ...' and works like `@defun`.

`@defspec name arguments...`

The `@defspec` command is the definition command for special forms. (In Lisp, a special form is an entity much like a function.) `@defspec` is equivalent to `@deffn {Special Form} ...' and works like `@defun`.

Variables and Similar Entities

Here are the commands for defining variables and similar entities:

`@defvr category name`

The `@defvr` command is a general definition command for something like a variable--an entity that records a value. You must choose a term to describe the category of entity being defined; for example, "Variable" could be used if the entity is a variable. Write the `@defvr` command at the beginning of a line and followed it on the same line by the category of the entity and the name of the entity.

Capitalize the category name like a title. If the name of the category contains spaces, as in the name `User Option', write braces around it. Otherwise, the second word will be mistaken for the name of the entity, for example:

```
@defvr {User Option} fill-column
This buffer-local variable specifies
the maximum width of filled lines.
...
@end defvr
```

Terminate the definition with `@end defvr` on a line of its own.

The template is:

```
@defvr category name
body-of-definition
@end defvr
```

`@defvr` creates an entry in the index of variables for name.

`@defvar name`

The `@defvar` command is the definition command for variables. `@defvar` is equivalent to `@defvr Variable ...'.

For example:

```
@defvar kill-ring
...
@end defvar
```

The template is:

```
@defvar name
body-of-definition
@end defvar
```

`@defvar` creates an entry in the index of variables for name.

`@defopt name`

The `@defopt` command is the definition command for user options. `@defopt` is equivalent to `@defvr {User Option} ...' and works like `@defvar`.

Functions in Typed Languages

The `@deftypefn` command and its variations are for describing functions in C or any other language in which you must declare types of variables and functions.

`@deftypefn category data-type name arguments...`

The `@deftypefn` command is the general definition command for functions and similar entities that may take arguments and that are typed. The `@deftypefn` command is written at the beginning of a line and is followed on the same line by the category of entity being described, the type of the returned value, the name of this particular entity, and its arguments, if any.

For example,

```
@deftypefn {Library Function} int foobar
   (int @var{foo}, float @var{bar})
...
```

```
@end deftypefn
```

(where the text before the "...", shown above as two lines, would actually be a single line in a real Texinfo file) produces the following in Info:

```
-- Library Function: int foobar (int FOO, float BAR)
...
```

In a printed manual, it produces:

> Library Function: int **foobar** *(int foo, float bar)*
>
> ...

This means that `foobar` is a "library function" that returns an `int`, and its arguments are foo (an `int`) and bar (a `float`).

The argument names that you write in `@deftypefn` are not subject to an implicit `@var`---since the actual names of the arguments in `@deftypefn` are typically scattered among data type names and keywords, Texinfo cannot find them without help. Instead, you must write `@var` explicitly around the argument names. In the example above, the argument names are `foo' and `bar'.

The template for `@deftypefn` is:

```
@deftypefn category data-type name arguments ...
body-of-description
@end deftypefn
```

Note that if the category or data type is more than one word then it must be enclosed in braces to make it a single argument.

If you are describing a procedure in a language that has packages, such as Ada, you might consider using `@deftypefn` in a manner somewhat contrary to the convention described in the preceding paragraphs.

For example:

```
@deftypefn stacks private push
        (@var{s}:in out stack;
        @var{n}:in integer)
...
@end deftypefn
```

(The `@deftypefn` arguments are shown split into three lines, but would be a single line in a real Texinfo file.)

In this instance, the procedure is classified as belonging to the package `stacks` rather than classified as a `procedure' and its data type is described as `private`. (The name of the procedure is `push`, and its arguments are s and n.)

`@deftypefn` creates an entry in the index of functions for name.

`@deftypefun data-type name arguments...`

The `@deftypefun` command is the specialized definition command for functions in typed languages. The command is equivalent to `@deftypefn Function ...'.

Thus,

```
@deftypefun int foobar (int @var{foo}, float @var{bar})
...
@end deftypefun
```

produces the following in Info:

```
-- Function: int foobar (int FOO, float BAR)
...
```

and the following in a printed manual:

Function: int **foobar** *(int foo, float bar)*

...

The template is:

```
@deftypefun type name arguments...
body-of-description
@end deftypefun
```

`@deftypefun` creates an entry in the index of functions for name.

Variables in Typed Languages

Variables in typed languages are handled in a manner similar to functions in typed languages. See section Functions in Typed Languages. The general definition command `@deftypevr` corresponds to `@deftypefn` and the specialized definition command `@deftypevar` corresponds to `@deftypefun`.

`@deftypevr category data-type name`

The `@deftypevr` command is the general definition command for something like a variable in a typed language--an entity that records a value. You must choose a term to describe the category of the entity being defined; for example, "Variable" could be used if the entity is a variable.

The `@deftypevr` command is written at the beginning of a line and is followed on the same line by the category of the entity being described, the data type, and the name of this particular entity.

For example:

```
@deftypevr {Global Flag} int enable
...
```

```
@end deftypevr
```

produces the following in Info:

```
-- Global Flag: int enable
...
```

and the following in a printed manual:

Global Flag: int **enable**

...

The template is:

```
@deftypevr category data-type name
body-of-description
@end deftypevr
```

`@deftypevr` creates an entry in the index of variables for name.

`@deftypevar data-type name`

The `@deftypevar` command is the specialized definition command for variables in typed languages. `@deftypevar` is equivalent to `@deftypevr Variable ...'.

For example:

```
@deftypevar int fubar
...
@end deftypevar
```

produces the following in Info:

```
-- Variable: int fubar
...
```

and the following in a printed manual:

Variable: int **fubar**

...

The template is:

```
@deftypevar data-type name
body-of-description
@end deftypevar
```

`@deftypevar` creates an entry in the index of variables for name.

Object-Oriented Programming

Here are the commands for formatting descriptions about abstract objects, such as are used in object-oriented programming. A class is a defined type of abstract object. An instance of a class is a particular object that has the type of the class. An instance variable is a variable that belongs to the class but for which each instance has its own value.

In a definition, if the name of a class is truly a name defined in the programming system for a class, then you should write an `@code` around it. Otherwise, it is printed in the usual text font.

`@defcv category class name`

The `@defcv` command is the general definition command for variables associated with classes in object-oriented programming. The `@defcv` command is followed by three arguments: the category of thing being defined, the class to which it belongs, and its name. Thus,

```
@defcv {Class Option} Window border-pattern
...
@end defcv
```

illustrates how you would write the first line of a definition of the `border-pattern` class option of the class `Window`.

The template is

```
@defcv category class name
...
@end defcv
```

`@defcv` creates an entry in the index of variables.

`@defivar class name`

The `@defivar` command is the definition command for instance variables in object-oriented programming. `@defivar` is equivalent to `@defcv {Instance Variable} ...'

The template is:

```
@defivar class instance-variable-name
body-of-definition
@end defivar
```

`@defivar` creates an entry in the index of variables.

`@defop category class name arguments...`

The `@defop` command is the general definition command for entities that may resemble methods in object-oriented programming. These entities take arguments, as functions do, but are associated with particular classes of objects.

For example, some systems have constructs called wrappers that are associated with classes as methods are, but that act more like macros than like functions. You could use `@defop Wrapper`

to describe one of these.

Sometimes it is useful to distinguish methods and operations. You can think of an operation as the specification for a method. Thus, a window system might specify that all window classes have a method named `expose`; we would say that this window system defines an `expose` operation on windows in general. Typically, the operation has a name and also specifies the pattern of arguments; all methods that implement the operation must accept the same arguments, since applications that use the operation do so without knowing which method will implement it.

Often it makes more sense to document operations than methods. For example, window application developers need to know about the `expose` operation, but need not be concerned with whether a given class of windows has its own method to implement this operation. To describe this operation, you would write:

```
@defop Operation windows expose
```

The `@defop` command is written at the beginning of a line and is followed on the same line by the overall name of the category of operation, the name of the class of the operation, the name of the operation, and its arguments, if any.

The template is:

```
@defop category class name arguments...
body-of-definition
@end defop
```

`@defop` creates an entry, such as `` `expose on windows' ``, in the index of functions.

`@defmethod class name arguments...`

The `@defmethod` command is the definition command for methods in object-oriented programming. A method is a kind of function that implements an operation for a particular class of objects and its subclasses. In the Lisp Machine, methods actually were functions, but they were usually defined with `defmethod`.

`@defmethod` is equivalent to `` `@defop Method ...' ``. The command is written at the beginning of a line and is followed by the name of the class of the method, the name of the method, and its arguments, if any.

For example,

```
@defmethod bar-class bar-method argument
...
@end defmethod
```

illustrates the definition for a method called `bar-method` of the class `bar-class`. The method takes an argument.

The template is:

```
@defmethod class method-name arguments...
body-of-definition
@end defmethod
```

`@defmethod` creates an entry in the index of functions, such as `` `bar-method on bar-class' ``.

Data Types

Here is the command for data types:

`@deftp category name attributes...`

The `@deftp` command is the generic definition command for data types. The command is written at the beginning of a line and is followed on the same line by the category, by the name of the type (which is a word like `int` or `float`), and then by names of attributes of objects of that type. Thus, you could use this command for describing `int` or `float`, in which case you could use `data type` as the category. (A data type is a category of certain objects for purposes of deciding which operations can be performed on them.)

In Lisp, for example, pair names a particular data type, and an object of that type has two slots called the CAR and the CDR. Here is how you would write the first line of a definition of `pair`.

```
@deftp {Data type} pair car cdr
...
@end deftp
```

The template is:

```
@deftp category name-of-type attributes...
body-of-definition
@end deftp
```

`@deftp` creates an entry in the index of data types.

Conventions for Writing Definitions

When you write a definition using `@deffn`, `@defun`, or one of the other definition commands, please take care to use arguments that indicate the meaning, as with the count argument to the `forward-word` function. Also, if the name of an argument contains the name of a type, such as integer, take care that the argument actually is of that type.

A Sample Function Definition

A function definition uses the `@defun` and `@end defun` commands. The name of the function follows immediately after the `@defun` command and it is followed, on the same line, by the parameter list.

Here is a definition from The GNU Emacs Lisp Reference Manual. (See section 'Calling Functions' in The GNU Emacs Lisp Reference Manual.)

> Function: **apply** *function &rest arguments*
>
> `apply` calls function with arguments, just like `funcall` but with one difference: the last of arguments is a list of arguments to give to function, rather than a single argument. We also say that this list is appended to the other arguments.
>
> `apply` returns the result of calling function. As with `funcall`, function must either be a Lisp function or a primitive function; special forms and macros do not make sense in `apply`.
>
> ```
> (setq f 'list)
>      => list
> (apply f 'x 'y 'z)
> error--> Wrong type argument: listp, z
> (apply '+ 1 2 '(3 4))
>      => 10
> (apply '+ '(1 2 3 4))
>      => 10
>
> (apply 'append '((a b c) nil (x y z) nil))
>      => (a b c x y z)
> ```
>
> An interesting example of using `apply` is found in the description of `mapcar`.

In the Texinfo source file, this example looks like this:

```
@defun apply function &rest arguments

@code{apply} calls @var{function} with
@var{arguments}, just like @code{funcall} but with one
difference: the last of @var{arguments} is a list of
arguments to give to @var{function}, rather than a single
argument.  We also say that this list is @dfn{appended}
to the other arguments.

@code{apply} returns the result of calling
@var{function}.  As with @code{funcall},
@var{function} must either be a Lisp function or a
primitive function; special forms and macros do not make
```

```
sense in @code{apply}.

@example
(setq f 'list)
     @result{} list
(apply f 'x 'y 'z)
@error{} Wrong type argument: listp, z
(apply '+ 1 2 '(3 4))
     @result{} 10
(apply '+ '(1 2 3 4))
     @result{} 10

(apply 'append '((a b c) nil (x y z) nil))
     @result{} (a b c x y z)
@end example

An interesting example of using @code{apply} is found
in the description of @code{mapcar}.@refill
@end defun
```

In this manual, this function is listed in the Command and Variable Index under `apply`.

Ordinary variables and user options are described using a format like that for functions except that variables do not take arguments.

Go to the previous, next section.

Go to the previous, next section.

Footnotes

A footnote is for a reference that documents or elucidates the primary text.(8)

In Texinfo, footnotes are created with the `@footnote` command. This command is followed immediately by a left brace, then by the text of the footnote, and then by a terminating right brace. The template is:

```
@footnote{text}
```

Footnotes may be of any length, but are usually short.

For example, this clause is followed by a sample footnote(9); in the Texinfo source, it looks like this:

```
...a sample footnote @footnote{Here is the sample
footnote.}; in the Texinfo source...
```

In a printed manual or book, the reference mark for a footnote is a small, superscripted number; the text of the footnote is written at the bottom of the page, below a horizontal line.

In Info, the reference mark for a footnote is a pair of parentheses with the footnote number between them, like this: `(1)'.

Info has two footnote styles, which determine where the text of the footnote is located:

- In the `End' node style, all the footnotes for a single node are placed at the end of that node. The footnotes are separated from the rest of the node by a line of dashes with the word `Footnotes' within it. Each footnote begins with an `(n)' reference mark.

  Here is an example of a single footnote in the end of node style:

  ```
  --------- Footnotes ---------

  (1)  Here is a sample footnote.
  ```

- In the `Separate' node style, all the footnotes for a single node are placed in an automatically constructed node of their own. In this style, a "footnote reference" follows each `(n)' reference mark in the body of the node. The footnote reference is actually a cross reference which you use to reach the footnote node.

  The name of the node containing the footnotes is constructed by appending `-Footnotes' to the name of the node that contains the footnotes. (Consequently, the footnotes' node for the `Footnotes' node is `Footnotes-Footnotes'!) The footnotes' node has an `Up' node pointer that leads back to its parent node.

  Here is how the first footnote in this manual looks after being formatted for Info in the separate

node style:

```
File: texinfo.info  Node: Overview-Footnotes, Up: Overview

(1) Note that the first syllable of "Texinfo" is
pronounced like "speck", not "hex". ...
```

A Texinfo file may be formatted into an Info file with either footnote style.

Use the `@footnotestyle` command to specify an Info file's footnote style. Write this command at the beginning of a line followed by an argument, either `end' for the end node style or `separate' for the separate node style.

For example,

```
@footnotestyle end
```

or

```
@footnotestyle separate
```

Write an `@footnotestyle` command before or shortly after the end-of-header line at the beginning of a Texinfo file. (If you include the `@footnotestyle` command between the start-of-header and end-of-header lines, the region formatting commands will format footnotes as specified.)

If you do not specify a footnote style, the formatting commands use their default style. Currently, `makeinfo` uses the `end' style, while `texinfo-format-buffer` and `texinfo-format-region` use the `separate' style.

This chapter contains two footnotes.

Go to the previous, next section.

Go to the previous, next section.

Conditionally Visible Text

Sometimes it is good to use different text for a printed manual and its corresponding Info file. In this case, you can use the conditional commands to specify which text is for the printed manual and which is for the Info file.

`@ifinfo` begins segments of text that should be ignored by TeX when it typesets the printed manual. The segment of text appears only in the Info file. The `@ifinfo` command should appear on a line by itself; end the Info-only text with a line containing `@end ifinfo` by itself. At the beginning of a Texinfo file, the Info permissions are contained within a region marked by `@ifinfo` and `@end ifinfo`. (See section Summary and Copying Permissions for Info.)

The `@iftex` and `@end iftex` commands are similar to the `@ifinfo` and `@end ifinfo` commands, except that they specify text that will appear in the printed manual but not in the Info file.

For example,

```
@iftex
This text will appear only in the printed manual.
@end iftex

@ifinfo
However, this text will appear only in Info.
@end ifinfo
```

The preceding example produces the following line:

This text will appear only in the printed manual.

Note how you only see one of the two lines, depending on whether you are reading the Info version or the printed version of this manual.

The `@titlepage` command is a special variant of `@iftex` that is used for making the title and copyright pages of the printed manual. (See section `@titlepage`.)

Using Ordinary TeX Commands

Inside a region delineated by `@iftex` and `@end iftex`, you can embed some PlainTeX commands. Info will ignore these commands since they are only in that part of the file which is seen by TeX. You can write the TeX commands as you would write them in a normal TeX file, except that you must replace the `\' used by TeX with an `@'. For example, in the `@titlepage` section of a Texinfo file, you can use the TeX command `@vskip` to format the copyright page. (The `@titlepage` command causes Info to ignore the region automatically, as it does with the `@iftex` command.)

However, many features of PlainTeX will not work, as they are overridden by features of Texinfo.

You can enter PlainTeX completely, and use `\' in the TeX commands, by delineating a region with the `@tex` and `@end tex` commands. (The `@tex` command also causes Info to ignore the region, like the `@iftex` command.)

For example, here is a mathematical expression written in PlainTeX:

```
@tex
$$ \chi^2 = \sum_{i=1}^N
          \left (y_i - (a + b x_i)
          \over \sigma_i\right)^2 $$
@end tex
```

The output of this example will appear only in a printed manual. If you are reading this in Info, you will not see anything after this paragraph. In a printed manual, the above expression looks like this:

`@set`, `@clear`, and `@value`

You can direct the Texinfo formatting commands to format or ignore parts of a Texinfo file with the `@set`, `@clear`, `@ifset`, and `@ifclear` commands.

In addition, you can use the `@set flag` command to set the value of flag to a string of characters; and use `@value{flag}` to insert that string. You can use `@set`, for example, to set a date and use `@value` to insert the date in several places in the Texinfo file.

`@ifset` and `@ifclear`

When a flag is set, the Texinfo formatting commands format text between subsequent pairs of `@ifset flag` and `@end ifset` commands. When the flag is cleared, the Texinfo formatting commands do *not* format the text.

Use the `@set flag` command to turn on, or set, a flag; a flag can be any single word. The format for the command looks like this:

```
@set flag
```

Write the conditionally formatted text between `@ifset flag` and `@end ifset` commands, like this:

```
@ifset flag
conditional-text
@end ifset
```

For example, you can create one document that has two variants, such as a manual for a `large' and `small' model:

```
You can use this machine to dig up shrubs
without hurting them.

@set large

@ifset large
It can also dig up fully grown trees.
@end ifset

Remember to replant promptly ...
```

In the example, the formatting commands will format the text between `@ifset large` and `@end ifset` because the `large` flag is set.

Use the `@clear flag` command to turn off, or clear, a flag. Clearing a flag is the opposite of setting a flag. The command looks like this:

```
@clear flag
```

Write the command on a line of its own.

When flag is cleared, the Texinfo formatting commands do *not* format the text between `@ifset flag` and `@end ifset`; that text is ignored and does not appear in either printed or Info output.

For example, if you clear the flag of the preceding example by writing an `@clear large` command after the `@set large` command (but before the conditional text), then the Texinfo formatting commands ignore the text between the `@ifset large` and `@end ifset` commands. In the formatted output, that text does not appear; in both printed and Info output, you see only the lines that say, "You can use this machine to dig up shrubs without hurting them. Remember to replant promptly ...".

If a flag is cleared with an `@clear flag` command, then the formatting commands format text between subsequent pairs of `@ifclear` and `@end ifclear` commands. But if the flag is set with `@set flag`, then the formatting commands do *not* format text between an `@ifclear` and an `@end ifclear` command; rather, they ignore that text. An `@ifclear` command looks like this:

```
@ifclear flag
```

In brief, the commands are:

`@set flag`
: Tell the Texinfo formatting commands that flag is set.

`@clear flag`
: Tell the Texinfo formatting commands that flag is cleared.

`@ifset flag`
: If flag is set, tell the Texinfo formatting commands to format the text up to the following `@end ifset` command.

If flag is cleared, tell the Texinfo formatting commands to ignore text up to the following `@end ifset` command.

`@ifclear flag`

If flag is set, tell the Texinfo formatting commands to ignore the text up to the following `@end ifclear` command.

If flag is cleared, tell the Texinfo formatting commands to format the text up to the following `@end ifclear` command.

@value

You can use the `@set` command to specify a value for a flag, which is expanded by the `@value` command. The value is a string a characters.

Write the `@set` command like this:

```
@set foo This is a string.
```

This sets the value of `foo` to "This is a string."

The Texinfo formatters replace an `@value{flag}` command with the string to which flag is set.

Thus, when `foo` is set as shown above, the Texinfo formatters convert

```
@value{foo}
to
This is a string.
```

You can write an `@value` command within a paragraph; but you must write an `@set` command on a line of its own.

If you write the `@set` command like this:

```
@set foo
```

without specifying a string, the value of `foo` is an empty string.

If you clear a previously set flag with an `@clear flag` command, a subsequent `@value{flag}` command is invalid and the string is replaced with an error message that says `{No value for "flag"}'.

For example, if you set `foo` as follows:

```
@set how-much very, very, very
```

then the formatters transform

```
It is a @value{how-much} wet day.
into
```

```
It is a very, very, very wet day.
```

If you write

```
@clear how-much
```

then the formatters transform

```
It is a @value{how-much} wet day.
into
It is a {No value for "how-much"} wet day.
```

@value Example

You can use the `@value` command to limit the number of places you need to change when you record an update to a manual. Here is how it is done in The GNU Make Manual:

Set the flags:

```
@set EDITION 0.35 Beta
@set VERSION 3.63 Beta
@set UPDATED 14 August 1992
@set UPDATE-MONTH August 1992
```

Write text for the first `@ifinfo` section, for people reading the Texinfo file:

```
This is Edition @value{EDITION},
last updated @value{UPDATED},
of @cite{The GNU Make Manual},
for @code{make}, Version @value{VERSION}.
```

Write text for the title page, for people reading the printed manual:

```
@title GNU Make
@subtitle A Program for Directing Recompilation
@subtitle Edition @value{EDITION}, ...
@subtitle @value{UPDATE-MONTH}
```

(On a printed cover, a date listing the month and the year looks less fussy than a date listing the day as well as the month and year.)

Write text for the Top node, for people reading the Info file:

```
This is Edition @value{EDITION}
of the @cite{GNU Make Manual},
last updated @value{UPDATED}
```

```
for @code{make} Version @value{VERSION}.
```

After you format the manual, the text in the first `@ifinfo` section looks like this:

```
This is Edition 0.35 Beta, last updated 14 August 1992,
of `The GNU Make Manual', for `make', Version 3.63 Beta.
```

When you update the manual, change only the values of the flags; you do not need to rewrite the three sections.

Go to the previous, next section.

Go to the previous, next section.

Format and Print Hardcopy

There are three major shell commands for making a printed manual from a Texinfo file: one for converting the Texinfo file into a file that will be printed, a second for sorting indices, and a third for printing the formatted document. When you use the shell commands, you can either work directly in the operating system shell or work within a shell inside GNU Emacs.

If you are using GNU Emacs, you can use commands provided by Texinfo mode instead of shell commands. In addition to the three commands to format a file, sort the indices, and print the result, Texinfo mode offers key bindings for commands to recenter the output buffer, show the print queue, and delete a job from the print queue.

The typesetting program called TeX is used for formatting a Texinfo file. TeX is a very powerful typesetting program and, if used right, does an exceptionally good job. See section How to Obtain TeX, for information on how to obtain TeX.

The `makeinfo`, `texinfo-format-region`, and `texinfo-format-buffer` commands read the very same @-commands in the Texinfo file as does TeX, but process them differently to make an Info file; see section Creating an Info File.

Format and Print Using Shell Commands

Format the Texinfo file with the shell command `tex` followed by the name of the Texinfo file. This produces a formatted DVI file as well as several auxiliary files containing indices, cross references, etc. The DVI file (for DeVice Independent file) can be printed on a wide variety of printers.

The `tex` formatting command itself does not sort the indices; it writes an output file of unsorted index data. This is a misfeature of TeX. Hence, to generate a printed index, you first need a sorted index to work from. The `texindex` command sorts indices. (The source file `` `texindex.c' `` comes as part of the standard GNU distribution and is usually installed when Emacs is installed.)

The `tex` formatting command outputs unsorted index files under names that obey a standard convention. These names are the name of your main input file to the `tex` formatting command, with everything after the first period thrown away, and the two letter names of indices added at the end. For example, the raw index output files for the input file `` `foo.texinfo' `` would be `` `foo.cp' ``, `` `foo.vr' ``, `` `foo.fn' ``, `` `foo.tp' ``, `` `foo.pg' `` and `` `foo.ky' ``. Those are exactly the arguments to give to `texindex`.

Or else, you can use `??' as "wild-cards" and give the command in this form:

```
texindex foo.??
```

This command will run `texindex` on all the unsorted index files, including any that you have defined yourself using `@defindex` or `@defcodeindex`. (You may execute `texindex foo.??' even if there are

similarly named files with two letter extensions that are not index files, such as `foo.el'. The `texinde` command reports but otherwise ignores such files.)

For each file specified, `texindex` generates a sorted index file whose name is made by appending `s' to the input file name. The `@printindex` command knows to look for a file of that name. `texindex` does not alter the raw index output file.

After you have sorted the indices, you need to rerun the `tex` formatting command on the Texinfo file. This regenerates a formatted DVI file with up-to-date index entries.(10)

To summarize, this is a three step process:

1. Run the `tex` formatting command on the Texinfo file. This generates the formatted DVI file as well as the raw index files with two letter extensions.
2. Run the shell command `texindex` on the raw index files to sort them. This creates the corresponding sorted index files.
3. Rerun the `tex` formatting command on the Texinfo file. This regenerates a formatted DVI file with the index entries in the correct order. This second run also corrects the page numbers for the cross references. (The tables of contents are always correct.)

You need not run `texindex` each time after you run the `tex` formatting. If you do not, on the next run, the `tex` formatting command will use whatever sorted index files happen to exist from the previous use of `texindex`. This is usually OK while you are debugging.

Rather than type the `tex` and `texindex` commands yourself, you can use `texi2dvi`. This shell script is designed to simplify the `tex---texindex---tex` sequence by figuring out whether index files and DVI files are up-to-date. It runs `texindex` and `tex` only when necessary.

The syntax for `texi2dvi` is like this (where `%' is the shell prompt):

```
% texi2dvi filename...
```

Finally, you can print the DVI file with the DVI print command. The precise command to use depends on the system; `lpr -d' is common. The DVI print command may require a file name without any extension or with a `.dvi' extension.

The following commands, for example, sort the indices, format, and print the Bison Manual (where `%' is the shell prompt):

```
% tex bison.texinfo
% texindex bison.??
% tex bison.texinfo
% lpr -d bison.dvi
```

(Remember that the shell commands may be different at your site; but these are commonly used versions.)

From an Emacs Shell ...

You can give formatting and printing commands from a shell within GNU Emacs. To create a shell within Emacs, type M-x shell. In this shell, you can format and print the document. See section Format and Print Using Shell Commands, for details.

You can switch to and from the shell buffer while `tex` is running and do other editing. If you are formatting a long document on a slow machine, this can be very convenient.

You can also use `texi2dvi` from an Emacs shell. For example, here is how to use `texi2dvi` to format and print Using and Porting GNU CC from a shell within Emacs (where `%' is the shell prompt):

```
% texi2dvi gcc.texinfo
% lpr -d gcc.dvi
```

Formatting and Printing in Texinfo Mode

Texinfo mode provides several predefined key commands for TeX formatting and printing. These include commands for sorting indices, looking at the printer queue, killing the formatting job, and recentering the display of the buffer in which the operations occur.

C-c C-t C-r

M-x texinfo-tex-region

Run TeX on the current region.

C-c C-t C-b

M-x texinfo-tex-buffer

Run TeX on the current buffer.

C-c C-t C-i

M-x texinfo-texindex

Sort the indices of a Texinfo file that have been formatted with `texinfo-tex-region` or `texinfo-tex-buffer`.

C-c C-t C-p

M-x texinfo-tex-print

Print a DVI file that was made with `texinfo-tex-region` or `texinfo-tex-buffer`.

C-c C-t C-q

M-x texinfo-show-tex-print-queue

Show the print queue.

C-c C-t C-d

M-x texinfo-delete-from-tex-print-queue

Delete a job from the print queue; you will be prompted for the job number shown by a preceding C-c C-t C-q command (`texinfo-show-tex-print-queue`).

C-c C-t C-k

M-x texinfo-kill-tex-job

Kill either the currently running TeX job that has been started by `texinfo-tex-region` or `texinfo-tex-buffer`, or any other process running in the Texinfo shell buffer.

C-c C-t C-x

M-x texinfo-quit-tex-job

Quit a TeX formatting job that has stopped because of an error by sending an x to it. When you do this, TeX preserves a record of what it did in a `` `.log' `` file.

C-c C-t C-l

M-x texinfo-recenter-tex-output-buffer

Redisplay the shell buffer in which the TeX printing and formatting commands are run to show its most recent output.

Thus, the usual sequence of commands for formatting a buffer is as follows (with comments to the right):

```
C-c C-t C-b             Run TeX on the buffer.
C-c C-t C-i             Sort the indices.
C-c C-t C-b             Rerun TeX to regenerate indices.
C-c C-t C-p             Print the DVI file.
C-c C-t C-q             Display the printer queue.
```

The Texinfo mode TeX formatting commands start a subshell in Emacs called the `` `*texinfo-tex-shell*' ``. The `texinfo-tex-command`, `texinfo-texindex-command`, and `tex-dvi-print-command` commands are all run in this shell.

You can watch the commands operate in the `*texinfo-tex-shell*' buffer, and you can switch to and from and use the `*texinfo-tex-shell*' buffer as you would any other shell buffer.

The formatting and print commands depend on the values of several variables. The default values are:

Variable	Default value
texinfo-tex-command	"tex"
texinfo-texindex-command	"texindex"
texinfo-tex-shell-cd-command	"cd"
texinfo-tex-dvi-print-command	"lpr -d"
texinfo-show-tex-queue-command	"lpq"
texinfo-delete-from-print-queue-command	"lprm"
texinfo-start-of-header	"%**start"
texinfo-end-of-header	"%**end"
texinfo-tex-trailer	"@bye"

The default values of both the `texinfo-tex-command` and the `texinfo-texindex-command` variables are set in the `` `texnfo-tex.el' `` file.

You can change the values of these variables with the M-x edit-options command (see section 'Editing Variable Values' in The GNU Emacs Manual), with the M-x set-variable command (see section 'Examining and Setting Variables' in The GNU Emacs Manual), or with your `.emacs' initialization file (see section 'Init File' in The GNU Emacs Manual).

Using the Local Variables List

Yet another way to apply the TeX formatting command to a Texinfo file is to put that command in a local variables list at the end of the Texinfo file. You can then specify the TeX formatting command as a `compile-command` and have Emacs run the TeX formatting command by typing M-x compile. This creates a special shell called the `*compilation buffer*' in which Emacs runs the compile command. For example, at the end of the `gdb.texinfo' file, after the `@bye`, you would put the following:

```
@c Local Variables:
@c compile-command: "tex gdb.texinfo"
@c End:
```

This technique is most often used by programmers who also compile programs this way; see section 'Compilation' in The GNU Emacs Manual.

TeX Formatting Requirements Summary

Every Texinfo file that is to be input to TeX must begin with a `\input` command and contain an `@settitle` command:

```
\input texinfo
@settitle name-of-manual
```

The first command instructs TeX to load the macros it needs to process a Texinfo file and the second command specifies the title of printed manual.

Every Texinfo file must end with a line that terminates TeX processing and forces out unfinished pages:

```
@bye
```

Strictly speaking, these three lines are all a Texinfo file needs for TeX, besides the body. (The `@setfilename` line is the only line that a Texinfo file needs for Info formatting.)

Usually, the file's first line contains an `@c -*-texinfo-*-' comment that causes Emacs to switch to Texinfo mode when you edit the file. In addition, the beginning usually includes an `@setfilename` for Info formatting, an `@setchapternewpage` command, a title page, a copyright page, and permissions. Besides an `@bye`, the end of a file usually includes indices and a table of contents.

For more information, see section `@setchapternewpage`, section Page Headings, section The Title and Copyright Pages, section Index Menus and Printing an Index, and section Generating a Table of

Contents.

Preparing to Use TeX

TeX needs to know where to find the `texinfo.tex' file that you have told it to input with the \input texinfo' command at the beginning of the first line. The `texinfo.tex' file tells TeX how to handle @-commands. (`texinfo.tex' is included in the standard GNU distributions.)

Usually, the `texinfo.tex' file is put in the default directory that contains TeX macros (the `/usr/lib/tex/macros' directory) when GNU Emacs or other GNU software is installed. In this case, TeX will find the file and you do not need to do anything special. Alternatively, you can put `texinfo.tex' in the directory in which the Texinfo source file is located, and TeX will find it there.

However, you may want to specify the location of the `\input' file yourself. One way to do this is to write the complete path for the file after the `\input' command. Another way is to set the `TEXINPUTS' environment variable in your `.cshrc' or `.profile' file. The `TEXINPUTS' environment variable will tell TeX where to find the `texinfo.tex' file and any other file that you might want TeX to use.

Whether you use a `.cshrc' or `.profile' file depends on whether you use `csh', `sh', or `bash' for your shell command interpreter. When you use `csh', it looks to the `.cshrc' file for initialization information, and when you use `sh' or `bash', it looks to the `.profile' file.

In a `.cshrc' file, you could use the following `csh' command sequence:

```
setenv TEXINPUTS .:/usr/me/mylib:/usr/lib/tex/macros
```

In a `.profile' file, you could use the following `sh' command sequence:

```
TEXINPUTS=.:/usr/me/mylib:/usr/lib/tex/macros
export TEXINPUTS
```

This would cause TeX to look for `\input' file first in the current directory, indicated by the `.', then in a hypothetical user's `me/mylib' directory, and finally in the system library.

Overfull "hboxes"

TeX is sometimes unable to typeset a line without extending it into the right margin. This can occur when TeX comes upon what it interprets as a long word that it cannot hyphenate, such as an electronic mail network address or a very long title. When this happens, TeX prints an error message like this:

```
Overfull \hbox (20.76302pt too wide)
```

(In TeX, lines are in "horizontal boxes", hence the term, "hbox". The backslash, `\', is the TeX equivalent of `@'.)

TeX also provides the line number in the Texinfo source file and the text of the offending line, which is

marked at all the places that TeX knows how to hyphenate words. See section Catching Errors with T Formatting, for more information about typesetting errors.

If the Texinfo file has an overfull hbox, you can rewrite the sentence so the overfull hbox does not occur, or you can decide to leave it. A small excursion into the right margin often does not matter and may not even be noticeable.

However, unless told otherwise, TeX will print a large, ugly, black rectangle beside the line that contains the overful hbox. This is so you will notice the location of the problem if you are correcting a draft.

To prevent such a monstrosity from marring your final printout, write the following in the beginning of the Texinfo file on a line of its own, before the `@titlepage` command:

```
@finalout
```

Printing "Small" Books

By default, TeX typesets pages for printing in an 8.5 by 11 inch format. However, you can direct TeX to typeset a document in a 7 by 9.25 inch format that is suitable for bound books by inserting the following command on a line by itself at the beginning of the Texinfo file, before the title page:

```
@smallbook
```

(Since regular sized books are often about 7 by 9.25 inches, this command might better have been called the `@regularbooksize` command, but it came to be called the `@smallbook` command by comparison to the 8.5 by 11 inch format.)

If you write the `@smallbook` command between the start-of-header and end-of-header lines, the Texinfo mode TeX region formatting command, `texinfo-tex-region`, will format the region in "small" book size (see section Start of Header).

The Free Software Foundation distributes printed copies of The GNU Emacs Manual and other manuals in the "small" book size. See section `@smallexample` and `@smalllisp`}, for information about commands that make it easier to produce examples for a smaller manual.

Printing on A4 Paper

You can tell TeX to typeset a document for printing on European size A4 paper with the `@afourpaper` command. Write the command on a line by itself between `@iftex` and `@end iftex` lines near the beginning of the Texinfo file, before the title page:

For example, this is how you would write the header for this manual:

```
\input texinfo    @c -*-texinfo-*-
@c %**start of header
```

```
@setfilename texinfo
@settitle Texinfo
@syncodeindex vr fn
@iftex
@afourpaper
@end iftex
@c %**end of header
```

Cropmarks and Magnification

You can attempt to direct TeX to print cropmarks at the corners of pages with the `@cropmarks` command. Write the `@cropmarks` command on a line by itself between `@iftex` and `@end iftex` lines near the beginning of the Texinfo file, before the title page, like this:

```
@iftex
@cropmarks
@end iftex
```

This command is mainly for printers that typeset several pages on one sheet of film; but you can attempt to use it to mark the corners of a book set to 7 by 9.25 inches with the `@smallbook` command. (Printers will not produce cropmarks for regular sized output that is printed on regular sized paper.) Since different printing machines work in different ways, you should explore the use of this command with a spirit of adventure. You may have to redefine the command in the `` `texinfo.tex' `` definitions file.

You can attempt to direct TeX to typeset pages larger or smaller than usual with the `\mag` TeX command. Everything that is typeset is scaled proportionally larger or smaller. (`\mag` stands for "magnification".) This is *not* a Texinfo @-command, but is a PlainTeX command that is prefixed with a backslash. You have to write this command between `@tex` and `@end tex` (see section Using Ordinary TeX Commands).

Follow the `\mag` command with an `=' and then a number that is 1000 times the magnification you desire. For example, to print pages at 1.2 normal size, write the following near the beginning of the Texinfo file, before the title page:

```
@tex
\mag=1200
@end tex
```

With some printing technologies, you can print normal-sized copies that look better than usual by using a larger-than-normal master.

Depending on your system, `\mag` may not work or may work only at certain magnifications. Be prepared to experiment.

Go to the previous, next section.

Go to the previous, next section.

Creating an Info File

`makeinfo` is a utility that converts a Texinfo file into an Info file; `texinfo-format-region` and `texinfo-format-buffer` are GNU Emacs functions that do the same.

A Texinfo file must possess an `@setfilename` line near its beginning, otherwise the Info formatting commands will fail.

For information on installing the Info file in the Info system, see section Installing an Info File.

The `makeinfo` utility creates an Info file from a Texinfo source file more quickly than either of the Emacs formatting commands and provides better error messages. We recommend it. `makeinfo` is a C program that is independent of Emacs. You do not need to run Emacs to use `makeinfo`, which means you can use `makeinfo` on machines that are too small to run Emacs. You can run `makeinfo` in any one of three ways: from an operating system shell, from a shell inside Emacs, or by typing a key command in Texinfo mode in Emacs.

The `texinfo-format-region` and the `texinfo-format-buffer` commands are useful if you cannot run `makeinfo`. Also, in some circumstances, they format short regions or buffers more quickly than `makeinfo`.

Invoking `makeinfo` from a Shell

To create an Info file from a Texinfo file, type `makeinfo` followed by the name of the Texinfo file. Thus, to create the Info file for Bison, type the following at the shell prompt (where `%' is the prompt):

```
% makeinfo bison.texinfo
```

(You can run a shell inside Emacs by typing M-x shell.)

Options for `makeinfo`

The `makeinfo` command takes a number of options. Most often, options are used to set the value of the fill column and specify the footnote style. Each command line option is a word preceded by `--'(11) or a letter preceded by `-'. You can use abbreviations for the option names as long as they are unique.

For example, you could use the following command to create an Info file for `bison.texinfo' in which each line is filled to only 68 columns (where `%' is the prompt):

```
% makeinfo --fill-column=68 bison.texinfo
```

You can write two or more options in sequence, like this:

```
% makeinfo --no-split --fill-column=70 ...
```

This would keep the Info file together as one possibly very long file and would also set the fill column to 70.

If you wish to discover which version of `makeinfo` you are using, type:

```
% makeinfo --version
```

The options are:

`-D var`

Cause var to be defined. This is equivalent to `@set var` in the Texinfo file.

`--error-limit limit`

Set the maximum number of errors that `makeinfo` will report before exiting (on the assumption that continuing would be useless). The default number of errors that can be reported before `makeinfo` gives up is 100.

`--fill-column width`

Specify the maximum number of columns in a line; this is the right-hand edge of a line. Paragraphs that are filled will be filled to this width. (Filling is the process of breaking up and connecting lines so that lines are the same length as or shorter than the number specified as the fill column. Lines are broken between words.) The default value for `fill-column` is 72.

`--footnote-style style`

Set the footnote style to style, either `end' for the end node style or `separate' for the separate node style. The value set by this option overrides the value set in a Texinfo file by an `@footnotestyle` command. When the footnote style is `separate', `makeinfo` makes a new node containing the footnotes found in the current node. When the footnote style is `end', `makeinfo` places the footnote references at the end of the current node.

`-I dir`

Add `dir` to the directory search list for finding files that are included using the `@include` command. By default, `makeinfo` searches only the current directory.

`--no-headers`

Do not include menus or node lines in the output. This results in an ASCII file that you cannot read in Info since it does not contain the requisite nodes or menus; but you can print such a file in a single, typewriter-like font and produce acceptable output.

`--no-split`

Suppress the splitting stage of `makeinfo`. Normally, large output files (where the size is greater than 70k bytes) are split into smaller subfiles, each one approximately 50k bytes. If you specify `--no-split', `makeinfo` will not split up the output file.

`--no-pointer-validate`

`--no-validate`

Suppress the pointer-validation phase of `makeinfo`. Normally, after a Texinfo file is processed,

some consistency checks are made to ensure that cross references can be resolved, etc. See sec Pointer Validation.

`--no-warn`

Suppress the output of warning messages. This does *not* suppress the output of error messages, only warnings. You might want this if the file you are creating has examples of Texinfo cross references within it, and the nodes that are referenced do not actually exist.

`--no-number-footnotes`

Supress automatic footnote numbering. By default, `makeinfo` numbers each footnote sequentially in a single node, resetting the current footnote number to 1 at the start of each node.

`--output file`

`-o file`

Specify that the output should be directed to file and not to the file name specified in the `@setfilename` command found in the Texinfo source. file can be the special token `-', which specifies standard output.

`--paragraph-indent indent`

Set the paragraph indentation style to indent. The value set by this option overrides the value set in a Texinfo file by an `@paragraphindent` command. The value of indent is interpreted as follows:

If the value of indent is `asis', do not change the existing indentation at the starts of paragraphs.

If the value of indent is zero, delete any existing indentation.

If the value of indent is greater than zero, indent each paragraph by that number of spaces.

`--reference-limit limit`

Set the value of the number of references to a node that `makeinfo` will make without reporting a warning. If a node has more than this number of references in it, `makeinfo` will make the references but also report a warning.

`-U var`

Cause var to be undefined. This is equivalent to `@clear var` in the Texinfo file.

`--verbose`

Cause `makeinfo` to display messages saying what it is doing. Normally, `makeinfo` only outputs messages if there are errors or warnings.

`--version`

Report the version number of this copy of `makeinfo`.

Pointer Validation

`makeinfo` will check the validity of the final Info file unless you suppress pointer-validation by using the `--no-pointer-validation' option. Mostly, this means ensuring that nodes you have referenced really exist. Here is a complete list of what is checked:

1. If a `Next', `Previous', or `Up' node reference is a reference to a node in the current file and is not an external reference such as to `(dir)', then the referenced node must exist.
2. In every node, if the `Previous' node is different from the `Up' node, then the `Previous' node must also be pointed to by a `Next' node.
3. Every node except the `Top' node must have an `Up' pointer.
4. The node referenced by an `Up' pointer must contain a reference to the current node in some manner other than through a `Next' reference. This includes menu entries and cross references.
5. If the `Next' reference of a node is not the same as the `Next' reference of the `Up' reference, then the node referenced by the `Next' pointer must have a `Previous' pointer that points back to the current node. This rule allows the last node in a section to point to the first node of the next chapter.

Running `makeinfo` inside Emacs

You can run `makeinfo` in GNU Emacs Texinfo mode by using either the `makeinfo-region` or the `makeinfo-buffer` commands. In Texinfo mode, the commands are bound to C-c C-m C-r and C-c C-m C-b by default.

C-c C-m C-r

M-x makeinfo-region

Format the current region for Info.

C-c C-m C-b

M-x makeinfo-buffer

Format the current buffer for Info.

When you invoke either `makeinfo-region` or `makeinfo-buffer`, Emacs prompts for a file name, offering the name of the visited file as the default. You can edit the default file name in the minibuffer if you wish, before typing RET to start the `makeinfo` process.

The Emacs `makeinfo-region` and `makeinfo-buffer` commands run the `makeinfo` program in a temporary shell buffer. If `makeinfo` finds any errors, Emacs displays the error messages in the temporary buffer.

You can parse the error messages by typing C-x ` (`next-error`). This causes Emacs to go to and position the cursor on the line in the Texinfo source that `makeinfo` thinks caused the error. See section 'Running `make` or Compilers Generally' in The GNU Emacs Manual, for more information about using the `next-error` command.

In addition, you can kill the shell in which the `makeinfo` command is running or make the shell buffer display its most recent output.

C-c C-m C-k

M-x makeinfo-kill-job

Kill the currently running job created by `makeinfo-region` or `makeinfo-buffer`.

C-c C-m C-l

M-x makeinfo-recenter-output-buffer

Redisplay the `makeinfo` shell buffer to display its most recent output.

(Note that the parallel commands for killing and recentering a TeX job are C-c C-t C-k and C-c C-t C-l. See section Formatting and Printing in Texinfo Mode.)

You can specify options for `makeinfo` by setting the `makeinfo-options` variable with either the M-x edit-options or the M-x set-variable command, or by setting the variable in your `` `.emacs' `` initialization file.

For example, you could write the following in your `` `.emacs' `` file:

```
(setq makeinfo-options
      "--paragraph-indent=0 --no-split
       --fill-column=70 --verbose")
```

For more information, see section Options for `makeinfo`}, as well as "Editing Variable Values,""Examining and Setting Variables," and "Init File" in the The GNU Emacs Manual.

The `texinfo-format...` Commands

In GNU Emacs in Texinfo mode, you can format part or all of a Texinfo file with the `texinfo-format-region` command. This formats the current region and displays the formatted text in a temporary buffer called `*Info Region*'.

Similarly, you can format a buffer with the `texinfo-format-buffer` command. This command creates a new buffer and generates the Info file in it. Typing C-x C-s will save the Info file under the name specified by the `@setfilename` line which must be near the beginning of the Texinfo file.

C-c C-e C-r

`texinfo-format-region`

Format the current region for Info.

C-c C-e C-b

`texinfo-format-buffer`

Format the current buffer for Info.

The `texinfo-format-region` and `texinfo-format-buffer` commands provide you with some error checking, and other functions can provide you with further help in finding formatting errors. These procedures are described in an appendix; see section Formatting Mistakes. However, the `makeinfo` program is often faster and provides better error checking (see section Running `makeinfo` inside Emacs).

Batch Formatting

You can format Texinfo files for Info using `batch-texinfo-format` and Emacs Batch mode. You can run Emacs in Batch mode from any shell, including a shell inside of Emacs. (See section 'Command Line Switches and Arguments' in The GNU Emacs Manual.)

Here is the command to format all the files that end in `.texinfo' in the current directory (where `%' is the shell prompt):

```
% emacs -batch -funcall batch-texinfo-format *.texinfo
```

Emacs processes all the files listed on the command line, even if an error occurs while attempting to format some of them.

Run `batch-texinfo-format` only with Emacs in Batch mode as shown; it is not interactive. It kills the Batch mode Emacs on completion.

`batch-texinfo-format` is convenient if you lack `makeinfo` and want to format several Texinfo files at once. When you use Batch mode, you create a new Emacs process. This frees your current Emacs, so you can continue working in it. (When you run `texinfo-format-region` or `texinfo-format-buffer`, you cannot use that Emacs for anything else until the command finishes.)

Tag Files and Split Files

If a Texinfo file has more than 30,000 bytes, `texinfo-format-buffer` automatically creates a tag table for its Info file; `makeinfo` always creates a tag table. With a tag table, Info can jump to new nodes more quickly than it can otherwise.

In addition, if the Texinfo file contains more than about 70,000 bytes, `texinfo-format-buffer` and `makeinfo` split the large Info file into shorter indirect subfiles of about 50,000 bytes each. Big files are split into smaller files so that Emacs does not need to make a large buffer to hold the whole of a large Info file; instead, Emacs allocates just enough memory for the small, split off file that is needed at the time. This way, Emacs avoids wasting memory when you run Info. (Before splitting was implemented, Info files were always kept short and include files were designed as a way to create a single, large printed manual out of the smaller Info files. See section Include Files, for more information. Include files are still used for very large documents, such as The Emacs Lisp Reference Manual, in which each chapter is a separate file.)

When a file is split, Info itself makes use of a shortened version of the original file that contains just the tag table and references to the files that were split off. The split off files are called indirect files.

The split off files have names that are created by appending `-1', `-2', `-3' and so on to the file name specified by the `@setfilename` command. The shortened version of the original file continues to have the name specified by `@setfilename`.

At one stage in writing this document, for example, the Info file was saved as `test-texinfo' and

that file looked like this:

```
Info file: test-texinfo,    -*-Text-*-
produced by texinfo-format-buffer
from file: new-texinfo-manual.texinfo

^_
Indirect:
test-texinfo-1: 102
test-texinfo-2: 50422
test-texinfo-3: 101300
^_^L
Tag table:
(Indirect)
Node: overview^?104
Node: info file^?1271
Node: printed manual^?4853
Node: conventions^?6855
...
```

(But `test-texinfo' had far more nodes than are shown here.) Each of the split off, indirect files, `test-texinfo-1', `test-texinfo-2', and `test-texinfo-3', is listed in this file after the line that says `Indirect:'. The tag table is listed after the line that says `Tag table:'.

In the list of indirect files, the number following the file name records the cumulative number of bytes in the preceding indirect files, not counting the file list itself, the tag table, or the permissions text in each file. In the tag table, the number following the node name records the location of the beginning of the node, in bytes from the beginning.

If you are using `texinfo-format-buffer` to create Info files, you may want to run the `Info-validate` command. (The `makeinfo` command does such a good job on its own, you do not need `Info-validate`.) However, you cannot run the M-x Info-validate node-checking command on indirect files. For information on how to prevent files from being split and how to validate the structure of the nodes, see section Running `Info-validate`.

Go to the previous, next section.

Go to the previous, next section.

Installing an Info File

Info files are usually kept in the `info' directory. (You can find the location of this directory within Emacs by typing C-h i to enter Info and then typing C-x C-f to see the full pathname to the `info' directory.)

For Info to work, the `info' directory must contain a file that serves as a top level directory for the Info system. By convention, this file is called `dir'. The `dir' file is itself an Info file. It contains the top level menu for all the Info files in the system. The menu looks like this:

```
* Menu:

* Info:    (info).     Documentation browsing system.
* Emacs:   (emacs).    The extensible, self-documenting
                       text editor.
* Texinfo: (texinfo).  With one source file, make
                       either a printed manual using
                       TeX or an Info file.
...
```

Each of these menu entries points to the `Top' node of the Info file that is named in parentheses. (The menu entry does not need to specify the `Top' node, since Info goes to the `Top' node if no node name is mentioned. See section Referring to Other Info Files.)

Thus, the `Info' entry points to the `Top' node of the `info' file and the `Emacs' entry points to the `Top' node of the `emacs' file.

In each of the Info files, the `Up' pointer of the `Top' node refers back to the `dir' file. For example, the line for the `Top' node of the Emacs manual looks like this in Info:

```
File: emacs  Node: Top, Up: (DIR), Next: Distrib
```

(Note that in this case, the `dir' file name is written in upper case letters--it can be written in either upper or lower case. Info has a feature that it will change the case of the file name to lower case if it cannot find the name as written.)

Listing a New Info File

To add a new Info file to your system, write a menu entry for it in the menu in the `dir' file in the `info' directory. Also, move the new Info file itself to the `info' directory. For example, if you were adding documentation for GDB, you would write the following new entry:

```
* GDB: (gdb).            The source-level C debugger.
```

The first part of the menu entry is the menu entry name, followed by a colon. The second part is the name of the Info file, in parentheses, followed by a period. The third part is the description.

Conventionally, the name of an Info file has a `.info' extension. Thus, you might list the name of the file like this:

```
* GDB: (gdb.info).            The source-level C debugger.
```

However, Info will look for a file with a `.info' extension if it does not find the file under the name given in the menu. This means that you can refer to the file `gdb.info' as `gdb', as shown in the first example. This looks better.

Info Files in Other Directories

If an Info file is not in the `info' directory, there are two ways to specify its location:

- Write the pathname as the menu's second part, or;
- Specify the `info' directory name in an environment variable in your `.profile' or `.cshrc' initialization file. (Only you and others with the same environment variable will be able to find Info files whose location is specified this way.)

For example, to reach a test file in the `~bob/manuals' directory, you could add an entry like this to the menu in the `dir' file:

```
* Test: (~bob/manuals/info-test).  Bob's own test file.
```

In this case, the absolute file name of the `info-test' file is written as the second part of the menu entry.

Alternatively, you can tell Info where to look by setting the `INFOPATH' environment variable in your `.cshrc' or `.profile' file.

If you use `sh' or `bash' for your shell command interpreter, you must set the `INFOPATH' environment variable in the `.profile' initialization file; but if you use `csh', you must set the variable in the `.cshrc' initialization file. The two files require slightly different command formats.

- In a `.cshrc' file, you could set the `INFOPATH' variable as follows:

  ```
  setenv INFOPATH .:~bob/manuals:/usr/local/emacs/info
  ```

- In a `.profile' file, you would achieve the same effect by writing:

  ```
  INFOPATH=.:~bob/manuals:/usr/local/emacs/info
  export INFOPATH
  ```

Either form would cause Info to look first in the current directory, indicated by the `.', then in the `~bob/manuals' directory, and finally in the `/usr/local/emacs/info' directory (which is a

common location for the standard Info directory).

Go to the previous, next section.

Go to the previous, next section.

@-Command List

Here is an alphabetical list of the @-commands in Texinfo. Square brackets, `[ ]`, indicate optional arguments; an ellipsis, `...', indicates repeated text.

`@*`

Force a line break. Do not end a paragraph that uses `@*` with an `@refill` command. See section @*: Generate Line Breaks.

`@.`

Stands for a period that really does end a sentence (usually after an end-of-sentence capital letter). See section Spacing After Colons and Periods.

`@:`

Indicate to TeX that an immediately preceding period, question mark, exclamation mark, or colon does not end a sentence. Prevent TeX from inserting extra whitespace as it does at the end of a sentence. The command has no effect on the Info file output. See section Spacing After Colons and Periods.

`@@`

Stands for `@'. See section Inserting `@', Braces, and Periods}.

`@{`

Stands for a left-hand brace, `{'. See section Inserting `@', Braces, and Periods.

`@}`

Stands for a right-hand brace, `}'. See section Inserting `@', Braces, and Periods.

`@appendix title`

Begin an appendix. The title appears in the table of contents of a printed manual. In Info, the title is underlined with asterisks. See section `@unnumbered, @appendix` and `@appendix` Commands}.

`@appendixsec title`

`@appendixsection title`

Begin an appendix section within an appendix. The section title appears in the table of contents of a printed manual. In Info, the title is underlined with equal signs. `@appendixsection` is a longer spelling of the `@appendixsec` command. See section `@unnumberedsec, @appendixsec, @heading`.

`@appendixsubsec title`

Begin an appendix subsection within an appendix. The title appears in the table of contents of a printed manual. In Info, the title is underlined with hyphens. See section The `@subsection`-like Commands.

`@appendixsubsubsec title`

Begin an appendix subsubsection within a subappendix. The title appears in the table of contents of a printed manual. In Info, the title is underlined with periods. See section The `subsub' Commands.

`@asis`

Used following `@table`, `@ftable`, and `@vtable` to print the table's first column without highlighting ("as is"). See section Making a Two-column Table.

`@author author`

Typeset author flushleft and underline it. See section `@title`, `@subtitle`, and `@author` and `@author` Commands}.

`@b{text}`

Print text in **bold** font. No effect in Info. See section Fonts for Printing, Not Info.

`@bullet{}`

Generate a large round dot, or the closest possible thing to one. See section `@bullet{}`.

`@bye`

Stop formatting a file. The formatters do not see the contents of a file following an `@bye` command. See section Ending a Texinfo File.

`@c comment`

Begin a comment in Texinfo. The rest of the line does not appear in either the Info file or the printed manual. A synonym for `@comment`. See section General Syntactic Conventions.

`@cartouche`

Highlight an example or quotation by drawing a box with rounded corners around it. Pair with `@end cartouche`. No effect in Info. See section Drawing Cartouches Around Examples.)

`@center line-of-text`

Center the line of text following the command. See section `@titlefont`, `@center`, and `@sp`.

`@chapheading title`

Print a chapter-like heading in the text, but not in the table of contents of a printed manual. In Info, the title is underlined with asterisks. See section `@majorheading`, `@chapheading`}.

`@chapter title`

Begin a chapter. The chapter title appears in the table of contents of a printed manual. In Info, the title is underlined with asterisks. See section `@chapter`.

`@cindex entry`

Add entry to the index of concepts. See section Making Index Entries.

`@cite{reference}`

Highlight the name of a book or other reference that lacks a companion Info file. See section `@cite`{reference}.

`@clear flag`

Unset flag, preventing the Texinfo formatting commands from formatting text between subsequent pairs of `@ifset flag` and `@end ifset` commands, and preventing `@value{flag}` from expanding to the value to which flag is set. See section `@set, @clear, and @value`.

`@code{sample-code}`

Highlight text that is an expression, a syntactically complete token of a program, or a program name. See section `@code{sample-code}`.

`@comment comment`

Begin a comment in Texinfo. The rest of the line does not appear in either the Info file or the printed manual. A synonym for `@c`. See section General Syntactic Conventions.

`@contents`

Print a complete table of contents. Has no effect in Info, which uses menus instead. See section Generating a Table of Contents.

`@copyright{}`

Generate a copyright symbol. See section `@copyright{}`.

`@defcodeindex index-name`

Define a new index and its indexing command. Print entries in an `@code` font. See section Defining New Indices.

`@defcv category class name`

Format a description for a variable associated with a class in object-oriented programming. Takes three arguments: the category of thing being defined, the class to which it belongs, and its name. See section Definition Commands.

`@deffn category name arguments...`

Format a description for a function, interactive command, or similar entity that may take arguments. `@deffn` takes as arguments the category of entity being described, the name of this particular entity, and its arguments, if any. See section Definition Commands.

`@defindex index-name`

Define a new index and its indexing command. Print entries in a roman font. See section Defining New Indices.

`@defivar class instance-variable-name`

Format a description for an instance variable in object-oriented programming. The command is equivalent to `@defcv {Instance Variable} ...'. See section Definition Commands.

`@defmac macro-name arguments...`

Format a description for a macro. The command is equivalent to `@deffn Macro ...'. See section Definition Commands.

`@defmethod class method-name arguments...`

Format a description for a method in object-oriented programming. The command is equivalent to `@defop Method ...'. Takes as arguments the name of the class of the method, the name of the method, and its arguments, if any. See section Definition Commands.

`@defop category class name arguments...`

Format a description for an operation in object-oriented programming. `@defop` takes as arguments the overall name of the category of operation, the name of the class of the operation, the name of the operation, and its arguments, if any. See section Definition Commands.

`@defopt option-name`

Format a description for a user option. The command is equivalent to `@defvr {User Option} ...'. See section Definition Commands.

`@defspec special-form-name arguments...`

Format a description for a special form. The command is equivalent to `@deffn {Special Form} ...'. See section Definition Commands.

`@deftp category name-of-type attributes...`

Format a description for a data type. `@deftp` takes as arguments the category, the name of the type (which is a word like `int' or `float'), and then the names of attributes of objects of that type. See section Definition Commands.

`@deftypefn classification data-type name arguments...`

Format a description for a function or similar entity that may take arguments and that is typed. `@deftypefn` takes as arguments the classification of entity being described, the type, the name of the entity, and its arguments, if any. See section Definition Commands.

`@deftypefun data-type function-name arguments...`

Format a description for a function in a typed language. The command is equivalent to `@deftypefn Function ...'. See section Definition Commands.

`@deftypevr classification data-type name`

Format a description for something like a variable in a typed language--an entity that records a value. Takes as arguments the classification of entity being described, the type, and the name of the entity. See section Definition Commands.

`@deftypevar data-type variable-name`

Format a description for a variable in a typed language. The command is equivalent to `@deftypevr Variable ...'. See section Definition Commands.

`@defun function-name arguments...`

Format a description for functions. The command is equivalent to `@deffn Function ...'. See section Definition Commands.

`@defvar variable-name`

Format a description for variables. The command is equivalent to `@defvr Variable ...'. See section Definition Commands.

`@defvr category name`

Format a description for any kind of variable. `@defvr` takes as arguments the category of the entity and the name of the entity. See section Definition Commands.

`@dfn{term}`

Highlight the introductory or defining use of a term. See section @dfn{term}.

`@display`

Begin a kind of example. Indent text, do not fill, do not select a new font. Pair with `@end display`. See section @display}.

`@dmn{dimension}`

Format a dimension. Cause TeX to insert a narrow space before dimension. No effect in Info. Use for writing a number followed by an abbreviation of a dimension name, such as `12pt', written as `12@dmn{pt}', with no space between the number and the `@dmn` command. See section @dmn{dimension}: Format a Dimension}.

`@dots{}`

Insert an ellipsis: `...'. See section @dots{}.

`@emph{text}`

Highlight text; text is displayed in *italics* in printed output, and surrounded by asterisks in Info. See section Emphasizing Text.

`@enumerate [number-or-letter]`

Begin a numbered list, using `@item` for each entry. Optionally, start list with number-or-letter. Pair with `@end enumerate`. See section Making a Numbered or Lettered List}.

`@equiv{}`

Indicate to the reader the exact equivalence of two forms with a glyph: `==='. See section ==: Indicating Equivalence.

`@error{}`

Indicate to the reader with a glyph that the following text is an error message: `error-->'. See section error-->: Indicating an Error Message.

`@evenfooting [left] @| [center] @| [right]`

Specify page footings for even-numbered (left-hand) pages. Not relevant to Info. See section How to Make Your Own Headings.

`@evenheading [left] @| [center] @| [right]`

Specify page headings for even-numbered (left-hand) pages. Not relevant to Info. See section How to Make Your Own Headings.

`@everyfooting [left] @| [center] @| [right]`

Specify page footings for every page. Not relevant to Info. See section How to Make Your Own Headings.

`@everyheading [left] @| [center] @| [right]`

Specify page headings for every page. Not relevant to Info. See section How to Make Your Own Headings.

`@example`

Begin an example. Indent text, do not fill, and select fixed-width font. Pair with `@end example`.

See section @example}.

`@exdent line-of-text`

Remove any indentation a line might have. See section @exdent: Undoing a Line's Indentation.

`@expansion{}`

Indicate the result of a macro expansion to the reader with a special glyph: `==>'. See section ==>: Indicating an Expansion.

`@file{filename}`

Highlight the name of a file, buffer, node, or directory. See section @file{file-name}}.

`@finalout`

Prevent TeX from printing large black warning rectangles beside over-wide lines. See section Overfull "hboxes".

`@findex entry`

Add entry to the index of functions. See section Making Index Entries.

`@flushleft`

Left justify every line but leave the right end ragged. Leave font as is. Pair with `@end flushleft`. See section @flushleft and @flushright}.

`@flushright`

Right justify every line but leave the left end ragged. Leave font as is. Pair with `@end flushright`. See section @flushleft and @flushright}.

`@footnote{text-of-footnote}`

Enter a footnote. Footnote text is printed at the bottom of the page by TeX; Info may format in either `End' node or `Separate' node style. See section Footnotes.

`@footnotestyle style`

Specify an Info file's footnote style, either `end' for the end node style or `separate' for the separate node style. See section Footnotes.

`@format`

Begin a kind of example. Like `@example` or `@display`, but do not narrow the margins and do not select the fixed-width font. Pair with `@end format`. See section @example}.

`@ftable formatting-command`

Begin a two-column table, using `@item` for each entry. Automatically enter each of the items in the first column into the index of functions. Pair with `@end ftable`. The same as `@table`, except for indexing. See section @ftable and @vtable and `@vtable`}.

`@group`

Hold text together that must appear on one printed page. Pair with `@end group`. Not relevant to Info. See section @group: Prevent Page Breaks}.

`@heading title`

Print an unnumbered section-like heading in the text, but not in the table of contents of a printed

manual. In Info, the title is underlined with equal signs. See section @unnumberedsec, @appendixsec, @heading.

`@headings on-off-single-double`

Turn page headings on or off, or specify single-sided or double-sided page headings for printing. `@headings on` is synonymous with `@headings double`. See section The @headings Command Command}.

`@i{text}`

Print text in *italic* font. No effect in Info. See section Fonts for Printing, Not Info.

`@ifclear flag`

If flag is cleared, the Texinfo formatting commands format text between `@ifclear flag` and the following `@end ifclear` command. See section @set, @clear, and @value.

`@ifinfo`

Begin a stretch of text that will be ignored by TeX when it typesets the printed manual. The text appears only in the Info file. Pair with `@end ifinfo`. See section Conditionally Visible Text.

`@ifset flag`

If flag is set, the Texinfo formatting commands format text between `@ifset flag` and the following `@end ifset` command. See section @set, @clear, and @value.

`@iftex`

Begin a stretch of text that will not appear in the Info file, but will be processed only by TeX. Pair with `@end iftex`. See section Conditionally Visible Text.

`@ignore`

Begin a stretch of text that will not appear in either the Info file or the printed output. Pair with `@end ignore`. See section Comments.

`@include filename`

Incorporate the contents of the file filename into the Info file or printed document. See section Include Files.

`@inforef{node-name, [entry-name], info-file-name}`

Make a cross reference to an Info file for which there is no printed manual. See section @inforef}.

`\input macro-definitions-file`

Use the specified macro definitions file. This command is used only in the first line of a Texinfo file to cause TeX to make use of the `` `texinfo' `` macro definitions file. The backslash in `\input` is used instead of an @ because TeX does not properly recognize @ until after it has read the definitions file. See section The Texinfo File Header.

`@item`

Indicate the beginning of a marked paragraph for `@itemize` and `@enumerate`; indicate the beginning of the text of a first column entry for `@table`, `@ftable`, and `@vtable`. See section Making Lists and Tables.

`@itemize mark-generating-character-or-command`

Produce a sequence of indented paragraphs, with a mark inside the left margin at the beginning of each paragraph. Pair with `@end itemize`. See section Making an Itemized List.

`@itemx`

Like `@item` but do not generate extra vertical space above the item text. See section `@itemx`.

`@kbd{keyboard-characters}`

Indicate text that consists of characters of input to be typed by users. See section `@kbd{keyboard-characters}`.

`@key{key-name}`

Highlight key-name, a conventional name for a key on a keyboard. See section `@key{key-name}`.

`@kindex entry`

Add entry to the index of keys. See section Making Index Entries.

`@lisp`

Begin an example of Lisp code. Indent text, do not fill, and select fixed-width font. Pair with `@end lisp`. See section `@lisp`}.

`@majorheading title`

Print a chapter-like heading in the text, but not in the table of contents of a printed manual. Generate more vertical whitespace before the heading than the `@chapheading` command. In Info, the chapter heading line is underlined with asterisks. See section `@majorheading`, `@chapheading` and `@chapheading`}.

`@menu`

Mark the beginning of a menu of nodes in Info. No effect in a printed manual. Pair with `@end menu`. See section Menus.

`@minus{}`

Generate a minus sign. See section `@minus{}`: Inserting a Minus Sign.

`@need n`

Start a new page in a printed manual if fewer than n mils (thousandths of an inch) remain on the current page. See section `@need mils`: Prevent Page Breaks}.

`@node name, next, previous, up`

Define the beginning of a new node in Info, and serve as a locator for references for TeX. See section The `@node` Command.

`@noindent`

Prevent text from being indented as if it were a new paragraph. See section `@noindent`.

`@oddfooting [left] @| [center] @| [right]`

Specify page footings for odd-numbered (right-hand) pages. Not relevant to Info. See section How to Make Your Own Headings.

`@oddheading [left] @| [center] @| [right]`

Specify page headings for odd-numbered (right-hand) pages. Not relevant to Info. See section How to Make Your Own Headings.

`@page`

Start a new page in a printed manual. No effect in Info. See section `@page`: Start a New Page.

`@paragraphindent indent`

Indent paragraphs by indent number of spaces; delete indentation if the value of indent is 0; and do not change indentation if indent is `asis`. See section Paragraph Indenting.

`@pindex entry`

Add entry to the index of programs. See section Making Index Entries.

`@point{}`

Indicate the position of point in a buffer to the reader with a glyph: `-!-'. See section Indicating Point in a Buffer.

`@print{}`

Indicate printed output to the reader with a glyph: `-|'. See section -|: Indicating Printed Output.

`@printindex index-name`

Print an alphabetized two-column index in a printed manual or generate an alphabetized menu of index entries for Info. See section Index Menus and Printing an Index.

`@pxref{node-name, [entry], [topic-or-title], [info-file], [manual]}`

Make a reference that starts with a lower case `see' in a printed manual. Use within parentheses only. Do not follow command with a punctuation mark. The Info formatting commands automatically insert terminating punctuation as needed, which is why you do not need to insert punctuation. Only the first argument is mandatory. See section `@pxref`.

`@quotation`

Narrow the margins to indicate text that is quoted from another real or imaginary work. Write command on a line of its own. Pair with `@end quotation`. See section `@quotation`}.

`@r{text}`

Print text in roman font. No effect in Info. See section Fonts for Printing, Not Info.

`@ref{node-name, [entry], [topic-or-title], [info-file], [manual]}`

Make a reference. In a printed manual, the reference does not start with a `See'. Follow command with a punctuation mark. Only the first argument is mandatory. See section `@ref`.

`@refill`

In Info, refill and indent the paragraph after all the other processing has been done. No effect on TeX, which always refills. This command is no longer needed, since all formatters now automatically refill. See section Refilling Paragraphs.

`@result{}`

Indicate the result of an expression to the reader with a special glyph: `=>'. See section =>: Indicating Evaluation.

`@samp{text}`

Highlight text that is a literal example of a sequence of characters. Used for single characters, for statements, and often for entire shell commands. See section `@samp{text}`.

`@sc{text}`

Set text in a printed output in THE SMALL CAPS FONT and set text in the Info file in uppercase letters. See section `@sc{text}`: The Small Caps Font.

`@section title`

Begin a section within a chapter. In a printed manual, the section title is numbered and appears in the table of contents. In Info, the title is underlined with equal signs. See section `@section`}.

`@set flag [string]`

Make flag active, causing the Texinfo formatting commands to format text between subsequent pairs of `@ifset flag` and `@end ifset` commands. Optionally, set value of flag to string. See section `@set`, `@clear`, and `@value`.

`@setchapternewpage on-off-odd`

Specify whether chapters start on new pages, and if so, whether on odd-numbered (right-hand) new pages. See section `@setchapternewpage`}.

`@setfilename info-file-name`

Provide a name for the Info file. See section General Syntactic Conventions.

`@settitle title`

Provide a title for page headers in a printed manual. See section General Syntactic Conventions.

`@shortcontents`

Print a short table of contents. Not relevant to Info, which uses menus rather than tables of contents. A synonym for `@summarycontents`. See section Generating a Table of Contents.

`@smallbook`

Cause TeX to produce a printed manual in a 7 by 9.25 inch format rather than the regular 8.5 by 11 inch format. See section Printing "Small" Books. Also, see section `@smallexample` and `@smalllisp` and `@smalllisp`}.

`@smallexample`

Indent text to indicate an example. Do not fill, select fixed-width font. In `@smallbook` format, print text in a smaller font than with `@example`. Pair with `@end smallexample`. See section `@smallexample` and `@smalllisp`}.

`@smalllisp`

Begin an example of Lisp code. Indent text, do not fill, select fixed-width font. In `@smallbook` format, print text in a smaller font. Pair with `@end smalllisp`. See section `@smallexample` and `@smalllisp` and `@smalllisp`}.

`@sp n`

Skip n blank lines. See section `@sp` n: Insert Blank Lines.

`@strong text`

Emphasize text by typesetting it in a **bold** font for the printed manual and by surrounding it wi asterisks for Info. See section @emph{text} and @strong{text}.

`@subheading title`

Print an unnumbered subsection-like heading in the text, but not in the table of contents of a printed manual. In Info, the title is underlined with hyphens. See section The @subsection-like Commands @appendixsubsec @subheading}.

`@subsection title`

Begin a subsection within a section. In a printed manual, the subsection title is numbered and appears in the table of contents. In Info, the title is underlined with hyphens. See section The @subsection Command}.

`@subsubheading title`

Print an unnumbered subsubsection-like heading in the text, but not in the table of contents of a printed manual. In Info, the title is underlined with periods. See section The `subsub' Commands.

`@subsubsection title`

Begin a subsubsection within a subsection. In a printed manual, the subsubsection title is numbered and appears in the table of contents. In Info, the title is underlined with periods. See section The `subsub' Commands.

`@subtitle title`

In a printed manual, set a subtitle in a normal sized font flush to the right-hand side of the page. Not relevant to Info, which does not have title pages. See section @title, @subtitle, and @author and @author Commands}.

`@summarycontents`

Print a short table of contents. Not relevant to Info, which uses menus rather than tables of contents. A synonym for @shortcontents. See section Generating a Table of Contents.

`@syncodeindex from-index into-index`

Merge the index named in the first argument into the index named in the second argument, printing the entries from the first index in @code font. See section Combining Indices.

`@synindex from-index into-index`

Merge the index named in the first argument into the index named in the second argument. Do not change the font of from-index entries. See section Combining Indices.

`@t{text}`

Print text in a fixed-width, typewriter-like font. No effect in Info. See section Fonts for Printing, Not Info.

`@table formatting-command`

Begin a two-column table, using @item for each entry. Write each first column entry on the same line as @item. First column entries are printed in the font resulting from formatting-command. Pair with @end table. See section Making a Two-column Table. Also see section @ftable and @vtable, and section @itemx.

`@TeX{}`

Insert the logo TeX. See section Inserting TeX and the Copyright Symbol.

`@tex`

Enter TeX completely. Pair with `@end tex`. See section Using Ordinary TeX Commands.

`@thischapter`

In a heading or footing, stands for the number and name of the current chapter, in the format `Chapter 1: Title'. See section How to Make Your Own Headings.

`@thischaptername`

In a heading or footing, stands for the name of the current chapter. See section How to Make Your Own Headings.

`@thisfile`

In a heading or footing, stands for the name of the current `@include` file. Does not insert anything if not within an `@include` file. See section How to Make Your Own Headings.

`@thispage`

In a heading or footing, stands for the current page number. See section How to Make Your Own Headings.

`@thistitle`

In a heading or footing, stands for the name of the document, as specified by the `@settitle` command. See section How to Make Your Own Headings.

`@tindex entry`

Add entry to the index of data types. See section Making Index Entries.

`@title title`

In a printed manual, set a title flush to the left-hand side of the page in a larger than normal font and underline it with a black rule. Not relevant to Info, which does not have title pages. See section `@title, @subtitle, and @author` `@subtitle` and `@author` Commands}.

`@titlefont{text}`

In a printed manual, print text in a larger than normal font. Not relevant to Info, which does not have title pages. See section `@titlefont, @center, and @sp` Commands}.

`@titlepage`

Indicate to Texinfo the beginning of the title page. Write command on a line of its own. Pair with `@end titlepage`. Nothing between `@titlepage` and `@end titlepage` appears in Info. See section `@titlepage`.

`@today{}`

Insert the current date, in `1 Jan 1900' style. See section How to Make Your Own Headings.

`@top title`

In a Texinfo file to be formatted with `makeinfo`, identify the topmost `@node` line in the file, which must be written on the line immediately preceding the `@top` command. Used for

`makeinfo`'s node pointer insertion feature. The title is underlined with asterisks. Both the `@n` line and the `@top` line normally should be enclosed by `@ifinfo` and `@end ifinfo`. In Te and `texinfo-format-buffer`, the `@top` command is merely a synonym for `@unnumbered`. See section Creating Pointers with `makeinfo`}.

`@unnumbered title`

In a printed manual, begin a chapter that appears without chapter numbers of any kind. The title appears in the table of contents of a printed manual. In Info, the title is underlined with asterisks. See section `@unnumbered`, `@appendix`}.

`@unnumberedsec title`

In a printed manual, begin a section that appears without section numbers of any kind. The title appears in the table of contents of a printed manual. In Info, the title is underlined with equal signs. See section `@unnumberedsec`, `@appendixsec`, `@heading`.

`@unnumberedsubsec title`

In a printed manual, begin an unnumbered subsection within a chapter. The title appears in the table of contents of a printed manual. In Info, the title is underlined with hyphens. See section The `@subsection`-like Commands `@appendixsubsec` `@subheading`}.

`@unnumberedsubsubsec title`

In a printed manual, begin an unnumbered subsubsection within a chapter. The title appears in the table of contents of a printed manual. In Info, the title is underlined with periods. See section The `subsub' Commands.

`@value{flag}`

Replace flag with the value to which it is set by `@set flag`. See section `@set`, `@clear`, and `@value`.

`@var{metasyntactic-variable}`

Highlight a metasyntactic variable, which is something that stands for another piece of text. See section `@var`{metasyntactic-variable}.

`@vindex entry`

Add entry to the index of variables. See section Making Index Entries.

`@vskip amount`

In a printed manual, insert whitespace so as to push text on the remainder of the page towards the bottom of the page. Used in formatting the copyright page with the argument `0pt plus 1filll'. (Note spelling of `filll'.) `@vskip` may be used only in contexts ignored for Info. See section Copyright Page and Permissions.

`@vtable formatting-command`

Begin a two-column table, using `@item` for each entry. Automatically enter each of the items in the first column into the index of variables. Pair with `@end vtable`. The same as `@table`, except for indexing. See section `@ftable` and `@vtable` and `@vtable`}.

`@w{text}`

Prevent text from being split across two lines. Do not end a paragraph that uses `@w` with an

`@refill` command. In the Texinfo file, keep text on one line. See section @w{text}: Prevent Breaks.

`@xref{node-name, [entry], [topic-or-title], [info-file], [manual]}`

Make a reference that starts with `See' in a printed manual. Follow command with a punctuation mark. Only the first argument is mandatory. See section `@xref`.

Go to the previous, next section.

Go to the previous, next section.

TOC

Tips and Hints

Here are some tips for writing Texinfo documentation:

- Write in the present tense, not in the past or the future.
- Write actively! For example, write "We recommend that ..." rather than "It is recommended that ...".
- Use 70 or 72 as your fill column. Longer lines are hard to read.
- Include a copyright notice and copying permissions.

Index, index, index!

Write many index entries, in different ways. Readers like indices; they are helpful and convenient.

Although it is easiest to write index entries as you write the body of the text, some people prefer to write entries afterwards. In either case, write an entry before the paragraph to which it applies. This way, an index entry points to the first page of a paragraph that is split across pages.

Here are more hints we have found valuable:

- Write each index entry differently, so each entry refers to a different place in the document. The index of an Info file lists only one location for each entry.
- Write index entries only where a topic is discussed significantly. For example, it is not useful to index "debugging information" in a chapter on reporting bugs. Someone who wants to know about debugging information will certainly not find it in that chapter.
- Consistently capitalize the first word of every index entry, or else use lower case. According to convention, you should capitalize the first word of an index entry. However, this practice may make an index look crowded. Some writers prefer lower case. Regardless of which you prefer, choose one style and stick to it. Mixing the two styles looks bad.
- Always capitalize or use upper case for those words in an index for which this is proper, such as names of countries or acronyms.
- Write the indexing commands that refer to a whole section immediately after the section command, and write the indexing commands that refer to the paragraph before the paragraph.

  In the example that follows, a blank line comes after the index entry for "Leaping":

```
@section The Dog and the Fox
@cindex Jumping, in general
@cindex Leaping

@cindex Dog, lazy, jumped over
@cindex Lazy dog jumped over
@cindex Fox, jumps over dog
```

```
@cindex Quick fox jumps over dog
The quick brown fox jumps over the lazy dog.
```

(Note that the example shows entries for the same concept that are written in different ways---`Lazy dog', and `Dog, lazy'---so readers can look up the concept in different ways.)

Blank lines

- Insert a blank line between a sectioning command and the first following sentence or paragraph, or between the indexing commands associated with the sectioning command and the first following sentence or paragraph, as shown in the tip on indexing. Otherwise, a formatter may fold title and paragraph together.
- Always insert a blank line before an `@table` command and after an `@end table` command; but never insert a blank line after an `@table` command or before an `@end table` command.

  For example,

```
Types of fox:

@table @samp
@item Quick
Jump over lazy dogs.

@item Brown
Also jump over lazy dogs.
@end table

@noindent
On the other hand, ...
```

  Insert blank lines before and after `@itemize` ... `@end itemize` and `@enumerate` ... `@end enumerate` in the same way.

Complete phrases

Complete phrases are easier to read than ...

- Write entries in an itemized list as complete sentences; or at least, as complete phrases. Incomplete expressions ... awkward ... like this.
- Write the prefatory sentence or phrase for a multi-item list or table as a complete expression. Do not write "You can set:"; instead, write "You can set these variables:". The former expression sounds cut off.

Editions, dates and versions

Write the edition and version numbers and date in three places in every manual:

1. In the first `@ifinfo` section, for people reading the Texinfo file.

2. In the `@titlepage` section, for people reading the printed manual.
3. In the `Top' node, for people reading the Info file.

Also, it helps to write a note before the first `@ifinfo` section to explain what you are doing.

For example:

```
@c ===> NOTE! <==
@c Specify the edition and version numbers and date
@c in *three* places:
@c   1. First ifinfo section  2. title page  3. top node
@c To find the locations, search for !!set

@ifinfo
@c !!set edition, date, version
This is Edition 4.03, January 1992,
of the @cite{GDB Manual} for GDB Version 4.3.
...
```

---or use `@set` and `@value` (see section `@value` Example).

Definition Commands

Definition commands are `@deffn`, `@defun`, `@defmac`, and the like, and enable you to write descriptions in a uniform format.

- Write just one definition command for each entity you define with a definition command. The automatic indexing feature creates an index entry that leads the reader to the definition.
- Use `@table` ... `@end table` in an appendix that contains a summary of functions, not `@deffn` or other definition commands.

Capitalization

- Capitalize `Texinfo'; it is a name. Do not write the `x' or `i' in upper case.
- Capitalize `Info'; it is a name.
- Write TeX using the `@TeX{}` command. Note the uppercase `T' and `X'. This command causes the formatters to typeset the name according to the wishes of Donald Knuth, who wrote TeX.

Spaces

Do not use spaces to format a Texinfo file, except inside of `@example` ... `@end example` and similar commands.

For example, TeX fills the following:

```
@kbd{C-x v}
@kbd{M-x vc-next-action}
```

```
Perform the next logical operation
on the version-controlled file
corresponding to the current buffer.
```

so it looks like this:

> C-x v M-x vc-next-action Perform the next logical operation on the version-controlled file corresponding to the current buffer.

In this case, the text should be formatted with `@table`, `@item`, and `@itemx`, to create a table.

@code, @samp, @var, and `---'

- Use `@code` around Lisp symbols, including command names. For example,

  ```
  The main function is @code{vc-next-action}, ...
  ```

- Avoid putting letters such as `s' immediately after an `@code'. Such letters look bad.
- Use `@var` around meta-variables. Do not write angle brackets around them.
- Use three hyphens in a row, `---', to indicate a long dash. TeX typesets these as a long dash and the Info formatters reduce three hyphens to two.

Periods Outside of Quotes

Place periods and other punctuation marks *outside* of quotations, unless the punctuation is part of the quotation. This practice goes against convention, but enables the reader to distinguish between the contents of the quotation and the whole passage.

For example, you should write the following sentence with the period outside the end quotation marks:

```
Evidently, `au' is an abbreviation for "author".
```

since `au' does *not* serve as an abbreviation for `author.' (with a period following the word).

Introducing New Terms

- Introduce new terms so that a user who does not know them can understand them from context; or write a definition for the term.

  For example, in the following, the terms "check in", "register" and "delta" are all appearing for the first time; the example sentence should be rewritten so they are understandable.

  > The major function assists you in checking in a file to your version control system and registering successive sets of changes to it as deltas.

- Use the `@dfn` command around a word being introduced, to indicate that the user should not expect to know the meaning already, and should expect to learn the meaning from this passage.

@pxref

Absolutely never use `@pxref` except in the special context for which it is designed: inside parenthe with the closing parenthesis following immediately after the closing brace. One formatter automatica inserts closing punctuation and the other does not. This means that the output looks right both in printed output and in an Info file, but only when the command is used inside parentheses.

Invoking from a Shell

You can invoke programs such as Emacs, GCC, and GAWK from a shell. The documentation for each program should contain a section that describes this. Unfortunately, if the node names and titles for these sections are all different, readers find it hard to search for the section.

Name such sections with a phrase beginning with the word `Invoking ...', as in `Invoking Emacs'; this way users can find the section easily.

ANSI C Syntax

When you use `@example` to describe a C function's calling conventions, use the ANSI C syntax, like this:

```
void dld_init (char *@var{path});
```

And in the subsequent discussion, refer to the argument values by writing the same argument names, again highlighted with `@var`.

Avoid the obsolete style that looks like this:

```
#include <dld.h>

dld_init (path)
char *path;
```

Also, it is best to avoid writing `#include` above the declaration just to indicate that the function is declared in a header file. The practice may give the misimpression that the `#include` belongs near the declaration of the function. Either state explicitly which header file holds the declaration or, better yet, name the header file used for a group of functions at the beginning of the section that describes the functions.

Bad Examples

Here are several examples of bad writing to avoid:

In this example, say, " ... you must `@dfn`{check in} the new version." That flows better.

> When you are done editing the file, you must perform a `@dfn`{check in}.

In the following example, say, "... makes a unified interface such as VC mode possible."

> SCCS, RCS and other version-control systems all perform similar functions in broadly similar ways (it is this resemblance which makes a unified control mode like this possible).

And in this example, you should specify what `it' refers to:

> If you are working with other people, it assists in coordinating everyone's changes so they do not step on each other.

And Finally ...

- Pronounce TeX as if the `X' were a Greek `chi', as the last sound in the name `Bach'. But pronounce Texinfo as in `speck': `teckinfo'.
- Write notes for yourself at the very end of a Texinfo file after the `@bye`. None of the formatters process text after the `@bye`; it is as if the text were within `@ignore` ... `@end ignore`.

Sample Permissions

Texinfo files should contain sections that tell the readers that they have the right to copy and distribute the Texinfo file, the Info file, and the printed manual.

Also, if you are writing a manual about software, you should explain that the software is free and either include the GNU General Public License (GPL) or provide a reference to it. See section 'Distribution' in The GNU Emacs Manual, for an example of the text that could be used in the software "Distribution", "General Public License", and "NO WARRANTY" sections of a document. See section Texinfo Copying Conditions, for an example of a brief explanation of how the copying conditions provide you with rights.

In a Texinfo file, the first `@ifinfo` section usually begins with a line that says what the file documents. This is what a person reading the unprocessed Texinfo file or using the advanced Info command g * sees first. @inforef{Expert, Advanced Info commands, info}, for more information. (A reader using the regular Info commands usually starts reading at the first node and skips this first section, which is not in a node.)

In the `@ifinfo` section, the summary sentence is followed by a copyright notice and then by the copying permission notice. One of the copying permission paragraphs is enclosed in `@ignore` and `@end ignore` commands. This paragraph states that the Texinfo file can be processed through TeX and printed, provided the printed manual carries the proper copying permission notice. This paragraph is not made part of the Info file since it is not relevant to the Info file; but it is a mandatory part of the Texinfo file since it permits people to process the Texinfo file in TeX and print the results.

In the printed manual, the Free Software Foundation copying permission notice follows the copyright notice and publishing information and is located within the region delineated by the `@titlepage` and `@end titlepage` commands. The copying permission notice is exactly the same as the notice in the `@ifinfo` section except that the paragraph enclosed in `@ignore` and `@end ignore` commands is not part of the notice.

To make it simple to insert a permission notice into each section of the Texinfo file, sample permission notices for each section are reproduced in full below.

Note that you may need to specify the correct name of a section mentioned in the permission notice. For example, in The GDB Manual, the name of the section referring to the General Public License is called the "GDB General Public License", but in the sample shown below, that section is referred to generically as the "GNU General Public License". If the Texinfo file does not carry a copy of the General Public License, leave out the reference to it, but be sure to include the rest of the sentence.

`ifinfo' Copying Permissions

In the `@ifinfo` section of a Texinfo file, the standard Free Software Foundation permission notice reads as follows:

```
This file documents ...

Copyright 1992 Free Software Foundation, Inc.

Permission is granted to make and distribute verbatim
copies of this manual provided the copyright notice and
this permission notice are preserved on all copies.

@ignore
Permission is granted to process this file through TeX
and print the results, provided the printed document
carries a copying permission notice identical to this
one except for the removal of this paragraph (this
paragraph not being relevant to the printed manual).

@end ignore
Permission is granted to copy and distribute modified
versions of this manual under the conditions for
verbatim copying, provided also that the sections
entitled "Copying" and "GNU General Public License"
are included exactly as in the original, and provided
that the entire resulting derived work is distributed
under the terms of a permission notice identical to this
one.

Permission is granted to copy and distribute
translations of this manual into another language,
under the above conditions for modified versions,
except that this permission notice may be stated in a
translation approved by the Free Software Foundation.
```

Titlepage Copying Permissions

In the `@titlepage` section of a Texinfo file, the standard Free Software Foundation copying permission notice follows the copyright notice and publishing information. The standard phrasing is as follows:

```
Permission is granted to make and distribute verbatim
```

Go to the previous, next section.

Go to the previous, next section.

Include Files

When TeX or an Info formatting command sees an `@include` command in a Texinfo file, it processes the contents of the file named by the command and incorporates them into the DVI or Info file being created. Index entries from the included file are incorporated into the indices of the output file.

Include files let you keep a single large document as a collection of conveniently small parts.

How to Use Include Files

To include another file within a Texinfo file, write the `@include` command at the beginning of a line and follow it on the same line by the name of a file to be included. For example:

```
@include buffers.texi
```

An included file should simply be a segment of text that you expect to be included as is into the overall or outer Texinfo file; it should not contain the standard beginning and end parts of a Texinfo file. In particular, you should not start an included file with a line saying `\input texinfo'; if you do, that phrase is inserted into the output file as is. Likewise, you should not end an included file with an `@bye` command; nothing after `@bye` is formatted.

In the past, you were required to write an `@setfilename` line at the beginning of an included file, but no longer. Now, it does not matter whether you write such a line. If an `@setfilename` line exists in an included file, it is ignored.

Conventionally, an included file begins with an `@node` line that is followed by an `@chapter` line. Each included file is one chapter. This makes it easy to use the regular node and menu creating and updating commands to create the node pointers and menus within the included file. However, the simple Emacs node and menu creating and updating commands do not work with multiple Texinfo files. Thus you cannot use these commands to fill in the `Next', `Previous', and `Up' pointers of the `@node` line that begins the included file. Also, you cannot use the regular commands to create a master menu for the whole file. Either you must insert the menus and the `Next', `Previous', and `Up' pointers by hand, or you must use the GNU Emacs Texinfo mode command, `texinfo-multiple-files-update`, that is designed for `@include` files.

texinfo-multiple-files-update

GNU Emacs Texinfo mode provides a command to handle included files called `texinfo-multiple-files-update`. This command creates or updates `Next', `Previous', and `Up' pointers of included files as well as those in the outer or overall Texinfo file, and it creates or updates a main menu in the outer file. Depending whether you call it with optional arguments, the command updates only the pointers in the first `@node` line of the included files or all of them:

M-x texinfo-multiple-files-update

Called without any arguments:

Create or update the `Next', `Previous', and `Up' pointers of the first `@node` line in each file included in an outer or overall Texinfo file.

Create or update the `Top' level node pointers of the outer or overall file.

Create or update a main menu in the outer file.

C-u M-x texinfo-multiple-files-update

Called with C-u as a prefix argument:

Create or update pointers in the first `@node` line in each included file.

Create or update the `Top' level node pointers of the outer file.

Create and insert a master menu in the outer file. The master menu is made from all the menus in all the included files.

C-u 8 M-x texinfo-multiple-files-update

Called with a numeric prefix argument, such as C-u 8:

Create or update **all** the `Next', `Previous', and `Up' pointers of all the included files.

Create or update **all** the menus of all the included files.

Create or update the `Top' level node pointers of the outer or overall file.

And then create a master menu in the outer file. This is similar to invoking `texinfo-master-menu` with an argument when you are working with just one file.

Note the use of the prefix argument in interactive use: with a regular prefix argument, just C-u, the `texinfo-multiple-files-update` command inserts a master menu; with a numeric prefix argument, such as C-u 8, the command updates **every** pointer and menu in **all** the files and then inserts a master menu.

Include File Requirements

If you plan to use the `texinfo-multiple-files-update` command, the outer Texinfo file that lists included files within it should contain nothing but the beginning and end parts of a Texinfo file, and a number of `@include` commands listing the included files. It should not even include indices, which should be listed in an included file of their own.

Moreover, each of the included files must contain exactly one highest level node (conventionally, `@chapter` or equivalent), and this node must be the first node in the included file. Furthermore, each of these highest level nodes in each included file must be at the same hierarchical level in the file structure. Usually, each is an `@chapter`, an `@appendix`, or an `@unnumbered` node. Thus, normally, each included file contains one, and only one, chapter or equivalent-level node.

The outer file should contain only *one* node, the `Top' node. It should *not* contain any nodes besides the single `Top' node. The `texinfo-multiple-files-update` command will not process them.

Sample File with `@include`

Here is an example of a complete outer Texinfo file with `@include` files within it before running `texinfo-multiple-files-update`, which would insert a main or master menu:

```
\input texinfo @c -*-texinfo-*-
@setfilename  include-example.info
@settitle Include Example

@setchapternewpage odd
@titlepage
@sp 12
@center @titlefont{Include Example}
@sp 2
@center by Whom Ever

@page
@vskip 0pt plus 1filll
Copyright @copyright{} 1990 Free Software Foundation, Inc.
@end titlepage

@ifinfo
@node Top, First, (dir), (dir)
@top Master Menu
@end ifinfo

@include foo.texinfo
@include bar.texinfo
@include concept-index.texinfo

@summarycontents
@contents

@bye
```

An included file, such as `` `foo.texinfo' ``, might look like this:

```
@node First, Second, , Top
@chapter First Chapter

Contents of first chapter ...
```

The full contents of `` `concept-index.texinfo' `` might be as simple as this:

```
@node Concept Index, , Second, Top
```

```
@unnumbered Concept Index

@printindex cp
```

The outer Texinfo source file for The GNU Emacs Lisp Reference Manual is named `elisp.texi'. This outer file contains a master menu with 417 entries and a list of 41 `@include` files.

Evolution of Include Files

When Info was first created, it was customary to create many small Info files on one subject. Each Info file was formatted from its own Texinfo source file. This custom meant that Emacs did not need to make a large buffer to hold the whole of a large Info file when someone wanted information; instead, Emacs allocated just enough memory for the small Info file that contained the particular information sought. This way, Emacs could avoid wasting memory.

References from one file to another were made by referring to the file name as well as the node name. (See section Referring to Other Info Files. Also, see section `@xref` with Four and Five Arguments with Four and Five Arguments}.)

Include files were designed primarily as a way to create a single, large printed manual out of several smaller Info files. In a printed manual, all the references were within the same document, so TeX could automatically determine the references' page numbers. The Info formatting commands used include files only for creating joint indices; each of the individual Texinfo files had to be formatted for Info individually. (Each, therefore, required its own `@setfilename` line.)

However, because large Info files are now split automatically, it is no longer necessary to keep them small.

Nowadays, multiple Texinfo files are used mostly for large documents, such as The GNU Emacs Lisp Reference Manual, and for projects in which several different people write different sections of a document simultaneously.

In addition, the Info formatting commands have been extended to work with the `@include` command so as to create a single large Info file that is split into smaller files if necessary. This means that you can write menus and cross references without naming the different Texinfo files.

TOC

Page Headings

Most printed manuals contain headings along the top of every page except the title and copyright pages. Some manuals also contain footings. (Headings and footings have no meaning to Info, which is not paginated.)

Texinfo provides standard page heading formats for manuals that are printed on one side of each sheet of paper and for manuals that are printed on both sides of the paper. Usually, you will use one or other of these formats, but you can specify your own format, if you wish.

In addition, you can specify whether chapters should begin on a new page, or merely continue the same page as the previous chapter; and if chapters begin on new pages, you can specify whether they must be odd-numbered pages.

By convention, a book is printed on both sides of each sheet of paper. When you open a book, the right-hand page is odd-numbered, and chapters begin on right-hand pages--a preceding left-hand page is left blank if necessary. Reports, however, are often printed on just one side of paper, and chapters begin on a fresh page immediately following the end of the preceding chapter. In short or informal reports, chapters often do not begin on a new page at all, but are separated from the preceding text by a small amount of whitespace.

The `@setchapternewpage` command controls whether chapters begin on new pages, and whether one of the standard heading formats is used. In addition, Texinfo has several heading and footing commands that you can use to generate your own heading and footing formats.

In Texinfo, headings and footings are single lines at the tops and bottoms of pages; you cannot create multiline headings or footings. Each header or footer line is divided into three parts: a left part, a middle part, and a right part. Any part, or a whole line, may be left blank. Text for the left part of a header or footer line is set flushleft; text for the middle part is centered; and, text for the right part is set flushright.

Standard Heading Formats

Texinfo provides two standard heading formats, one for manuals printed on one side of each sheet of paper, and the other for manuals printed on both sides of the paper.

By default, nothing is specified for the footing of a Texinfo file, so the footing remains blank.

The standard format for single-sided printing consists of a header line in which the left-hand part contains the name of the chapter, the central part is blank, and the right-hand part contains the page number.

A single-sided page looks like this:

```
|                          |
| chapter   page number    |
|                          |
| Start of text ...        |
| ...                      |
|                          |
```

The standard format for two-sided printing depends on whether the page number is even or odd. By convention, even-numbered pages are on the left- and odd-numbered pages are on the right. (TeX will adjust the widths of the left- and right-hand margins. Usually, widths are correct, but during double-sided printing, it is wise to check that pages will bind properly--sometimes a printer will produce output in which the even-numbered pages have a larger right-hand margin than the odd-numbered pages.)

In the standard double-sided format, the left part of the left-hand (even-numbered) page contains the page number, the central part is blank, and the right part contains the title (specified by the `@settitle` command). The left part of the right-hand (odd-numbered) page contains the name of the chapter, the central part is blank, and the right part contains the page number.

Two pages, side by side as in an open book, look like this:

```
 _________________________     _________________________
|                         |   |                         |
| page number     title   |   | chapter   page number   |
|                         |   |                         |
| Start of text ...       |   | More  text ...          |
| ...                     |   | ...                     |
|                         |   |                         |
```

The chapter name is preceded by the word `Chapter', the chapter number and a colon. This makes it easier to keep track of where you are in the manual.

Specifying the Type of Heading

TeX does not begin to generate page headings for a standard Texinfo file until it reaches the `@end titlepage` command. Thus, the title and copyright pages are not numbered. The `@end titlepage` command causes TeX to begin to generate page headings according to a standard format specified by the `@setchapternewpage` command that precedes the `@titlepage` section.

There are four possibilities:

No `@setchapternewpage` command

> Cause TeX to specify the single-sided heading format, with chapters on new pages. This is the same as `@setchapternewpage on`.

`@setchapternewpage on`

Specify the single-sided heading format, with chapters on new pages.

`@setchapternewpage off`

Cause TeX to start a new chapter on the same page as the last page of the preceding chapter, after skipping some vertical whitespace. Also cause TeX to typeset for single-sided printing. (You can override the headers format with the `@headings double` command; see section The `@headings` Command.)

`@setchapternewpage odd`

Specify the double-sided heading format, with chapters on new pages.

Texinfo lacks an `@setchapternewpage even` command.

How to Make Your Own Headings

You can use the standard headings provided with Texinfo or specify your own.

Texinfo provides six commands for specifying headings and footings. The `@everyheading` command and `@everyfooting` command generate page headers and footers that are the same for both even- and odd-numbered pages. The `@evenheading` command and `@evenfooting` command generate headers and footers for even-numbered (left-hand) pages; and the `@oddheading` command and `@oddfooting` command generate headers and footers for odd-numbered (right-hand) pages.

Write custom heading specifications in the Texinfo file immediately after the `@end titlepage` command. Enclose your specifications between `@iftex` and `@end iftex` commands since the `texinfo-format-buffer` command may not recognize them. Also, you must cancel the predefined heading commands with the `@headings off` command before defining your own specifications.

Here is how to tell TeX to place the chapter name at the left, the page number in the center, and the date at the right of every header for both even- and odd-numbered pages:

```
@iftex
@headings off
@everyheading @thischapter @| @thispage @| @today{}
@end iftex
```

You need to divide the left part from the central part and the central part from the right had part by inserting `@|' between parts. Otherwise, the specification command will not be able to tell where the text for one part ends and the next part begins.

Each part can contain text or @-commands. The text is printed as if the part were within an ordinary paragraph in the body of the page. The @-commands replace themselves with the page number, date, chapter name, or whatever.

Here are the six heading and footing commands:

```
@everyheading left @| center @| right
@everyfooting left @| center @| right
```

The `every' commands specify the format for both even- and odd-numbered pages. These commands are for documents that are printed on one side of each sheet of paper, or for documents in which you want symmetrical headers or footers.

```
@evenheading left @| center @| right
@oddheading left @| center @| right
@evenfooting left @| center @| right
@oddfooting left @| center @| right
```

The `even' and `odd' commands specify the format for even-numbered pages and odd-numbered pages. These commands are for books and manuals that are printed on both sides of each sheet of paper.

Use the `@this...' series of @-commands to provide the names of chapters and sections and the page number. You can use the `@this...' commands in the left, center, or right portions of headers and footers, or anywhere else in a Texinfo file so long as they are between `@iftex` and `@end iftex` commands.

Here are the `@this...' commands:

`@thispage`

Expands to the current page number.

`@thischaptername`

Expands to the name of the current chapter.

`@thischapter`

Expands to the number and name of the current chapter, in the format `Chapter 1: Title'.

`@thistitle`

Expands to the name of the document, as specified by the `@settitle` command.

`@thisfile`

For `@include` files only: expands to the name of the current `@include` file. If the current Texinfo source file is not an `@include` file, this command has no effect. This command does *not* provide the name of the current Texinfo source file unless it is an `@include` file. (See section Include Files, for more information about `@include` files.)

You can also use the `@today{}` command, which expands to the current date, in `1 Jan 1900' format.

Other @-commands and text are printed in a header or footer just as if they were in the body of a page. It is useful to incorporate text, particularly when you are writing drafts:

```
@iftex
@headings off
@everyheading @emph{Draft!} @| @thispage @| @thischapter
@everyfooting @| @| Version: 0.27: @today{}
@end iftex
```

Beware of overlong titles: they may overlap another part of the header or footer and blot it out.

Go to the previous, next section.

Go to the previous, next section.

Formatting Mistakes

Besides mistakes in the content of your documentation, there are two kinds of mistake you can make with Texinfo: you can make mistakes with @-commands, and you can make mistakes with the structure of the nodes and chapters.

Emacs has two tools for catching the @-command mistakes and two for catching structuring mistakes.

For finding problems with @-commands, you can run TeX or a region formatting command on the region that has a problem; indeed, you can run these commands on each region as you write it.

For finding problems with the structure of nodes and chapters, you can use C-c C-s (`texinfo-show-structure`) and the related `occur` command and you can use the M-x Info-validate command.

The `makeinfo` program does an excellent job of catching errors and reporting them--far better than either the `texinfo-format-region` or the `texinfo-format-buffer` command. In addition, the various functions for automatically creating and updating node pointers and menus remove many opportunities for human error.

If you can, use the updating commands to create and insert pointers and menus. These prevent many errors. Then use `makeinfo` (or its Texinfo mode manifestations, `makeinfo-region` and `makeinfo-buffer`) to format your file and check for other errors. This is the best way to work with Texinfo. But if you cannot use `makeinfo`, or your problem is very puzzling, then you may want to use the tools described in this appendix.

Catching Errors with Info Formatting

After you have written part of a Texinfo file, you can use the `texinfo-format-region` or the `makeinfo-region` command to see whether the region formats properly.

Most likely, however, you are reading this section because for some reason you cannot use the `makeinfo-region` command; therefore, the rest of this section presumes that you are using `texinfo-format-region`.

If you make a mistake with an @-command, `texinfo-format-region` will stop processing at or after the error and display an error message. To see where in the buffer the error occurred, switch to the `*Info Region*' buffer; the cursor will be in a position that is after the location of the error. Also, the text will not be formatted after the place where the error occurred (or more precisely, where it was detected).

For example, if you accidentally end a menu with the command `@end menus` with an `s' on the end, instead of with `@end menu`, you will see an error message that says:

```
@end menus is not handled by texinfo
```

The cursor will stop at the point in the buffer where the error occurs, or not long after it. The buffer will look like this:

```
---------- Buffer: *Info Region* ----------
* Menu:

* Using texinfo-show-structure::  How to use
                                  `texinfo-show-structure'
                                  to catch mistakes.
* Running Info-Validate::         How to check for
                                  unreferenced nodes.
@end menus
-!-
---------- Buffer: *Info Region* ----------
```

The `texinfo-format-region` command sometimes provides slightly odd error messages. For example, the following cross reference fails to format:

```
(@xref{Catching Mistakes, for more info.)
```

In this case, `texinfo-format-region` detects the missing closing brace but displays a message that says `Unbalanced parentheses' rather than `Unbalanced braces'. This is because the formatting command looks for mismatches between braces as if they were parentheses.

Sometimes `texinfo-format-region` fails to detect mistakes. For example, in the following, the closing brace is swapped with the closing parenthesis:

```
(@xref{Catching Mistakes), for more info.}
```

Formatting produces:

```
(*Note for more info.: Catching Mistakes)
```

The only way for you to detect this error is to realize that the reference should have looked like this:

```
(*Note Catching Mistakes::, for more info.)
```

Incidentally, if you are reading this node in Info and type f RET (`Info-follow-reference`), you will generate an error message that says:

```
No such node: "Catching Mistakes) The only way ...
```

This is because Info perceives the example of the error as the first cross reference in this node and if you type a RET immediately after typing the Info f command, Info will attempt to go to the referenced node. If you type f catch TAB RET, Info will complete the node name of the correctly written example and take you to the `Catching Mistakes' node. (If you try this, you can return from the `Catching Mistakes'

node by typing l (`Info-last`).)

Catching Errors with TeX Formatting

You can also catch mistakes when you format a file with TeX.

Usually, you do this after you have run `texinfo-format-buffer` (or, better, `makeinfo-buffer`) on the same file, because `texinfo-format-buffer` sometimes displays error messages that make more sense than TeX. (See section Catching Errors with Info Formatting, for more information.)

For example, TeX was run on a Texinfo file, part of which is shown here:

```
---------- Buffer: texinfo.texi ----------
name of the texinfo file as an extension.  The
@samp{??} are `wildcards' that cause the shell to
substitute all the raw index files.  (@xref{sorting
indices, for more information about sorting
indices.)@refill
---------- Buffer: texinfo.texi ----------
```

(The cross reference lacks a closing brace.) TeX produced the following output, after which it stopped:

```
---------- Buffer: *texinfo-tex-shell* ----------
Runaway argument?
{sorting indices, for more information about sorting
indices.) @refill @ETC.
! Paragraph ended before @xref was complete.
<to be read again>
                   @par
l.27

?
---------- Buffer: *texinfo-tex-shell* ----------
```

In this case, TeX produced an accurate and understandable error message:

```
Paragraph ended before @xref was complete.
```

`@par' is an internal TeX command of no relevance to Texinfo. `l.27' means that TeX detected the problem on line 27 of the Texinfo file. The `?' is the prompt TeX uses in this circumstance.

Unfortunately, TeX is not always so helpful, and sometimes you must truly be a Sherlock Holmes to discover what went wrong.

In any case, if you run into a problem like this, you can do one of three things.

1. You can tell TeX to continue running and ignore just this error by typing RET at the `?' prompt.
2. You can tell TeX to continue running and to ignore all errors as best it can by typing r RET at the `?' prompt.

   This is often the best thing to do. However, beware: the one error may produce a cascade of additional error messages as its consequences are felt through the rest of the file. (To stop TeX when it is producing such an avalanche of error messages, type C-d (or C-c C-d, if you are running a shell inside Emacs Version 18.))
3. You can tell TeX to stop this run by typing x RET at the `?' prompt.

Please note that if you are running TeX inside Emacs, you need to switch to the shell buffer and line at which TeX offers the `?' prompt.

Sometimes TeX will format a file without producing error messages even though there is a problem. This usually occurs if a command is not ended but TeX is able to continue processing anyhow. For example, if you fail to end an itemized list with the `@end itemize` command, TeX will write a DVI file that you can print out. The only error message that TeX will give you is the somewhat mysterious comment that

```
(@end occurred inside a group at level 1)
```

However, if you print the DVI file, you will find that the text of the file that follows the itemized list is entirely indented as if it were part of the last item in the itemized list. The error message is the way TeX says that it expected to find an `@end` command somewhere in the file; but that it could not determine where it was needed.

Another source of notoriously hard-to-find errors is a missing `@end group` command. If you ever are stumped by incomprehensible errors, look for a missing `@end group` command first.

If the Texinfo file lacks header lines, TeX may stop in the beginning of its run and display output that looks like the following. The `*' indicates that TeX is waiting for input.

```
This is TeX, Version 2.0 for Berkeley UNIX
(preloaded format=plain-cm 87.10.25)
(test.texinfo [1])
*
```

In this case, simply type \end RET after the asterisk. Then write the header lines in the Texinfo file and run the TeX command again. (Note the use of the backslash, `\'. TeX uses `\' instead of `@'; and in this circumstance, you are working directly with TeX, not with Texinfo.)

Using `texinfo-show-structure`

It is not always easy to keep track of the nodes, chapters, sections, and subsections of a Texinfo file. This is especially true if you are revising or adding to a Texinfo file that someone else has written.

In GNU Emacs, in Texinfo mode, the `texinfo-show-structure` command lists all the lines that begin with the @-commands that specify the structure: `@chapter`, `@section`, `@appendix`, and so

on. With an argument (C-u as prefix argument, if interactive), the command also shows the `@node` l
The `texinfo-show-structure` command is bound to C-c C-s in Texinfo mode, by default.

The lines are displayed in a buffer called the `*Occur*' buffer. For example, when `texinfo-show-structure` was run on an earlier version of this appendix, it produced the following:

```
Lines matching "^@\\(chapter \\|sect\\|sub\\|unnum\\|major\\|
heading \\|appendix\\)" in buffer texinfo.texi.
  4:@appendix Formatting Mistakes
 52:@appendixsec Catching Errors with Info Formatting
222:@appendixsec Catching Errors with @TeX{} Formatting
338:@appendixsec Using @code{texinfo-show-structure}
407:@appendixsubsec Using @code{occur}
444:@appendixsec Finding Badly Referenced Nodes
513:@appendixsubsec Running @code{Info-validate}
573:@appendixsubsec Splitting a File Manually
```

This says that lines 4, 52, and 222 of `` `texinfo.texi' `` begin with the `@appendix`, `@appendixsec`, and `@appendixsec` commands respectively. If you move your cursor into the `*Occur*' window, you can position the cursor over one of the lines and use the C-c C-c command (`occur-mode-goto-occurrence`), to jump to the corresponding spot in the Texinfo file. See section 'Using Occur' in The GNU Emacs Manual, for more information about `occur-mode-goto-occurrence`.

The first line in the `*Occur*' window describes the regular expression specified by texinfo-heading-pattern. This regular expression is the pattern that `texinfo-show-structure` looks for. See section 'Using Regular Expressions' in The GNU Emacs Manual, for more information.

When you invoke the `texinfo-show-structure` command, Emacs will display the structure of the whole buffer. If you want to see the structure of just a part of the buffer, of one chapter, for example, use the C-x n (`narrow-to-region`) command to mark the region. (See section 'Narrowing' in The GNU Emacs Manual.) This is how the example used above was generated. (To see the whole buffer again, use C-x w (`widen`).)

If you call `texinfo-show-structure` with a prefix argument by typing C-u C-c C-s, it will list lines beginning with `@node` as well as the lines beginning with the @-sign commands for `@chapter`, `@section`, and the like.

You can remind yourself of the structure of a Texinfo file by looking at the list in the `*Occur*' window; and if you have mis-named a node or left out a section, you can correct the mistake.

Using occur

Sometimes the `texinfo-show-structure` command produces too much information. Perhaps you want to remind yourself of the overall structure of a Texinfo file, and are overwhelmed by the detailed list produced by `texinfo-show-structure`. In this case, you can use the `occur` command

directly. To do this, type

```
M-x occur
```

and then, when prompted, type a regexp, a regular expression for the pattern you want to match. (See section 'Regular Expressions' in The GNU Emacs Manual.) The `occur` command works from the current location of the cursor in the buffer to the end of the buffer. If you want to run `occur` on the whole buffer, place the cursor at the beginning of the buffer.

For example, to see all the lines that contain the word `@chapter' in them, just type `@chapter'. This will produce a list of the chapters. It will also list all the sentences with `@chapter' in the middle of the line.

If you want to see only those lines that start with the word `@chapter', type `^@chapter' when prompted by `occur`. If you want to see all the lines that end with a word or phrase, end the last word with a `$'; for example, `catching mistakes$'. This can be helpful when you want to see all the nodes that are part of the same chapter or section and therefore have the same `Up' pointer.

See section 'Using Occur' in The GNU Emacs Manual, for more information.

Finding Badly Referenced Nodes

You can use the `Info-validate` command to check whether any of the `Next', `Previous', `Up' or other node pointers fail to point to a node. This command checks that every node pointer points to an existing node. The `Info-validate` command works only on Info files, not on Texinfo files.

The `makeinfo` program validates pointers automatically, so you do not need to use the `Info-validate` command if you are using `makeinfo`. You only may need to use `Info-validate` if you are unable to run `makeinfo` and instead must create an Info file using `texinfo-format-region` or `texinfo-format-buffer`, or if you write an Info file from scratch.

Running `Info-validate`

To use `Info-validate`, visit the Info file you wish to check and type:

```
M-x Info-validate
```

(Note that the `Info-validate` command requires an upper case `I'. You may also need to create a tag table before running `Info-validate`. See section Tagifying a File.)

If your file is valid, you will receive a message that says "File appears valid". However, if you have a pointer that does not point to a node, error messages will be displayed in a buffer called `*problems in info file*'.

For example, `Info-validate` was run on a test file that contained only the first node of this manual. One of the messages said:

```
In node "Overview", invalid Next: Texinfo Mode
```

This meant that the node called `Overview' had a `Next' pointer that did not point to anything (which was true in this case, since the test file had only one node in it).

Now suppose we add a node named `Texinfo Mode' to our test case but we do not specify a `Previous' for this node. Then we will get the following error message:

```
In node "Texinfo Mode", should have Previous: Overview
```

This is because every `Next' pointer should be matched by a `Previous' (in the node where the `Next' points) which points back.

`Info-validate` also checks that all menu entries and cross references point to actual nodes.

Note that `Info-validate` requires a tag table and does not work with files that have been split. (The `texinfo-format-buffer` command automatically splits large files.) In order to use `Info-validate` on a large file, you must run `texinfo-format-buffer` with an argument so that it does not split the Info file; and you must create a tag table for the unsplit file.

Creating an Unsplit File

You can run `Info-validate` only on a single Info file that has a tag table. The command will not work on the indirect subfiles that are generated when a master file is split. If you have a large file (longer than 70,000 bytes or so), you need to run the `texinfo-format-buffer` or `makeinfo-buffer` command in such a way that it does not create indirect subfiles. You will also need to create a tag table for the Info file. After you have done this, you can run `Info-validate` and look for badly referenced nodes.

The first step is to create an unsplit Info file.

To prevent `texinfo-format-buffer` from splitting a Texinfo file into smaller Info files, give a prefix to the M-x texinfo-format-buffer command:

```
C-u M-x texinfo-format-buffer
```

or else

```
C-u C-c C-e C-b
```

When you do this, Texinfo will not split the file and will not create a tag table for it.

Tagifying a File

After creating an unsplit Info file, you must create a tag table for it. Visit the Info file you wish to tagify and type:

```
M-x Info-tagify
```

(Note the upper case I in `Info-tagify`.) This creates an Info file with a tag table that you can vali

The third step is to validate the Info file:

```
M-x Info-validate
```

(Note the upper case I in `Info-validate`.) In brief, the steps are:

```
C-u M-x texinfo-format-buffer
M-x Info-tagify
M-x Info-validate
```

After you have validated the node structure, you will be able to rerun `texinfo-format-buffer` in the normal way so it will construct a tag table and split the file automatically, or you can make the tag table and split the file manually.

Splitting a File Manually

You should split a large file or else let the `texinfo-format-buffer` or `makeinfo-buffer` command do it for you automatically. (Generally you will let one of the formatting commands do this job for you. See section Creating an Info File.)

The split-off files are called the indirect subfiles.

Info files are split to save memory. With smaller files, Emacs does not have make such a large buffer to hold the information.

If an Info file has more than 30 nodes, you should also make a tag table for it. See section Running `Info-validate`, for information about creating a tag table. (Again, tag tables are usually created automatically by the formatting command; you only need to create a tag table yourself if you are doing the job manually. Most likely, you will do this for a large, unsplit file on which you have run `Info-validate`.)

Visit the Info file you wish to tagify and split and type the two commands:

```
M-x Info-tagify
M-x Info-split
```

(Note that the `I' in `Info' is upper case.)

When you use the `Info-split` command, the buffer is modified into a (small) Info file which lists the indirect subfiles. This file should be saved in place of the original visited file. The indirect subfiles are written in the same directory the original file is in, with names generated by appending `-' and a number to the original file name.

The primary file still functions as an Info file, but it contains just the tag table and a directory of subfiles.

Go to the previous, next section.

Go to the previous, next section.

Refilling Paragraphs

The `@refill` command refills and, optionally, indents the first line of a paragraph.(12) The `@refill` command is no longer important, but we describe it here because you once needed it. You will see it in many old Texinfo files.

Without refilling, paragraphs containing long @-constructs may look bad after formatting because the formatter removes @-commands and shortens some lines more than others. In the past, neither `texinfo-format-region` nor `texinfo-format-buffer` refilled paragraphs automatically. The `@refill` command had to be written at the end of every paragraph to cause these formatters to fill them. (Both TeX and `makeinfo` have always refilled paragraphs automatically.) Now, all the Info formatters automatically fill and indent those paragraphs that need to be filled and indented.

The `@refill` command causes both the `texinfo-format-region` command and the `texinfo-format-buffer` command to refill a paragraph in the Info file *after* all the other processing has been done. For this reason, you can not use `@refill` with a paragraph containing either `@*` or `@w{ ... }` since the refilling action will override those two commands.

The `texinfo-format-region` and `texinfo-format-buffer` commands now automatically append `@refill` to the end of each paragraph that should be filled. They do not append `@refill` to the ends of paragraphs that contain `@*` or `@w{ ...}` and therefore do not refill or indent them.

Go to the previous, next section.

Go to the previous, next section.

@-Command Syntax

The character `@' is used to start special Texinfo commands. (It has the same meaning that `\' has in PlainTeX.) Texinfo has four types of @-command:

1. Non-alphabetic commands.

   These commands consist of an @ followed by a punctuation mark or other character that is not part of the alphabet. Non-alphabetic commands are almost always part of the text within a paragraph, and never take any argument. The two characters (@ and the other one) are complete in themselves; none is followed by braces. The non-alphabetic commands are: `@.`, `@:`, `@*`, `@@`, `@{`, and `@}`.

2. Alphabetic commands that do not require arguments.

   These commands start with @ followed by a word followed by left- and right-hand braces. These commands insert special symbols in the document; they do not require arguments. For example, `@dots{}` => `...', `@equiv{}` => `==', `@TeX{}` => `TeX', and `@bullet{}` => `*'.

3. Alphabetic commands that require arguments within braces.

   These commands start with @ followed by a letter or a word, followed by an argument within braces. For example, the command `@dfn` indicates the introductory or defining use of a term; it is used as follows: `In Texinfo, @@-commands are @dfn{mark-up} commands.'

4. Alphabetic commands that occupy an entire line.

   These commands occupy an entire line. The line starts with @, followed by the name of the command (a word); for example, `@center` or `@cindex`. If no argument is needed, the word is followed by the end of the line. If there is an argument, it is separated from the command name by a space. Braces are not used.

Thus, the alphabetic commands fall into classes that have different argument syntaxes. You cannot tell to which class a command belongs by the appearance of its name, but you can tell by the command's meaning: if the command stands for a glyph, it is in class 2 and does not require an argument; if it makes sense to use the command together with other text as part of a paragraph, the command is in class 3 and must be followed by an argument in braces; otherwise, it is in class 4 and uses the rest of the line as its argument.

The purpose of having a different syntax for commands of classes 3 and 4 is to make Texinfo files easier to read, and also to help the GNU Emacs paragraph and filling commands work properly. There is only one exception to this rule: the command `@refill`, which is always used at the end of a paragraph immediately following the final period or other punctuation character. `@refill` takes no argument and does *not* require braces. `@refill` never confuses the Emacs paragraph commands because it cannot appear at the beginning of a line.

Go to the previous, next section.

How to Obtain TeX

TeX is freely redistributable. You can obtain TeX for Unix systems from the University of Washington for a distribution fee.

To order a full distribution, send $200.00 for a 1/2-inch 9-track 1600 bpi (`tar` or `cpio`) tape reel, or $210.00 for a 1/4-inch 4-track QIC-24 (`tar` or `cpio`) cartridge, to:

```
Northwest Computing Support Center
DR-10, Thomson Hall 35
University of Washington
Seattle, Washington 98195
```

Please make checks payable to the University of Washington.

Prepaid orders are preferred but purchase orders are acceptable; however, purchase orders carry an extra charge of $10.00, to pay for processing.

Overseas sites: please add to the base cost $20.00 for shipment via air parcel post, or $30.00 for shipment via courier.

Please check with the Northwest Computing Support Center at the University of Washington for current prices and formats:

```
telephone:  (206) 543-6259
email:      elisabet@u.washington.edu
```

Go to the previous, next section.

Go to the previous, next section.

Second Edition Features

The second edition of the Texinfo manual describes more than 20 new Texinfo mode commands and more than 50 previously undocumented Texinfo @-commands. This edition is more than twice the length of the first edition.

Here is a brief description of the new commands.

New Texinfo Mode Commands

Texinfo mode provides commands and features especially designed for working with Texinfo files. More than 20 new commands have been added, including commands for automatically creating and updating both nodes and menus. This is a tedious task when done by hand.

The keybindings are intended to be somewhat mnemonic.

Update all nodes and menus

The `texinfo-master-menu` command is the primary command:

C-c C-u m

M-x texinfo-master-menu

> Create or update a master menu. With C-u as a prefix argument, first create or update all nodes and regular menus.

Update Pointers

Create or update `Next', `Previous', and `Up' node pointers.

See section Updating Nodes and Menus.

C-c C-u C-n

M-x texinfo-update-node

> Update a node.

C-c C-u C-e

M-x texinfo-every-node-update

> Update every node in the buffer.

Update Menus

Create or update menus.

See section Updating Nodes and Menus.

C-c C-u C-m

M-x texinfo-make-menu

Make or update a menu.

C-c C-u C-a

M-x texinfo-all-menus-update

Make or update all the menus in a buffer. With C-u as a prefix argument, first update all the nodes.

Insert Title as Description

Insert a node's chapter or section title in the space for the description in a menu entry line; position point so you can edit the insert. (This command works somewhat differently than the other insertion commands, which insert only a predefined string.)

See section Inserting Frequently Used Commands.

C-c C-c C-d

Insert title.

Format for Info

Provide keybindings both for the Info formatting commands that are written in Emacs Lisp and for `makeinfo` that is written in C.

See section Formatting for Info.

Use the Emacs lisp `texinfo-format...` commands:

C-c C-e C-r

Format the region.

C-c C-e C-b

Format the buffer.

Use `makeinfo`:

C-c C-m C-r

Format the region.

C-c C-m C-b

Format the buffer.

C-c C-m C-l

Recenter the `makeinfo` output buffer.

C-c C-m C-k
: Kill the `makeinfo` formatting job.

Typeset and Print

Typeset and print Texinfo documents from within Emacs.

See section Formatting and Printing.

C-c C-t C-r
: Run TeX on the region.

C-c C-t C-b
: Run TeX on the buffer.

C-c C-t C-i
: Run `texindex`.

C-c C-t C-p
: Print the DVI file.

C-c C-t C-q
: Show the print queue.

C-c C-t C-d
: Delete a job from the print queue.

C-c C-t C-k
: Kill the current TeX formatting job.

C-c C-t C-x
: Quit a currently stopped TeX formatting job.

C-c C-t C-l
: Recenter the output buffer.

Other Updating Commands

The "other updating commands" do not have standard keybindings because they are used less frequently.

See section Other Updating Commands.

M-x texinfo-insert-node-lines
: Insert missing `@node` lines using section titles as node names.

M-x texinfo-multiple-files-update
: Update a multi-file document. With a numeric prefix, such as C-u 8, update **every** pointer and menu in **all** the files and then insert a master menu.

M-x texinfo-indent-menu-description
: Indent descriptions in menus.

M-x texinfo-sequential-node-update

Insert node pointers in strict sequence.

New Texinfo @-Commands

The second edition of the Texinfo manual describes more than 50 commands that were not described in the first edition. A third or so of these commands existed in Texinfo but were not documented in the manual; the others are new. Here is a listing, with brief descriptions of them:

Indexing

Create your own index, and merge indices.

See section Creating Indices.

@defindex index-name

Define a new index and its indexing command. See also the `@defcodeindex` command.

@synindex from-index into-index

Merge the from-index index into the into-index index. See also the `@syncodeindex` command.

Definitions

Describe functions, variables, macros, commands, user options, special forms, and other such artifacts in a uniform format.

See section Definition Commands.

@deffn category name arguments...

Format a description for functions, interactive commands, and similar entities.

@defvr, @defop, ...

15 other related commands.

Glyphs

Indicate the results of evaluation, expansion, printed output, an error message, equivalence of expressions, and the location of point.

See section Glyphs for Examples.

@equiv{}

==

Equivalence:

@error{}

error-->

Error message

@expansion{}
==>
: Macro expansion

@point{}
-!-
: Position of point

@print{}
-|
: Printed output

@result{}
=>
: Result of an expression

Page Headings

Customize page headings.

See section Page Headings.

@headings on-off-single-double
: Headings on or off, single, or double-sided.

@evenfooting [left] @| [center] @| [right]
: Footings for even-numbered (left-hand) pages.

@evenheading, @everyheading, @oddheading, ...
: Five other related commands.

@thischapter
: Insert name of chapter and chapter number.

@thischaptername, @thisfile, @thistitle, @thispage
: Related commands.

Formatting

Format blocks of text.

See section Quotations and Examples, and
section Making Lists and Tables.

@cartouche
: Draw rounded box surrounding text (not in Info).

@enumerate optional-arg
: Enumerate a list with letters or numbers.

@exdent line-of-text

Remove indentation.

@flushleft

Left justify.

@flushright

Right justify.

@format

Do not narrow nor change font.

@ftable formatting-command

@vtable formatting-command

Two-column table with indexing.

@lisp

For an example of Lisp code.

@smallexample

@smalllisp

Like @table and @lisp but for @smallbook.

Conditionals

Conditionally format text.

See section `@set`, `@clear`, and `@value`.

@set flag [string]

Set a flag. Optionally, set value of flag to string.

@clear flag

Clear a flag.

@value{flag}

Replace with value to which flag is set.

@ifset flag

Format, if flag is set.

@ifclear flag

Ignore, if flag is set.

@heading series for Titles

Produce unnumbered headings that do not appear in a table of contents.

See section Chapter Structuring.

@heading title

Unnumbered section-like heading not listed in the table of contents of a printed manual.

@chapheading, @majorheading, @subheading, @subsubheading

Related commands.

Font commands

See section @sc{text}: The Small Caps Font, and
section Fonts for Printing, Not Info.

@r{text}

Print in roman font.

@sc{text}

Print in SMALL CAPS font.

Miscellaneous

See section @title, @subtitle, and @author,
see section Overfull "hboxes",
see section Footnotes,
see section @dmn{dimension}: Format a Dimension,
see section @minus{}: Inserting a Minus Sign,
see section Paragraph Indenting,
see section Different Cross Reference Commands,
see section @title, @subtitle, and @author, and
see section How to Make Your Own Headings.

@author author

Typeset author's name.

@finalout

Produce cleaner printed output.

@footnotestyle

Specify footnote style.

@dmn{dimension}

Format a dimension.

@minus{}

Generate a minus sign.

@paragraphindent

Specify paragraph indentation.

@ref{node-name, [entry], [topic-or-title], [info-file], [manual]}

Make a reference. In the printed manual, the reference does not start with the word `see'.

@title title

Typeset title in the alternative title page format.

@subtitle subtitle

Typeset subtitle in the alternative title page format.

@today{}

Insert the current date.

Go to the previous, next section.

Go to the previous, next section.

Command and Variable Index

This is an alphabetical list of all the @-commands and several variables. To make the list easier to use, the commands are listed without their preceding `@'.

Texinfo

(1)

Note that the first syllable of "Texinfo" is pronounced like "speck", not "hex". This odd pronunciation is derived from, but is not the same as, the pronunciation of TeX. In the word TeX, the `X' is actually the Greek letter "chi" rather than the English letter "ex". Pronounce TeX as if the `X' were the last sound in the name `Bach'; but pronounce Texinfo as if the `x' were a `k'. Spell "Texinfo" with a capital "T" and write the other letters in lower case.

(2)

In some documents, the first child has no `Previous' pointer. Occasionally, the last child has the node name of the next following higher level node as its `Next' pointer.

(3)

You can also use the `texi2roff` program if you do not have TeX; since Texinfo is designed for use with TeX, `texi2roff` is not described here. `texi2roff` is part of the standard GNU distribution.

(4)

The word argument comes from the way it is used in mathematics and does not refer to a disputation between two people; it refers to the information presented to the command. According to the Oxford English Dictionary, the word derives from the Latin for to make clear, prove; thus it came to mean `the evidence offered as proof', which is to say, `the information offered', which led to its mathematical meaning. In its other thread of derivation, the word came to mean `to assert in a manner against which others may make counter assertions', which led to the meaning of `argument' as a disputation.

(5)

We have found that it is helpful to refer to versions of manuals as `editions' and versions of programs as `versions'; otherwise, we find we are liable to confuse each other in conversation by referring to both the documentation and the software with the same words.

(6)

Menus can carry you to any node, regardless of the hierarchical structure; even to nodes in a different Info file. However, the GNU Emacs Texinfo mode updating commands work only to create menus of subordinate nodes. Conventionally, cross references are used to refer to other nodes.

(7)

It would be straightforward to extend Texinfo to work in a similar fashion for C, FORTRAN, or other languages.

(8)

A footnote should complement or expand upon the primary text, but a reader should not need to read a footnote to understand the primary text. For a thorough discussion of footnotes, see The Chicago Manual of Style, which is published by the University of Chicago Press.

(9)

Here is the sample footnote.

(10)

If you use more than one index and have cross references to an index other than the first, you must run `tex` *three times* to get correct output: once to generate raw index data; again (after `texindex`) to output the text of the indices and determine their true page numbers; and a third time to output correct page numbers in cross references to them. However, cross references to indices are rare.

(11)

`--' has replaced `+', the old introductory character, to maintain POSIX.2 compatibility without losing long-named options.

(12)

Perhaps the command should have been called the `@refillandindent` command, but `@refill` is shorter and the name was chosen before indenting was possible.

GNU textutils

A set of text utilities

for version 1.19, 27 June 1996

David MacKenzie et al.

Go to the next section.

@defcodeindex op

Introduction

This manual is incomplete: No attempt is made to explain basic concepts in a way suitable for novices. Thus, if you are interested, please get involved in improving this manual. The entire GNU community will benefit.

The GNU text utilities are mostly compatible with the POSIX.2 standard.

Please report bugs to `bug-gnu-utils@prep.ai.mit.edu'. Remember to include the version number, machine architecture, input files, and any other information needed to reproduce the bug: your input, what you expected, what you got, and why it is wrong. Diffs are welcome, but please include a description of the problem as well, since this is sometimes difficult to infer. See section 'Bugs' in GNU CC.

This manual is based on the Unix man pages in the distribution, which were originally written by David MacKenzie and updated by Jim Meyering. The original `fmt` man page was written by Ross Paterson. Pinard did the initial conversion to Texinfo format. Karl Berry did the indexing, some reorganization, and editing of the results. Richard Stallman contributed his usual invaluable insights to the overall process.

Go to the next section.

Go to the previous, next section.

Common options

Certain options are available in all these programs. Rather than writing identical descriptions for each of the programs, they are described here. (In fact, every GNU program accepts (or should accept) these options.)

A few of these programs take arbitrary strings as arguments. In those cases, `--help' and `--version' are taken as these options only if there is one and exactly one command line argument.

`--help'

@opindex --help Print a usage message listing all available options, then exit successfully.

`--version'

@opindex --version Print the version number, then exit successfully.

Go to the previous, next section.

Go to the previous, next section.

TOC

Output of entire files

These commands read and write entire files, possibly transforming them in some way.

`cat`: Concatenate and write files

`cat` copies each file (`-' means standard input), or standard input if none are given, to standard output. Synopsis:

```
cat [option] [file]...
```

The program accepts the following options. Also see section Common options.

`-A'

`--show-all'

@opindex -A @opindex --show-all Equivalent to `-vET'.

`-b'

`--number-nonblank'

@opindex -b @opindex --number-nonblank Number all nonblank output lines, starting with 1.

`-e'

@opindex -e Equivalent to `-vE'.

`-E'

`--show-ends'

@opindex -E @opindex --show-ends Display a `$' after the end of each line.

`-n'

`--number'

@opindex -n @opindex --number Number all output lines, starting with 1.

`-s'

`--squeeze-blank'

@opindex -s @opindex --squeeze-blank Replace multiple adjacent blank lines with a single blank line.

`-t'

@opindex -t Equivalent to `-vT'.

`-T'

`--show-tabs'

@opindex -T @opindex --show-tabs Display TAB characters as `^I'.

`-u'

@opindex -u Ignored; for Unix compatibility.

`-v'

`--show-nonprinting'

@opindex -v @opindex --show-nonprinting Display control characters except for LFD and TAB using `^' notation and precede characters that have the high bit set with `M-'.

`tac`: Concatenate and write files in reverse

`tac` copies each file (`-' means standard input), or standard input if none are given, to standard output, reversing the records (lines by default) in each separately. Synopsis:

```
tac [option]... [file]...
```

Records are separated by instances of a string (newline by default). By default, this separator string is attached to the end of the record that it follows in the file.

The program accepts the following options. Also see section Common options.

`-b'

`--before'

@opindex -b @opindex --before The separator is attached to the beginning of the record that it precedes in the file.

`-r'

`--regex'

@opindex -r @opindex --regex Treat the separator string as a regular expression.

`-s separator'

`--separator=separator'

@opindex -s @opindex --separator Use separator as the record separator, instead of newline.

`nl`: Number lines and write files

`nl` writes each file (`-' means standard input), or standard input if none are given, to standard output, with line numbers added to some or all of the lines. Synopsis:

```
nl [option]... [file]...
```

`nl` decomposes its input into (logical) pages; by default, the line number is reset to 1 at the top of each logical page. `nl` treats all of the input files as a single document; it does not reset line numbers or logical pages between files.

A logical page consists of three sections: header, body, and footer. Any of the sections can be empty. Each can be numbered in a different style from the others.

The beginnings of the sections of logical pages are indicated in the input file by a line containing exa one of these delimiter strings:

`\:\:\:'

start of header;

`\:\:'

start of body;

`\:'

start of footer.

The two characters from which these strings are made can be changed from `\' and `:' via options (see below), but the pattern and length of each string cannot be changed.

A section delimiter is replaced by an empty line on output. Any text that comes before the first section delimiter string in the input file is considered to be part of a body section, so `nl` treats a file that contains no section delimiters as a single body section.

The program accepts the following options. Also see section Common options.

`-b style'

`--body-numbering=style'

@opindex -b @opindex --body-numbering Select the numbering style for lines in the body section of each logical page. When a line is not numbered, the current line number is not incremented, but the line number separator character is still prepended to the line. The styles are:

`a'

number all lines,

`t'

number only nonempty lines (default for body),

`n'

do not number lines (default for header and footer),

`pregexp'

number only lines that contain a match for regexp.

- -d cd
- --section-delimiter=cd @opindex -d @opindex --section-delimiter Set the section delimiter characters to cd; default is `\:'. If only c is given, the second remains `:'. (Remember to protect `\' or other metacharacters from shell expansion with quotes or extra backslashes.)
- -f style
- --footer-numbering=style @opindex -f @opindex --footer-numbering Analogous to `--body-numbering'.
- -h style
- --header-numbering=style @opindex -h @opindex --header-numbering Analogous to `--body-numbering'.

- -i number
- --page-increment=number @opindex -i @opindex --page-increment Increment line numbers by number (default 1).
- -l number
- --join-blank-lines=number @opindex -l @opindex --join-blank-lines Consider number (default 1) consecutive empty lines to be one logical line for numbering, and only number the last one. Where fewer than number consecutive empty lines occur, do not number them. An empty line is one that contains no characters, not even spaces or tabs.
- -n format
- --number-format=format @opindex -n @opindex --number-format Select the line numbering format (default is `rn`):

`ln'

@opindex ln format for `nl` left justified, no leading zeros;

`rn'

@opindex rn format for `nl` right justified, no leading zeros;

`rz'

@opindex rz format for `nl` right justified, leading zeros.

- -p
- --no-renumber @opindex -p @opindex --no-renumber Do not reset the line number at the start of a logical page.
- -s string
- --number-separator=string @opindex -s @opindex --number-separator Separate the line number from the text line in the output with string (default is TAB).
- -v number
- --starting-line-number=number @opindex -v @opindex --starting-line-number Set the initial line number on each logical page to number (default 1).
- -w number
- --number-width=number @opindex -w @opindex --number-width Use number characters for line numbers (default 6).

od: Write files in octal or other formats

`od` writes an unambiguous representation of each file (`-' means standard input), or standard input if none are given. Synopsis:

```
od [option]... [file]...
od -C [file] [[+]offset [[+]label]]
```

Each line of output consists of the offset in the input, followed by groups of data from the file. By default, `od` prints the offset in octal, and each group of file data is two bytes of input printed as a single

octal number.

The program accepts the following options. Also see section Common options.

`-A radix'

`--address-radix=radix'

@opindex -A @opindex --address-radix Select the base in which file offsets are printed. radix can be one of the following:

`d'

decimal;

`o'

octal;

`x'

hexadecimal;

`n'

none (do not print offsets).

The default is octal.

- -j bytes
- --skip-bytes=bytes @opindex -j @opindex --skip-bytes Skip bytes input bytes before formatting and writing. If bytes begins with `0x' or `0X', it is interpreted in hexadecimal; otherwise, if it begins with `0', in octal; otherwise, in decimal. Appending `b' multiplies bytes by 512, `k' by 1024, and `m' by 1048576.
- -N bytes
- --read-bytes=bytes @opindex -N @opindex --read-bytes Output at most bytes bytes of the input. Prefixes and suffixes on `bytes` are interpreted as for the `-j' option.
- -s [n]
- --strings[=n] @opindex -s @opindex --strings Instead of the normal output, output only string constants: at least n (3 by default) consecutive ASCII graphic characters, followed by a null (zero) byte.
- -t type
- --format=type @opindex -t @opindex --format Select the format in which to output the file data. type is a string of one or more of the below type indicator characters. If you include more than one type indicator character in a single type string, or use this option more than once, `od` writes one copy of each output line using each of the data types that you specified, in the order that you specified.

`a'

named character,

`c'

ASCII character or backslash escape,

`d'

signed decimal,

`f'

floating point,

`o'

octal,

`u'

unsigned decimal,

`x'

hexadecimal.

The type `a` outputs things like `sp' for space, `nl' for newline, and `nul' for a null (zero) byte. Type `c` outputs ` ', `\n', and `\0`, respectively.

Except for types `a' and `c', you can specify the number of bytes to use in interpreting each number in the given data type by following the type indicator character with a decimal integer. Alternately, you can specify the size of one of the C compiler's built-in data types by following the type indicator character with one of the following characters. For integers (`d', `o', `u', `x'):

`C'

char,

`S'

short,

`I'

int,

`L'

long.

For floating point (`f`):

F

float,

D

double,

L

long double.

- -v
- --output-duplicates @opindex -v @opindex --output-duplicates Output consecutive lines that are identical. By default, when two or more consecutive output lines would be identical, `od` outputs only the first line, and puts just an asterisk on the following line to indicate the elision.
- -w[n]
- --width[=n] @opindex -w @opindex --width Dump `n` input bytes per output line. This must be a multiple of the least common multiple of the sizes associated with the specified output types. If n is omitted, the default is 32. If this option is not given at all, the default is 16.

The next several options map the old, pre-POSIX format specification options to the corresponding

POSIX format specs. GNU `od` accepts any combination of old- and new-style options. Format specification options accumulate.

`-a'

@opindex -a Output as named characters. Equivalent to `-ta'.

`-b'

@opindex -b Output as octal bytes. Equivalent to `-toC'.

`-c'

@opindex -c Output as ASCII characters or backslash escapes. Equivalent to `-tc'.

`-d'

@opindex -d Output as unsigned decimal shorts. Equivalent to `-tu2'.

`-f'

@opindex -f Output as floats. Equivalent to `-tfF'.

`-h'

@opindex -h Output as hexadecimal shorts. Equivalent to `-tx2'.

`-i'

@opindex -i Output as decimal shorts. Equivalent to `-td2'.

`-l'

@opindex -l Output as decimal longs. Equivalent to `-td4'.

`-o'

@opindex -o Output as octal shorts. Equivalent to `-to2'.

`-x'

@opindex -x Output as hexadecimal shorts. Equivalent to `-tx2'.

`-C'

`--traditional'

@opindex --traditional Recognize the pre-POSIX non-option arguments that traditional `od` accepted. The following syntax:

```
od --traditional [file] [[+]offset[.][b] [[+]label[.][b]]]
```

can be used to specify at most one file and optional arguments specifying an offset and a pseudo-start address, label. By default, offset is interpreted as an octal number specifying how many input bytes to skip before formatting and writing. The optional trailing decimal point forces the interpretation of offset as a decimal number. If no decimal is specified and the offset begins with `0x' or `0X' it is interpreted as a hexadecimal number. If there is a trailing `b', the number of bytes skipped will be offset multiplied by 512. The label argument is interpreted just like offset, but it specifies an initial pseudo-address. The pseudo-addresses are displayed in parentheses following any normal address.

Go to the previous, next section.

Go to the previous, next section.

Formatting file contents

These commands reformat the contents of files.

`fmt`: Reformat paragraph text

`fmt` fills and joins lines to produce output lines of (at most) a given number of characters (75 by default). Synopsis:

```
fmt [option]... [file]...
```

`fmt` reads from the specified file arguments (or standard input if none are given), and writes to standard output.

By default, blank lines, spaces between words, and indentation are preserved in the output; successive input lines with different indentation are not joined; tabs are expanded on input and introduced on output.

`fmt` prefers breaking lines at the end of a sentence, and tries to avoid line breaks after the first word of a sentence or before the last word of a sentence. A sentence break is defined as either the end of a paragraph or a word ending in any of `.?!', followed by two spaces or end of line, ignoring any intervening parentheses or quotes. Like TeX, `fmt` reads entire "paragraphs" before choosing line breaks; the algorithm is a variant of that in "Breaking Paragraphs Into Lines" (Donald E. Knuth and Michael F. Plass, Software--Practice and Experience, 11 (1981), 1119--1184).

The program accepts the following options. Also see section Common options.

`-c'

`--crown-margin'

@opindex -c @opindex --crown-margin Crown margin mode: preserve the indentation of the first two lines within a paragraph, and align the left margin of each subsequent line with that of the second line.

`-t'

`--tagged-paragraph'

@opindex -t @opindex --tagged-paragraph Tagged paragraph mode: like crown margin mode, except that if indentation of the first line of a paragraph is the same as the indentation of the second, the first line is treated as a one-line paragraph.

`-s'

`--split-only'

@opindex -s @opindex --split-only Split lines only. Do not join short lines to form longer ones. This prevents sample lines of code, and other such "formatted" text from being unduly combined.

`-u'

`--uniform-spacing'

@opindex -u @opindex --uniform-spacing Uniform spacing. Reduce spacing between words to one space, and spacing between sentences to two spaces.

`-width'

`-w width'

`--width=width'

@opindex -width @opindex -w @opindex --width Fill output lines up to width characters (default 75). `fmt` initially tries to make lines about 7% shorter than this, to give it room to balance line lengths.

`-p prefix'

`--prefix=prefix'

Only lines beginning with prefix (possibly preceded by whitespace) are subject to formatting. The prefix and any preceding whitespace are stripped for the formatting and then re-attached to each formatted output line. One use is to format certain kinds of program comments, while leaving the code unchanged.

`pr`: Paginate or columnate files for printing

`pr` writes each file (`-' means standard input), or standard input if none are given, to standard output, paginating and optionally outputting in multicolumn format. Synopsis:

```
pr [option]... [file]...
```

By default, a 5-line header is printed: two blank lines; a line with the date, the file name, and the page count; and two more blank lines. A five line footer (entirely) is also printed.

Form feeds in the input cause page breaks in the output.

The program accepts the following options. Also see section Common options.

`+page'

Begin printing with page page.

`-column'

@opindex -column Produce column-column output and print columns down. The column width is automatically decreased as column increases; unless you use the `-w' option to increase the page width as well, this option might well cause some input to be truncated.

`-a'

@opindex -a Print columns across rather than down.

`-b'

@opindex -b Balance columns on the last page.

`-c'

@opindex -c Print control characters using hat notation (e.g., `^G'); print other unprintable

characters in octal backslash notation. By default, unprintable characters are not changed.

`-d'

@opindex -d Double space the output.

`-e[in-tabchar[in-tabwidth]]'

@opindex -e Expand tabs to spaces on input. Optional argument in-tabchar is the input tab character (default is TAB). Second optional argument in-tabwidth is the input tab character's width (default is 8).

`-f'

`-F'

@opindex -F @opindex -f Use a formfeed instead of newlines to separate output pages.

`-h header'

@opindex -h Replace the file name in the header with the string header.

`-i[out-tabchar[out-tabwidth]]'

@opindex -i Replace spaces with tabs on output. Optional argument out-tabchar is the output tab character (default is TAB). Second optional argument out-tabwidth is the output tab character's width (default is 8).

`-l n'

@opindex -l Set the page length to n (default 66) lines. If n is less than 10, the headers and footers are omitted, as if the `-t' option had been given.

`-m'

@opindex -m Print all files in parallel, one in each column.

`-n[number-separator[digits]]'

@opindex -n Precede each column with a line number; with parallel files (`-m'), precede each line with a line number. Optional argument number-separator is the character to print after each number (default is TAB). Optional argument digits is the number of digits per line number (default is 5).

`-o n'

@opindex -o Indent each line with n (default is zero) spaces wide, i.e., set the left margin. The total page width is `n' plus the width set with the `-w' option.

`-r'

@opindex -r Do not print a warning message when an argument file cannot be opened. (The exit status will still be nonzero, however.)

`-s[c]'

@opindex -s Separate columns by the single character c. If c is omitted, the default is space; if this option is omitted altogether, the default is TAB.

`-t'

@opindex -t Do not print the usual 5-line header and the 5-line footer on each page, and do not fill out the bottoms of pages (with blank lines or formfeeds).

`-v'

@opindex -v Print unprintable characters in octal backslash notation.

`-w n'

@opindex -w Set the page width to n (default is 72) columns.

`fold`: Wrap input lines to fit in specified width

`fold` writes each file (`-' means standard input), or standard input if none are given, to standard output, breaking long lines. Synopsis:

```
fold [option]... [file]...
```

By default, `fold` breaks lines wider than 80 columns. The output is split into as many lines as necessary.

`fold` counts screen columns by default; thus, a tab may count more than one column, backspace decreases the column count, and carriage return sets the column to zero.

The program accepts the following options. Also see section Common options.

`-b'

`--bytes'

@opindex -b @opindex --bytes Count bytes rather than columns, so that tabs, backspaces, and carriage returns are each counted as taking up one column, just like other characters.

`-s'

`--spaces'

@opindex -s @opindex --spaces Break at word boundaries: the line is broken after the last blank before the maximum line length. If the line contains no such blanks, the line is broken at the maximum line length as usual.

`-w width'

`--width=width'

@opindex -w @opindex --width Use a maximum line length of width columns instead of 80.

Go to the previous, next section.

Go to the previous, next section.

Output of parts of files

These commands output pieces of the input.

head: Output the first part of files

`head` prints the first part (10 lines by default) of each file; it reads from standard input if no files are given or when given a file of `-'. Synopses:

```
head [option]... [file]...
head -number [option]... [file]...
```

If more than one file is specified, `head` prints a one-line header consisting of

```
==> file name <==
```

before the output for each file.

`head` accepts two option formats: the new one, in which numbers are arguments to the options (`-q -n 1'), and the old one, in which the number precedes any option letters (`-1q').

The program accepts the following options. Also see section Common options.

`-countoptions'

@opindex -count This option is only recognized if it is specified first. count is a decimal number optionally followed by a size letter (`b', `k', `m') as in `-c`, or `l' to mean count by lines, or other option letters (`cqv').

`-c bytes'

`--bytes=bytes'

@opindex -c @opindex --bytes Print the first bytes bytes, instead of initial lines. Appending `b' multiplies bytes by 512, `k' by 1024, and `m' by 1048576.

`-n n'

`--lines=n'

@opindex -n @opindex --lines Output the first n lines.

`-q'

`--quiet'

`--silent'

@opindex -q @opindex --quiet @opindex --silent Never print file name headers.

`-v'

`--verbose'

@opindex -v @opindex --verbose Always print file name headers.

`tail`: Output the last part of files

`tail` prints the last part (10 lines by default) of each file; it reads from standard input if no files are given or when given a file of `-'. Synopses:

```
tail [option]... [file]...
tail -number [option]... [file]...
tail +number [option]... [file]...
```

If more than one file is specified, `tail` prints a one-line header consisting of

```
==> file name <==
```

before the output for each file.

GNU `tail` can output any amount of data (some other versions of `tail` cannot). It also has no `-r' option (print in reverse), since reversing a file is really a different job from printing the end of a file; BSD `tail` (which is the one with `-r`) can only reverse files that are at most as large as its buffer, which is typically 32k. A more reliable and versatile way to reverse files is the GNU `tac` command.

`tail` accepts two option formats: the new one, in which numbers are arguments to the options (`-n 1'), and the old one, in which the number precedes any option letters (`-1' or `+1').

If any option-argument is a number n starting with a `+', `tail` begins printing with the nth item from the start of each file, instead of from the end.

The program accepts the following options. Also see section Common options.

`-count'

`+count'

@opindex -count @opindex +count This option is only recognized if it is specified first. count is a decimal number optionally followed by a size letter (`b', `k', `m') as in `-c`, or `l' to mean count by lines, or other option letters (`cfqv').

`-c bytes'

`--bytes=bytes'

@opindex -c @opindex --bytes Output the last bytes bytes, instead of final lines. Appending `b' multiplies bytes by 512, `k' by 1024, and `m' by 1048576.

`-f'

`--follow'

@opindex -f @opindex --follow Loop forever trying to read more characters at the end of the file, presumably because the file is growing. Ignored if reading from a pipe. If more than one file is given, `tail` prints a header whenever it gets output from a different file, to indicate which file that output is from.

`-n n'

`--lines=n'

@opindex -n @opindex --lines Output the last n lines.

`-q'

`-quiet'

`--silent'

@opindex -q @opindex --quiet @opindex --silent Never print file name headers.

`-v'

`--verbose'

@opindex -v @opindex --verbose Always print file name headers.

`split`: Split a file into fixed-size pieces

`split` creates output files containing consecutive sections of input (standard input if none is given or input is `-'). Synopsis:

```
split [option] [input [prefix]]
```

By default, `split` puts 1000 lines of input (or whatever is left over for the last section), into each output file.

The output files' names consist of prefix (`x' by default) followed by a group of letters `aa', `ab', and so on, such that concatenating the output files in sorted order by file name produces the original input file. (If more than 676 output files are required, `split` uses `zaa', `zab', etc.)

The program accepts the following options. Also see section Common options.

`-lines'

`-l lines'

`--lines=lines'

@opindex -l @opindex --lines Put lines lines of input into each output file.

`-b bytes'

`--bytes=bytes'

@opindex -b @opindex --bytes Put the first bytes bytes of input into each output file. Appending `b' multiplies bytes by 512, `k' by 1024, and `m' by 1048576.

`-C bytes'

`--line-bytes=bytes'

@opindex -C @opindex --line-bytes Put into each output file as many complete lines of input as possible without exceeding bytes bytes. For lines longer than bytes bytes, put bytes bytes into each output file until less than bytes bytes of the line are left, then continue normally. bytes has the same format as for the `--bytes' option.

`--verbose=bytes'

@opindex --verbose Write a diagnostic to standard error just before each output file is opened.

`csplit`: Split a file into context-determined pieces

`csplit` creates zero or more output files containing sections of input (standard input if input is `-'). Synopsis:

```
csplit [option]... input pattern...
```

The contents of the output files are determined by the pattern arguments, as detailed below. An error occurs if a pattern argument refers to a nonexistent line of the input file (e.g., if no remaining line matches a given regular expression). After every pattern has been matched, any remaining input is copied into one last output file.

By default, `csplit` prints the number of bytes written to each output file after it has been created.

The types of pattern arguments are:

`n'

Create an output file containing the input up to but not including line n (a positive integer). If followed by a repeat count, also create an output file containing the next line lines of the input file once for each repeat.

`/regexp/[offset]'

Create an output file containing the current line up to (but not including) the next line of the input file that contains a match for regexp. The optional offset is a `+' or `-' followed by a positive integer. If it is given, the input up to the matching line plus or minus offset is put into the output file, and the line after that begins the next section of input.

`%regexp%[offset]'

Like the previous type, except that it does not create an output file, so that section of the input file is effectively ignored.

`{repeat-count}'

Repeat the previous pattern repeat-count additional times. repeat-count can either be a positive integer or an asterisk, meaning repeat as many times as necessary until the input is exhausted.

The output files' names consist of a prefix (`xx' by default) followed by a suffix. By default, the suffix is an ascending sequence of two-digit decimal numbers from `00' and up to `99'. In any case, concatenating the output files in sorted order by filename produces the original input file.

By default, if `csplit` encounters an error or receives a hangup, interrupt, quit, or terminate signal, it removes any output files that it has created so far before it exits.

The program accepts the following options. Also see section Common options.

`-f prefix'

`--prefix=prefix'

@opindex -f @opindex --prefix Use prefix as the output file name prefix.

`-b suffix'

`--suffix=suffix'

@opindex -b @opindex --suffix Use suffix as the output file name suffix. When this option is specified, the suffix string must include exactly one `printf(3)`-style conversion specification, possibly including format specification flags, a field width, a precision specifications, or all of these kinds of modifiers. The format letter must convert a binary integer argument to readable form; thus, only `d', `i', `u', `o', `x', and `X' conversions are allowed. The entire suffix is given (with the current output file number) to `sprintf(3)` to form the file name suffixes for each of the individual output files in turn. If this option is used, the `--digits' option is ignored.

`-n digits'

`--digits=digits'

@opindex -n @opindex --digits Use output file names containing numbers that are digits digits long instead of the default 2.

`-k'

`--keep-files'

@opindex -k @opindex --keep-files Do not remove output files when errors are encountered.

`-z'

`--elide-empty-files'

@opindex -z @opindex --elide-empty-files Suppress the generation of zero-length output files. (In cases where the section delimiters of the input file are supposed to mark the first lines of each of the sections, the first output file will generally be a zero-length file unless you use this option.) The output file sequence numbers always run consecutively starting from 0, even when this option is specified.

`-s'

`-q'

`--silent'

`--quiet'

@opindex -s @opindex -q @opindex --silent @opindex --quiet Do not print counts of output file sizes.

Go to the previous, next section.

Go to the previous, next section.

Summarizing files

These commands generate just a few numbers representing entire contents of files.

wc: Print byte, word, and line counts

`wc` counts the number of bytes, whitespace-separated words, and newlines in each given file, or standard input if none are given or for a file of `-'. Synopsis:

```
wc [option]... [file]...
```

`wc` prints one line of counts for each file, and if the file was given as an argument, it prints the file name following the counts. If more than one file is given, `wc` prints a final line containing the cumulative counts, with the file name `total'. The counts are printed in this order: newlines, words, bytes.

By default, `wc` prints all three counts. Options can specify that only certain counts be printed. Options do not undo others previously given, so

```
wc --bytes --words
```

prints both the byte counts and the word counts.

The program accepts the following options. Also see section Common options.

`-c'

`--bytes'

`--chars'

@opindex -c @opindex --bytes @opindex --chars Print only the byte counts.

`-w'

`--words'

@opindex -w @opindex --words Print only the word counts.

`-l'

`--lines'

@opindex -l @opindex --lines Print only the newline counts.

sum: Print checksum and block counts

`sum` computes a 16-bit checksum for each given file, or standard input if none are given or for a file of `-'. Synopsis:

```
sum [option]... [file]...
```

`sum` prints the checksum for each file followed by the number of blocks in the file (rounded up). If more than one file is given, file names are also printed (by default). (With the `--sysv' option, corresponding file name are printed when there is at least one file argument.)

By default, GNU `sum` computes checksums using an algorithm compatible with BSD `sum` and prints file sizes in units of 1024-byte blocks.

The program accepts the following options. Also see section Common options.

`-r'

@opindex -r Use the default (BSD compatible) algorithm. This option is included for compatibility with the System V `sum`. Unless `-s' was also given, it has no effect.

`-s'

`--sysv'

@opindex -s @opindex --sysv Compute checksums using an algorithm compatible with System V `sum`'s default, and print file sizes in units of 512-byte blocks.

`sum` is provided for compatibility; the `cksum` program (see next section) is preferable in new applications.

`cksum`: Print CRC checksum and byte counts

`cksum` computes a cyclic redundancy check (CRC) checksum for each given file, or standard input if none are given or for a file of `-'. Synopsis:

```
cksum [option]... [file]...
```

`cksum` prints the CRC checksum for each file along with the number of bytes in the file, and the filename unless no arguments were given.

`cksum` is typically used to ensure that files transferred by unreliable means (e.g., netnews) have not been corrupted, by comparing the `cksum` output for the received files with the `cksum` output for the original files (typically given in the distribution).

The CRC algorithm is specified by the POSIX.2 standard. It is not compatible with the BSD or System V `sum` algorithms (see the previous section); it is more robust.

The only options are `--help' and `--version'. See section Common options.

`md5sum`: Print or check message-digests

`md5sum` computes a 128-bit checksum (or fingerprint or message-digest) for each specified file. If a file is specified as `-' or if no files are given `md5sum` computes the checksum for the standard input. `md5sum` can also determine whether a file and checksum are consistent. Synopsis:

```
md5sum [option]... [file]...
md5sum [option]... --check [file]
md5sum [option]... --string=string ...
```

For each file, `md5sum' outputs the MD5 checksum, a flag indicating a binary or text input file, and the filename. If file is omitted or specified as `-', standard input is read.

The program accepts the following options. Also see section Common options.

`-b'

`--binary'

@opindex -b @opindex --binary Treat all input files as binary. This option has no effect on Unix systems, since they don't distinguish between binary and text files. This option is useful on systems that have different internal and external character representations.

`-c'

`--check'

Read filenames and checksum information from the single file (or from stdin if no file was specified) and report whether each named file and the corresponding checksum data are consistent. The input to this mode of `md5sum` is usually the output of a prior, checksum-generating run of `md5sum'. Each valid line of input consists of an MD5 checksum, a binary/text flag, and then a filename. Binary files are marked with `*', text with ` '. For each such line, `md5sum` reads the named file and computes its MD5 checksum. Then, if the computed message digest does not match the one on the line with the filename, the file is noted as having failed the test. Otherwise, the file passes the test. By default, for each valid line, one line is written to standard output indicating whether the named file passed the test. After all checks have been performed, if there were any failures, a warning is issued to standard error. Use the `--status' option to inhibit that output. If any listed file cannot be opened or read, if any valid line has an MD5 checksum inconsistent with the associated file, or if no valid line is found, `md5sum` exits with nonzero status. Otherwise, it exits successfully.

`--status'

@opindex --status This option is useful only when verifying checksums. When verifying checksums, don't generate the default one-line-per-file diagnostic and don't output the warning summarizing any failures. Failures to open or read a file still evoke individual diagnostics to standard error. If all listed files are readable and are consistent with the associated MD5 checksums, exit successfully. Otherwise exit with a status code indicating there was a failure.

`--string=string'

@opindex --string Compute the message digest for string, instead of for a file. The result is the same as for a file that contains exactly string.

`-t'

`--text'

@opindex -t @opindex --text Treat all input files as text files. This is the reverse of `--binary'.

`-w'

`--warn'

@opindex -w @opindex --warn When verifying checksums, warn about improperly formated MD5 checksum lines. This option is useful only if all but a few lines in the checked input are valid.

Go to the previous, next section.

Go to the previous, next section.

Operating on sorted files

These commands work with (or produce) sorted files.

`sort`: Sort text files

`sort` sorts, merges, or compares all the lines from the given files, or standard input if none are given or for a file of `-'. By default, `sort` writes the results to standard output. Synopsis:

```
sort [option]... [file]...
```

`sort` has three modes of operation: sort (the default), merge, and check for sortedness. The following options change the operation mode:

`-c'

@opindex -c Check whether the given files are already sorted: if they are not all sorted, print an error message and exit with a status of 1. Otherwise, exit successfully.

`-m'

@opindex -m Merge the given files by sorting them as a group. Each input file must always be individually sorted. It always works to sort instead of merge; merging is provided because it is faster, in the case where it works.

A pair of lines is compared as follows: if any key fields have been specified, `sort` compares each pair of fields, in the order specified on the command line, according to the associated ordering options, until a difference is found or no fields are left.

If any of the global options `Mbdfinr' are given but no key fields are specified, `sort` compares the entire lines according to the global options.

Finally, as a last resort when all keys compare equal (or if no ordering options were specified at all), `sort` compares the lines byte by byte in machine collating sequence. The last resort comparison honors the `-r' global option. The `-s' (stable) option disables this last-resort comparison so that lines in which all fields compare equal are left in their original relative order. If no fields or global options are specified, `-s' has no effect.

GNU `sort` (as specified for all GNU utilities) has no limits on input line length or restrictions on bytes allowed within lines. In addition, if the final byte of an input file is not a newline, GNU `sort` silently supplies one.

Upon any error, `sort` exits with a status of `2'.

If the environment variable `TMPDIR` is set, `sort` uses its value as the directory for temporary files instead of `/tmp'. The `-T tempdir' option in turn overrides the environment variable.

The following options affect the ordering of output lines. They may be specified globally or as part of a

specific key field. If no key fields are specified, global options apply to comparison of entire lines; otherwise the global options are inherited by key fields that do not specify any special options of their c

`-b'

@opindex -b Ignore leading blanks when finding sort keys in each line.

`-d'

@opindex -d Sort in phone directory order: ignore all characters except letters, digits and blanks when sorting.

`-f'

@opindex -f Fold lowercase characters into the equivalent uppercase characters when sorting so that, for example, `b' and `B' sort as equal.

`-g'

@opindex -g Sort numerically, but use strtod(3) to arrive at the numeric values. This allows floating point numbers to be specified in scientific notation, like `1.0e-34` and `10e100`. Use this option only if there is no alternative; it is much slower than `-n' and numbers with too many significant digits will be compared as if they had been truncated. In addition, numbers outside the range of representable double precision floating point numbers are treated as if they were zeroes; overflow and underflow are not reported.

`-i'

@opindex -i Ignore characters outside the printable ASCII range 040-0176 octal (inclusive) when sorting.

`-M'

@opindex -M An initial string, consisting of any amount of whitespace, followed by three letters abbreviating a month name, is folded to UPPER case and compared in the order `JAN' < `FEB' < ... < `DEC'. Invalid names compare low to valid names.

`-n'

@opindex -n Sort numerically: the number begins each line; specifically, it consists of optional whitespace, an optional `-' sign, and zero or more digits, optionally followed by a decimal point and zero or more digits.

`sort -n` uses what might be considered an unconventional method to compare strings representing floating point numbers. Rather than first converting each string to the C `double` type and then comparing those values, sort aligns the decimal points in the two strings and compares the strings a character at a time. One benefit of using this approach is its speed. In practice this is much more efficient than performing the two corresponding string-to-double (or even string-to-integer) conversions and then comparing doubles. In addition, there is no corresponding loss of precision. Converting each string to `double` before comparison would limit precision to about 16 digits on most systems.

Neither a leading `+' nor exponential notation is recognized. To compare such strings numerically, use the `-g' option.

`-r'

@opindex -r Reverse the result of comparison, so that lines with greater key values appear earlier in the output instead of later.

Other options are:

`-o output-file'

@opindex -o Write output to output-file instead of standard output. If output-file is one of the input files, `sort` copies it to a temporary file before sorting and writing the output to output-file.

`-t separator'

@opindex -t Use character separator as the field separator when finding the sort keys in each line. By default, fields are separated by the empty string between a non-whitespace character and a whitespace character. That is, given the input line ` foo bar', `sort` breaks it into fields ` foo' and ` bar'. The field separator is not considered to be part of either the field preceding or the field following.

`-u'

@opindex -u For the default case or the `-m' option, only output the first of a sequence of lines that compare equal. For the `-c' option, check that no pair of consecutive lines compares equal.

`-k pos1[,pos2]'

@opindex -k The recommended, POSIX, option for specifying a sort field. The field consists of the line between pos1 and pos2 (or the end of the line, if pos2 is omitted), inclusive. Fields and character positions are numbered starting with 1. See below.

`-z'

@opindex -z Treat the input as a set of lines, each terminated by a zero byte (ASCII NUL (Null) character) instead of a ASCII LF (Line Feed.) This option can be useful in conjunction with `perl -0' or `find -print0' and `xargs -0' which do the same in order to reliably handle arbitrary pathnames (even those which contain Line Feed characters.)

`+pos1[-pos2]'

The obsolete, traditional option for specifying a sort field. The field consists of the line between pos1 and up to but *not including* pos2 (or the end of the line if pos2 is omitted). Fields and character positions are numbered starting with 0. See below.

In addition, when GNU `sort` is invoked with exactly one argument, options `--help' and `--version' are recognized. See section Common options.

Historical (BSD and System V) implementations of `sort` have differed in their interpretation of some options, particularly `-b', `-f', and `-n'. GNU sort follows the POSIX behavior, which is usually (but not always!) like the System V behavior. According to POSIX, `-n' no longer implies `-b'. For consistency, `-M' has been changed in the same way. This may affect the meaning of character positions in field specifications in obscure cases. The only fix is to add an explicit `-b'.

A position in a sort field specified with the `-k' or `+' option has the form `f.c', where f is the number of the field to use and c is the number of the first character from the beginning of the field (for `+pos') or from the end of the previous field (for `-pos'). If the `.c' is omitted, it is taken to be the first character in the field. If the `-b' option was specified, the `.c' part of a field specification is counted from the first nonblank character of the field (for `+pos') or from the first nonblank character following the previous field (for `-pos').

A sort key option may also have any of the option letters `Mbdfinr' appended to it, in which case the global ordering options are not used for that particular field. The `-b' option may be independently attached to either or both of the `+pos' and `-pos' parts of a field specification, and if it is inherited from the global options it will be attached to both. If a `-n' or `-M' option is used, thus implying a `-b' option, the `-b' option

is taken to apply to both the `+pos' and the `-pos' parts of a key specification. Keys may span multiple fields.

Here are some examples to illustrate various combinations of options. In them, the POSIX `-k' option is used to specify sort keys rather than the obsolete `+pos1-pos2' syntax.

- Sort in descending (reverse) numeric order.

  ```
  sort -nr
  ```

  Sort alphabetically, omitting the first and second fields. This uses a single key composed of the characters beginning at the start of field three and extending to the end of each line.

  ```
  sort -k3
  ```

- Sort numerically on the second field and resolve ties by sorting alphabetically on the third and fourth characters of field five. Use `:' as the field delimiter.

  ```
  sort -t : -k 2,2n -k 5.3,5.4
  ```

  Note that if you had written `-k 2' instead of `-k 2,2' `sort' would have used all characters beginning in the second field and extending to the end of the line as the primary *numeric* key. For the large majority of applications, treating keys spanning more than one field as numeric will not do what you expect.

  Also note that the `n' modifier was applied to the field-end specifier for the first key. It would have been equivalent to specify `-k 2n,2' or `-k 2n,2n'. All modifiers except `b' apply to the associated *field*, regardless of whether the modifier character is attached to the field-start and/or the field-end part of the key specifier.

- Sort the password file on the fifth field and ignore any leading white space. Sort lines with equal values in field five on the numeric user ID in field three.

  ```
  sort -t : -k 5b,5 -k 3,3n /etc/passwd
  ```

  An alternative is to use the global numeric modifier `-n'.

  ```
  sort -t : -n -k 5b,5 -k 3,3 /etc/passwd
  ```

- Generate a tags file in case insensitive sorted order.

  ```
  find src -type f -print0 | sort -t / -z -f | xargs -0 etags --append
  ```

  The use of `-print0', `-z', and `-0' in this case mean that pathnames that contain Line Feed characters will not get broken up by the sort operation.

  Finally, to ignore both leading and trailing white space, you could have applied the `b' modifier to the field-end specifier for the first key,

  ```
  sort -t : -n -k 5b,5b -k 3,3 /etc/passwd
  ```

or by using the global `-b' modifier instead of `-n' and an explicit `n' with the second key specifie

```
sort -t : -b -k 5,5 -k 3,3n /etc/passwd
```

uniq: Uniqify files

`uniq` writes the unique lines in the given `input', or standard input if nothing is given or for an input name of `-'. Synopsis:

```
uniq [option]... [input [output]]
```

By default, `uniq` prints the unique lines in a sorted file, i.e., discards all but one of identical successive lines. Optionally, it can instead show only lines that appear exactly once, or lines that appear more than once.

The input must be sorted. If your input is not sorted, perhaps you want to use `sort -u`.

If no output file is specified, `uniq` writes to standard output.

The program accepts the following options. Also see section Common options.

`-n'

`-f n'

`--skip-fields=n'

@opindex -n @opindex -f @opindex --skip-fields Skip n fields on each line before checking for uniqueness. Fields are sequences of non-space non-tab characters that are separated from each other by at least one spaces or tabs.

`+n'

`-s n'

`--skip-chars=n'

@opindex +n @opindex -s @opindex --skip-chars Skip n characters before checking for uniqueness. If you use both the field and character skipping options, fields are skipped over first.

`-c'

`--count'

@opindex -c @opindex --count Print the number of times each line occurred along with the line.

`-i'

`--ignore-case'

@opindex -i @opindex --ignore-case Ignore differences in case when comparing lines.

`-d'

`--repeated'

@opindex -d @opindex --repeated Print only duplicate lines.

`-u'

`--unique'

@opindex -u @opindex --unique Print only unique lines.

`-w n'

`--check-chars=n'

@opindex -w @opindex --check-chars Compare n characters on each line (after skipping any specified fields and characters). By default the entire rest of the lines are compared.

comm: Compare two sorted files line by line

`comm` writes to standard output lines that are common, and lines that are unique, to two input files; a file name of `-' means standard input. Synopsis:

```
comm [option]... file1 file2
```

The input files must be sorted before `comm` can be used.

With no options, `comm` produces three column output. Column one contains lines unique to file1, column two contains lines unique to file2, and column three contains lines common to both files. Columns are separated by TAB.

@opindex -1 @opindex -2 @opindex -3 The options `-1', `-2', and `-3' suppress printing of the corresponding columns. Also see section Common options.

Go to the previous, next section.

Go to the previous, next section.

Operating on fields within a line

`cut`: Print selected parts of lines

`cut` writes to standard output selected parts of each line of each input file, or standard input if no files are given or for a file name of `-'. Synopsis:

```
cut [option]... [file]...
```

In the table which follows, the byte-list, character-list, and field-list are one or more numbers or ranges (two numbers separated by a dash) separated by commas. Bytes, characters, and fields are numbered from starting at 1. Incomplete ranges may be given: `-m' means `1-m'; `n-' means `n' through end of line or last field.

The program accepts the following options. Also see section Common options.

`-b byte-list'

`--bytes=byte-list'

@opindex -b @opindex --bytes Print only the bytes in positions listed in byte-list. Tabs and backspaces are treated like any other character; they take up 1 byte.

`-c character-list'

`--characters=character-list'

@opindex -c @opindex --characters Print only characters in positions listed in character-list. The same as `-b' for now, but internationalization will change that. Tabs and backspaces are treated like any other character; they take up 1 character.

`-f field-list'

`--fields=field-list'

@opindex -f @opindex --fields Print only the fields listed in field-list. Fields are separated by a TAB by default.

`-d delim'

`--delimiter=delim'

@opindex -d @opindex --delimiter For `-f', fields are separated by the first character in delim (default is TAB).

`-n'

@opindex -n Do not split multi-byte characters (no-op for now).

`-s'

`--only-delimited'

@opindex -s @opindex --only-delimited For `-f', do not print lines that do not contain the field

separator character.

`paste`: Merge lines of files

`paste` writes to standard output lines consisting of sequentially corresponding lines of each given file, separated by TAB. Standard input is used for a file name of `-' or if no input files are given.

Synopsis:

```
paste [option]... [file]...
```

The program accepts the following options. Also see section Common options.

`-s'

`--serial'

@opindex -s @opindex --serial Paste the lines of one file at a time rather than one line from each file.

`-d delim-list'

`--delimiters delim-list'

@opindex -d @opindex --delimiters Consecutively use the characters in delim-list instead of TAB to separate merged lines. When delim-list is exhausted, start again at its beginning.

`join`: Join lines on a common field

`join` writes to standard output a line for each pair of input lines that have identical join fields. Synopsis:

```
join [option]... file1 file2
```

Either file1 or file2 (but not both) can be `-', meaning standard input. file1 and file2 should be already sorted in increasing order (not numerically) on the join fields; unless the `-t' option is given, they should be sorted ignoring blanks at the start of the join field, as in `sort -b`. If the `--ignore-case' option is given, lines should be sorted without regard to the case of characters in the join field, as in `sort -f`.

The defaults are: the join field is the first field in each line; fields in the input are separated by one or more blanks, with leading blanks on the line ignored; fields in the output are separated by a space; each output line consists of the join field, the remaining fields from file1, then the remaining fields from file2.

The program accepts the following options. Also see section Common options.

`-a file-number'

@opindex -a Print a line for each unpairable line in file file-number (either `1' or `2'), in addition to the normal output.

`-e string'

@opindex -e Replace those output fields that are missing in the input with string.

`-i'

`--ignore-case'

@opindex -i @opindex --ignore-case Ignore differences in case when comparing keys. With this option, the lines of the input files must be ordered in the same way. Use `sort -f' to produce this ordering.

`-1 field'

`-j1 field'

@opindex -1 @opindex -j1 Join on field field (a positive integer) of file 1.

`-2 field'

`-j2 field'

@opindex -2 @opindex -j2 Join on field field (a positive integer) of file 2.

`-j field'

Equivalent to `-1 field -2 field'.

`-o field-list...'

Construct each output line according to the format in field-list. Each element in field-list is either the single character `0' or has the form m.n where the file number, m, is `1' or `2' and n is a positive field number.

A field specification of `0' denotes the join field. In most cases, the functionality of the `0' field spec may be reproduced using the explicit m.n that corresponds to the join field. However, when printing unpairable lines (using either of the `-a' or `-v' options), there is no way to specify the join field using m.n in field-list if there are unpairable lines in both files. To give `join` that functionality, POSIX invented the `0' field specification notation.

The elements in field-list are separated by commas or blanks. Multiple field-list arguments can be given after a single `-o' option; the values of all lists given with `-o' are concatenated together. All output lines -- including those printed because of any -a or -v option -- are subject to the specified field-list.

`-t char'

Use character char as the input and output field separator.

`-v file-number'

Print a line for each unpairable line in file file-number (either `1' or `2'), instead of the normal output.

In addition, when GNU `join` is invoked with exactly one argument, options `--help' and `--version' are recognized. See section Common options.

Go to the previous, next section.

Go to the previous, next section.

Operating on characters

This commands operate on individual characters.

`tr`: Translate, squeeze, and/or delete characters

Synopsis:

```
tr [option]... set1 [set2]
```

`tr` copies standard input to standard output, performing one of the following operations:

- translate, and optionally squeeze repeated characters in the result,
- squeeze repeated characters,
- delete characters,
- delete characters, then squeeze repeated characters from the result.

The set1 and (if given) set2 arguments define ordered sets of characters, referred to below as set1 and set2. These sets are the characters of the input that `tr` operates on. The `--complement' (`-c') option replaces set1 with its complement (all of the characters that are not in set1).

Specifying sets of characters

The format of the set1 and set2 arguments resembles the format of regular expressions; however, they are not regular expressions, only lists of characters. Most characters simply represent themselves in these strings, but the strings can contain the shorthands listed below, for convenience. Some of them can be used only in set1 or set2, as noted below.

Backslash escapes.

A backslash followed by a character not listed below causes an error message.

`\a'
: Control-G,

`\b'
: Control-H,

`\f'
: Control-L,

`\n'
: Control-J,

`\r'

Control-M,

`\t'

Control-I,

`\v'

Control-K,

`\ooo'

The character with the value given by ooo, which is 1 to 3 octal digits,

`\\'

A backslash.

- Ranges.

The notation `m-n' expands to all of the characters from m through n, in ascending order. m should collate before n; if it doesn't, an error results. As an example, `0-9' is the same as `0123456789'. Although GNU `tr` does not support the System V syntax that uses square brackets to enclose ranges, translations specified in that format will still work as long as the brackets in string1 correspond to identical brackets in string2.

- Repeated characters.

The notation `[c*n]' in set2 expands to n copies of character c. Thus, `[y*6]' is the same as `yyyyyy'. The notation `[c*]' in string2 expands to as many copies of c as are needed to make set2 as long as set1. If n begins with `0', it is interpreted in octal, otherwise in decimal.

- Character classes.

The notation `[:class:]' expands to all of the characters in the (predefined) class class. The characters expand in no particular order, except for the `upper` and `lower` classes, which expand in ascending order. When the `--delete' (`-d') and `--squeeze-repeats' (`-s') options are both given, any character class can be used in set2. Otherwise, only the character classes `lower` and `upper` are accepted in set2, and then only if the corresponding character class (`upper` and `lower`, respectively) is specified in the same relative position in set1. Doing this specifies case conversion. The class names are given below; an error results when an invalid class name is given.

`alnum`

@opindex alnum Letters and digits.

`alpha`

@opindex alpha Letters.

`blank`

@opindex blank Horizontal whitespace.

`cntrl`

@opindex cntrl Control characters.

`digit`

@opindex digit Digits.

`graph`

@opindex graph Printable characters, not including space.

`lower`

@opindex lower Lowercase letters.

`print`

@opindex print Printable characters, including space.

`punct`

@opindex punct Punctuation characters.

`space`

@opindex space Horizontal or vertical whitespace.

`upper`

@opindex upper Uppercase letters.

`xdigit`

@opindex xdigit Hexadecimal digits.

- Equivalence classes.

The syntax `[=c=]' expands to all of the characters that are equivalent to c, in no particular order. Equivalence classes are a relatively recent invention intended to support non-English alphabets. But there seems to be no standard way to define them or determine their contents. Therefore, they are not fully implemented in GNU `tr`; each character's equivalence class consists only of that character, which is of no particular use.

Translating

`tr` performs translation when set1 and set2 are both given and the `--delete' (`-d') option is not given. `tr` translates each character of its input that is in set1 to the corresponding character in set2. Characters not in set1 are passed through unchanged. When a character appears more than once in set1 and the corresponding characters in set2 are not all the same, only the final one is used. For example, these two commands are equivalent:

```
tr aaa xyz
tr a z
```

A common use of `tr` is to convert lowercase characters to uppercase. This can be done in many ways. Here are three of them:

```
tr abcdefghijklmnopqrstuvwxyz ABCDEFGHIJKLMNOPQRSTUVWXYZ
tr a-z A-Z
tr '[:lower:]' '[:upper:]'
```

When `tr` is performing translation, set1 and set2 typically have the same length. If set1 is shorter than set2, the extra characters at the end of set2 are ignored.

On the other hand, making set1 longer than set2 is not portable; POSIX.2 says that the result is

undefined. In this situation, BSD `tr` pads set2 to the length of set1 by repeating the last character of as many times as necessary. System V `tr` truncates set1 to the length of set2.

By default, GNU `tr` handles this case like BSD `tr`. When the `--truncate-set1' (`-t') option is given, GNU `tr` handles this case like the System V `tr` instead. This option is ignored for operations other than translation.

Acting like System V `tr` in this case breaks the relatively common BSD idiom:

```
tr -cs A-Za-z0-9 '\012'
```

because it converts only zero bytes (the first element in the complement of set1), rather than all non-alphanumerics, to newlines.

Squeezing repeats and deleting

When given just the `--delete' (`-d') option, `tr` removes any input characters that are in set1.

When given just the `--squeeze-repeats' (`-s') option, `tr` replaces each input sequence of a repeated character that is in set1 with a single occurrence of that character.

When given both `--delete' and `--squeeze-repeats', `tr` first performs any deletions using set1, then squeezes repeats from any remaining characters using set2.

The `--squeeze-repeats' option may also be used when translating, in which case `tr` first performs translation, then squeezes repeats from any remaining characters using set2.

Here are some examples to illustrate various combinations of options:

- Remove all zero bytes:

  ```
  tr -d '\000'
  ```

- Put all words on lines by themselves. This converts all non-alphanumeric characters to newlines, then squeezes each string of repeated newlines into a single newline:

  ```
  tr -cs '[a-zA-Z0-9]' '[\n*]'
  ```

- Convert each sequence of repeated newlines to a single newline:

  ```
  tr -s '\n'
  ```

Warning messages

Setting the environment variable `POSIXLY_CORRECT` turns off the following warning and error messages, for strict compliance with POSIX.2. Otherwise, the following diagnostics are issued:

1. When the `--delete' option is given but `--squeeze-repeats' is not, and set2 is given, GNU `tr` by default prints a usage message and exits, because set2 would not be used. The POSIX specification says that set2 must be ignored in this case. Silently ignoring arguments is a bad idea.

2. When an ambiguous octal escape is given. For example, `\400' is actually `\40' followed by the digit `0', because the value 400 octal does not fit into a single byte.

GNU `tr` does not provide complete BSD or System V compatibility. For example, it is impossible to disable interpretation of the POSIX constructs `[:alpha:]', `[=c=]', and `[c*10]'. Also, GNU `tr` does not delete zero bytes automatically, unlike traditional Unix versions, which provide no way to preserve zero bytes.

expand: Convert tabs to spaces

`expand` writes the contents of each given file, or standard input if none are given or for a file of `-', to standard output, with tab characters converted to the appropriate number of spaces. Synopsis:

```
expand [option]... [file]...
```

By default, `expand` converts all tabs to spaces. It preserves backspace characters in the output; they decrement the column count for tab calculations. The default action is equivalent to `-8' (set tabs every 8 columns).

The program accepts the following options. Also see section Common options.

`-tab1[,tab2]...'

`-t tab1[,tab2]...'

`--tabs=tab1[,tab2]...'

@opindex -tab @opindex -t @opindex --tabs If only one tab stop is given, set the tabs tab1 spaces apart (default is 8). Otherwise, set the tabs at columns tab1, tab2, ... (numbered from 0), and replace any tabs beyond the last tabstop given with single spaces. If the tabstops are specified with the `-t' or `--tabs' option, they can be separated by blanks as well as by commas.

`-i'

`--initial'

@opindex -i @opindex --initial Only convert initial tabs (those that precede all non-space or non-tab characters) on each line to spaces.

unexpand: Convert spaces to tabs

`unexpand` writes the contents of each given file, or standard input if none are given or for a file of `-', to standard output, with strings of two or more space or tab characters converted to as many tabs as possible followed by as many spaces as are needed. Synopsis:

```
unexpand [option]... [file]...
```

By default, `unexpand` converts only initial spaces and tabs (those that precede all non space or tab characters) on each line. It preserves backspace characters in the output; they decrement the column count for tab calculations. By default, tabs are set at every 8th column.

The program accepts the following options. Also see section Common options.

`-tab1[,tab2]...'

`-t tab1[,tab2]...'

`--tabs=tab1[,tab2]...'

@opindex -tab @opindex -t @opindex --tabs If only one tab stop is given, set the tabs tab1 spaces apart instead of the default 8. Otherwise, set the tabs at columns tab1, tab2, ... (numbered from 0), and leave spaces and tabs beyond the tabstops given unchanged. If the tabstops are specified with the `-t' or `--tabs' option, they can be separated by blanks as well as by commas. This option implies the `-a' option.

`-a'

`--all'

@opindex -a @opindex --all Convert all strings of two or more spaces or tabs, not just initial ones, to tabs.

Go to the previous, next section.

Go to the previous, next section.

Opening the software toolbox

This chapter originally appeared in Linux Journal, volume 1, number 2, in the What's GNU? column. It was written by Arnold Robbins.

Toolbox introduction

This month's column is only peripherally related to the GNU Project, in that it describes a number of the GNU tools on your Linux system and how they might be used. What it's really about is the "Software Tools" philosophy of program development and usage.

The software tools philosophy was an important and integral concept in the initial design and development of Unix (of which Linux and GNU are essentially clones). Unfortunately, in the modern day press of Internetworking and flashy GUIs, it seems to have fallen by the wayside. This is a shame, since it provides a powerful mental model for solving many kinds of problems.

Many people carry a Swiss Army knife around in their pants pockets (or purse). A Swiss Army knife is a handy tool to have: it has several knife blades, a screwdriver, tweezers, toothpick, nail file, corkscrew, and perhaps a number of other things on it. For the everyday, small miscellaneous jobs where you need a simple, general purpose tool, it's just the thing.

On the other hand, an experienced carpenter doesn't build a house using a Swiss Army knife. Instead, he has a toolbox chock full of specialized tools--a saw, a hammer, a screwdriver, a plane, and so on. And he knows exactly when and where to use each tool; you won't catch him hammering nails with the handle of his screwdriver.

The Unix developers at Bell Labs were all professional programmers and trained computer scientists. They had found that while a one-size-fits-all program might appeal to a user because there's only one program to use, in practice such programs are

1. difficult to write,
2. difficult to maintain and debug, and
3. difficult to extend to meet new situations.

Instead, they felt that programs should be specialized tools. In short, each program "should do one thing well." No more and no less. Such programs are simpler to design, write, and get right--they only do one thing.

Furthermore, they found that with the right machinery for hooking programs together, that the whole was greater than the sum of the parts. By combining several special purpose programs, you could accomplish a specific task that none of the programs was designed for, and accomplish it much more quickly and easily than if you had to write a special purpose program. We will see some (classic) examples of this further on in the column. (An important additional point was that, if necessary, take a detour and build any software tools you may need first, if you don't already have something appropriate in the toolbox.)

I/O redirection

Hopefully, you are familiar with the basics of I/O redirection in the shell, in particular the concepts of "standard input," "standard output," and "standard error". Briefly, "standard input" is a data source, where data comes from. A program should not need to either know or care if the data source is a disk file, a keyboard, a magnetic tape, or even a punched card reader. Similarly, "standard output" is a data sink, where data goes to. The program should neither know nor care where this might be. Programs that only read their standard input, do something to the data, and then send it on, are called "filters", by analogy to filters in a water pipeline.

With the Unix shell, it's very easy to set up data pipelines:

```
program_to_create_data | filter1 | .... | filterN > final.pretty.data
```

We start out by creating the raw data; each filter applies some successive transformation to the data, until by the time it comes out of the pipeline, it is in the desired form.

This is fine and good for standard input and standard output. Where does the standard error come in to play? Well, think about `filter1` in the pipeline above. What happens if it encounters an error in the data it sees? If it writes an error message to standard output, it will just disappear down the pipeline into `filter2`'s input, and the user will probably never see it. So programs need a place where they can send error messages so that the user will notice them. This is standard error, and it is usually connected to your console or window, even if you have redirected standard output of your program away from your screen.

For filter programs to work together, the format of the data has to be agreed upon. The most straightforward and easiest format to use is simply lines of text. Unix data files are generally just streams of bytes, with lines delimited by the ASCII LF (Line Feed) character, conventionally called a "newline" in the Unix literature. (This is `'\n'` if you're a C programmer.) This is the format used by all the traditional filtering programs. (Many earlier operating systems had elaborate facilities and special purpose programs for managing binary data. Unix has always shied away from such things, under the philosophy that it's easiest to simply be able to view and edit your data with a text editor.)

OK, enough introduction. Let's take a look at some of the tools, and then we'll see how to hook them together in interesting ways. In the following discussion, we will only present those command line options that interest us. As you should always do, double check your system documentation for the full story.

The `who` command

The first program is the `who` command. By itself, it generates a list of the users who are currently logged in. Although I'm writing this on a single-user system, we'll pretend that several people are logged in:

```
$ who
arnold   console Jan 22 19:57
```

```
miriam   ttyp0   Jan 23 14:19(:0.0)
bill     ttyp1   Jan 21 09:32(:0.0)
arnold   ttyp2   Jan 23 20:48(:0.0)
```

Here, the `$' is the usual shell prompt, at which I typed `who`. There are three people logged in, and I am logged in twice. On traditional Unix systems, user names are never more than eight characters long. This little bit of trivia will be useful later. The output of `who` is nice, but the data is not all that exciting.

The `cut` command

The next program we'll look at is the `cut` command. This program cuts out columns or fields of input data. For example, we can tell it to print just the login name and full name from the `` `/etc/passwd file' ``. The `` `/etc/passwd' `` file has seven fields, separated by colons:

```
arnold:xyzzy:2076:10:Arnold D. Robbins:/home/arnold:/bin/ksh
```

To get the first and fifth fields, we would use cut like this:

```
$ cut -d: -f1,5 /etc/passwd
root:Operator
...
arnold:Arnold D. Robbins
miriam:Miriam A. Robbins
...
```

With the `-c' option, `cut` will cut out specific characters (i.e., columns) in the input lines. This command looks like it might be useful for data filtering.

The `sort` command

Next we'll look at the `sort` command. This is one of the most powerful commands on a Unix-style system; one that you will often find yourself using when setting up fancy data plumbing. The `sort` command reads and sorts each file named on the command line. It then merges the sorted data and writes it to standard output. It will read standard input if no files are given on the command line (thus making it into a filter). The sort is based on the machine collating sequence (ASCII) or based on user-supplied ordering criteria.

The `uniq` command

Finally (at least for now), we'll look at the `uniq` program. When sorting data, you will often end up with duplicate lines, lines that are identical. Usually, all you need is one instance of each line. This is where `uniq` comes in. The `uniq` program reads its standard input, which it expects to be sorted. It only prints out one copy of each duplicated line. It does have several options. Later on, we'll use the `-c' option, which prints each unique line, preceded by a count of the number of times that line occurred in the input.

Putting the tools together

Now, let's suppose this is a large BBS system with dozens of users logged in. The management wants the SysOp to write a program that will generate a sorted list of logged in users. Furthermore, even if a user is logged in multiple times, his or her name should only show up in the output once.

The SysOp could sit down with the system documentation and write a C program that did this. It would take perhaps a couple of hundred lines of code and about two hours to write it, test it, and debug it. However, knowing the software toolbox, the SysOp can instead start out by generating just a list of logged on users:

```
$ who | cut -c1-8
arnold
miriam
bill
arnold
```

Next, sort the list:

```
$ who | cut -c1-8 | sort
arnold
arnold
bill
miriam
```

Finally, run the sorted list through `uniq`, to weed out duplicates:

```
$ who | cut -c1-8 | sort | uniq
arnold
bill
miriam
```

The `sort` command actually has a `-u' option that does what `uniq` does. However, `uniq` has other uses for which one cannot substitute `sort -u'.

The SysOp puts this pipeline into a shell script, and makes it available for all the users on the system:

```
# cat > /usr/local/bin/listusers
who | cut -c1-8 | sort | uniq
^D
# chmod +x /usr/local/bin/listusers
```

There are four major points to note here. First, with just four programs, on one command line, the SysOp was able to save about two hours worth of work. Furthermore, the shell pipeline is just about as efficient as the C program would be, and it is much more efficient in terms of programmer time. People time is

much more expensive than computer time, and in our modern "there's never enough time to do everything" society, saving two hours of programmer time is no mean feat.

Second, it is also important to emphasize that with the *combination* of the tools, it is possible to do a special purpose job never imagined by the authors of the individual programs.

Third, it is also valuable to build up your pipeline in stages, as we did here. This allows you to view the data at each stage in the pipeline, which helps you acquire the confidence that you are indeed using these tools correctly.

Finally, by bundling the pipeline in a shell script, other users can use your command, without having to remember the fancy plumbing you set up for them. In terms of how you run them, shell scripts and compiled programs are indistinguishable.

After the previous warm-up exercise, we'll look at two additional, more complicated pipelines. For them, we need to introduce two more tools.

The first is the `tr` command, which stands for "transliterate." The `tr` command works on a character-by-character basis, changing characters. Normally it is used for things like mapping upper case to lower case:

```
$ echo ThIs ExAmPlE HaS MIXED case! | tr '[A-Z]' '[a-z]'
this example has mixed case!
```

There are several options of interest:

`-c'
: work on the complement of the listed characters, i.e., operations apply to characters not in the given set

`-d'
: delete characters in the first set from the output

`-s'
: squeeze repeated characters in the output into just one character.

We will be using all three options in a moment.

The other command we'll look at is `comm`. The `comm` command takes two sorted input files as input data, and prints out the files' lines in three columns. The output columns are the data lines unique to the first file, the data lines unique to the second file, and the data lines that are common to both. The `-1', `-2', and `-3' command line options omit the respective columns. (This is non-intuitive and takes a little getting used to.) For example:

```
$ cat f1
11111
22222
33333
44444
```

```
$ cat f2
00000
22222
33333
55555
$ comm f1 f2
        00000
11111
                22222
                33333
44444
        55555
```

The single dash as a filename tells `comm` to read standard input instead of a regular file.

Now we're ready to build a fancy pipeline. The first application is a word frequency counter. This helps an author determine if he or she is over-using certain words.

The first step is to change the case of all the letters in our input file to one case. "The" and "the" are the same word when doing counting.

```
$ tr '[A-Z]' '[a-z]' < whats.gnu | ...
```

The next step is to get rid of punctuation. Quoted words and unquoted words should be treated identically; it's easiest to just get the punctuation out of the way.

```
$ tr '[A-Z]' '[a-z]' < whats.gnu | tr -cd '[A-Za-z0-9_ \012]' | ...
```

The second `tr` command operates on the complement of the listed characters, which are all the letters, the digits, the underscore, and the blank. The `\012' represents the newline character; it has to be left alone. (The ASCII TAB character should also be included for good measure in a production script.)

At this point, we have data consisting of words separated by blank space. The words only contain alphanumeric characters (and the underscore). The next step is break the data apart so that we have one word per line. This makes the counting operation much easier, as we will see shortly.

```
$ tr '[A-Z]' '[a-z]' < whats.gnu | tr -cd '[A-Za-z0-9_ \012]' |
> tr -s '[ ]' '\012' | ...
```

This command turns blanks into newlines. The `-s' option squeezes multiple newline characters in the output into just one. This helps us avoid blank lines. (The `>' is the shell's "secondary prompt." This is what the shell prints when it notices you haven't finished typing in all of a command.)

We now have data consisting of one word per line, no punctuation, all one case. We're ready to count each word:

```
$ tr '[A-Z]' '[a-z]' < whats.gnu | tr -cd '[A-Za-z0-9_ \012]' |
```

```
> tr -s '[ ]' '\012' | sort | uniq -c | ...
```

At this point, the data might look something like this:

```
  60 a
   2 able
   6 about
   1 above
   2 accomplish
   1 acquire
   1 actually
   2 additional
```

The output is sorted by word, not by count! What we want is the most frequently used words first. Fortunately, this is easy to accomplish, with the help of two more `sort` options:

`-n'
: do a numeric sort, not an ASCII one

`-r'
: reverse the order of the sort

The final pipeline looks like this:

```
$ tr '[A-Z]' '[a-z]' < whats.gnu | tr -cd '[A-Za-z0-9_ \012]' |
> tr -s '[ ]' '\012' | sort | uniq -c | sort -nr
 156 the
  60 a
  58 to
  51 of
  51 and
 ...
```

Whew! That's a lot to digest. Yet, the same principles apply. With six commands, on two lines (really one long one split for convenience), we've created a program that does something interesting and useful, in much less time than we could have written a C program to do the same thing.

A minor modification to the above pipeline can give us a simple spelling checker! To determine if you've spelled a word correctly, all you have to do is look it up in a dictionary. If it is not there, then chances are that your spelling is incorrect. So, we need a dictionary. If you have the Slackware Linux distribution, you have the file `/usr/lib/ispell/ispell.words', which is a sorted, 38,400 word dictionary.

Now, how to compare our file with the dictionary? As before, we generate a sorted list of words, one per line:

```
$ tr '[A-Z]' '[a-z]' < whats.gnu | tr -cd '[A-Za-z0-9_ \012]' |
> tr -s '[ ]' '\012' | sort -u | ...
```

Now, all we need is a list of words that are *not* in the dictionary. Here is where the `comm` command comes in.

```
$ tr '[A-Z]' '[a-z]' < whats.gnu | tr -cd '[A-Za-z0-9_ \012]' |
> tr -s '[ ]' '\012' | sort -u |
> comm -23 - /usr/lib/ispell/ispell.words
```

The `-2' and `-3' options eliminate lines that are only in the dictionary (the second file), and lines that are in both files. Lines only in the first file (standard input, our stream of words), are words that are not in the dictionary. These are likely candidates for spelling errors. This pipeline was the first cut at a production spelling checker on Unix.

There are some other tools that deserve brief mention.

`grep`
: search files for text that matches a regular expression

`egrep`
: like `grep`, but with more powerful regular expressions

`wc`
: count lines, words, characters

`tee`
: a T-fitting for data pipes, copies data to files and to standard output

`sed`
: the stream editor, an advanced tool

`awk`
: a data manipulation language, another advanced tool

The software tools philosophy also espoused the following bit of advice: "Let someone else do the hard part." This means, take something that gives you most of what you need, and then massage it the rest of the way until it's in the form that you want.

To summarize:

1. Each program should do one thing well. No more, no less.
2. Combining programs with appropriate plumbing leads to results where the whole is greater than the sum of the parts. It also leads to novel uses of programs that the authors might never have imagined.
3. Programs should never print extraneous header or trailer data, since these could get sent on down a pipeline. (A point we didn't mention earlier.)
4. Let someone else do the hard part.
5. Know your toolbox! Use each program appropriately. If you don't have an appropriate tool, build one.

As of this writing, all the programs we've discussed are available via anonymous `ftp` from

`prep.ai.mit.edu` as `` `/pub/gnu/textutils-1.9.tar.gz' `` directory.(1)

None of what I have presented in this column is new. The Software Tools philosophy was first introduced in the book Software Tools, by Brian Kernighan and P.J. Plauger (Addison-Wesley, ISBN 0-201-03669-X). This book showed how to write and use software tools. It was written in 1976, using a preprocessor for FORTRAN named `ratfor` (RATional FORtran). At the time, C was not as ubiquitous as it is now; FORTRAN was. The last chapter presented a `ratfor` to FORTRAN processor, written in `ratfor`. `ratfor` looks an awful lot like C; if you know C, you won't have any problem following the code.

In 1981, the book was updated and made available as Software Tools in Pascal (Addison-Wesley, ISBN 0-201-10342-7). Both books remain in print, and are well worth reading if you're a programmer. They certainly made a major change in how I view programming.

Initially, the programs in both books were available (on 9-track tape) from Addison-Wesley. Unfortunately, this is no longer the case, although you might be able to find copies floating around the Internet. For a number of years, there was an active Software Tools Users Group, whose members had ported the original `ratfor` programs to essentially every computer system with a FORTRAN compiler. The popularity of the group waned in the middle '80s as Unix began to spread beyond universities.

With the current proliferation of GNU code and other clones of Unix programs, these programs now receive little attention; modern C versions are much more efficient and do more than these programs do. Nevertheless, as exposition of good programming style, and evangelism for a still-valuable philosophy, these books are unparalleled, and I recommend them highly.

Acknowledgment: I would like to express my gratitude to Brian Kernighan of Bell Labs, the original Software Toolsmith, for reviewing this column.

DGD
: Deutsche Gesellschaft fuer Dokumentation [e.v.] org.

DGIS
: Direct Graphics Interface Standard

DGP
: Dissimilar Gateway Protocol

DGPS
: Differential Global Positioning System (GPS)

DGS
: Display GhostScript (GNU, GNUStep, PS)

DGSA
: Defense Goal Security Architecture mil., USA

DGUX
: Data General / UniX (Unix), "DG/UX"

DHCF
: Distributed Host Command Facility (IBM, CCS)

DHCP
: Dynamic Host Configuration Protocol (TCP/IP, IETF, RFC 2131)

DHIS
: Distributed Heterogeneous Information Systems

DI
: Destination Index [register] CPU, Intel, assembler

DIA
: Deutsche Informatik Akademie org.

DIA
: Document Interchange Architecture (IBM, CCS)

DIAMOND
: Development and Integration of Accurate Mathematical Operations in Numerical Data-processing (ESPRIT)

DIANE
: DIrect Access Network for Europe

DIB
: Defense Information Base mil., USA

DIB
: Device Independent Bitmap

DIB
: Directory Information Base (X.500, DS)

DIB
: DOS Info Block (BIOS, DOS)

DIB
: Dual Independent Bus

DIC
: Digital Interface Controller

DID
: Digital Image Design

DIESEL
: Dumb Interpretatively Evaluated String Expression Language (AutoCAD)

DIF
: Document Interchange Format

DIFMOS
: Double Injection Floating Gate MOS

DIGI
: Deutsche InteressenGemeinschaft Internet [e.v.] org., ISP

DII
: Defense Information Infrastructure mil., USA, DISA

DII
: Dynamic Invocation Interface

DIICC
: Defense Information Infrastructure Control Concept mil., USA

DIICOE
: Defense Info Infrastructure Common Operating Environment DISA, mil., USA, "DII COE"

DIL
: Dual InLine

DIME
: Desktop Integrated Media Environment (COSE)

DIME
: DIrect Memory Execute (AGP)

DIMSS
: DSN Integrated Management Support System DSN, mil., USA

DIN
: Deutsches Institut fuer Normung org.

DINAH
: Desktop INterface to AUTODIN Host AutoDIN, mil., USA

DINO
: Deutsches InterNet Organisationssystem WWW, Uni Goettingen, Germany

DIP
: Dial-up Internet Protocol (Linux)

DIP
: Dual In-line Package (IC, DRAM)

DIRMU
: DIstributed and Reconfigurable MUltiprocessor (MP)

DIS
: Defense Information System mil., USA

DIS
: Digital Identification Signal (HDLC)

DIS
: Draft International Standard (ISO)

DISA
: Data Interchange Standards Association org.

DISA
: Defense Information Systems Agency Org., mil., USA

DISAIS
: DISA Information System mil., USA, "DISA-IS"

DISANET
: DISA Information Network mil., USA, DISA, Netzwerk, "DISANet"

DISC
: Defense Information System Council mil., USA

DISK
: Deutschsprachige Internationale SAS-benutzer Konferenz

DISN
: Defense Information Systems Network mil., USA

DISNET
: Defense Integrated Secure Network Netzwerk, mil., USA, Vorlaeufer, DSNET

DISNNT
: Defense Information Systems Network - Near Term DISN, mil., USA, "DISN-NT"

DISOSS

DIStributed Office Support System (IBM, MVS)

DISP
: Directory Information Shadowing Protocol

DISP
: Draft International Standardized Profiles (ISO)

DISP
: Dutch Independent Shareware Programmer Org., Netherlands, "D.I.S.P."

DISSP
: Defense Information System Security Program mil., USA

DIT
: Directory Information Tree (X.500)

DITCO
: Defense Information Technology Contracting Office Org., mil., DISA, USA

DIU
: Digital Interface Unit

DIVE
: Direct Interface Video Extensions (IBM, MMPM/2)

DIVX
: DIgital Video eXpress (DVD), "Divx"

DIX
: DEC, Intel, Xerox ethernet, DEC, Intel, Xerox

DKE
: Deutsche Elektrotechnische Kommission org., DIN, VDE

DKRZ
: Deutsches KlimaRechenZentrum org.

DL
: Distribution List

DLC
: Data Link Control

DLCI
: Data Link Connection Identifier (ATM)

DLD
: Deutsche Linux Distribution (Linux)

DLE
: Data Link Escape

DLG
: Digital Line Graph

DLKL
: ??? (DB)

DLL
: Dynamic Link Library

DLL
: Dynamic Link Loader (BS2000)

DLP
: Digital Light Processing (TI)

DLP
: Discrete Logarithmic Problem

DLPI
: Data Link Provider Interaface (X/Open)

DLR
: Dynamic Link Routine

DLS
: DOS LAN Services (IBM, LAN Server)

DLSW
: Data Link SWitching (APPN, MPTN, RFC 1795, SNA, NETBIOS), "DLSw"

DLT
: Digital Line Tape (DEC)

DM
: Delta Modulation

DM
: Disconnect Mode (LAPB)

DMA
: Direct Memory Access

DMAC
: Direct Memory Access Controller

DMB
: Digital Multimedia Broadcasting (Telekom, Blaupunkt, DAB)

DMC
: Desktop Multimedia Conferencing

DMD
: Device Manager Driver (OS/2)

DMD
: Differential Mode Delay Gigabit-, ethernet

DMD

Digital Micromirror Device (IC, DLP, TI)

DMD

Directory Management DOMAIN (OSI, DS)

DMDAC

Dual MAC Dual Attached Concentrator (FDDI, DAC)

DMDD

Distributed Multiplexing Distributed Demultiplexing

DMDF

Distributed Management Data Facility (DCE, DME)

DME

Distributed Management Environment (OSF)

DMF

Digest Message Format (Internet, RFC 1153)

DMF

Distribution Media Format [diskette] (FDD)

DMI

Definition of Management Information (OSI)

DMI

Desktop Management Interface (DTMF)

DMI

Digital Multiplexed Interface

DML

Data Manipulation Language

DML

Data Manipulation Logic

DMOS

Diffusion Metal Oxide Semiconductor (IC)

DMP

Dot Matrix Printer

DMS

Data Management System

DMS

Defense Message System mil., USA

DMS

Digital Multiplexed System

DMS

Distributed Media Services (COSE)

DMS
: Document Management System

DMSCMS
: Display Management System/Conversional Monitor System, "DMS/CMS"

DMSIG
: Defense Message System Implementation Group Org., DMS, mil., USA

DMSP
: Distributed Mail System Protocol (Internet)

DMSTWG
: Defense Message System Transition Working Group Org., DMS, mil., USA

DMT
: Discrete Monitor Timings (VESA)

DMT
: Discrete Multitone Technology (ADSL, Amati Communications, ANSI)

DMTF
: Desktop Management Task Force

DMU
: Data Manipulation Unit

DMV
: Daten- und MedienVerlag

DMV
: Deutsche Mathematiker-Vereinigung org.

DN
: Distinguished Name (X.500)

DN
: Distribution Network

DNA
: Digital Network Architecture (DEC)

DNA
: Direct Network Attach (Xyratex, RAID)

DNA
: Distributed Network Architecture (NCR)

DNAE
: DatenNet-AnschlussEinrichtung (Telekom)

DNAT
: Dynamic Network Address Translation

DNC

Direct Numerical Control (CNC)

DNC

Dynamic Network Controller

DNCMPE

Direct Numerical Control / ??? (CNC), "DNC/MPE"

DNCP

[PPP] DECNet phase iv Control Protocol (RFC 1762, DECNET, PPP)

DNCRI

Division of Networking and Communication Research and Infrastructure

DNHR

Dynamic Non Hierarchical Routing

DNI

DECnet Network Interface

DNIC

Data Network Identification Code (X.121)

DNR

Digital Noise Reduction

DNS

DOMAIN Name System (Internet)

DNSO

Defense Network Systems Organization Org., USA, mil.

DNSTAN

Digitale NebenSTellenANlagen (Telekom), "DNStAn"

DNX

Departmental Network eXchange [bridging router] (SNA, SDLC, Proteon)

DO

Distributed Objects (NeXT)

DOAM

Distributed Office Applications Model (ISO, IEC, DIS 10031-1 f.)

DOCC

DISA Operations Control Complex DISA, mil., USA

DODISS

Department Of Defense Index of Specifications and Standards mil., USA

DOE

Distributed Objects Everywhere (Sun)

DOMAIN

Distributed Operating Multi Access Interactive Network (Apollo, Internet)

DOMF
: Distributed Object Management Facility (Sun)

DOOM
: Decentralised Object Orientated Machine

DOP
: Directory Operational binding management Protocol

DOS
: Disk Operating System (OS)

DOSS
: Dedicated Office Systems and Services

DOV
: Data Over Voice [MODEM]

DOW
: Direct OverWrite (MO, ...)

DP
: Data Processing

DP
: Detection Point (IN)

DP
: Draft Proposal (ISO)

DPB

DPI
: [SNMP] Distributed Program Interface (SNMP, RFC 1228)

DPI
: [SNMP] Distributed Protocol Interface (SNMP, RFC 1592)

DPI
: Data Processing Installation

DPI
: Dots Per Inch

DPL

Descriptor Privilege Level (OS/2, NT)

DPM

Defects Per Million

DPMA

Data Processing Management Association org.

DPMA

Demand Priority Access Method

DPMI

DOS Protected Mode Interface (DOS, MS, Intel)

DPMS

Display Power Management Signalling [standard] (VESA)

DPMS

DOS Protected Mode Services (Novell, DOS)

DPN

Data Packet Network (Nortel)

DPN

Data Processing Node (MODEM)

DPN

Deutsches Provider Network (ISP)

DPNPH

Data Packet Network-Packet Handler, "DPN-PH"

DPP

Distributed Parallel Processing

DPQ

Data Processing Quality

DPRL

Digital Property Rights Language (Xerox)

DPS

Display PostScript (NeXT, GUI)

DPSK

Differential Phase Shift Keying (DFUE)

DPT

Distributed Processing Technology manufacturer

DPT

Drive Parameter Table

DPV

DatenPaketVermittlung [srechner]

DQDB
: Distributed Queue Dual Bus (ISO, IEC, IS 8802/6, IEEE 802.6)

DQL
: Database Query Language (DB)

DR
: Developer Release (Linux)

DR
: Digital Research manufacturer

DRAM
: Dynamic Random Access Memory (RAM, IC)

DRB
: DRAM Row Boundary [register] (DRAM, PCI)

DRC
: Design Rule Checks (CAD)

DRD
: Data Reading Device

DRDA
: Distributed Relational Database Architecture (IBM, DB)

DRDAAS
: Distributed Relational Database Architecture Application Server (IBM, DB), "DRDA AS"

DRDOS
: Digital Research Disk Operating System (DR, OS), "DR-DOS"

DREN
: Defense Research and Engineering Network network

DRG

: Host Access Protocol (RFC 907/1221)

HAS
: High Availability Subsystem (Bull)

HAT
: Hashed Address Table

HBA
: Host Bus Adapter (SCSI)

HBCI
: HomeBanking Computer Interface Internet, banking

HCI
: Human Computer Interaction BCS, conference

HCL
: Host Control Links

HCSDS
: High Capacity Satellite Digital Service

HCSS
: High Capacity Storage System (Novell, Netware)

HCT
: Hamburger ComputerTage fair

HCT
: High-speed CMOS [logic] with TTT-compatible [logic] levels (IC, MOS)

HCTDS
: High-Capacity Terrestrial Digital Service

HD
: High Density

HDB
: HoneyDanBer [standard] (Unix)

HDB3
: High Density Bipolar 3

HDBMS
: Hierachical DataBase Management System (DBMS, DB)

HDC
: Hard Disk Controller

HDCD
: High Density Compact Disk (CD, Sony, Phillips)

HDD
: Hard Disk Drive

HDF
: Hierarchical Data Format (NCSA)

HDH
: HDLC Distant Host

HDI
: HOOPS Device Interface (VAGI)

HDL
: Hardware Description Language (ASIC)

HDLC
: High-level Data Link Control (ISO)

HDM
: Hardware Device Module (I2O)

HDN
: Hochgeschwindigkeits-DatenNetz

HDR

High availability Data Replication (Informix, DB)

HDR

High Dynamic Range

HDSL

High data / bit rate Digital Subscriber Line (BELLCORE, AT&T, DSL)

HDSL

High-level Data Specification Language

HDX

Half DupleX

HEA

Hyundai Electronics of America manufacturer

HEC

Header Error Check

HEC

Header Error Control (ATM)

HECTOR

HEterogeneous Computer TOgetheR IBM, Uni Karlsruhe, Germany

HEL

Hardware Emulation Layer

HEL

Header Extension Length

HEMT

High Electron Mobility Transistor

HEPNET

High Energy Physics NETwork network

HERMES

Heuristic Emergency Response Management Expert System (XPS)

HERODE

Handling the Electronic Representation of mixed text - image Office Documents based on ECMA standard 101 (ESPRIT, SNI, TITN, ECMA, ODA)

HES

Home Electronic System (SNI)

HFD

Hauptanschluss fuer Direktruf / Datenleitung (Telekom), "HfD"

HFDS

Highly Functional Distributed System (MTRON)

HFS

Hierachical File System (Apple, CD)

HFT

High Function Terminal (AIX, IBM)

HGA

Hercules Graphics Adapter

HGC

Hercules Graphics Card

HHI

Heinrich Hertz Institut org., Deutschland

HI

Hochschulverband Informationswissenschaften org.

HIC

Human Interaction Component

HIC

Hybrid Integrated Circuit

HID

Human Interface Device (MS)

HIFD

HIgh capacity Floppy Disk (Sony, Fuji), "HiFD"

HIFI

Hypertext Interface For Information (ESPRIT)

HIFIVE

HIgh Fidelity Interactive Visual Environment (DEC), "Hi-FIVE"

HIGGENS

Human Interface Graphical GENeration System (Uni Colorado)

HINT

Hierachical INTegration [benchmark]

HIPPI

HIgh Performance Parallel Interface

HIPPI

High Performance Peripheral Interface

HIRD

HURD of Interface Representing Depth (GNU, HURD)

HISP

HIgh SPeed channel connector (Cray, I/O)

HLL

High Level Language

HLLAPI

High Level Language Application Programming Interface (IBM, API)

HLPI

Higher Layer Protocol Identifier

HLR

Home Location Register (LR, GSM)

HLS

Hue, Luminance, Saturation color system, DTP

HMA

High Memory Area

HMAC

keyed-Hashing for Message AuthentiCation cryptography, RFC 2104

HMC

Highspeed Memory Controller (Apple)

HMD

Head Mounted Display (VR)

HMI

Human-Machine Interface

HMMP

HyperMedia Management Protocol (MS, Intel, Cisco, WWW, HMMS)

HMMS

HyperMedia Management Schema (MS, Intel, Cisco, WWW)

HMOS

High performance Metal Oxide Semiconductor (IC)

HMP

Host Monitoring Protocol (RFC 869)

HMUX

Hybrid MUltipleXer (FDDI), "H-MUX"

HNF

Heinz Nixdorf Museumsforum org., Paderborn

HNI

Heinz Nixdorf Institut org., ZIT

HOL

Head Of Line

HOOPS

Hierachical Object Orientated Picture System (Ithaca, Autodesk, OOP)

HP
: Hewlett Packard manufacturer

HPBIDS
: Hewlett Packard Broadband Internet Delivery System (HP, Internet), "HP BIDS"

HPC
: High Performance Computing

HPCC
: High Performance Computing and Communication

HPCS
: Hifh Performance Communication Server (Tobit, NLM, Netware)

HPF
: High Performance FORTAN

HPFS
: High Performance FileSystem (OS/2)

HPGL
: Hewlett Packard Graphics Language (CAD, CAM, HP)

HPIB
: Hewlett Packard Interface Bus

HPM
: Hyper Page Mode

HPMI
: ??? [Schnittstelle] (CAD), "HP-MI"

HPOFS
: High Performance Optical File System (IBM, OS/2, MOD)

HPPA
: Hewlett Packard Precision Architecture (HP, RISC)

HPPCL
: Hewlett Packard Printer Control Language

HPR
: High Priority Request (VUMA)

HPTS
: High Performance Transaction Systems

HPUX
: Hewlett Packard / UniX (Unix), "HP/UX"

HPVEE
: Hewlett Packard ??? (HP), "HP VEE"

HPVUE

Hewlett Packard - Visual User Environment (HP, GUI), "HP-VUE"

HRC
: Hybrid Ring Control (FDDI)

HS
: High Speed (MODEM)

HSA
: High Speed Access

HSB
: Hue Saturation Brightness (DTP)

HSC
: Hierarchical Storage Controller

HSFS
: High Sierra File System

HSI
: High Speed Interface

HSI
: Hue, Saturation, Intensity (DTP)

HSIS
: ??? High Speed Interface / SNA, "HSI/S"

HSLAN
: High Speed Local Area Network, "HS-LAN"

HSLFX

MIME [e-mail encapsulation of aggregate documents, such as] HTML (MIME, HTML, RFC 2110)

MIAW

Movie In A Window

MIB

Management Information Base (OSI, SNMP)

MIC

Media Interface Connector (FDDI, PMD)

MIC

Memory in Cassette (Seagate, EEPROM)

MIC

Message Integrity Check / Code

MIC

Multiple Interface Connection (Kyocera)

MICA

MODEM ISDN Channel Integration (Telebit, MODEM, ISDN)

MICE

Modular Integrated Communications Environment

MICO

MICO Is CORBA (ORB, CORBA, Uni Frankfurt)

MID

Message IDentifier (ATM)

MIDI

Musical Instruments Digital Interface

MIDL

Microsoft Interface Definition Language (NT)

MIF

Module Interconnection Facility (Proteus)

MIG

Mach Interface Generator (Mach)

MII

Media Independent Interface

MIL

Matrox Imaging Library

MILNET

MILitary NETwork USA, mil., Netzwerk

MILSTAR

Military Strategic TActical Relay mil., USA

MILSTD

Military STandarD mil., USA, "MIL-STD"

MIMD

Multiple Instruction [stream], Multiple Data [stream]

MIME

Multipurpose Internet Mail Extensions (RFC 2045/2046/2047/2048/2049, IETF)

MIMOLA

Machine Independent MicrOprogramming LAnguage (HDL)

MIN

Multistage Interconnection Networks

MINISTREL

Models for INformatIon STorage and REtrievaL (OA, BIS, ESPRIT)

MINT

Mint is Not TOS (Atari), "MiNT"

MINT

Multimedia-kommunikation aif Integrierten Netzen und Terminals

MINX

Multimedia Information Network eXchange

MIO

Memory Input/Output (Motorola)

MIO

Modular Input/Output (HP)

MIPS

Microprocessor without Interlocked Piped Stages

MIPS

Million Instructions Per Second (CPU)

MIR

Maximum Information Rate

MIR

Micro-Instruction Register

MIS

Management Information System

MISS

Mecklenburg Internet Service System (ISP)

MISSI

Multilevel Information System Security Initiative org.

MISX

Metered Services Information eXchange (Internet)

NSF Network Service Center org., NSF

NNTP

Network News Transfer Protocol (Internet, RFC 977, Usenet)

NNX

Network Numbering eXchange

NOA

Net On Air (Internet)

NOC

Network Operations Center

NOCS

Network Operations Center System

NODIS

NSSDC Online Data and Information Service (NSSDC)

NOI

Node Operator Interface

NOMA

National Online Media Association org., USA

NORGEN

Network Operations Report GENerator

NORMA

NO Remote Memory Access (OSF/1, Multi-Server)

NOS

Network Operating System

NOTIS

Network Operator Trouble Information System

NP

Network Performance

NPA

Network Performance Analyzer

NPA

Network Printer Alliance (IEEE 1284, IBM, Lexmark, Xerox)

NPA

Network Professional Association org., USA

NPAC
: Northeast Parallel Architectures Center org., USA, HPC

NPC
: Network Parameter Control

NPDA
: Network Problem Determination Application (IBM)

NPH
: No Parse Headers (HTML)

NPI
: Network Printer Interface

NPL
: Non-Procedural Language

NPM
: Network Performance Monitor

NPMS
: Named Pipes / Mail Slots (MS)

NPSI
: NCP Packet Switching Interface (IBM, NCP)

NPSI
: Network Protocol Service Interface

NPSS
: NASA Packet Switch System (NASA)

NPTN
: National Public Telecomputing Network network, USA

NPV
: Net Present Value

NQS
: Network Queuing System

NRC
: National Research Council org., USA

NRCLSE
: National Resource for Computers in Life Science Education (USA)

NREN
: National Research and Education Network USA, network

NRFD
: Not Ready for Data

NRM

Network Resource Management

NRN

National Research Network USA, network

NRN

No Reply Necessary slang, Usenet

NROFF

New Run-OFF (Unix)

NRS

Name Registration System

NRS

Novell Replication Services (Novell, Netware)

NRT

Non-Requesting Terminal

NRTVBR

Non-RealTime Variable Bit Rate (VBR, ATM), "nrt-VBR"

NRZ

Non-Return-to-Zero [recording]

NRZI

Non-Return-to-Zero, Invert to ones [encoding]

NS

Name Server (DNS, Unix)

NS

National Standard

NSA

National Security Agency org., USA

NSAI

National Standards Authority of Ireland org., Irland

NSAP

Network Service Access Point (OSI, OSI/RM, SAP)

NSAPA

Network Service Access Point Address (OSI, NSAP)

NSAPI

Netscape Server Application Programmer's Interface (Netscape, WWW, C/S, API)

NSB

National Science Board USA, org.

NSC

National Security Council org., USA

NSC
: National SemiConductor manufacturer

NSC
: Network Service Center

NSCA
: National institute for Supercomputing Applications

NSD
: National Security Directive (USA)

NSE
: Network Support Encyclopedia (Novell)

NSEC
: Network Switching Engineering Center

NSERC
: Natural Sciences and Research Council org., USA

NSF
: National Science Foundation org., USA

NSF
: Norges StandardiseringsForbund org., Norwegen

NSFIP
: NextStep Fuer IntelProzessoren, "NSfIP"

NSFNET
: National Science Foundation NETwork network, USA, Internet, "NSFnet"

NSG
: Network Services Group

NSI
: Name Service Independent (DCE/RPC, CDS)

NSI
: NASA Science Internet NASA, network

NSIS
: National Schengen Information System SIS, Europe

NSN
: NASA Science Network USA, network

NSP
: Native Signal Processing (Intel, CPU)

NSP
: Network Service Point

NSP

Network Service Provider

NSP

Network Services Protocol (DNA)

NSPMP

Network Switching Performance Measurement Plan

NSR

Non-Source Routed

NSRD

National Software Reuse Directory (USA)

NSS

Namespace Specific String (URN)

NSS

Nodal Switching Subsystem (NSFNET)

NSSA

Not So Stubby Area (OSPF, RFC 1587)

NSSDC

National Space Science Data Center org., USA

NST

Newfoundland Standard Time (TZ)

NST

North Sumatra Time [+0630] (TZ)

NSTAN

NebenSTellenANlagen (Telekom, CBX), "NStAn"

NSTC

National Science and Technology Council org., USA

NSTL

National Software Testing Lab org., USA

NSTS

National Secure Telephone System

NT

Netzwerk Terminator, Network Terminator (ISDN)

NT

New Technology (MS, OS)

NT

Nome Time [-1100] (TZ)

NT1

Network Termination [unit] 1 (ISDN)

NTAS
: NT Advanced Server MS, Windows NT

NTC
: National Telecommunications Conference conference, USA

NTE
: Network Terminal Equipment

NTFS
: [windows] New Technology File System

NTIA
: National Telecommunications and Information Administration / Agency org., USA

NTK
: Need-To-Know slang, Usenet, IRC

NTK
: Newton ToolKit (Apple)

NTN
: National Telecommunications Network

NTO
: Network Terminal Option

NTP
: Network Time Protocol (Internet, RFC 1119)

NTS
: Network Technical Support

NTS
: Network Test System

NTS2
: Network Transport Services /2 (IBM), "NTS/2"

NTSA
: Netware Telephony Services Architecture

NTSC
: National Television Standards Committee org., USA

NTSC
: Never The Same Color slang

NTT
: Nippon Telephone & Telegraph org., Japan

NUA
: Network User Address

NUI

Network User Identification (Datex-P)

NUISSH

Natur- und UmweltInformationsSystem Schleswig-Holstein (UIS), "NUIS-SH"

NUMA

Non Uniform Memory Access (SMP)

NURB

Non Uniform Rational B-spline

NURBS

Non-Uniform Rational B-Spline (CAD, Animation)

NUS

National University of Singapore org.

NUTEK

[National Board for Industrial and Technical Development] org., Schweden

NVDM2

NetView Distribution Manager /2 (OS/2, IBM), "NVDM/2"

NVN

National Videotex Network USA, network

NVP

Network Voice Protocol

NVRAM

Non-Volatile Random Access Memory (RAM, IC)

NVS

NachrichtenVermittlungsSystem (INPOL)

NVT

Network Virtual Terminal (Telnet, Internet)

NWCS

Netware Workstation Compatible Service (Netware, Windows NT)

NWIP

NetWare Internet Protocol (Novell, Netware)

NWNET

NorthWestern states NETwork network, USA, "NWNet"

NYSERNET

New York State Education and Research NETwork network, USA, "NYSERNet"

NZCS

New Zealand Computer Society org., Neuseeland

NZT

New Zealand Time [+1130] (TZ)

TOC

NZUSUGI

New Zealand Unix System User Group, Inc. org., Unix, User group

SubNetwork Dependent Convergence Procedure (ISO, IS 8648, OSI, SNDC)

SNEPS

Semantic NEtwork Processing System (GNU, LISP), "SNePS"

SNF

Server Natural Format (Fonts, X)

SNF

Shared Network Facilities

SNG

Satellite News Gathering

SNI

Siemens Nixdorf Informationssysteme [AG] manufacturer

SNI

SNA Network Interconnection (IBM, VTAM, SNA)

SNI

Subscriber Network Interface (SMDS)

SNIC
: SubNetwork Independent Convergence [functions] (OSI)

SNICP
: SubNetwork Independent Convergence Procedure (ISO, IS 8648, OSI, SNIC)

SNMP
: Simple Network Management Protocol (RFC 1157/1902, TCP/IP, IETF)

SNNS
: Stuttgart Neural Network Simulator (IPVR)

SNOBOL
: StriNg Orientated symBOlic Language

SNP
: SubNetwork Protocol

SNPA
: Sub-Network Point of Attachment

SNPP
: Simple Network Paging Protocol (RFC 1861, SMS)

SNR
: Serial NumbeR (IMEI, GSM)

SNR
: Signal-to-Noise Ratio

SNRM
: Set Normal Response Mode (SDLC, HDLC, ADDCP, LAPB)

SNRME
: Set Normal Response Mode Extension (SNRME)

SNS
: Secure Network Server

SNTP
: Simple Network Time Protocol (RFC 2030)

SOA
: Start Of Authority record (DNS)

SOA
: State Of the Art slang

SOAP
: Symbolic Optimizer and Assembly Program

SOB
: Start Of Block

SOC

System-On-a-Chip

SOC

Systems and Option Catalog

SOCKS

SOCKet Secure

SODA

System Optimization and Design Algorithm

SODIMM

Small Outline Dual Inline Memory Module (DRAM, DIMM)

SODIS

SOftware Dokumentations- und InformationsSystem

SOE

Standard Operating Environment

SOE

Standards of Excellence

SOEP

Secondary Operand Execution Pipeline (Motorola, CPU), "sOEP"

SOFABED

[davenport] Standard Open Formal Architecture for Browsable Electronic Documents

SOH

Section OverHead

SOH

Start Of Header

SOHO

Small Office / Home Office [market]

SOIF

Summary Object Interchange Format (WWW)

SOJ

Small-Outline J-lead [chip] (IC, DRAM)

SOL

Simulation-Oriented Language

SOM

Self-Organizing Machine

SOM

Structured Object Method

SOM

System Object Model (IBM, ORB, CORBA)

SONDS
: Small Office Network Data System

SONET
: Synchronous Optical NETwork (FDDI, ATM)

SOP
: Standard Operating Procedure

About...

V.E.R.A. is a free list of acronyms all of which are used in the field of computing.

V.E.R.A. is primarily meant to be used as an online reference, although some efforts have been taken to make its TeX output looking acceptable. However I doubt that somebody would like to print it. The original release compiled to 250 pages.

This edition is a special contribution to the GNU project similar to the version 4.4 of V.E.R.A. It contains approximately 7433 acronyms.

The idea to make V.E.R.A. available in Texinfo fomat came after reading two other Info files both of which are available on the Internet, the *Standards* and the *Languages* file, both dealing with antique DEC mainframe environments and both distributed stand-alone; that is, both are not serving as a software manual like most of Texinfo files. I thought it would be very handy to have a list of acronyms available while using Emacs.

It may be considered only a very little contribution. However I make it to express my appreciation for the GNU project and its philosophy. This project does not only make software available free to everyone, it also seems that it sets the only standard `everyone' supports nowadays.

I started V.E.R.A. around easter 1993. The ASCII version is being posted to the German=speaking newsgroups *z-netz.alt.listen* and *de.etc.lists* every three months. It is not being posted to an international newsgroup, because the introduction as well as many internal references are only available in German.

Please note that the original version of V.E.R.A. is not related to the to the Free Software Foundation or the GNU project at all.

The list is far from being complete as dozens of new acronyms evolve every month. Also I am not an every day Unix user, so I am pretty sure that a lot of acronyms from the Unix world are missing. The same is true for the Apple world. Please don't be angry if your field of computing seems little or not represented at all. Instead please consider contributeing the missing acronyms to let other people know what you know.

The shift from the original format of V.E.R.A. to Texinfo format took a whole week. Please forgive any errors which still remain. For hints how to submit corrections or to report bugs, please see section Release notes and other useful information.

For a more in-depth discussion of some of the more common acronyms contained in this document you may want to consider visiting the *Free Online Dictionary of Computing (FOLDOC)*, at least if you have access to the World Wide Web. It can be found at http://wombat.doc.ic.ac.uk/foldoc (as of June 1997).

Go to the previous, next section.

TOC

List format

Some notes on the systematic approach of the acronym list:

Because often acronyms are being referenced not very unique in style, the acronyms in V.E.R.A. do not contain any special characters; only characters and numbers are used. Please remember this, when you are searching for acronyms.

German umlauts are expressed with AE, ae, OE, oe, UE, ue and ss.

Examples:

ASN.1 = ASN1
OS/2 = OS2
DFUE, Foerderung, Grossforschungseinrichtung, ...

What is thought to be the common style can be found at the end of the line(s) in quotation marks.

Examples:

ASN1

: Abstract Syntax Notation One (OSI), "ASN.1"

ATT

: American Telephone and Telegraph, "AT&T"

Style of the acronym expansions

The acronym expansions basically follow their acronyms in style. Exceptions are made if expansions are containing acronyms theirselves. This often leads to an kind of odd or even wrong orthogaphical style.

Examples:

AUX

: Apple UniX, "A/UX"

XT

: eXtended Technology

ACL

: Advanced CMOS Logic

Alternative expansions

If alternative expansions for the same acronym are known these are separated by a slash. However that is not true for acronyms of basically different meanings.

Examples:

AE

Apple Events

AE

Application Entity / Environment / Engineering (APE)

Additional explanations

Terms in square brackets show additional explanations, of which do not directly belong to the acronym's expansion, but rather to the acronym's meaning.

Examples:

ARM

Annotated [c++] Reference Manual

RLL

Run Length Limited [encoding]

Reference tags for acronyms

The terms in parenthesis which often appear behind the expansions are reference links to certain topics or firms and should help you to get an idea of in which context an acronym is being used.

Examples:

WB

WorkBench (Amiga)

WYSIWYG

What You See Is What You Get (DTP)

Please note that the original version of V.E.R.A. is meant to be formatted in a hypertext environment. Thus some references may seem redundant in an environment which does not support such links.

Examples:

API

Application Program Interface (API)

Concatenated acronyms

Often-used concatenated acronyms appear without the space or any special characters between them.

Examples:

AMTPE

Apple Media Tool Programming Environment (Apple), "AMT PE"

RISCOS

RISC Operating System (Acorn), "RISC OS"

Acronyms pointing to versions

When there is a series of related acronyms differing by a number at the end, V.E.R.A. usually has just one entry, which omits the number. For example, there are many versions of MNP (Microcom Networking Protocol), distinguished by numbers; but we do not list MNP4, MNP5 or MNP10, only MNP.

So if you look for an acronym that ends in a number, and you don't find it, try leaving out the number(s).

File extensions

Please note that file extensions are not covered by V.E.R.A. at the moment, although some exceptions were made. You will not find things like EPS (Encapsulated PostScript) or GIF (Graphics Interchange Format).

There are many such lists on the Internet if you should be looking for file extensions.

Gaps

You will probably notice that some acronym expansions or references are tagged with three question marks (`???'). This indicates that an expansion or reference is still missing or uncertain.

Go to the previous, next section.

Go to the previous, next section.

TOC

Acronym

An acronym is a word derived from the initial letters or groups of letters of several other words.

Popular examples are:
Laser, from "**l**ight **a**mplification by **s**timulated **e**mission of **r**adition", *Radar*, from "**ra**dio **d**etecting **a**nd **r**anging" or *snafu*, which should politely be rendered as "**s**ituation **n**ormal, **a**ll **f**ouled **u**p".

The word acronym itself derives from the greek words *akros* "the highest, the most outer" and *onyma* "name".

Please note that acronyms are always pronounced as the spelling indicates.

Go to the previous, next section.

Release notes and other useful information

Version 4.4

Version 4.4 (Texinfo release 1.3) contains about 250 acronyms more than the initial release. Now V.E.R.A. knows about more than 7400 acronyms.

Version 4.2 had accidently been released containing ISO 8859-1 characters. I received no complaints, but I believe not everyone can display these characters as meant to be, so I switched back to 7 bit with this version.

Recently V.E.R.A. ran into copyright/trademark problems. It's unbelievable how small the name space in the computer field went over the years. To give you an example there are acronyms in this list which have five or more different meanings. However Systems Science Inc. agreed to solve the problem by including the following sentence into the distribution: "This dictionary has nothing to do with Systems Science Inc. or its products." Please don't wonder if you surprisingly run into this sentence.

Version 4.3

I found no time to release V.E.R.A. 4.3 as Texinfo version in March 1998 as I was busy with other things. As compiling the Texinfo version is always additional work to do, I thought of to spare the March version and release the next Texinfo version on the next release date (June, 1st).

Version 4.2

Version 4.2 contains about 180 acronyms more than the last release. I also received a mail from the folks who maintain the GNU catalogue. This may mean that V.E.R.A. will be included on the GNU CD-ROM distribution, but I'm not sure.

Version 4.1

Version 4.1 contains about 500 acronyms more than the initial release. Now V.E.R.A. knows about more than 7000 acronyms.

Besides I wrote a script which automagically translates the german references sometimes to be found behind the acronym expansions in the original version of V.E.R.A. into the appropriate english terms. It also adds `Germany' to german locations. However I still may have missed some german terms or locations. It is kind of awful to proof-read 7000 acronym expansions. If you still spot german terms in the references, please let me know about.

Installation as Info file

If you like to install V.E.R.A. in your Info environment, there are three steps to do so:

1. Make an Info file from the Texinfo source, type:

makeinfo vera.texi

(The file extension may differ in your environment.)

2. Copy the files generated by the previous step to the directory where the Info files reside on your site.
3. Go to your Info directory and edit the `dir` file. Insert a line like the following where appropriate.

   * V.E.R.A.: (vera). Virtual Entity of Relevant Aconyms

Bugs

This edition of V.E.R.A. has been translated from German and has not been intensively proofread. Please report bugs concerning the use of broken or unsound English used in this document to the current maintainer of this document.

If you spot any faults in the acronym chapters, these will be considered a bug too. Please report those bugs to the current maintainer of this document.

Call for submissions

This acronym list is not and will never be complete. However if you feel that something particular is missing, please submit it to the current maintainer. Your submission will be included in the next edition of V.E.R.A.

Disclaimer

This is a special GNU edition of V.E.R.A., a list dealing with computational acronyms. It is currently maintained by Oliver Heidelbach <oheiabbd@zedat.fu-berlin.de>.

Although V.E.R.A. has been corrected and worked over for quite a long time, no guarantee can be given for the correctness of any part of its contents. Please don't get it wrong and help to correct any faults you may find.

Please send corrections to the current maintainer.

The author suggests not to redistribute corrected versions of this document, but instead to inform the actual maintainer about corrections you might have. This would help not to confuse users because of different versions.

Within the above restrictions the distribution of this document is explicitly encouraged and I hope you'll find it of some value.

Please note that another version of V.E.R.A. exists, which is not related to the GNU project.

This dictionary has nothing to do with Systems Science Inc. or its products.

Oliver Heidelbach (original author)

VIP

Go to the next section.

VIP

A Vi Package for GNU Emacs (Version 3.5, September 15, 1987)

Masahiko Sato

Distribution

Go to the next section.

Go to the previous, next section.

Introduction

VIP is a Vi emulating package written in Emacs Lisp. VIP implements most Vi commands including Ex commands. It is therefore hoped that this package will enable you to do Vi style editing under the powerful GNU Emacs environment. This manual describes the usage of VIP assuming that you are fairly accustomed to Vi but not so much with Emacs. Also we will concentrate mainly on differences from Vi, especially features unique to VIP.

It is recommended that you read chapters on survey and on customization before you start using VIP. Other chapters may be used as future references.

Comments and bug reports are welcome. Please send messages to `ms@Sail.Stanford.Edu` if you are outside of Japan and to `masahiko@unsun.riec.tohoku.junet` if you are in Japan.

Go to the previous, next section.

Go to the previous, next section.

A Survey of VIP

In this chapter we describe basics of VIP with emphasis on the features not found in Vi and on how to use VIP under GNU Emacs.

Basic Concepts

We begin by explaining some basic concepts of Emacs. These concepts are explained in more detail in the GNU Emacs Manual.

Conceptually, a buffer is just a string of ASCII characters and two special characters PNT (point) and MRK (mark) such that the character PNT occurs exactly once and MRK occurs at most once. The text of a buffer is obtained by deleting the occurrences of PNT and MRK. If, in a buffer, there is a character following PNT then we say that point is looking at the character; otherwise we say that point is at the end of buffer. PNT and MRK are used to indicate positions in a buffer and they are not part of the text of the buffer. If a buffer contains a MRK then the text between MRK and PNT is called the region of the buffer.

Emacs provides (multiple) windows on the screen, and you can see the content of a buffer through the window associated with the buffer. The cursor of the screen is always positioned on the character after PNT.

A keymap is a table that records the bindings between characters and command functions. There is the global keymap common to all the buffers. Each buffer has its local keymap that determines the mode of the buffer. Local keymap overrides global keymap, so that if a function is bound to some key in the local keymap then that function will be executed when you type the key. If no function is bound to a key in the local map, however, the function bound to the key in the global map becomes in effect.

Loading VIP

The recommended way to load VIP automatically is to include the line:

```
(load "vip")
```

in your `.emacs' file. The `.emacs' file is placed in your home directory and it will be executed every time you invoke Emacs. If you wish to be in vi mode whenever Emacs starts up, you can include the following line in your `.emacs' file instead of the above line:

```
(setq term-setup-hook 'vip-mode)
```

(See section Vi Mode, for the explanation of vi mode.)

Even if your `.emacs' file does not contain any of the above lines, you can load VIP and enter vi mode by typing the following from within Emacs.

M-x vip-mode

Modes in VIP

Loading VIP has the effect of globally binding C-z (Control-z) to the function `vip-change-mode-to-vi`. The default binding of C-z in GNU Emacs is `suspend-emacs`, but, you can also call `suspend-emacs` by typing C-x C-z. Other than this, all the key bindings of Emacs remain the same after loading VIP.

Now, if you hit C-z, the function `vip-change-mode-to-vi` will be called and you will be in vi mode. (Some major modes may locally bind C-z to some special functions. In such cases, you can call `vip-change-mode-to-vi` by `execute-extended-command` which is invoked by M-x. Here M-x means Meta-x, and if your terminal does not have a META key you can enter it by typing ESC x. The same effect can also be achieve by typing M-x vip-mode.)

You can observe the change of mode by looking at the mode line. For instance, if the mode line is:

```
-----Emacs: *scratch*                (Lisp Interaction)----All-----------
```

then it will change to:

```
-----Vi:    *scratch*                (Lisp Interaction)----All-----------
```

Thus the word `Emacs' in the mode line will change to `Vi'.

You can go back to the original emacs mode by typing C-z in vi mode. Thus C-z toggles between these two modes.

Note that modes in VIP exist orthogonally to modes in Emacs. This means that you can be in vi mode and at the same time, say, shell mode.

Vi mode corresponds to Vi's command mode. From vi mode you can enter insert mode (which corresponds to Vi's insert mode) by usual Vi command keys like i, a, o ... etc.

In insert mode, the mode line will look like this:

```
-----Insert *scratch*                (Lisp Interaction)----All-----------
```

You can exit from insert mode by hitting ESC key as you do in Vi.

That VIP has three modes may seem very complicated, but in fact it is not so. VIP is implemented so that you can do most editing remaining only in the two modes for Vi (that is vi mode and insert mode).

Emacs Mode

You will be in this mode just after you loaded VIP. You can do all normal Emacs editing in this mode. Note that the key C-z is globally bound to `vip-change-mode-to-vi`. So, if you type C-z in this mode then you will be in vi mode.

Vi Mode

This mode corresponds to Vi's command mode. Most Vi commands work as they do in Vi. You can go back to emacs mode by typing C-z. You can enter insert mode, just as in Vi, by typing i, a etc.

Insert Mode

The key bindings in this mode is the same as in the emacs mode except for the following 4 keys. So, you can move around in the buffer and change its content while you are in insert mode.

ESC

This key will take you back to vi mode.

C-h

Delete previous character.

C-w

Delete previous word.

C-z

Typing this key has the same effect as typing ESC in emacs mode. Thus typing C-z x in insert mode will have the same effect as typing ESC x in emacs mode.

Differences from Vi

The major differences from Vi are explained below.

Undoing

You can repeat undoing by the . key. So, u will undo a single change, while u . . ., for instance, will undo 4 previous changes. Undo is undoable as in Vi. So the content of the buffer will be the same before and after u u.

Changing

Some commands which change a small number of characters are executed slightly differently. Thus, if point is at the beginning of a word `foo' and you wished to change it to `bar' by typing c w, then VIP will prompt you for a new word in the minibuffer by the prompt `foo => '. You can then enter `bar' followed by RET or ESC to complete the command. Before you enter RET or ESC you can abort the command by typing C-g. In general, you can abort a partially formed command by typing C-g.

Searching

As in Vi, searching is done by / and ?. The string will be searched literally by default. To invoke a regular expression search, first execute the search command / (or ?) with empty search string. (I.e, type / followed by RET.) A search for empty string will toggle the search mode between vanilla search and regular expression search. You cannot give an offset to the search string. (It is a limitation.) By default, search will

wrap around the buffer as in Vi. You can change this by rebinding the variable `vip-search-wrap-around`. See section Customization, for how to do this.

z Command

For those of you who cannot remember which of z followed by RET, . and - do what. You can also use z followed by H, M and L to place the current line in the Home (Middle, and Last) line of the window.

Counts

Some Vi commands which do not accept a count now accept one

p
P

Given counts, text will be yanked (in Vi's sense) that many times. Thus 3 p is the same as p p p.

o
O

Given counts, that many copies of text will be inserted. Thus o a b c ESC will insert 3 lines of `abc' below the current line.

/
?

Given a count n, n-th occurrence will be searched.

Marking

Typing an m followed by a lower case character ch marks the point to the register named ch as in Vi. In addition to these, we have following key bindings for marking.

m <

Set mark at the beginning of buffer.

m >

Set mark at the end of buffer.

m .

Set mark at point (and push old mark on mark ring).

m ,

Jump to mark (and pop mark off the mark ring).

Region Commands

Vi operators like d, c etc. are usually used in combination with motion commands. It is now possible to use current region as the argument to these operators. (A region is a part of buffer delimited by point and mark.) The key r is used for this purpose. Thus d r will delete the current region. If R is used instead of r the region will first be enlarged so that it will become the smallest region containing the original region and consisting of whole lines. Thus m . d R will have the same effect as d d.

Some New Commands

Note that the keys below (except for R) are not used in Vi.

C-a

Move point to the beginning of line.

C-n

If you have two or more windows in the screen, this key will move point to the next window.

C-o

Insert a newline and leave point before it, and then enter insert mode.

C-r

Backward incremental search.

C-s

Forward incremental search.

C-c

C-x

ESC

These keys will exit from vi mode and return to emacs mode temporarily. If you hit one of these keys, Emacs will be in emacs mode and will believe that you hit that key in emacs mode. For example, if you hit C-x followed by 2, then the current window will be split into 2 and you will be in vi mode again.

\

Escape to emacs mode. Hitting \ will take you to emacs mode, and you can execute a single Emacs command. After executing the Emacs command you will be in vi mode again. You can give a count before typing \. Thus 5 \ *, as well as \ C-u 5 *, will insert `*****' before point. Similarly 1 0 \ C-p will move the point 10 lines above the current line.

K

Kill current buffer if it is not modified. Useful when you selected a buffer which you did not want.

Q

R

Q is for query replace and R is for replace. By default, string to be replaced are treated literally. If you wish to do a regular expression replace, first do replace with empty string as the string to be replaced. In this way, you can toggle between vanilla and regular expression replacement.

v

V

These keys are used to Visit files. v will switch to a buffer visiting file whose name can be entered in the minibuffer. V is similar, but will use window different from the current window.

#

If followed by a certain character ch, it becomes an operator whose argument is the region determined by the motion command that follows. Currently, ch can be one of c, C, g, q and s.

c

Change upper case characters in the region to lower case (`downcase-region`).

C

Change lower case characters in the region to upper case. For instance, # C 3 w will capitalize 3 words from the current point (`upcase-region`).

g

Execute last keyboard macro for each line in the region (`vip-global-execute`).

q

Insert specified string at the beginning of each line in the region (`vip-quote-region`).

s

Check spelling of words in the region (`spell-region`).

*

Call last keyboard macro.

New Key Bindings

In VIP the meanings of some keys are entirely different from Vi. These key bindings are done deliberately in the hope that editing under Emacs will become easier. It is however possible to rebind these keys to functions which behave similarly as in Vi. See section Customizing Key Bindings, for details.

C-g

g

In Vi, C-g is used to get information about the file associated to the current buffer. Here, g will do that, and C-g is used to abort a command (this is for compatibility with emacs mode.)

SPC

RET

Now these keys will scroll up and down the text of current window. Convenient for viewing the text.

s

S

They are used to switch to a specified buffer. Useful for switching to already existing buffer since buffer name completion is provided. Also a default buffer will be given as part of the prompt, to which you can switch by just typing RET key. s is used to select buffer in the current window, while S selects buffer in another window.

C

X

These keys will exit from vi mode and return to emacs mode temporarily. If you type C (X), Emacs will be in emacs mode and will believe that you have typed C-c (C-x, resp.) in emacs mode. Moreover, if the following character you type is an upper case letter, then Emacs will believe that you have typed the corresponding control character. You will be in vi mode again after the command is executed. For example, typing X S in vi mode is the same as typing C-x C-s in emacs mode. You get the same effect by typing C-x C-s in vi mode, but the idea here is that you can execute useful

Emacs commands without typing control characters. For example, if you hit X (or C-x) followed 2, then the current window will be split into 2 and you will be in vi mode again.

In addition to these, `ctl-x-map` is slightly modified:

X 3

C-x 3

This is equivalent to C-x 1 C-x 2 (1 + 2 = 3).

Window Commands

In this and following subsections, we give a summary of key bindings for basic functions related to windows, buffers and files.

C-n

Switch to next window.

X 1

C-x 1

Delete other windows.

X 2

C-x 2

Split current window into two windows.

X 3

C-x 3

Show current buffer in two windows.

Buffer Commands

s

Switch to the specified buffer in the current window (`vip-switch-to-buffer`).

S

Switch to the specified buffer in another window (`vip-switch-to-buffer-other-window`).

K

Kill the current buffer if it is not modified.

X S

C-x C-s

Save the current buffer in the file associated to the buffer.

File Commands

v

Visit specified file in the current window.

V

Visit specified file in another window.

X W

C-x C-w

Write current buffer into the specified file.

X I

C-x C-i

Insert specified file at point.

Miscellaneous Commands

X (

C-x (

Start remembering keyboard macro.

X)

C-x)

Finish remembering keyboard macro.

*

Call last remembered keyboard macro.

X Z

C-x C-z

Suspend Emacs.

Z Z

Exit Emacs.

Q

Query replace.

R

Replace.

Go to the previous, next section.

Go to the previous, next section.

Vi Commands

This chapter describes Vi commands other than Ex commands implemented in VIP. Except for the last section which discusses insert mode, all the commands described in this chapter are to be used in vi mode.

Numeric Arguments

Most Vi commands accept a numeric argument which can be supplied as a prefix to the commands. A numeric argument is also called a count. In many cases, if a count is given, the command is executed that many times. For instance, 5 d d deletes 5 lines while simple d d deletes a line. In this manual the metavariable n will denote a count.

Important Keys

The keys C-g and C-l are unique in that their associated functions are the same in any of emacs, vi and insert mode.

C-g

Quit. Cancel running or partially typed command (`keyboard-quit`).

C-l

Clear the screen and reprint everything (`recenter`).

In Emacs many commands are bound to the key strokes that start with C-x, C-c and ESC. These commands can be accessed from vi mode as easily as from emacs mode.

C-x

C-c

ESC

Typing one of these keys have the same effect as typing it in emacs mode. Appropriate command will be executed according as the keys you type after it. You will be in vi mode again after the execution of the command. For instance, if you type ESC < (in vi mode) then the cursor will move to the beginning of the buffer and you will still be in vi mode.

C

X

Typing one of these keys have the effect of typing the corresponding control character in emacs mode. Moreover, if you type an upper case character following it, that character will also be translated to the corresponding control character. Thus typing X W in vi mode is the same as typing C-x C-w in emacs mode. You will be in vi mode again after the execution of a command.

\

Escape to emacs mode. Hitting the \ key will take you to emacs mode, and you can execute a single Emacs command. After executing the Emacs command you will be in vi mode again. You can give a count before typing \. Thus 5 \ +, as well as \ C-u 5 +, will insert `+++++' before point.

Buffers and Windows

In Emacs the text you edit is stored in a buffer. See GNU Emacs Manual, for details. There is always one selected buffer which is called the current buffer.

You can see the contents of buffers through windows created by Emacs. When you have multiple windows on the screen only one of them is selected. Each buffer has a unique name, and each window has a mode line which shows the name of the buffer associated with the window and other information about the status of the buffer. You can change the format of the mode line, but normally if you see `**' at the beginning of a mode line it means that the buffer is modified. If you write out the content of the buffer to a file, then the buffer will become not modified. Also if you see `%%' at the beginning of the mode line, it means that the file associated with the buffer is write protected.

We have the following commands related to windows and buffers.

C-n

Move cursor to the next-window (`vip-next-window`).

X 1

Delete other windows and make the selected window fill the screen (`delete-other-windows`).

X 2

Split current window into two windows (`split-window-vertically`).

X 3

Show current buffer in two windows.

s buffer RET

Select or create a buffer named buffer (`vip-switch-to-buffer`).

S buffer RET

Similar but select a buffer named buffer in another window (`vip-switch-to-buffer-other-window`).

K

Kill the current buffer if it is not modified or if it is not associated with a file (`vip-kill-buffer`).

X B

List the existing buffers (`list-buffers`).

As buffer name completion is provided, you have only to type in initial substring of the buffer name which is sufficient to identify it among names of existing buffers. After that, if you hit TAB the rest of the buffer name will be supplied by the system, and you can confirm it by RET. The default buffer name to switch to will also be prompted, and you can select it by giving a simple RET. See GNU Emacs

Manual for details of completion.

Files

We have the following commands related to files. They are used to visit, save and insert files.

v file RET

Visit specified file in the current window (`vip-find-file`).

V file RET

Visit specified file in another window (`vip-find-file-other-window`).

X S

Save current buffer to the file associated with the buffer. If no file is associated with the buffer, the name of the file to write out the content of the buffer will be asked in the minibuffer.

X W file RET

Write current buffer into a specified file.

X I file RET

Insert a specified file at point.

g

Give information on the file associated with the current buffer. Tell you the name of the file associated with the buffer, the line number of the current point and total line numbers in the buffer. If no file is associated with the buffer, this fact will be indicated by the null file name `"".

In Emacs, you can edit a file by visiting it. If you wish to visit a file in the current window, you can just type v. Emacs maintains the default directory which is specific to each buffer. Suppose, for instance, that the default directory of the current buffer is `` `/usr/masahiko/lisp/' ``. Then you will get the following prompt in the minibuffer.

```
visit file: /usr/masahiko/lisp/
```

If you wish to visit, say, `` `vip.el' `` in this directory, then you can just type `vip.el' followed by RET. If the file `` `vip.el' `` already exists in the directory, Emacs will visit that file, and if not, the file will be created. Emacs will use the file name (`` `vip.el' ``, in this case) as the name of the buffer visiting the file. In order to make the buffer name unique, Emacs may append `<2>', `<3>' etc., to the buffer name. As the file name completion is provided here, you can sometime save typing. For instance, suppose there is only one file in the default directory whose name starts with `v', that is `vip.el'. Then if you just type v TAB then it will be completed to `vip.el'. Thus, in this case, you just have to type v v TAB RET to visit `` `/usr/masahiko/lisp/vip.el' ``. Continuing the example, let us now suppose that you wished to visit the file `` `/usr/masahiko/man/vip.texinfo' ``. Then to the same prompt which you get after you typed v, you can enter `/usr/masahiko/man/vip.texinfo' or `../man/vip.texinfo' followed by RET.

Use V instead of v, if you wish to visit a file in another window.

You can verify which file you are editing by typing g. (You can also type X B to get nformation on other buffers too.) If you type g you will get an information like below in the echo area:

```
"/usr/masahiko/man/vip.texinfo" line 921 of 1949
```

After you edited the buffer (`vip.texinfo', in our example) for a while, you may wish to save it in a file. If you wish to save it in the file associated with the buffer (`/usr/masahiko/man/vip.texinfo', in this case), you can just say X S. If you wish to save it in another file, you can type X W. You will then get a similar prompt as you get for v, to which you can enter the file name.

Viewing the Buffer

In this and next section we discuss commands for moving around in the buffer. These command do not change the content of the buffer. The following commands are useful for viewing the content of the current buffer.

SPC

C-f

Scroll text of current window upward almost full screen. You can go *forward* in the buffer by this command (`vip-scroll`).

RET

C-b

Scroll text of current window downward almost full screen. You can go *backward* in the buffer by this command (`vip-scroll-back`).

C-d

Scroll text of current window upward half screen. You can go *down* in the buffer by this command (`vip-scroll-down`).

C-u

Scroll text of current window downward half screen. You can go *up* in the buffer by this command (`vip-scroll-up`).

C-y

Scroll text of current window upward by one line (`vip-scroll-down-one`).

C-e

Scroll text of current window downward by one line (`vip-scroll-up-one`).

You can repeat these commands by giving a count. Thus, 2 SPC has the same effect as SPC SPC.

The following commands reposition point in the window.

z H

z RET

Put point on the top (*home*) line in the window. So the current line becomes the top line in the window. Given a count n, point will be placed in the n-th line from top (`vip-line-to-top`).

z M

z .

Put point on the *middle* line in the window. Given a count n, point will be placed in the n-th lir from the middle line (`vip-line-to-middle`).

z L

z -

Put point on the *bottom* line in the window. Given a count n, point will be placed in the n-th line from bottom (`vip-line-to-bottom`).

C-l

Center point in window and redisplay screen (`recenter`).

Mark Commands

The following commands are used to mark positions in the buffer.

m ch

Store current point in the register ch. ch must be a lower case character between a and z.

m <

Set mark at the beginning of current buffer.

m >

Set mark at the end of current buffer.

m .

Set mark at point.

m ,

Jump to mark (and pop mark off the mark ring).

Emacs uses the mark ring to store marked positions. The commands m <, m > and m . not only set mark but also add it as the latest element of the mark ring (replacing the oldest one). By repeating the command `m ,' you can visit older and older marked positions. You will eventually be in a loop as the mark ring is a ring.

Motion Commands

Commands for moving around in the current buffer are collected here. These commands are used as an `argument' for the delete, change and yank commands to be described in the next section.

h

Move point backward by one character. Signal error if point is at the beginning of buffer, but (unlike Vi) do not complain otherwise (`vip-backward-char`).

l

Move point backward by one character. Signal error if point is at the end of buffer, but (unlike Vi) do not complain otherwise (`vip-forward-char`).

j

Move point to the next line keeping the current column. If point is on the last line of the buffer, a new line will be created and point will move to that line (`vip-next-line`).

k

Move point to the previous line keeping the current column (`vip-next-line`).

+

Move point to the next line at the first non-white character. If point is on the last line of the buffer, a new line will be created and point will move to the beginning of that line (`vip-next-line-at-bol`).

-

Move point to the previous line at the first non-white character (`vip-previous-line-at-bol`).

If a count is given to these commands, the commands will be repeated that many times.

0

Move point to the beginning of line (`vip-beginning-of-line`).

^

Move point to the first non-white character on the line (`vip-bol-and-skip-white`).

$

Move point to the end of line (`vip-goto-eol`).

n |

Move point to the n-th column on the line (`vip-goto-col`).

Except for the | command, these commands neglect a count.

w

Move point forward to the beginning of the next word (`vip-forward-word`).

W

Move point forward to the beginning of the next word, where a word is considered as a sequence of non-white characters (`vip-forward-Word`).

b

Move point backward to the beginning of a word (`vip-backward-word`).

B

Move point backward to the beginning of a word, where a *word* is considered as a sequence of non-white characters (`vip-forward-Word`).

e

Move point forward to the end of a word (`vip-end-of-word`).

E

Move point forward to the end of a word, where a *word* is considered as a sequence of non-white characters (`vip-end-of-Word`).

Here the meaning of the word `word' for the w, b and e commands is determined by the syntax table effective in the current buffer. Each major mode has its syntax mode, and therefore the meaning of a

word also changes as the major mode changes. See GNU Emacs Manual for details of syntax table.

H

Move point to the beginning of the *home* (top) line of the window. Given a count n, go to the n-th line from top (`vip-window-top`).

M

Move point to the beginning of the *middle* line of the window. Given a count n, go to the n-th line from the middle line (`vip-window-middle`).

L

Move point to the beginning of the *lowest* (bottom) line of the window. Given count, go to the n-th line from bottom (`vip-window-bottom`).

These commands can be used to go to the desired line visible on the screen.

(

Move point backward to the beginning of the sentence (`vip-backward-sentence`).

)

Move point forward to the end of the sentence (`vip-forward-sentence`).

{

Move point backward to the beginning of the paragraph (`vip-backward-paragraph`).

}

Move point forward to the end of the paragraph (`vip-forward-paragraph`).

A count repeats the effect for these commands.

G

Given a count n, move point to the n-th line in the buffer on the first non-white character. Without a count, go to the end of the buffer (`vip-goto-line`).

` `

Exchange point and mark (`vip-goto-mark`).

` ch

Move point to the position stored in the register ch. ch must be a lower case letter.

' '

Exchange point and mark, and then move point to the first non-white character on the line (`vip-goto-mark-and-skip-white`).

' ch

Move point to the position stored in the register ch and skip to the first non-white character on the line. ch must be a lower case letter.

%

Move point to the matching parenthesis if point is looking at (,), {, }, [or] (`vip-paren-match`).

The command G mark point before move, so that you can return to the original point by ` `. The original point will also be stored in the mark ring.

The following commands are useful for moving points on the line. A count will repeat the effect.

f ch

Move point forward to the character ch on the line. Signal error if ch could not be found (`vip-find-char-forward`).

F ch

Move point backward to the character ch on the line. Signal error if ch could not be found (`vip-find-char-backward`).

t ch

Move point forward upto the character ch on the line. Signal error if ch could not be found (`vip-goto-char-forward`).

T ch

Move point backward upto the character ch on the line. Signal error if ch could not be found (`vip-goto-char-backward`).

;

Repeat previous f, t, F or T command (`vip-repeat-find`).

,

Repeat previous f, t, F or T command, in the opposite direction (`vip-repeat-find-opposite`).

Searching and Replacing

Following commands are available for searching and replacing.

/ string RET

Search the first occurrence of the string string forward starting from point. Given a count n, the n-th occurrence of string will be searched. If the variable `vip-re-search` has value `t` then regular expression search is done and the string matching the regular expression string is found. If you give an empty string as string then the search mode will change from vanilla search to regular expression search and vice versa (`vip-search-forward`).

? string RET

Same as /, except that search is done backward (`vip-search-backward`).

n

Search the previous search pattern in the same direction as before (`vip-search-next`).

N

Search the previous search pattern in the opposite direction (`vip-search-Next`).

C-s

Search forward incrementally. See GNU Emacs Manual for details (`isearch-forward`).

C-r

Search backward incrementally (`isearch-backward`).

R string RET newstring

There are two modes of replacement, vanilla and regular expression. If the mode is *vanilla* you will get a prompt `Replace string:', and if the mode is *regular expression* you will ge a prompt `Replace regexp:'. The mode is initially *vanilla*, but you can toggle these modes by giving a null string as string. If the mode is vanilla, this command replaces every occurrence of string with newstring. If the mode is regular expression, string is treated as a regular expression and every string matching the regular expression is replaced with newstring (`vip-replace-string`).

Q string RET newstring

Same as R except that you will be asked form confirmation before each replacement (`vip-query-replace`).

r ch

Replace the character point is looking at by the character ch. Give count, replace that many characters by ch (`vip-replace-char`).

The commands / and ? mark point before move, so that you can return to the original point by ``.

Modifying Commands

In this section, commands for modifying the content of a buffer are described. These commands affect the region determined by a motion command which is given to the commands as their argument.

We classify motion commands into point commands and line commands. The point commands are as follows:

```
h, l, 0, ^, $, w, W, b, B, e, E, (, ), /, ?, `, f, F, t, T, %, ;, ,
```

The line commands are as follows:

```
j, k, +, -, H, M, L, {, }, G, '
```

If a point command is given as an argument to a modifying command, the region determined by the point command will be affected by the modifying command. On the other hand, if a line command is given as an argument to a modifying command, the region determined by the line command will be enlarged so that it will become the smallest region properly containing the region and consisting of whole lines (we call this process expanding the region), and then the enlarged region will be affected by the modifying command.

Delete Commands

d motion-command

Delete the region determined by the motion command motion-command.

For example, d $ will delete the region between point and end of current line since $ is a point command that moves point to end of line. d G will delete the region between the beginning of current line and end of the buffer, since G is a line command. A count given to the command above will become the count for the associated motion command. Thus, 3 d w will delete three words.

It is also possible to save the deleted text into a register you specify. For example, you can say " t 3 d to delete three words and save it to register t. The name of a register is a lower case letter between a and z. If you give an upper case letter as an argument to a delete command, then the deleted text will be appended to the content of the register having the corresponding lower case letter as its name. So, " T d w will delete a word and append it to register t. Other modifying commands also accept a register name as their argument, and we will not repeat similar explanations.

We have more delete commands as below.

d d

Delete a line. Given a count n, delete n lines.

d r

Delete current region.

d R

Expand current region and delete it.

D

Delete to the end of a line (`vip-kill-line`).

x

Delete a character after point. Given n, delete n characters (`vip-delete-char`).

DEL

Delete a character before point. Given n, delete n characters (`vip-delete-backward-char`).

Yank Commands

Yank commands yank a text of buffer into a (usually anonymous) register. Here the word `yank' is used in Vi's sense. Thus yank commands do not alter the content of the buffer, and useful only in combination with commands that put back the yanked text into the buffer.

y motion-command

Yank the region determined by the motion command motion-command.

For example, y $ will yank the text between point and the end of line into an anonymous register, while "c y $ will yank the same text into register c.

Use the following command to yank consecutive lines of text.

y y

Y

Yank a line. Given n, yank n lines (`vip-yank-line`).

y r

Yank current region.

y R

Expand current region and yank it.

Put Back Commands

Deleted or yanked texts can be put back into the buffer by the command below.

p

Insert, after the character point is looking at, most recently deleted/yanked text from anonymous register. Given a register name argument, the content of the named register will be put back. Given a count, the command will be repeated that many times. This command also checks if the text to put back ends with a new line character, and if so the text will be put below the current line (`vip-put-back`).

P

Insert at point most recently deleted/yanked text from anonymous register. Given a register name argument, the content of the named register will be put back. Given a count, the command will be repeated that many times. This command also checks if the text to put back ends with a new line character, and if so the text will be put above the current line rather than at point (`vip-Put-back`).

Thus, " c p will put back the content of the register c into the buffer. It is also possible to specify number register which is a numeral between 1 and 9. If the number register n is specified, n-th previously deleted/yanked text will be put back. It is an error to specify a number register for the delete/yank commands.

Change Commands

Most commonly used change command takes the following form.

c motion-command

Replace the content of the region determined by the motion command motion-command by the text you type. If the motion command is a point command then you will type the text into minibuffer, and if the motion command is a line command then the region will be deleted first and you can insert the text in insert mode.

For example, if point is at the beginning of a word `foo' and you wish to change it to `bar', you can type c w. Then, as w is a point command, you will get the prompt `foo =>' in the minibuffer, for which you can type b a r RET to complete the change command.

c c

Change a line. Given a count, that many lines are changed.

c r

Change current region.

c R

Expand current region and change it.

Repeating and Undoing Modifications

VIP records the previous modifying command, so that it is easy to repeat it. It is also very easy to undo changes made by modifying commands.

u

Undo the last change. You can undo more by repeating undo by the repeat command `.'. For example, you can undo 5 previous changes by typing `u....'. If you type `uu', then the second `u' undoes the first undo command (`vip-undo`).

.

Repeat the last modifying command. Given count n it becomes the new count for the repeated command. Otherwise, the count for the last modifying command is used again (`vip-repeat`).

Other Vi Commands

Miscellaneous Vi commands are collected here.

Z Z

Exit Emacs. If modified buffers exist, you will be asked whether you wish to save them or not (`save-buffers-kill-emacs`).

! motion-command format-command

n ! ! format-command

The region determined by the motion command motion-command will be given to the shell command format-command and the region will be replaced by its output. If a count is given, it will be passed to motion-command. For example, `3!Gsort' will sort the region between point and the 3rd line. If ! is used instead of motion-command then n lines will be processed by format-command (`vip-command-argument`).

J

Join two lines. Given count, join that many lines. A space will be inserted at each junction (`vip-join-lines`).

< motion-command

n < <

Shift region determined by the motion command motion-command to left by shift-width (default is 8). If < is used instead of motion-command then shift n lines (`vip-command-argument`).

> motion-command

n > >

Shift region determined by the motion command motion-command to right by shift-width (default is 8). If < is used instead of motion-command then shift n lines (`vip-command-argument`).

= motion-command

Indent region determined by the motion command motion-command. If = is used instead of

motion-command then indent n lines (`vip-command-argument`).

*

Call last remembered keyboard macro.

#

A new vi operator. See section Some New Commands, for more details.

The following keys are reserved for future extensions, and currently assigned to a function that just beeps (`vip-nil`).

`&, @, U, [, ], _, q, ~`

VIP uses a special local keymap to interpret key strokes you enter in vi mode. The following keys are bound to nil in the keymap. Therefore, these keys are interpreted by the global keymap of Emacs. We give below a short description of the functions bound to these keys in the global keymap. See GNU Emacs Manual for details.

C-@

Set mark and push previous mark on mark ring (`set-mark-command`).

TAB

Indent line for current major mode (`indent-for-tab-command`).

LFD

Insert a newline, then indent according to mode (`newline-and-indent`).

C-k

Kill the rest of the current line; before a newline, kill the newline. With a numeric argument, kill that many lines from point. Negative arguments kill lines backward (`kill-line`).

C-l

Clear the screen and reprint everything (`recenter`).

n C-p

Move cursor vertically up n lines (`previous-line`).

C-q

Read next input character and insert it. Useful for inserting control characters (`quoted-insert`).

C-r

Search backward incrementally (`isearch-backward`).

C-s

Search forward incrementally (`isearch-forward`).

n C-t

Interchange characters around point, moving forward one character. With count n, take character before point and drag it forward past n other characters. If no argument and at end of line, the previous two characters are exchanged (`transpose-chars`).

n C-v

Scroll text upward n lines. If n is not given, scroll near full screen (`scroll-up`).

C-w

Kill between point and mark. The text is save in the kill ring. The command P or p can retrieve it from kill ring (`kill-region`).

Insert Mode

You can enter insert mode by one of the following commands. In addition to these, you will enter insert mode if you give a change command with a line command as the motion command. Insert commands are also modifying commands and you can repeat them by the repeat command . (`vip-repeat`).

i

Enter insert mode at point (`vip-insert`).

I

Enter insert mode at the first non white character on the line (`vip-Insert`).

a

Move point forward by one character and then enter insert mode (`vip-append`).

A

Enter insert mode at end of line (`vip-Append`).

o

Open a new line below the current line and enter insert mode (`vip-open-line`).

O

Open a new line above the current line and enter insert mode (`vip-Open-line`).

C-o

Insert a newline and leave point before it, and then enter insert mode (`vip-open-line-at-point`).

Insert mode is almost like emacs mode. Only the following 4 keys behave differently from emacs mode.

ESC

This key will take you back to vi mode (`vip-change-mode-to-vi`).

C-h

Delete previous character (`delete-backward-char`).

C-w

Delete previous word (`vip-delete-backward-word`).

C-z

This key simulates ESC key in emacs mode. For instance, typing C-z x in insert mode iw the same as typing ESC x in emacs mode (`vip-ESC`).

You can also bind C-h to `help-command` if you like. (See section Customizing Key Bindings, for details.) Binding C-h to `help-command` has the effect of making the meaning of C-h uniform among

emacs, vi and insert modes.

When you enter insert mode, VIP records point as the start point of insertion, and when you leave insert mode the region between point and start point is saved for later use by repeat command etc. Therefore, repeat command will not really repeat insertion if you move point by emacs commands while in insert mode.

Go to the previous, next section.

Go to the previous, next section.

Ex Commands

In vi mode, you can execute an Ex command ex-command by typing:

```
: ex-command RET
```

Every Ex command follows the following pattern:

```
address command ! parameters count flags
```

where all parts are optional. For the syntax of address, the reader is referred to the reference manual of Ex.

In the current version of VIP, searching by Ex commands is always magic. That is, search patterns are always treated as regular expressions. For example, a typical forward search would be invoked by :/pat/. If you wish to include `/' as part of pat you must preceded it by `\'. VIP strips off these \'s before / and the resulting pat becomes the actual search pattern. Emacs provides a different and richer class or regular expressions than Vi/Ex, and VIP uses Emacs' regular expressions. See GNU Emacs Manual for details of regular expressions.

Several Ex commands can be entered in a line by separating them by a pipe character `|'.

Ex Command Reference

In this section we briefly explain all the Ex commands supported by VIP. Most Ex commands expect address as their argument, and they use default addresses if they are not explicitly given. In the following, such default addresses will be shown in parentheses.

Most command names can and preferably be given in abbreviated forms. In the following, optional parts of command names will be enclosed in brackets. For example, `co[py]' will mean that copy command can be give as `co' or `cop' or `copy'.

If command is empty, point will move to the beginning of the line specified by the address. If address is also empty, point will move to the beginning of the current line.

Some commands accept flags which are one of p, l and #. If flags are given, the text affected by the commands will be displayed on a temporary window, and you will be asked to hit return to continue. In this way, you can see the text affected by the commands before the commands will be executed. If you hit C-g instead of RET then the commands will be aborted. Note that the meaning of flags is different in VIP from that in Vi/Ex.

(.,.) co[py] addr flags

(.,.) t addr flags

Place a copy of specified lines after addr. If addr is 0, it will be placed before the first line.

(.,.) d[elete] register count flags

Delete specified lines. Text will be saved in a named register if a lower case letter is given, and appended to a register if a capital letter is given.

e[dit] ! +addr file

e[x] ! +addr file

vi[sual] ! +addr file

Edit a new file file in the current window. The command will abort if current buffer is modified, which you can override by giving !. If +addr is given, addr becomes the current line.

file

Give information about the current file.

(1,$) g[lobal] ! /pat/ cmds

(1,$) v /pat/ cmds

Among specified lines first mark each line which matches the regular expression pat, and then execute cmds on each marked line. If ! is given, cmds will be executed on each line not matching pat. v is same as g!.

(.,.+1) j[oin] ! count flags

Join specified lines into a line. Without !, a space character will be inserted at each junction.

(.) k ch

(.) mar[k] ch

Mark specified line by a lower case character ch. Then the addressing form 'ch will refer to this line. No white space is required between k and ch. A white space is necessary between mark and ch, however.

map ch rhs

Define a macro for vi mode. After this command, the character ch will be expanded to rhs in vi mode.

(.,.) m[ove] addr

Move specified lines after addr.

(.) pu[t] register

Put back previously deleted or yanked text. If register is given, the text saved in the register will be put back; otherwise, last deleted or yanked text will be put back.

q[uit] !

Quit from Emacs. If modified buffers with associated files exist, you will be asked whether you wish to save each of them. At this point, you may choose not to quit, by hitting C-g. If ! is given, exit from Emacs without saving modified buffers.

(.) r[ead] file

Read in the content of the file file after the specified line.

(.) r[ead] ! command

Read in the output of the shell command command after the specified line.

se[t]

Set a variable's value. See section Customizing Constants, for the list of variables you can set.

sh[ell]

Run a subshell in a window.

(.,.) s[ubstitute] /pat/repl/ options count flags

(.,.) & options count flags

On each specified line, the first occurrence of string matching regular expression pat is replaced by replacement pattern repl. Option characters are g and c. If global option character g appears as part of options, all occurrences are substituted. If confirm option character c appears, you will be asked to give confirmation before each substitution. If /pat/repl/ is missing, the last substitution is repeated.

st[op]

Suspend Emacs.

ta[g] tag

Find first definition of tag. If no tag is given, previously given tag is used and next alternate definition is find. By default, the file `TAGS' in the current directory becomes the selected tags table. You can select another tags table by set command. See section Customizing Constants, for details.

und[o]

Undo the last change.

unm[ap] ch

The macro expansion associated with ch is removed.

ve[rsion]

Tell the version number of VIP.

(1,$) w[rite] ! file

Write out specified lines into file file. If no file is given, text will be written to the file associated to the current buffer. Unless ! is given, if file is different from the file associated to the current buffer and if the file file exists, the command will not be executed. Unlike Ex, file becomes the file associated to the current buffer.

(1,$) w[rite]>> file

Write out specified lines at the end of file file. file becomes the file associated to the current buffer.

(1,$) wq ! file

Same as write and then quit. If ! is given, same as write ! then quit.

(.,.) y[ank] register count

Save specified lines into register register. If no register is specified, text will be saved in an anonymous register.

addr ! command

Execute shell command command. The output will be shown in a new window. If addr is given, specified lines will be used as standard input to command.

($) =

Print the line number of the addressed line.

(.,.) > count flags

Shift specified lines to the right. The variable `vip-shift-width` (default value is 8) determines the amount of shift.

(.,.) < count flags

Shift specified lines to the left. The variable `vip-shift-width` (default value is 8) determines the amount of shift.

(.,.) ~ options count flags

Repeat the previous substitute command using previous search pattern as pat for matching.

The following Ex commands are available in Vi, but not implemented in VIP.

```
abbreviate, list, next, print, preserve, recover, rewind, source,
unabbreviate, xit, z
```

Go to the previous, next section.

Customization

If you have a file called `.vip' in your home directory, then it will also be loaded when VIP is loaded. This file is thus useful for customizing VIP.

Customizing Constants

An easy way to customize VIP is to change the values of constants used in VIP. Here is the list of the constants used in VIP and their default values.

`vip-shift-width 8`

The number of columns shifted by > and < command.

`vip-re-replace nil`

If `t` then do regexp replace, if `nil` then do string replace.

`vip-search-wrap-around t`

If `t`, search wraps around the buffer.

`vip-re-search nil`

If `t` then search is reg-exp search, if `nil` then vanilla search.

`vip-case-fold-search nil`

If `t` search ignores cases.

`vip-re-query-replace nil`

If `t` then do reg-exp replace in query replace.

`vip-open-with-indent nil`

If `t` then indent to the previous current line when open a new line by o or O command.

`vip-tags-file-name "TAGS"`

The name of the file used as the tags table.

`vip-help-in-insert-mode nil`

If `t` then C-h is bound to `help-command` in insert mode, if `nil` then it sis bound to `delete-backward-char`.

You can reset these constants in VIP by the Ex command set. Or you can include a line like this in your `.vip' file:

```
(setq vip-case-fold-search t)
```

Customizing Key Bindings

VIP uses `vip-command-mode-map` as the local keymap for vi mode. For example, in vi mode, SPC is bound to the function `vip-scroll`. But, if you wish to make SPC and some other keys behave like Vi, you can include the following lines in your `` `.vip' `` file.

```
(define-key vip-command-mode-map "\C-g" 'vip-info-on-file)
(define-key vip-command-mode-map "\C-h" 'vip-backward-char)
(define-key vip-command-mode-map "\C-m" 'vip-next-line-at-bol)
(define-key vip-command-mode-map " " 'vip-forward-char)
(define-key vip-command-mode-map "g" 'vip-keyboard-quit)
(define-key vip-command-mode-map "s" 'vip-substitute)
(define-key vip-command-mode-map "C" 'vip-change-to-eol)
(define-key vip-command-mode-map "R" 'vip-change-to-eol)
(define-key vip-command-mode-map "S" 'vip-substitute-line)
(define-key vip-command-mode-map "X" 'vip-delete-backward-char)
```
