where keylist is a list of key values. If there is exactly one value, and it is not a cons cell or the symbol `nil` or `t`, then it can be used by itself as a keylist without being enclosed in a list. All key values in the `case` form must be distinct. The final clauses may use `t` in place of a keylist to indicate a default clause that should be taken if none of the other clauses match. (The symbol `otherwise` is also recognized in place of `t`. To make a clause that matches the actual symbol `t`, `nil`, or `otherwise`, enclose the symbol in a list.)

For example, this expression reads a keystroke, then does one of four things depending on whether it is an `a', a `b', a RET or LFD, or anything else.

```
(case (read-char)
  (?a (do-a-thing))
  (?b (do-b-thing))
  ((?\r ?\n) (do-ret-thing))
  (t (do-other-thing)))
```

Special Form: **ecase** *keyform clause...*

This macro is just like `case`, except that if the key does not match any of the clauses, an error is signaled rather than simply returning `nil`.

Special Form: **typecase** *keyform clause...*

This macro is a version of `case` that checks for types rather than values. Each clause is of the form `(type body...)'. See section Type Predicates, for a description of type specifiers. For example,

```
(typecase x
  (integer (munch-integer x))
  (float (munch-float x))
  (string (munch-integer (string-to-int x)))
  (t (munch-anything x)))
```

The type specifier `t` matches any type of object; the word `otherwise` is also allowed. To make one clause match any of several types, use an `(or ...)` type specifier.

Special Form: **etypecase** *keyform clause...*

This macro is just like `typecase`, except that if the key does not match any of the clauses, an error is signaled rather than simply returning `nil`.

Blocks and Exits

Common Lisp blocks provide a non-local exit mechanism very similar to `catch` and `throw`, but lexically rather than dynamically scoped. This package actually implements `block` in terms of `catch`; however, the lexical scoping allows the optimizing byte-compiler to omit the costly `catch` step if the body of the block does not actually `return-from` the block.

Special Form: **block** *name forms...*

The forms are evaluated as if by a `progn`. However, if any of the forms execute `(return-from name)`, they will jump out and return directly from the `block` form. The `block` returns the result of the last form unless a `return-from` occurs.

The `block`/`return-from` mechanism is quite similar to the `catch`/`throw` mechanism. The main differences are that block names are unevaluated symbols, rather than forms (such as quoted symbols) which evaluate to a tag at run-time; and also that blocks are lexically scoped whereas `catch`/`throw` are dynamically scoped. This means that functions called from the body of a `catch` can also `throw` to the `catch`, but the `return-from` referring to a block name must appear physically within the forms that make up the body of the block. They may not appear within other called functions, although they may appear within macro expansions or `lambda`s in the body. Block names and `catch` names form independent name-spaces.

In true Common Lisp, `defun` and `defmacro` surround the function or expander bodies with implicit blocks with the same name as the function or macro. This does not occur in Emacs Lisp, but this package

provides `defun*` and `defmacro*` forms which do create the implicit block.

The Common Lisp looping constructs defined by this package, such as `loop` and `dolist`, also create implicit blocks just as in Common Lisp.

Because they are implemented in terms of Emacs Lisp `catch` and `throw`, blocks have the same overhead as actual `catch` constructs (roughly two function calls). However, Zawinski and Furuseth's optimizing byte compiler (standard in Emacs 19) will optimize away the `catch` if the block does not in fact contain any `return` or `return-from` calls that jump to it. This means that `do` loops and `defun*` functions which don't use `return` don't pay the overhead to support it.

Special Form: **return-from** *name [result]*

This macro returns from the block named name, which must be an (unevaluated) symbol. If a result form is specified, it is evaluated to produce the result returned from the `block`. Otherwise, `nil` is returned.

Special Form: **return** *[result]*

This macro is exactly like `(return-from nil result)`. Common Lisp loops like `do` and `dolist` implicitly enclose themselves in `nil` blocks.

Iteration

The macros described here provide more sophisticated, high-level looping constructs to complement Emacs Lisp's basic `while` loop.

Special Form: **loop** *forms...*

The CL package supports both the simple, old-style meaning of `loop` and the extremely powerful and flexible feature known as the Loop Facility or Loop Macro. This more advanced facility is discussed in the following section; see section Loop Facility. The simple form of `loop` is described here.

If `loop` is followed by zero or more Lisp expressions, then `(loop exprs...)` simply creates an infinite loop executing the expressions over and over. The loop is enclosed in an implicit `nil` block. Thus,

```
(loop (foo)  (if (no-more) (return 72))  (bar))
```

is exactly equivalent to

```
(block nil (while t (foo)  (if (no-more) (return 72))  (bar)))
```

If any of the expressions are plain symbols, the loop is instead interpreted as a Loop Macro specification as described later. (This is not a restriction in practice, since a plain symbol in the above notation would simply access and throw away the value of a variable.)

Special Form: **do** *(spec...) (end-test [result...]) forms...*

This macro creates a general iterative loop. Each spec is of the form

```
(var [init [step]])
```

The loop works as follows: First, each var is bound to the associated init value as if by a `let` form. Then, in each iteration of the loop, the end-test is evaluated; if true, the loop is finished. Otherwise, the body forms are evaluated, then each var is set to the associated step expression (as if by a `psetq` form) and the next iteration begins. Once the end-test becomes true, the result forms are evaluated (with the vars still bound to their values) to produce the result returned by `do`.

The entire `do` loop is enclosed in an implicit `nil` block, so that you can use `(return)` to break out of the loop at any time.

If there are no result forms, the loop returns `nil`. If a given var has no step form, it is bound to its init value but not otherwise modified during the `do` loop (unless the code explicitly modifies it); this case is just a shorthand for putting a `(let ((var init)) ...)` around the loop. If init is also omitted it defaults to `nil`, and in this case a plain `var' can be used in place of `(var)', again following the analogy with `let`.

This example (from Steele) illustrates a loop which applies the function `f` to successive pairs of values from the lists `foo` and `bar`; it is equivalent to the call `(mapcar* 'f foo bar)`. Note that this loop has no body forms at all, performing all its work as side effects of the rest of the loop.

```
(do ((x foo (cdr x))
     (y bar (cdr y))
     (z nil (cons (f (car x) (car y)) z)))
  ((or (null x) (null y))
   (nreverse z)))
```

Special Form: **do*** *(spec...) (end-test [result...]) forms...*

This is to `do` what `let*` is to `let`. In particular, the initial values are bound as if by `let*` rather than `let`, and the steps are assigned as if by `setq` rather than `psetq`.

Here is another way to write the above loop:

```
(do* ((xp foo (cdr xp))
      (yp bar (cdr yp))
      (x (car xp) (car xp))
      (y (car yp) (car yp))
      z)
  ((or (null xp) (null yp))
   (nreverse z))
  (push (f x y) z))
```

Special Form: **dolist** *(var list [result]) forms...*

This is a more specialized loop which iterates across the elements of a list. list should evaluate to a list; the body forms are executed with var bound to each element of the list in turn. Finally, the result form (or

`nil`) is evaluated with var bound to `nil` to produce the result returned by the loop. The loop is surrounded by an implicit `nil` block.

Special Form: **dotimes** *(var count [result]) forms...*

This is a more specialized loop which iterates a specified number of times. The body is executed with var bound to the integers from zero (inclusive) to count (exclusive), in turn. Then the `result` form is evaluated with var bound to the total number of iterations that were done (i.e., `(max 0 count)`) to get the return value for the loop form. The loop is surrounded by an implicit `nil` block.

Special Form: **do-symbols** *(var [obarray [result]]) forms...*

This loop iterates over all interned symbols. If obarray is specified and is not `nil`, it loops over all symbols in that obarray. For each symbol, the body forms are evaluated with var bound to that symbol. The symbols are visited in an unspecified order. Afterward the result form, if any, is evaluated (with var bound to `nil`) to get the return value. The loop is surrounded by an implicit `nil` block.

Special Form: **do-all-symbols** *(var [result]) forms...*

This is identical to `do-symbols` except that the obarray argument is omitted; it always iterates over the default obarray.

See section Mapping over Sequences, for some more functions for iterating over vectors or lists.

Loop Facility

A common complaint with Lisp's traditional looping constructs is that they are either too simple and limited, such as Common Lisp's `dotimes` or Emacs Lisp's `while`, or too unreadable and obscure, like Common Lisp's `do` loop.

To remedy this, recent versions of Common Lisp have added a new construct called the "Loop Facility" or "`loop` macro," with an easy-to-use but very powerful and expressive syntax.

Loop Basics

The `loop` macro essentially creates a mini-language within Lisp that is specially tailored for describing loops. While this language is a little strange-looking by the standards of regular Lisp, it turns out to be very easy to learn and well-suited to its purpose.

Since `loop` is a macro, all parsing of the loop language takes place at byte-compile time; compiled `loop`s are just as efficient as the equivalent `while` loops written longhand.

Special Form: **loop** *clauses...*

A loop construct consists of a series of clauses, each introduced by a symbol like `for` or `do`. Clauses are simply strung together in the argument list of `loop`, with minimal extra parentheses. The various types of clauses specify initializations, such as the binding of temporary variables, actions to be taken in the loop, stepping actions, and final cleanup.

Common Lisp specifies a certain general order of clauses in a loop:

```
(loop name-clause
      var-clauses...
      action-clauses...)
```

The name-clause optionally gives a name to the implicit block that surrounds the loop. By default, the implicit block is named `nil`. The var-clauses specify what variables should be bound during the loop, and how they should be modified or iterated throughout the course of the loop. The action-clauses are things to be done during the loop, such as computing, collecting, and returning values.

The Emacs version of the `loop` macro is less restrictive about the order of clauses, but things will behave most predictably if you put the variable-binding clauses `with`, `for`, and `repeat` before the action clauses. As in Common Lisp, `initially` and `finally` clauses can go anywhere.

Loops generally return `nil` by default, but you can cause them to return a value by using an accumulation clause like `collect`, an end-test clause like `always`, or an explicit `return` clause to jump out of the implicit block. (Because the loop body is enclosed in an implicit block, you can also use regular Lisp `return` or `return-from` to break out of the loop.)

The following sections give some examples of the Loop Macro in action, and describe the particular loop clauses in great detail. Consult the second edition of Steele's Common Lisp, the Language, for additional discussion and examples of the `loop` macro.

Loop Examples

Before listing the full set of clauses that are allowed, let's look at a few example loops just to get a feel for the `loop` language.

```
(loop for buf in (buffer-list)
      collect (buffer-file-name buf))
```

This loop iterates over all Emacs buffers, using the list returned by `buffer-list`. For each buffer `buf`, it calls `buffer-file-name` and collects the results into a list, which is then returned from the `loop` construct. The result is a list of the file names of all the buffers in Emacs' memory. The words `for`, `in`, and `collect` are reserved words in the `loop` language.

```
(loop repeat 20 do (insert "Yowsa\n"))
```

This loop inserts the phrase "Yowsa" twenty times in the current buffer.

```
(loop until (eobp) do (munch-line) (forward-line 1))
```

This loop calls `munch-line` on every line until the end of the buffer. If point is already at the end of the buffer, the loop exits immediately.

```
(loop do (munch-line) until (eobp) do (forward-line 1))
```

This loop is similar to the above one, except that `munch-line` is always called at least once.

```
(loop for x from 1 to 100
      for y = (* x x)
      until (>= y 729)
      finally return (list x (= y 729)))
```

This more complicated loop searches for a number `x` whose square is 729. For safety's sake it only examines `x` values up to 100; dropping the phrase `to 100' would cause the loop to count upwards with no limit. The second `for` clause defines `y` to be the square of `x` within the loop; the expression after the `=` sign is reevaluated each time through the loop. The `until` clause gives a condition for terminating the loop, and the `finally` clause says what to do when the loop finishes. (This particular example was written less concisely than it could have been, just for the sake of illustration.)

Note that even though this loop contains three clauses (two `for`s and an `until`) that would have been enough to define loops all by themselves, it still creates a single loop rather than some sort of triple-nested loop. You must explicitly nest your `loop` constructs if you want nested loops.

For Clauses

Most loops are governed by one or more `for` clauses. A `for` clause simultaneously describes variables to be bound, how those variables are to be stepped during the loop, and usually an end condition based on those variables.

The word `as` is a synonym for the word `for`. This word is followed by a variable name, then a word like `from` or `across` that describes the kind of iteration desired. In Common Lisp, the phrase `being the` sometimes precedes the type of iteration; in this package both `being` and `the` are optional. The word `each` is a synonym for `the`, and the word that follows it may be singular or plural: `for x being the elements of y' or `for x being each element of y'. Which form you use is purely a matter of style.

The variable is bound around the loop as if by `let`:

```
(setq i 'happy)
(loop for i from 1 to 10 do (do-something-with i))
i
     => happy
```

`for var from expr1 to expr2 by expr3`

This type of `for` clause creates a counting loop. Each of the three sub-terms is optional, though there must be at least one term so that the clause is marked as a counting clause.

The three expressions are the starting value, the ending value, and the step value, respectively, of the variable. The loop counts upwards by default (expr3 must be positive), from expr1 to expr2 inclusively. If you omit the `from` term, the loop counts from zero; if you omit the `to` term, the loop counts forever without stopping (unless stopped by some other loop clause, of course); if you omit the `by` term, the loop counts in steps of one.

You can replace the word `from` with `upfrom` or `downfrom` to indicate the direction of the l Likewise, you can replace `to` with `upto` or `downto`. For example, `for x from 5 downto 1' executes five times with `x` taking on the integers from 5 down to 1 in turn. Also, you can replace `to` with `below` or `above`, which are like `upto` and `downto` respectively except that they are exclusive rather than inclusive limits:

```
(loop for x to 10 collect x)
     => (0 1 2 3 4 5 6 7 8 9 10)
(loop for x below 10 collect x)
     => (0 1 2 3 4 5 6 7 8 9)
```

The `by` value is always positive, even for downward-counting loops. Some sort of `from` value is required for downward loops; `for x downto 5' is not a legal loop clause all by itself.

`for var in list by function`

This clause iterates var over all the elements of list, in turn. If you specify the `by` term, then function is used to traverse the list instead of `cdr`; it must be a function taking one argument. For example:

```
(loop for x in '(1 2 3 4 5 6) collect (* x x))
     => (1 4 9 16 25 36)
(loop for x in '(1 2 3 4 5 6) by 'cddr collect (* x x))
     => (1 9 25)
```

`for var on list by function`

This clause iterates var over all the cons cells of list.

```
(loop for x on '(1 2 3 4) collect x)
     => ((1 2 3 4) (2 3 4) (3 4) (4))
```

With `by`, there is no real reason that the `on` expression must be a list. For example:

```
(loop for x on first-animal by 'next-animal collect x)
```

where `(next-animal x)` takes an "animal" x and returns the next in the (assumed) sequence of animals, or `nil` if x was the last animal in the sequence.

`for var in-ref list by function`

This is like a regular `in` clause, but var becomes a `setf`-able "reference" onto the elements of the list rather than just a temporary variable. For example,

```
(loop for x in-ref my-list do (incf x))
```

increments every element of `my-list` in place. This clause is an extension to standard Common Lisp.

`for var across array`

This clause iterates var over all the elements of array, which may be a vector or a string.

```
(loop for x across "aeiou"
      do (use-vowel (char-to-string x)))
```

`for var across-ref array`

This clause iterates over an array, with var a `setf`-able reference onto the elements; see `in-ref` above.

`for var being the elements of sequence`

This clause iterates over the elements of sequence, which may be a list, vector, or string. Since the type must be determined at run-time, this is somewhat less efficient than `in` or `across`. The clause may be followed by the additional term `using (index var2)' to cause var2 to be bound to the successive indices (starting at 0) of the elements.

This clause type is taken from older versions of the `loop` macro, and is not present in modern Common Lisp. The `using (sequence ...)' term of the older macros is not supported.

`for var being the elements of-ref sequence`

This clause iterates over a sequence, with var a `setf`-able reference onto the elements; see `in-ref` above.

`for var being the symbols [of obarray]`

This clause iterates over symbols, either over all interned symbols or over all symbols in obarray. The loop is executed with var bound to each symbol in turn. The symbols are visited in an unspecified order.

As an example,

```
(loop for sym being the symbols
      when (fboundp sym)
      when (string-match "^map" (symbol-name sym))
      collect sym)
```

returns a list of all the functions whose names begin with `map'.

The Common Lisp words `external-symbols` and `present-symbols` are also recognized but are equivalent to `symbols` in Emacs Lisp.

Due to a minor implementation restriction, it will not work to have more than one `for` clause iterating over symbols, hash tables, keymaps, overlays, or intervals in a given `loop`. Fortunately, it would rarely if ever be useful to do so. It *is* legal to mix one of these types of clauses with other clauses like `for ... to` or `while`.

`for var being the hash-keys of hash-table`

This clause iterates over the entries in hash-table. For each hash table entry, var is bound to the entry's key. If you write `the hash-values' instead, var is bound to the values of the entries. The clause may be followed by the additional term `using (hash-values var2)' (where `hash-values` is the opposite word of the word following `the`) to cause var and var2 to be bound to the two parts of each hash table entry.

`for var being the key-codes of keymap`

This clause iterates over the entries in keymap. In GNU Emacs 18 and 19, keymaps are either alists or vectors, and key-codes are integers or symbols. In Lucid Emacs 19, keymaps are a special new data type, and key-codes are symbols or lists of symbols. The iteration does not enter nested keymaps or inherited (parent) keymaps. You can use `the key-bindings' to access the commands bound to the keys rather than the key codes, and you can add a `using` clause to access both the codes and the bindings together.

`for var being the key-seqs of keymap`

This clause iterates over all key sequences defined by keymap and its nested keymaps, where var takes on values which are strings in Emacs 18 or vectors in Emacs 19. The strings or vectors are reused for each iteration, so you must copy them if you wish to keep them permanently. You can add a `using (key-bindings ...)' clause to get the command bindings as well.

`for var being the overlays [of buffer] ...`

This clause iterates over the Emacs 19 "overlays" or Lucid Emacs "extents" of a buffer (the clause `extents` is synonymous with `overlays`). Under Emacs 18, this clause iterates zero times. If the `of` term is omitted, the current buffer is used. This clause also accepts optional `from pos' and `to pos' terms, limiting the clause to overlays which overlap the specified region.

`for var being the intervals [of buffer] ...`

This clause iterates over all intervals of a buffer with constant text properties. The variable var will be bound to conses of start and end positions, where one start position is always equal to the previous end position. The clause allows `of`, `from`, `to`, and `property` terms, where the latter term restricts the search to just the specified property. The `of` term may specify either a buffer or a string. This clause is useful only in GNU Emacs 19; in other versions, all buffers and strings consist of a single interval.

`for var being the frames`

This clause iterates over all frames, i.e., X window system windows open on Emacs files. This clause works only under Emacs 19. The clause `screens` is a synonym for `frames`. The frames are visited in `next-frame` order starting from `selected-frame`.

`for var being the windows [of frame]`

This clause iterates over the windows (in the Emacs sense) of the current frame, or of the specified frame. (In Emacs 18 there is only ever one frame, and the `of` term is not allowed there.)

`for var being the buffers`

This clause iterates over all buffers in Emacs. It is equivalent to `for var in (buffer-list)'.

`for var = expr1 then expr2`

This clause does a general iteration. The first time through the loop, var will be bound to expr1. On the second and successive iterations it will be set by evaluating expr2 (which may refer to the old value of var). For example, these two loops are effectively the same:

```
(loop for x on my-list by 'cddr do ...)
(loop for x = my-list then (cddr x) while x do ...)
```

Note that this type of `for` clause does not imply any sort of terminating condition; the above

example combines it with a `while` clause to tell when to end the loop.

If you omit the `then` term, expr1 is used both for the initial setting and for successive settings:

```
(loop for x = (random) when (> x 0) return x)
```

This loop keeps taking random numbers from the `(random)` function until it gets a positive one, which it then returns.

If you include several `for` clauses in a row, they are treated sequentially (as if by `let*` and `setq`). You can instead use the word `and` to link the clauses, in which case they are processed in parallel (as if by `let` and `psetq`).

```
(loop for x below 5 for y = nil then x collect (list x y))
     => ((0 nil) (1 1) (2 2) (3 3) (4 4))
(loop for x below 5 and y = nil then x collect (list x y))
     => ((0 nil) (1 0) (2 1) (3 2) (4 3))
```

In the first loop, `y` is set based on the value of `x` that was just set by the previous clause; in the second loop, `x` and `y` are set simultaneously so `y` is set based on the value of `x` left over from the previous time through the loop.

Another feature of the `loop` macro is destructuring, similar in concept to the destructuring provided by `defmacro`. The var part of any `for` clause can be given as a list of variables instead of a single variable. The values produced during loop execution must be lists; the values in the lists are stored in the corresponding variables.

```
(loop for (x y) in '((2 3) (4 5) (6 7)) collect (+ x y))
     => (5 9 13)
```

In loop destructuring, if there are more values than variables the trailing values are ignored, and if there are more variables than values the trailing variables get the value `nil`. If `nil` is used as a variable name, the corresponding values are ignored. Destructuring may be nested, and dotted lists of variables like `(x . y)` are allowed.

Iteration Clauses

Aside from `for` clauses, there are several other loop clauses that control the way the loop operates. They might be used by themselves, or in conjunction with one or more `for` clauses.

`repeat integer`

This clause simply counts up to the specified number using an internal temporary variable. The loops

```
(loop repeat n do ...)
(loop for temp to n do ...)
```

are identical except that the second one forces you to choose a name for a variable you aren't actually going to use.

`while condition`

This clause stops the loop when the specified condition (any Lisp expression) becomes `nil`. For example, the following two loops are equivalent, except for the implicit `nil` block that surrounds the second one:

```
(while cond forms...)
(loop while cond do forms...)
```

`until condition`

This clause stops the loop when the specified condition is true, i.e., non-`nil`.

`always condition`

This clause stops the loop when the specified condition is `nil`. Unlike `while`, it stops the loop using `return nil` so that the `finally` clauses are not executed. If all the conditions were non-`nil`, the loop returns `t`:

```
(if (loop for size in size-list always (> size 10))
    (some-big-sizes)
  (no-big-sizes))
```

`never condition`

This clause is like `always`, except that the loop returns `t` if any conditions were false, or `nil` otherwise.

`thereis condition`

This clause stops the loop when the specified form is non-`nil`; in this case, it returns that non-`nil` value. If all the values were `nil`, the loop returns `nil`.

Accumulation Clauses

These clauses cause the loop to accumulate information about the specified Lisp form. The accumulated result is returned from the loop unless overridden, say, by a `return` clause.

`collect form`

This clause collects the values of form into a list. Several examples of `collect` appear elsewhere in this manual.

The word `collecting` is a synonym for `collect`, and likewise for the other accumulation clauses.

`append form`

This clause collects lists of values into a result list using `append`.

`nconc form`

This clause collects lists of values into a result list by destructively modifying the lists rather than copying them.

`concat form`

This clause concatenates the values of the specified form into a string. (It and the following clause are extensions to standard Common Lisp.)

`vconcat form`

This clause concatenates the values of the specified form into a vector.

`count form`

This clause counts the number of times the specified form evaluates to a non-`nil` value.

`sum form`

This clause accumulates the sum of the values of the specified form, which must evaluate to a number.

`maximize form`

This clause accumulates the maximum value of the specified form, which must evaluate to a number. The return value is undefined if `maximize` is executed zero times.

`minimize form`

This clause accumulates the minimum value of the specified form.

Accumulation clauses can be followed by `into var' to cause the data to be collected into variable var (which is automatically `let`-bound during the loop) rather than an unnamed temporary variable. Also, `into` accumulations do not automatically imply a return value. The loop must use some explicit mechanism, such as `finally return`, to return the accumulated result.

It is legal for several accumulation clauses of the same type to accumulate into the same place. From Steele:

```
(loop for name in '(fred sue alice joe june)
      for kids in '((bob ken) () () (kris sunshine) ())
      collect name
      append kids)
     => (fred bob ken sue alice joe kris sunshine june)
```

Other Clauses

This section describes the remaining loop clauses.

`with var = value`

This clause binds a variable to a value around the loop, but otherwise leaves the variable alone during the loop. The following loops are basically equivalent:

```
(loop with x = 17 do ...)
(let ((x 17)) (loop do ...))
(loop for x = 17 then x do ...)
```

Naturally, the variable var might be used for some purpose in the rest of the loop. For example:

```
(loop for x in my-list  with res = nil  do (push x res)
      finally return res)
```

This loop inserts the elements of `my-list` at the front of a new list being accumulated in `res`, then returns the list `res` at the end of the loop. The effect is similar to that of a `collect` clause, but the list gets reversed by virtue of the fact that elements are being pushed onto the front of `res` rather than the end.

If you omit the `=` term, the variable is initialized to `nil`. (Thus the `= nil' in the above example is unnecessary.)

Bindings made by `with` are sequential by default, as if by `let*`. Just like `for` clauses, `with` clauses can be linked with `and` to cause the bindings to be made by `let` instead.

`if condition clause`

This clause executes the following loop clause only if the specified condition is true. The following clause should be an accumulation, `do`, `return`, `if`, or `unless` clause. Several clauses may be linked by separating them with `and`. These clauses may be followed by `else` and a clause or clauses to execute if the condition was false. The whole construct may optionally be followed by the word `end` (which may be used to disambiguate an `else` or `and` in a nested `if`).

The actual non-`nil` value of the condition form is available by the name `it` in the "then" part. For example:

```
(setq funny-numbers '(6 13 -1))
     => (6 13 -1)
(loop for x below 10
      if (oddp x)
        collect x into odds
        and if (memq x funny-numbers) return (cdr it) end
      else
        collect x into evens
      finally return (vector odds evens))
     => [(1 3 5 7 9) (0 2 4 6 8)]
(setq funny-numbers '(6 7 13 -1))
     => (6 7 13 -1)
(loop <same thing again>)
     => (13 -1)
```

Note the use of `and` to put two clauses into the "then" part, one of which is itself an `if` clause. Note also that `end`, while normally optional, was necessary here to make it clear that the `else` refers to the outermost `if` clause. In the first case, the loop returns a vector of lists of the odd and even values of x. In the second case, the odd number 7 is one of the `funny-numbers` so the loop returns early; the actual returned value is based on the result of the `memq` call.

`when condition clause`

This clause is just a synonym for `if`.

`unless condition clause`

The `unless` clause is just like `if` except that the sense of the condition is reversed.

`named name`

This clause gives a name other than `nil` to the implicit block surrounding the loop. The name is the symbol to be used as the block name.

`initially [do] forms...`

This keyword introduces one or more Lisp forms which will be executed before the loop itself begins (but after any variables requested by `for` or `with` have been bound to their initial values). `initially` clauses can appear anywhere; if there are several, they are executed in the order they appear in the loop. The keyword `do` is optional.

`finally [do] forms...`

This introduces Lisp forms which will be executed after the loop finishes (say, on request of a `for` or `while`). `initially` and `finally` clauses may appear anywhere in the loop construct, but they are executed (in the specified order) at the beginning or end, respectively, of the loop.

`finally return form`

This says that form should be executed after the loop is done to obtain a return value. (Without this, or some other clause like `collect` or `return`, the loop will simply return `nil`.) Variables bound by `for`, `with`, or `into` will still contain their final values when form is executed.

`do forms...`

The word `do` may be followed by any number of Lisp expressions which are executed as an implicit `progn` in the body of the loop. Many of the examples in this section illustrate the use of `do`.

`return form`

This clause causes the loop to return immediately. The following Lisp form is evaluated to give the return value of the `loop` form. The `finally` clauses, if any, are not executed. Of course, `return` is generally used inside an `if` or `unless`, as its use in a top-level loop clause would mean the loop would never get to "loop" more than once.

The clause `return form' is equivalent to `do (return form)' (or `return-from` if the loop was named). The `return` clause is implemented a bit more efficiently, though.

While there is no high-level way to add user extensions to `loop` (comparable to `defsetf` for `setf`, say), this package does offer two properties called `cl-loop-handler` and `cl-loop-for-handler` which are functions to be called when a given symbol is encountered as a top-level loop clause or `for` clause, respectively. Consult the source code in file `` `cl-macs.el' `` for details.

This package's `loop` macro is compatible with that of Common Lisp, except that a few features are not implemented: `loop-finish` and data-type specifiers. Naturally, the `for` clauses which iterate over keymaps, overlays, intervals, frames, windows, and buffers are Emacs-specific extensions.

Multiple Values

Common Lisp functions can return zero or more results. Emacs Lisp functions, by contrast, always return exactly one result. This package makes no attempt to emulate Common Lisp multiple return values; Emacs versions of Common Lisp functions that return more than one value either return just the first value (as in `compiler-macroexpand`) or return a list of values (as in `get-setf-method`). This package *does* define placeholders for the Common Lisp functions that work with multiple values, but in Emacs Lisp these functions simply operate on lists instead. The `values` form, for example, is a synonym for `list` in Emacs.

Special Form: **multiple-value-bind** *(var...) values-form forms...*

This form evaluates values-form, which must return a list of values. It then binds the vars to these respective values, as if by `let`, and then executes the body forms. If there are more vars than values, the extra vars are bound to `nil`. If there are fewer vars than values, the excess values are ignored.

Special Form: **multiple-value-setq** *(var...) form*

This form evaluates form, which must return a list of values. It then sets the vars to these respective values, as if by `setq`. Extra vars or values are treated the same as in `multiple-value-bind`.

The older Quiroz package attempted a more faithful (but still imperfect) emulation of Common Lisp multiple values. The old method "usually" simulated true multiple values quite well, but under certain circumstances would leave spurious return values in memory where a later, unrelated `multiple-value-bind` form would see them.

Since a perfect emulation is not feasible in Emacs Lisp, this package opts to keep it as simple and predictable as possible.

Go to the previous, next section.

Macros

This package implements the various Common Lisp features of `defmacro`, such as destructuring, `&environment`, and `&body`. Top-level `&whole` is not implemented for `defmacro` due to technical difficulties. See section Argument Lists.

Destructuring is made available to the user by way of the following macro:

Special Form: **destructuring-bind** *arglist expr forms...*

This macro expands to code which executes forms, with the variables in arglist bound to the list of values returned by expr. The arglist can include all the features allowed for `defmacro` argument lists, including destructuring. (The `&environment` keyword is not allowed.) The macro expansion will signal an error if expr returns a list of the wrong number of arguments or with incorrect keyword arguments.

This package also includes the Common Lisp `define-compiler-macro` facility, which allows you to define compile-time expansions and optimizations for your functions.

Special Form: **define-compiler-macro** *name arglist forms...*

This form is similar to `defmacro`, except that it only expands calls to name at compile-time; calls processed by the Lisp interpreter are not expanded, nor are they expanded by the `macroexpand` function.

The argument list may begin with a `&whole` keyword and a variable. This variable is bound to the macro-call form itself, i.e., to a list of the form `(name args...)'. If the macro expander returns this form unchanged, then the compiler treats it as a normal function call. This allows compiler macros to work as optimizers for special cases of a function, leaving complicated cases alone.

For example, here is a simplified version of a definition that appears as a standard part of this package:

```
(define-compiler-macro member* (&whole form a list &rest keys)
  (if (and (null keys)
           (eq (car-safe a) 'quote)
           (not (floatp-safe (cadr a))))
      (list 'memq a list)
    form))
```

This definition causes `(member* a list)` to change to a call to the faster `memq` in the common case where a is a non-floating-point constant; if a is anything else, or if there are any keyword arguments in the call, then the original `member*` call is left intact. (The actual compiler macro for `member*` optimizes a number of other cases, including common `:test` predicates.)

Function: **compiler-macroexpand** *form*

This function is analogous to `macroexpand`, except that it expands compiler macros rather than re macros. It returns form unchanged if it is not a call to a function for which a compiler macro has bee defined, or if that compiler macro decided to punt by returning its `&whole` argument. Like `macroexpand`, it expands repeatedly until it reaches a form for which no further expansion is possible.

See section Macro Bindings, for descriptions of the `macrolet` and `symbol-macrolet` forms for making "local" macro definitions.

Go to the previous, next section.

Go to the previous, next section.

Declarations

Common Lisp includes a complex and powerful "declaration" mechanism that allows you to give the compiler special hints about the types of data that will be stored in particular variables, and about the ways those variables and functions will be used. This package defines versions of all the Common Lisp declaration forms: `declare`, `locally`, `proclaim`, `declaim`, and `the`.

Most of the Common Lisp declarations are not currently useful in Emacs Lisp, as the byte-code system provides little opportunity to benefit from type information, and `special` declarations are redundant in a fully dynamically-scoped Lisp. A few declarations are meaningful when the optimizing Emacs 19 byte compiler is being used, however. Under the earlier non-optimizing compiler, these declarations will effectively be ignored.

Function: **proclaim** *decl-spec*

This function records a "global" declaration specified by decl-spec. Since `proclaim` is a function, decl-spec is evaluated and thus should normally be quoted.

Special Form: **declaim** *decl-specs...*

This macro is like `proclaim`, except that it takes any number of decl-spec arguments, and the arguments are unevaluated and unquoted. The `declaim` macro also puts an `(eval-when (compile load eval) ...)` around the declarations so that they will be registered at compile-time as well as at run-time. (This is vital, since normally the declarations are meant to influence the way the compiler treats the rest of the file that contains the `declaim` form.)

Special Form: **declare** *decl-specs...*

This macro is used to make declarations within functions and other code. Common Lisp allows declarations in various locations, generally at the beginning of any of the many "implicit `progn`s" throughout Lisp syntax, such as function bodies, `let` bodies, etc. Currently the only declaration understood by `declare` is `special`.

Special Form: **locally** *declarations... forms...*

In this package, `locally` is no different from `progn`.

Special Form: **the** *type form*

Type information provided by `the` is ignored in this package; in other words, `(the type form)` is equivalent to form. Future versions of the optimizing byte-compiler may make use of this information.

For example, `mapcar` can map over both lists and arrays. It is hard for the compiler to expand `mapcar` into an in-line loop unless it knows whether the sequence will be a list or an array ahead of time. With `(mapcar 'car (the vector foo))`, a future compiler would have enough information to expand the loop in-line. For now, Emacs Lisp will treat the above code as exactly equivalent to

```
(mapcar 'car foo).
```

Each decl-spec in a `proclaim`, `declaim`, or `declare` should be a list beginning with a symbol that says what kind of declaration it is. This package currently understands `special`, `inline`, `notinline`, `optimize`, and `warn` declarations. (The `warn` declaration is an extension of standard Common Lisp.) Other Common Lisp declarations, such as `type` and `ftype`, are silently ignored.

`special`

Since all variables in Emacs Lisp are "special" (in the Common Lisp sense), `special` declarations are only advisory. They simply tell the optimizing byte compiler that the specified variables are intentionally being referred to without being bound in the body of the function. The compiler normally emits warnings for such references, since they could be typographical errors for references to local variables.

The declaration `(declare (special var1 var2))` is equivalent to `(defvar var1)` `(defvar var2)` in the optimizing compiler, or to nothing at all in older compilers (which do not warn for non-local references).

In top-level contexts, it is generally better to write `(defvar var)` than `(declaim (special var))`, since `defvar` makes your intentions clearer. But the older byte compilers can not handle `defvar`s appearing inside of functions, while `(declare (special var))` takes care to work correctly with all compilers.

`inline`

The `inline` decl-spec lists one or more functions whose bodies should be expanded "in-line" into calling functions whenever the compiler is able to arrange for it. For example, the Common Lisp function `cadr` is declared `inline` by this package so that the form `(cadr x)` will expand directly into `(car (cdr x))` when it is called in user functions, for a savings of one (relatively expensive) function call.

The following declarations are all equivalent. Note that the `defsubst` form is a convenient way to define a function and declare it inline all at once, but it is available only in Emacs 19.

```
(declaim (inline foo bar))
(eval-when (compile load eval) (proclaim '(inline foo bar)))
(proclaim-inline foo bar)      ; Lucid Emacs only
(defsubst foo (...) ...)       ; instead of defun; Emacs 19 only
```

Note: This declaration remains in effect after the containing source file is done. It is correct to use it to request that a function you have defined should be inlined, but it is impolite to use it to request inlining of an external function.

In Common Lisp, it is possible to use `(declare (inline ...))` before a particular call to a function to cause just that call to be inlined; the current byte compilers provide no way to implement this, so `(declare (inline ...))` is currently ignored by this package.

`notinline`

The `notinline` declaration lists functions which should not be inlined after all; it cancels a previous `inline` declaration.

`optimize`

This declaration controls how much optimization is performed by the compiler. Naturally, it is ignored by the earlier non-optimizing compilers.

The word `optimize` is followed by any number of lists like `(speed 3)` or `(safety 2)`. Common Lisp defines several optimization "qualities"; this package ignores all but `speed` and `safety`. The value of a quality should be an integer from 0 to 3, with 0 meaning "unimportant" and 3 meaning "very important." The default level for both qualities is 1.

In this package, with the Emacs 19 optimizing compiler, the `speed` quality is tied to the `byte-compile-optimize` flag, which is set to `nil` for `(speed 0)` and to `t` for higher settings; and the `safety` quality is tied to the `byte-compile-delete-errors` flag, which is set to `t` for `(safety 3)` and to `nil` for all lower settings. (The latter flag controls whether the compiler is allowed to optimize out code whose only side-effect could be to signal an error, e.g., rewriting `(progn foo bar)` to `bar` when it is not known whether `foo` will be bound at run-time.)

Note that even compiling with `(safety 0)`, the Emacs byte-code system provides sufficient checking to prevent real harm from being done. For example, barring serious bugs in Emacs itself, Emacs will not crash with a segmentation fault just because of an error in a fully-optimized Lisp program.

The `optimize` declaration is normally used in a top-level `proclaim` or `declaim` in a file; Common Lisp allows it to be used with `declare` to set the level of optimization locally for a given form, but this will not work correctly with the current version of the optimizing compiler. (The `declare` will set the new optimization level, but that level will not automatically be unset after the enclosing form is done.)

`warn`

This declaration controls what sorts of warnings are generated by the byte compiler. Again, only the optimizing compiler generates warnings. The word `warn` is followed by any number of "warning qualities," similar in form to optimization qualities. The currently supported warning types are `redefine`, `callargs`, `unresolved`, and `free-vars`; in the current system, a value of 0 will disable these warnings and any higher value will enable them. See the documentation for the optimizing byte compiler for details.

Go to the previous, next section.

Go to the previous, next section.

Symbols

This package defines several symbol-related features that were missing from Emacs Lisp.

Property Lists

These functions augment the standard Emacs Lisp functions `get` and `put` for operating on properties attached to symbols. There are also functions for working with property lists as first-class data structures not attached to particular symbols.

Function: **get*** *symbol property &optional default*

This function is like `get`, except that if the property is not found, the default argument provides the return value. (The Emacs Lisp `get` function always uses `nil` as the default; this package's `get*` is equivalent to Common Lisp's `get`.)

The `get*` function is `setf`-able; when used in this fashion, the default argument is allowed but ignored.

Function: **remprop** *symbol property*

This function removes the entry for property from the property list of symbol. It returns a true value if the property was indeed found and removed, or `nil` if there was no such property. (This function was probably omitted from Emacs originally because, since `get` did not allow a default, it was very difficult to distinguish between a missing property and a property whose value was `nil`; thus, setting a property to `nil` was close enough to `remprop` for most purposes.)

Function: **getf** *place property &optional default*

This function scans the list place as if it were a property list, i.e., a list of alternating property names and values. If an even-numbered element of place is found which is `eq` to property, the following odd-numbered element is returned. Otherwise, default is returned (or `nil` if no default is given).

In particular,

```
(get sym prop)  ==  (getf (symbol-plist sym) prop)
```

It is legal to use `getf` as a `setf` place, in which case its place argument must itself be a legal `setf` place. The default argument, if any, is ignored in this context. The effect is to change (via `setcar`) the value cell in the list that corresponds to property, or to cons a new property-value pair onto the list if the property is not yet present.

```
(put sym prop val)  ==  (setf (getf (symbol-plist sym) prop) val)
```

The `get` and `get*` functions are also `setf`-able. The fact that `default` is ignored can sometimes be

useful:

```
(incf (get* 'foo 'usage-count 0))
```

Here, symbol `foo`'s `usage-count` property is incremented if it exists, or set to 1 (an incremented 0) otherwise.

When not used as a `setf` form, `getf` is just a regular function and its place argument can actually be any Lisp expression.

Special Form: **remf** *place property*

This macro removes the property-value pair for property from the property list stored at place, which is any `setf`-able place expression. It returns true if the property was found. Note that if property happens to be first on the list, this will effectively do a `(setf place (cddr place))`, whereas if it occurs later, this simply uses `setcdr` to splice out the property and value cells.

@secno=2

Creating Symbols

These functions create unique symbols, typically for use as temporary variables.

Function: **gensym** *&optional x*

This function creates a new, uninterned symbol (using `make-symbol`) with a unique name. (The name of an uninterned symbol is relevant only if the symbol is printed.) By default, the name is generated from an increasing sequence of numbers, `G1000', `G1001', `G1002', etc. If the optional argument x is a string, that string is used as a prefix instead of `G'. Uninterned symbols are used in macro expansions for temporary variables, to ensure that their names will not conflict with "real" variables in the user's code.

Variable: ***gensym-counter***

This variable holds the counter used to generate `gensym` names. It is incremented after each use by `gensym`. In Common Lisp this is initialized with 0, but this package initializes it with a random (time-dependent) value to avoid trouble when two files that each used `gensym` in their compilation are loaded together. (Uninterned symbols become interned when the compiler writes them out to a file and the Emacs loader loads them, so their names have to be treated a bit more carefully than in Common Lisp where uninterned symbols remain uninterned after loading.)

Function: **gentemp** *&optional x*

This function is like `gensym`, except that it produces a new *interned* symbol. If the symbol that is generated already exists, the function keeps incrementing the counter and trying again until a new symbol is generated.

The Quiroz `` `cl.el' `` package also defined a `defkeyword` form for creating self-quoting keyword symbols. This package automatically creates all keywords that are called for by `&key` argument specifiers, and discourages the use of keywords as data unrelated to keyword arguments, so the

`defkeyword` form has been discontinued.

@chapno=11

Go to the previous, next section.

Numbers

This section defines a few simple Common Lisp operations on numbers which were left out of Emacs Lisp.

@secno=1

Predicates on Numbers

These functions return `t` if the specified condition is true of the numerical argument, or `nil` otherwise.

Function: **plusp** *number*

This predicate tests whether number is positive. It is an error if the argument is not a number.

Function: **minusp** *number*

This predicate tests whether number is negative. It is an error if the argument is not a number.

Function: **oddp** *integer*

This predicate tests whether integer is odd. It is an error if the argument is not an integer.

Function: **evenp** *integer*

This predicate tests whether integer is even. It is an error if the argument is not an integer.

Function: **floatp-safe** *object*

This predicate tests whether object is a floating-point number. On systems that support floating-point, this is equivalent to `floatp`. On other systems, this always returns `nil`.

@secno=3

Numerical Functions

These functions perform various arithmetic operations on numbers.

Function: **abs** *number*

This function returns the absolute value of number. (Newer versions of Emacs provide this as a built-in function; this package defines `abs` only for Emacs 18 versions which don't provide it as a primitive.)

Function: **expt** *base power*

This function returns base raised to the power of number. (Newer versions of Emacs provide this as a

built-in function; this package defines `expt` only for Emacs 18 versions which don't provide it as a primitive.)

Function: **gcd** *&rest integers*

This function returns the Greatest Common Divisor of the arguments. For one argument, it returns the absolute value of that argument. For zero arguments, it returns zero.

Function: **lcm** *&rest integers*

This function returns the Least Common Multiple of the arguments. For one argument, it returns the absolute value of that argument. For zero arguments, it returns one.

Function: **isqrt** *integer*

This function computes the "integer square root" of its integer argument, i.e., the greatest integer less than or equal to the true square root of the argument.

Function: **floor*** *number &optional divisor*

This function implements the Common Lisp `floor` function. It is called `floor*` to avoid name conflicts with the simpler `floor` function built-in to Emacs 19.

With one argument, `floor*` returns a list of two numbers: The argument rounded down (toward minus infinity) to an integer, and the "remainder" which would have to be added back to the first return value to yield the argument again. If the argument is an integer x, the result is always the list `(x 0)`. If the argument is an Emacs 19 floating-point number, the first result is a Lisp integer and the second is a Lisp float between 0 (inclusive) and 1 (exclusive).

With two arguments, `floor*` divides number by divisor, and returns the floor of the quotient and the corresponding remainder as a list of two numbers. If `(floor* x y)` returns `(q r)`, then `q*y + r = x`, with r between 0 (inclusive) and r (exclusive). Also, note that `(floor* x)` is exactly equivalent to `(floor* x 1)`.

This function is entirely compatible with Common Lisp's `floor` function, except that it returns the two results in a list since Emacs Lisp does not support multiple-valued functions.

Function: **ceiling*** *number &optional divisor*

This function implements the Common Lisp `ceiling` function, which is analogous to `floor` except that it rounds the argument or quotient of the arguments up toward plus infinity. The remainder will be between 0 and minus r.

Function: **truncate*** *number &optional divisor*

This function implements the Common Lisp `truncate` function, which is analogous to `floor` except that it rounds the argument or quotient of the arguments toward zero. Thus it is equivalent to `floor*` if the argument or quotient is positive, or to `ceiling*` otherwise. The remainder has the same sign as number.

Function: **round*** *number &optional divisor*

This function implements the Common Lisp `round` function, which is analogous to `floor` except that it rounds the argument or quotient of the arguments to the nearest integer. In the case of a tie (the argument or quotient is exactly halfway between two integers), it rounds to the even integer.

Function: **mod*** *number divisor*

This function returns the same value as the second return value of `floor`.

Function: **rem*** *number divisor*

This function returns the same value as the second return value of `truncate`.

These definitions are compatible with those in the Quiroz `` `cl.el' `` package, except that this package appends `` `*' `` to certain function names to avoid conflicts with existing Emacs 19 functions, and that the mechanism for returning multiple values is different.

@secno=8

Random Numbers

This package also provides an implementation of the Common Lisp random number generator. It uses its own additive-congruential algorithm, which is much more likely to give statistically clean random numbers than the simple generators supplied by many operating systems.

Function: **random*** *number &optional state*

This function returns a random nonnegative number less than number, and of the same type (either integer or floating-point). The state argument should be a `random-state` object which holds the state of the random number generator. The function modifies this state object as a side effect. If state is omitted, it defaults to the variable `*random-state*`, which contains a pre-initialized `random-state` object.

Variable: ***random-state***

This variable contains the system "default" `random-state` object, used for calls to `random*` that do not specify an alternative state object. Since any number of programs in the Emacs process may be accessing `*random-state*` in interleaved fashion, the sequence generated from this variable will be irreproducible for all intents and purposes.

Function: **make-random-state** *&optional state*

This function creates or copies a `random-state` object. If state is omitted or `nil`, it returns a new copy of `*random-state*`. This is a copy in the sense that future sequences of calls to `(random* n)` and `(random* n s)` (where s is the new random-state object) will return identical sequences of random numbers.

If state is a `random-state` object, this function returns a copy of that object. If state is `t`, this function returns a new `random-state` object seeded from the date and time. As an extension to Common Lisp, state may also be an integer in which case the new object is seeded from that integer; each different integer seed will result in a completely different sequence of random numbers.

It is legal to print a `random-state` object to a buffer or file and later read it back with `read`. If a program wishes to use a sequence of pseudo-random numbers which can be reproduced later for debugging, it can call `(make-random-state t)` to get a new sequence, then print this sequence to a file. When the program is later rerun, it can read the original run's random-state from the file.

Function: **random-state-p** *object*

This predicate returns `t` if object is a `random-state` object, or `nil` otherwise.

Implementation Parameters

This package defines several useful constants having to with numbers.

Variable: **most-positive-fixnum**

This constant equals the largest value a Lisp integer can hold. It is typically `2^23-1` or `2^25-1`.

Variable: **most-negative-fixnum**

This constant equals the smallest (most negative) value a Lisp integer can hold.

The following parameters have to do with floating-point numbers. This package determines their values by exercising the computer's floating-point arithmetic in various ways. Because this operation might be slow, the code for initializing them is kept in a separate function that must be called before the parameters can be used.

Function: **cl-float-limits**

This function makes sure that the Common Lisp floating-point parameters like `most-positive-float` have been initialized. Until it is called, these parameters will be `nil`. If this version of Emacs does not support floats (e.g., most versions of Emacs 18), the parameters will remain `nil`. If the parameters have already been initialized, the function returns immediately.

The algorithm makes assumptions that will be valid for most modern machines, but will fail if the machine's arithmetic is extremely unusual, e.g., decimal.

Since true Common Lisp supports up to four different floating-point precisions, it has families of constants like `most-positive-single-float`, `most-positive-double-float`, `most-positive-long-float`, and so on. Emacs has only one floating-point precision, so this package omits the precision word from the constants' names.

Variable: **most-positive-float**

This constant equals the largest value a Lisp float can hold. For those systems whose arithmetic supports infinities, this is the largest *finite* value. For IEEE machines, the value is approximately `1.79e+308`.

Variable: **most-negative-float**

This constant equals the most-negative value a Lisp float can hold. (It is assumed to be equal to `(-most-positive-float)`.)

Variable: **least-positive-float**

This constant equals the smallest Lisp float value greater than zero. For IEEE machines, it is about `4.94e-324` if denormals are supported or `2.22e-308` if not.

Variable: **least-positive-normalized-float**

This constant equals the smallest *normalized* Lisp float greater than zero, i.e., the smallest value for which IEEE denormalization will not result in a loss of precision. For IEEE machines, this value is about `2.22e-308`. For machines that do not support the concept of denormalization and gradual underflow, this constant will always equal `least-positive-float`.

Variable: **least-negative-float**

This constant is the negative counterpart of `least-positive-float`.

Variable: **least-negative-normalized-float**

This constant is the negative counterpart of `least-positive-normalized-float`.

Variable: **float-epsilon**

This constant is the smallest positive Lisp float that can be added to 1.0 to produce a distinct value. Adding a smaller number to 1.0 will yield 1.0 again due to roundoff. For IEEE machines, epsilon is about `2.22e-16`.

Variable: **float-negative-epsilon**

This is the smallest positive value that can be subtracted from 1.0 to produce a distinct value. For IEEE machines, it is about `1.11e-16`.

Sequences

Common Lisp defines a number of functions that operate on sequences, which are either lists, strings, or vectors. Emacs Lisp includes a few of these, notably `elt` and `length`; this package defines most of the rest.

Sequence Basics

Many of the sequence functions take keyword arguments; see section Argument Lists. All keyword arguments are optional and, if specified, may appear in any order.

The `:key` argument should be passed either `nil`, or a function of one argument. This key function is used as a filter through which the elements of the sequence are seen; for example, `(find x y :key 'car)` is similar to `(assoc* x y)`: It searches for an element of the list whose `car` equals `x`, rather than for an element which equals `x` itself. If `:key` is omitted or `nil`, the filter is effectively the identity function.

The `:test` and `:test-not` arguments should be either `nil`, or functions of two arguments. The test function is used to compare two sequence elements, or to compare a search value with sequence elements. (The two values are passed to the test function in the same order as the original sequence function arguments from which they are derived, or, if they both come from the same sequence, in the same order as they appear in that sequence.) The `:test` argument specifies a function which must return true (non-`nil`) to indicate a match; instead, you may use `:test-not` to give a function which returns *false* to indicate a match. The default test function is `:test 'eql`.

Many functions which take item and `:test` or `:test-not` arguments also come in `-if` and `-if-not` varieties, where a predicate function is passed instead of item, and sequence elements match if the predicate returns true on them (or false in the case of `-if-not`). For example:

```
(remove* 0 seq :test '=)  ==  (remove-if 'zerop seq)
```

to remove all zeros from sequence `seq`.

Some operations can work on a subsequence of the argument sequence; these function take `:start` and `:end` arguments which default to zero and the length of the sequence, respectively. Only elements between start (inclusive) and end (exclusive) are affected by the operation. The end argument may be passed `nil` to signify the length of the sequence; otherwise, both start and end must be integers, with `0 <= start <= end <= (length seq)`. If the function takes two sequence arguments, the limits are defined by keywords `:start1` and `:end1` for the first, and `:start2` and `:end2` for the second.

A few functions accept a `:from-end` argument, which, if non-`nil`, causes the operation to go from right-to-left through the sequence instead of left-to-right, and a `:count` argument, which specifies an integer maximum number of elements to be removed or otherwise processed.

The sequence functions make no guarantees about the order in which the `:test`, `:test-not`, and `:key` functions are called on various elements. Therefore, it is a bad idea to depend on side effects of these functions. For example, `:from-end` may cause the sequence to be scanned actually in reverse, or it may be scanned forwards but computing a result "as if" it were scanned backwards. (Some functions, like `mapcar*` and `every`, *do* specify exactly the order in which the function is called so side effects are perfectly acceptable in those cases.)

Strings in GNU Emacs 19 may contain "text properties" as well as character data. Except as noted, it is undefined whether or not text properties are preserved by sequence functions. For example, `(remove* ?A str)` may or may not preserve the properties of the characters copied from str into the result.

Mapping over Sequences

These functions "map" the function you specify over the elements of lists or arrays. They are all variations on the theme of the built-in function `mapcar`.

Function: **mapcar*** *function seq &rest more-seqs*

This function calls function on successive parallel sets of elements from its argument sequences. Given a single seq argument it is equivalent to `mapcar`; given n sequences, it calls the function with the first elements of each of the sequences as the n arguments to yield the first element of the result list, then with the second elements, and so on. The mapping stops as soon as the shortest sequence runs out. The argument sequences may be any mixture of lists, strings, and vectors; the return sequence is always a list.

Common Lisp's `mapcar` accepts multiple arguments but works only on lists; Emacs Lisp's `mapcar` accepts a single sequence argument. This package's `mapcar*` works as a compatible superset of both.

Function: **map** *result-type function seq &rest more-seqs*

This function maps function over the argument sequences, just like `mapcar*`, but it returns a sequence of type result-type rather than a list. result-type must be one of the following symbols: `vector`, `string`, `list` (in which case the effect is the same as for `mapcar*`), or `nil` (in which case the results are thrown away and `map` returns `nil`).

Function: **maplist** *function list &rest more-lists*

This function calls function on each of its argument lists, then on the `cdr`s of those lists, and so on, until the shortest list runs out. The results are returned in the form of a list. Thus, `maplist` is like `mapcar*` except that it passes in the list pointers themselves rather than the `car`s of the advancing pointers.

Function: **mapc** *function seq &rest more-seqs*

This function is like `mapcar*`, except that the values returned by function are ignored and thrown away rather than being collected into a list. The return value of `mapc` is seq, the first sequence.

Function: **mapl** *function list &rest more-lists*

This function is like `maplist`, except that it throws away the values returned by function.

Function: **mapcan** *function seq &rest more-seqs*

This function is like `mapcar*`, except that it concatenates the return values (which must be lists) using `nconc`, rather than simply collecting them into a list.

Function: **mapcon** *function list &rest more-lists*

This function is like `maplist`, except that it concatenates the return values using `nconc`.

Function: **some** *predicate seq &rest more-seqs*

This function calls predicate on each element of seq in turn; if predicate returns a non-`nil` value, `some` returns that value, otherwise it returns `nil`. Given several sequence arguments, it steps through the sequences in parallel until the shortest one runs out, just as in `mapcar*`. You can rely on the left-to-right order in which the elements are visited, and on the fact that mapping stops immediately as soon as predicate returns non-`nil`.

Function: **every** *predicate seq &rest more-seqs*

This function calls predicate on each element of the sequence(s) in turn; it returns `nil` as soon as predicate returns `nil` for any element, or `t` if the predicate was true for all elements.

Function: **notany** *predicate seq &rest more-seqs*

This function calls predicate on each element of the sequence(s) in turn; it returns `nil` as soon as predicate returns a non-`nil` value for any element, or `t` if the predicate was `nil` for all elements.

Function: **notevery** *predicate seq &rest more-seqs*

This function calls predicate on each element of the sequence(s) in turn; it returns a non-`nil` value as soon as predicate returns `nil` for any element, or `t` if the predicate was true for all elements.

Function: **reduce** *function seq* `&key :from-end :start :end :initial-value :key`

This function combines the elements of seq using an associative binary operation. Suppose function is `*` and seq is the list `(2 3 4 5)`. The first two elements of the list are combined with `(* 2 3) = 6`; this is combined with the next element, `(* 6 4) = 24`, and that is combined with the final element: `(* 24 5) = 120`. Note that the `*` function happens to be self-reducing, so that `(* 2 3 4 5)` has the same effect as an explicit call to `reduce`.

If `:from-end` is true, the reduction is right-associative instead of left-associative:

```
(reduce '- '(1 2 3 4))
     == (- (- (- 1 2) 3) 4) => -8
(reduce '- '(1 2 3 4) :from-end t)
     == (- 1 (- 2 (- 3 4))) => -2
```

If `:key` is specified, it is a function of one argument which is called on each of the sequence elements in turn.

If `:initial-value` is specified, it is effectively added to the front (or rear in the case of

`:from-end`) of the sequence. The `:key` function is *not* applied to the initial value.

If the sequence, including the initial value, has exactly one element then that element is returned without ever calling function. If the sequence is empty (and there is no initial value), then function is called with no arguments to obtain the return value.

All of these mapping operations can be expressed conveniently in terms of the `loop` macro. In compiled code, `loop` will be faster since it generates the loop as in-line code with no function calls.

Sequence Functions

This section describes a number of Common Lisp functions for operating on sequences.

Function: **subseq** *sequence start &optional end*

This function returns a given subsequence of the argument sequence, which may be a list, string, or vector. The indices start and end must be in range, and start must be no greater than end. If end is omitted, it defaults to the length of the sequence. The return value is always a copy; it does not share structure with sequence.

As an extension to Common Lisp, start and/or end may be negative, in which case they represent a distance back from the end of the sequence. This is for compatibility with Emacs' `substring` function. Note that `subseq` is the *only* sequence function that allows negative start and end.

You can use `setf` on a `subseq` form to replace a specified range of elements with elements from another sequence. The replacement is done as if by `replace`, described below.

Function: **concatenate** *result-type &rest seqs*

This function concatenates the argument sequences together to form a result sequence of type result-type, one of the symbols `vector`, `string`, or `list`. The arguments are always copied, even in cases such as `(concatenate 'list '(1 2 3))` where the result is identical to an argument.

Function: **fill** *seq item* `&key :start :end`

This function fills the elements of the sequence (or the specified part of the sequence) with the value item.

Function: **replace** *seq1 seq2* `&key :start1 :end1 :start2 :end2`

This function copies part of seq2 into part of seq1. The sequence seq1 is not stretched or resized; the amount of data copied is simply the shorter of the source and destination (sub)sequences. The function returns seq1.

If seq1 and seq2 are `eq`, then the replacement will work correctly even if the regions indicated by the start and end arguments overlap. However, if seq1 and seq2 are lists which share storage but are not `eq`, and the start and end arguments specify overlapping regions, the effect is undefined.

Function: **remove*** *item seq* `&key :test :test-not :key :count :start :end :from-end`

This returns a copy of seq with all elements matching item removed. The result may share storage with or be `eq` to seq in some circumstances, but the original seq will not be modified. The `:test`, `:test-not`, and `:key` arguments define the matching test that is used; by default, elements `eql` to item are removed. The `:count` argument specifies the maximum number of matching elements that can be removed (only the leftmost count matches are removed). The `:start` and `:end` arguments specify a region in seq in which elements will be removed; elements outside that region are not matched or removed. The `:from-end` argument, if true, says that elements should be deleted from the end of the sequence rather than the beginning (this matters only if count was also specified).

Function: **delete*** *item seq* `&key :test :test-not :key :count :start :end :from-end`

This deletes all elements of seq which match item. It is a destructive operation. Since Emacs Lisp does not support stretchable strings or vectors, this is the same as `remove*` for those sequence types. On lists, `remove*` will copy the list if necessary to preserve the original list, whereas `delete*` will splice out parts of the argument list. Compare `append` and `nconc`, which are analogous non-destructive and destructive list operations in Emacs Lisp.

The predicate-oriented functions `remove-if`, `remove-if-not`, `delete-if`, and `delete-if-not` are defined similarly.

Function: **delete** *item list*

This MacLisp-compatible function deletes from list all elements which are `equal` to item. The `delete` function is built-in to Emacs 19; this package defines it equivalently in Emacs 18.

Function: **remove** *item list*

This function removes from list all elements which are `equal` to item. This package defines it for symmetry with `delete`, even though `remove` is not built-in to Emacs 19.

Function: **remq** *item list*

This function removes from list all elements which are `eq` to item. This package defines it for symmetry with `delq`, even though `remq` is not built-in to Emacs 19.

Function: **remove-duplicates** *seq* `&key :test :test-not :key :start :end :from-end`

This function returns a copy of seq with duplicate elements removed. Specifically, if two elements from the sequence match according to the `:test`, `:test-not`, and `:key` arguments, only the rightmost one is retained. If `:from-end` is true, the leftmost one is retained instead. If `:start` or `:end` is specified, only elements within that subsequence are examined or removed.

Function: **delete-duplicates** *seq* `&key :test :test-not :key :start :end :from-end`

This function deletes duplicate elements from seq. It is a destructive version of `remove-duplicates`.

Function: **substitute** *new old seq* `&key :test :test-not :key :count :start :end :from-end`

This function returns a copy of seq, with all elements matching old replaced with new. The `:count`,

`:start`, `:end`, and `:from-end` arguments may be used to limit the number of substitutions made.

Function: **nsubstitute** *new old seq* `&key :test :test-not :key :count :start :end :from-end`

This is a destructive version of `substitute`; it performs the substitution using `setcar` or `aset` rather than by returning a changed copy of the sequence.

The `substitute-if`, `substitute-if-not`, `nsubstitute-if`, and `nsubstitute-if-not` functions are defined similarly. For these, a predicate is given in place of the old argument.

Searching Sequences

These functions search for elements or subsequences in a sequence. (See also `member*` and `assoc*`; see section Lists.)

Function: **find** *item seq* `&key :test :test-not :key :start :end :from-end`

This function searches seq for an element matching item. If it finds a match, it returns the matching element. Otherwise, it returns `nil`. It returns the leftmost match, unless `:from-end` is true, in which case it returns the rightmost match. The `:start` and `:end` arguments may be used to limit the range of elements that are searched.

Function: **position** *item seq* `&key :test :test-not :key :start :end :from-end`

This function is like `find`, except that it returns the integer position in the sequence of the matching item rather than the item itself. The position is relative to the start of the sequence as a whole, even if `:start` is non-zero. The function returns `nil` if no matching element was found.

Function: **count** *item seq* `&key :test :test-not :key :start :end`

This function returns the number of elements of seq which match item. The result is always a nonnegative integer.

The `find-if`, `find-if-not`, `position-if`, `position-if-not`, `count-if`, and `count-if-not` functions are defined similarly.

Function: **mismatch** *seq1 seq2* `&key :test :test-not :key :start1 :end1 :start2 :end2 :from-end`

This function compares the specified parts of seq1 and seq2. If they are the same length and the corresponding elements match (according to `:test`, `:test-not`, and `:key`), the function returns `nil`. If there is a mismatch, the function returns the index (relative to seq1) of the first mismatching element. This will be the leftmost pair of elements which do not match, or the position at which the shorter of the two otherwise-matching sequences runs out.

If `:from-end` is true, then the elements are compared from right to left starting at `(1- end1)` and `(1- end2)`. If the sequences differ, then one plus the index of the rightmost difference (relative to seq1) is returned.

An interesting example is `(mismatch str1 str2 :key 'upcase)`, which compares two str case-insensitively.

Function: **search** *seq1 seq2* `&key :test :test-not :key :from-end :start1 :end1 :start2 :end2`

This function searches seq2 for a subsequence that matches seq1 (or part of it specified by `:start1` and `:end1`.) Only matches which fall entirely within the region defined by `:start2` and `:end2` will be considered. The return value is the index of the leftmost element of the leftmost match, relative to the start of seq2, or `nil` if no matches were found. If `:from-end` is true, the function finds the *rightmost* matching subsequence.

Sorting Sequences

Function: **sort*** *seq predicate* `&key :key`

This function sorts seq into increasing order as determined by using predicate to compare pairs of elements. predicate should return true (non-`nil`) if and only if its first argument is less than (not equal to) its second argument. For example, `<` and `string-lessp` are suitable predicate functions for sorting numbers and strings, respectively; `>` would sort numbers into decreasing rather than increasing order.

This function differs from Emacs' built-in `sort` in that it can operate on any type of sequence, not just lists. Also, it accepts a `:key` argument which is used to preprocess data fed to the predicate function. For example,

```
(setq data (sort data 'string-lessp :key 'downcase))
```

sorts data, a sequence of strings, into increasing alphabetical order without regard to case. A `:key` function of `car` would be useful for sorting association lists.

The `sort*` function is destructive; it sorts lists by actually rearranging the `cdr` pointers in suitable fashion.

Function: **stable-sort** *seq predicate* `&key :key`

This function sorts seq stably, meaning two elements which are equal in terms of predicate are guaranteed not to be rearranged out of their original order by the sort.

In practice, `sort*` and `stable-sort` are equivalent in Emacs Lisp because the underlying `sort` function is stable by default. However, this package reserves the right to use non-stable methods for `sort*` in the future.

Function: **merge** *type seq1 seq2 predicate* `&key :key`

This function merges two sequences seq1 and seq2 by interleaving their elements. The result sequence, of type type (in the sense of `concatenate`), has length equal to the sum of the lengths of the two input sequences. The sequences may be modified destructively. Order of elements within seq1 and seq2 is preserved in the interleaving; elements of the two sequences are compared by predicate (in the sense of

`sort`) and the lesser element goes first in the result. When elements are equal, those from seq1 prec those from seq2 in the result. Thus, if seq1 and seq2 are both sorted according to predicate, then the result will be a merged sequence which is (stably) sorted according to predicate.

Go to the previous, next section.

Go to the previous, next section.

Lists

The functions described here operate on lists.

List Functions

This section describes a number of simple operations on lists, i.e., chains of cons cells.

Function: **caddr** *x*

This function is equivalent to `(car (cdr (cdr x)))`. Likewise, this package defines all 28 `cxxxr` functions where xxx is up to four `a's and/or `d's. All of these functions are `setf`-able, and calls to them are expanded inline by the byte-compiler for maximum efficiency.

Function: **first** *x*

This function is a synonym for `(car x)`. Likewise, the functions `second`, `third`, ..., through `tenth` return the given element of the list x.

Function: **rest** *x*

This function is a synonym for `(cdr x)`.

Function: **endp** *x*

Common Lisp defines this function to act like `null`, but signaling an error if `x` is neither a `nil` nor a cons cell. This package simply defines `endp` as a synonym for `null`.

Function: **list-length** *x*

This function returns the length of list x, exactly like `(length x)`, except that if x is a circular list (where the cdr-chain forms a loop rather than terminating with `nil`), this function returns `nil`. (The regular `length` function would get stuck if given a circular list.)

Function: **last** *x &optional n*

This function returns the last cons, or the nth-to-last cons, of the list x. If n is omitted it defaults to 1. The "last cons" means the first cons cell of the list whose `cdr` is not another cons cell. (For normal lists, the `cdr` of the last cons will be `nil`.) This function returns `nil` if x is `nil` or shorter than n. Note that the last *element* of the list is `(car (last x))`.

Function: **butlast** *x &optional n*

This function returns the list x with the last element, or the last n elements, removed. If n is greater than zero it makes a copy of the list so as not to damage the original list. In general, `(append (butlast x n) (last x n))` will return a list equal to x.

Function: **nbutlast** *x &optional n*

This is a version of `butlast` that works by destructively modifying the `cdr` of the appropriate element, rather than making a copy of the list.

Function: **list*** *arg &rest others*

This function constructs a list of its arguments. The final argument becomes the `cdr` of the last cell constructed. Thus, `(list* a b c)` is equivalent to `(cons a (cons b c))`, and `(list* a b nil)` is equivalent to `(list a b)`.

(Note that this function really is called `list*` in Common Lisp; it is not a name invented for this package like `member*` or `defun*`.)

Function: **ldiff** *list sublist*

If sublist is a sublist of list, i.e., is `eq` to one of the cons cells of list, then this function returns a copy of the part of list up to but not including sublist. For example, `(ldiff x (cddr x))` returns the first two elements of the list `x`. The result is a copy; the original list is not modified. If sublist is not a sublist of list, a copy of the entire list is returned.

Function: **copy-list** *list*

This function returns a copy of the list list. It copies dotted lists like `(1 2 . 3)` correctly.

Function: **copy-tree** *x &optional vecp*

This function returns a copy of the tree of cons cells x. Unlike `copy-sequence` (and its alias `copy-list`), which copies only along the `cdr` direction, this function copies (recursively) along both the `car` and the `cdr` directions. If x is not a cons cell, the function simply returns x unchanged. If the optional vecp argument is true, this function copies vectors (recursively) as well as cons cells.

Function: **tree-equal** *x y* `&key :test :test-not :key`

This function compares two trees of cons cells. If x and y are both cons cells, their `car`s and `cdr`s are compared recursively. If neither x nor y is a cons cell, they are compared by `eql`, or according to the specified test. The `:key` function, if specified, is applied to the elements of both trees. See section Sequences.

@secno=3

Substitution of Expressions

These functions substitute elements throughout a tree of cons cells. (See section Sequence Functions, for the `substitute` function, which works on just the top-level elements of a list.)

Function: **subst** *new old tree* `&key :test :test-not :key`

This function substitutes occurrences of old with new in tree, a tree of cons cells. It returns a substituted tree, which will be a copy except that it may share storage with the argument tree in parts where no

substitutions occurred. The original tree is not modified. This function recurses on, and compares ag
old, both `car`s and `cdr`s of the component cons cells. If old is itself a cons cell, then matching cells
the tree are substituted as usual without recursively substituting in that cell. Comparisons with old a
done according to the specified test (`eql` by default). The `:key` function is applied to the elements of the tree but not to old.

Function: **nsubst** *new old tree* `&key :test :test-not :key`

This function is like `subst`, except that it works by destructive modification (by `setcar` or `setcdr`) rather than copying.

The `subst-if`, `subst-if-not`, `nsubst-if`, and `nsubst-if-not` functions are defined similarly.

Function: **sublis** *alist tree* `&key :test :test-not :key`

This function is like `subst`, except that it takes an association list alist of old-new pairs. Each element of the tree (after applying the `:key` function, if any), is compared with the `car`s of alist; if it matches, it is replaced by the corresponding `cdr`.

Function: **nsublis** *alist tree* `&key :test :test-not :key`

This is a destructive version of `sublis`.

Lists as Sets

These functions perform operations on lists which represent sets of elements.

Function: **member** *item list*

This MacLisp-compatible function searches list for an element which is `equal` to item. The `member` function is built-in to Emacs 19; this package defines it equivalently in Emacs 18. See the following function for a Common-Lisp compatible version.

Function: **member*** *item list* `&key :test :test-not :key`

This function searches list for an element matching item. If a match is found, it returns the cons cell whose `car` was the matching element. Otherwise, it returns `nil`. Elements are compared by `eql` by default; you can use the `:test`, `:test-not`, and `:key` arguments to modify this behavior. See section Sequences.

Note that this function's name is suffixed by `*' to avoid the incompatible `member` function defined in Emacs 19. (That function uses `equal` for comparisons; it is equivalent to `(member* item list :test 'equal)`.)

The `member-if` and `member-if-not` functions analogously search for elements which satisfy a given predicate.

Function: **tailp** *sublist list*

This function returns `t` if sublist is a sublist of list, i.e., if sublist is `eql` to list or to any of its `cdr`s.

Function: **adjoin** *item list* `&key :test :test-not :key`

This function conses item onto the front of list, like `(cons item list)`, but only if item is not already present on the list (as determined by `member*`). If a `:key` argument is specified, it is applied to item as well as to the elements of list during the search, on the reasoning that item is "about" to become part of the list.

Function: **union** *list1 list2* `&key :test :test-not :key`

This function combines two lists which represent sets of items, returning a list that represents the union of those two sets. The result list will contain all items which appear in list1 or list2, and no others. If an item appears in both list1 and list2 it will be copied only once. If an item is duplicated in list1 or list2, it is undefined whether or not that duplication will survive in the result list. The order of elements in the result list is also undefined.

Function: **nunion** *list1 list2* `&key :test :test-not :key`

This is a destructive version of `union`; rather than copying, it tries to reuse the storage of the argument lists if possible.

Function: **intersection** *list1 list2* `&key :test :test-not :key`

This function computes the intersection of the sets represented by list1 and list2. It returns the list of items which appear in both list1 and list2.

Function: **nintersection** *list1 list2* `&key :test :test-not :key`

This is a destructive version of `intersection`. It tries to reuse storage of list1 rather than copying. It does *not* reuse the storage of list2.

Function: **set-difference** *list1 list2* `&key :test :test-not :key`

This function computes the "set difference" of list1 and list2, i.e., the set of elements that appear in list1 but *not* in list2.

Function: **nset-difference** *list1 list2* `&key :test :test-not :key`

This is a destructive `set-difference`, which will try to reuse list1 if possible.

Function: **set-exclusive-or** *list1 list2* `&key :test :test-not :key`

This function computes the "set exclusive or" of list1 and list2, i.e., the set of elements that appear in exactly one of list1 and list2.

Function: **nset-exclusive-or** *list1 list2* `&key :test :test-not :key`

This is a destructive `set-exclusive-or`, which will try to reuse list1 and list2 if possible.

Function: **subsetp** *list1 list2* `&key :test :test-not :key`

This function checks whether list1 represents a subset of list2, i.e., whether every element of list1 also

appears in list2.

Association Lists

An association list is a list representing a mapping from one set of values to another; any list whose elements are cons cells is an association list.

Function: **assoc*** *item a-list* `&key :test :test-not :key`

This function searches the association list a-list for an element whose `car` matches (in the sense of `:test`, `:test-not`, and `:key`, or by comparison with `eql`) a given item. It returns the matching element, if any, otherwise `nil`. It ignores elements of a-list which are not cons cells. (This corresponds to the behavior of `assq` and `assoc` in Emacs Lisp; Common Lisp's `assoc` ignores `nil`s but considers any other non-cons elements of a-list to be an error.)

Function: **rassoc*** *item a-list* `&key :test :test-not :key`

This function searches for an element whose `cdr` matches item. If a-list represents a mapping, this applies the inverse of the mapping to item.

Function: **rassoc** *item a-list*

This function searches like `rassoc*` with a `:test` argument of `equal`. It is analogous to Emacs Lisp's standard `assoc` function, which derives from the MacLisp rather than the Common Lisp tradition.

The `assoc-if`, `assoc-if-not`, `rassoc-if`, and `rassoc-if-not` functions are defined similarly.

Two simple functions for constructing association lists are:

Function: **acons** *key value alist*

This is equivalent to `(cons (cons key value) alist)`.

Function: **pairlis** *keys values &optional alist*

This is equivalent to `(nconc (mapcar* 'cons keys values) alist)`.

Go to the previous, next section.

Go to the previous, next section.

Hash Tables

A hash table is a data structure that maps "keys" onto "values." Keys and values can be arbitrary Lisp data objects. Hash tables have the property that the time to search for a given key is roughly constant; simpler data structures like association lists take time proportional to the number of entries in the list.

Function: **make-hash-table** *&key :test :size*

This function creates and returns a hash-table object whose function for comparing elements is `:test` (`eql` by default), and which is allocated to fit about `:size` elements. The `:size` argument is purely advisory; the table will stretch automatically if you store more elements in it. If `:size` is omitted, a reasonable default is used.

Common Lisp allows only `eq`, `eql`, `equal`, and `equalp` as legal values for the `:test` argument. In this package, any reasonable predicate function will work, though if you use something else you should check the details of the hashing function described below to make sure it is suitable for your predicate.

Some versions of Emacs (like Lucid Emacs 19) include a built-in hash table type; in these versions, `make-hash-table` with a test of `eq` will use these built-in hash tables. In all other cases, it will return a hash-table object which takes the form of a list with an identifying "tag" symbol at the front. All of the hash table functions in this package can operate on both types of hash table; normally you will never know which type is being used.

This function accepts the additional Common Lisp keywords `:rehash-size` and `:rehash-threshold`, but it ignores their values.

Function: **gethash** *key table &optional default*

This function looks up key in table. If key exists in the table, in the sense that it matches any of the existing keys according to the table's test function, then the associated value is returned. Otherwise, default (or `nil`) is returned.

To store new data in the hash table, use `setf` on a call to `gethash`. If key already exists in the table, the corresponding value is changed to the stored value. If key does not already exist, a new entry is added to the table and the table is reallocated to a larger size if necessary. The default argument is allowed but ignored in this case. The situation is exactly analogous to that of `get*`; see section Property Lists.

Function: **remhash** *key table*

This function removes the entry for key from table. If an entry was removed, it returns `t`. If key does not appear in the table, it does nothing and returns `nil`.

Function: **clrhash** *table*

This function removes all the entries from table, leaving an empty hash table.

Function: **maphash** *function table*

This function calls function for each entry in table. It passes two arguments to function, the key and the value of the given entry. The return value of function is ignored; maphash itself returns `nil`. See section Loop Facility, for an alternate way of iterating over hash tables.

Function: **hash-table-count** *table*

This function returns the number of entries in table. **Warning:** The current implementation of Lucid Emacs 19 hash-tables does not decrement the stored `count` when `remhash` removes an entry. Therefore, the return value of this function is not dependable if you have used `remhash` on the table and the table's test is `eq`. A slower, but reliable, way to count the entries is `(loop for x being the hash-keys of table count t)`.

Function: **hash-table-p** *object*

This function returns `t` if object is a hash table, `nil` otherwise. It recognizes both types of hash tables (both Lucid Emacs built-in tables and tables implemented with special lists.)

Sometimes when dealing with hash tables it is useful to know the exact "hash function" that is used. This package implements hash tables using Emacs Lisp "obarrays," which are the same data structure that Emacs Lisp uses to keep track of symbols. Each hash table includes an embedded obarray. Key values given to `gethash` are converted by various means into strings, which are then looked up in the obarray using `intern` and `intern-soft`. The symbol, or "bucket," corresponding to a given key string includes as its `symbol-value` an association list of all key-value pairs which hash to that string. Depending on the test function, it is possible for many entries to hash to the same bucket. For example, if the test is `eql`, then the symbol `foo` and two separately built strings `"foo"` will create three entries in the same bucket. Search time is linear within buckets, so hash tables will be most effective if you arrange not to store too many things that hash the same.

The following algorithm is used to convert Lisp objects to hash strings:

- Strings are used directly as hash strings. (However, if the test function is `equalp`, strings are `downcase`d first.)
- Symbols are hashed according to their `symbol-name`.
- Integers are hashed into one of 16 buckets depending on their value modulo 16. Floating-point numbers are truncated to integers and hashed modulo 16.
- Cons cells are hashed according to their `car`s; nonempty vectors are hashed according to their first element.
- All other types of objects hash into a single bucket named `"*"`.

Thus, for example, searching among many buffer objects in a hash table will devolve to a (still fairly fast) linear-time search through a single bucket, whereas searching for different symbols will be very fast since each symbol will, in general, hash into its own bucket.

The size of the obarray in a hash table is automatically adjusted as the number of elements increases.

As a special case, `make-hash-table` with a `:size` argument of 0 or 1 will create a hash-table object that uses a single association list rather than an obarray of many lists. For very small tables this structure will be more efficient since lookup does not require converting the key to a string or looking it up in an

TOC

obarray. However, such tables are guaranteed to take time proportional to their size to do a search.

Structures

The Common Lisp structure mechanism provides a general way to define data types similar to C's `struct` types. A structure is a Lisp object containing some number of slots, each of which can hold any Lisp data object. Functions are provided for accessing and setting the slots, creating or copying structure objects, and recognizing objects of a particular structure type.

In true Common Lisp, each structure type is a new type distinct from all existing Lisp types. Since the underlying Emacs Lisp system provides no way to create new distinct types, this package implements structures as vectors (or lists upon request) with a special "tag" symbol to identify them.

Special Form: **defstruct** *name slots...*

The `defstruct` form defines a new structure type called name, with the specified slots. (The slots may begin with a string which documents the structure type.) In the simplest case, name and each of the slots are symbols. For example,

```
(defstruct person name age sex)
```

defines a struct type called `person` which contains three slots. Given a `person` object p, you can access those slots by calling `(person-name p)`, `(person-age p)`, and `(person-sex p)`. You can also change these slots by using `setf` on any of these place forms:

```
(incf (person-age birthday-boy))
```

You can create a new `person` by calling `make-person`, which takes keyword arguments `:name`, `:age`, and `:sex` to specify the initial values of these slots in the new object. (Omitting any of these arguments leaves the corresponding slot "undefined," according to the Common Lisp standard; in Emacs Lisp, such uninitialized slots are filled with `nil`.)

Given a `person`, `(copy-person p)` makes a new object of the same type whose slots are `eq` to those of p.

Given any Lisp object x, `(person-p x)` returns true if x looks like a `person`, false otherwise. (Again, in Common Lisp this predicate would be exact; in Emacs Lisp the best it can do is verify that x is a vector of the correct length which starts with the correct tag symbol.)

Accessors like `person-name` normally check their arguments (effectively using `person-p`) and signal an error if the argument is the wrong type. This check is affected by `(optimize (safety ...))` declarations. Safety level 1, the default, uses a somewhat optimized check that will detect all incorrect arguments, but may use an uninformative error message (e.g., "expected a vector" instead of "expected a `person`"). Safety level 0 omits all checks except as provided by the underlying `aref` call; safety levels 2 and 3 do rigorous checking that will always print a descriptive error message for incorrect inputs. See section Declarations.

```
(setq dave (make-person :name "Dave" :sex 'male))
     => [cl-struct-person "Dave" nil male]
(setq other (copy-person dave))
     => [cl-struct-person "Dave" nil male]
(eq dave other)
     => nil
(eq (person-name dave) (person-name other))
     => t
(person-p dave)
     => t
(person-p [1 2 3 4])
     => nil
(person-p "Bogus")
     => nil
(person-p '[cl-struct-person counterfeit person object])
     => t
```

In general, name is either a name symbol or a list of a name symbol followed by any number of struct options; each slot is either a slot symbol or a list of the form `(slot-name default-value slot-options...)'. The default-value is a Lisp form which is evaluated any time an instance of the structure type is created without specifying that slot's value.

Common Lisp defines several slot options, but the only one implemented in this package is `:read-only`. A non-`nil` value for this option means the slot should not be `setf`-able; the slot's value is determined when the object is created and does not change afterward.

```
(defstruct person
  (name nil :read-only t)
  age
  (sex 'unknown))
```

Any slot options other than `:read-only` are ignored.

For obscure historical reasons, structure options take a different form than slot options. A structure option is either a keyword symbol, or a list beginning with a keyword symbol possibly followed by arguments. (By contrast, slot options are key-value pairs not enclosed in lists.)

```
(defstruct (person (:constructor create-person)
                   (:type list)
                   :named)
  name age sex)
```

The following structure options are recognized.

@itemmax=0 in @advance@leftskip-.5@tableindent

`:conc-name`

The argument is a symbol whose print name is used as the prefix for the names of slot accesso functions. The default is the name of the struct type followed by a hyphen. The option `(:conc-name p-)` would change this prefix to `p-`. Specifying `nil` as an argument means no prefix, so that the slot names themselves are used to name the accessor functions.

`:constructor`

In the simple case, this option takes one argument which is an alternate name to use for the constructor function. The default is `make-name`, e.g., `make-person`. The above example changes this to `create-person`. Specifying `nil` as an argument means that no standard constructor should be generated at all.

In the full form of this option, the constructor name is followed by an arbitrary argument list. See section Program Structure, for a description of the format of Common Lisp argument lists. All options, such as `&rest` and `&key`, are supported. The argument names should match the slot names; each slot is initialized from the corresponding argument. Slots whose names do not appear in the argument list are initialized based on the default-value in their slot descriptor. Also, `&optional` and `&key` arguments which don't specify defaults take their defaults from the slot descriptor. It is legal to include arguments which don't correspond to slot names; these are useful if they are referred to in the defaults for optional, keyword, or `&aux` arguments which *do* correspond to slots.

You can specify any number of full-format `:constructor` options on a structure. The default constructor is still generated as well unless you disable it with a simple-format `:constructor` option.

```
(defstruct
 (person
  (:constructor nil)   ; no default constructor
  (:constructor new-person (name sex &optional (age 0)))
  (:constructor new-hound (&key (name "Rover")
                                (dog-years 0)
                          &aux (age (* 7 dog-years))
                               (sex 'canine))))
 name age sex)
```

The first constructor here takes its arguments positionally rather than by keyword. (In official Common Lisp terminology, constructors that work By Order of Arguments instead of by keyword are called "BOA constructors." No, I'm not making this up.) For example, `(new-person "Jane" 'female)` generates a person whose slots are `"Jane"`, 0, and `female`, respectively.

The second constructor takes two keyword arguments, `:name`, which initializes the `name` slot and defaults to `"Rover"`, and `:dog-years`, which does not itself correspond to a slot but which is used to initialize the `age` slot. The `sex` slot is forced to the symbol `canine` with no syntax for overriding it.

`:copier`

The argument is an alternate name for the copier function for this type. The default is `copy-name`. `nil` means not to generate a copier function. (In this implementation, all copier

functions are simply synonyms for `copy-sequence`.)

`:predicate`

The argument is an alternate name for the predicate which recognizes objects of this type. The default is `name-p`. `nil` means not to generate a predicate function. (If the `:type` option is used without the `:named` option, no predicate is ever generated.)

In true Common Lisp, `typep` is always able to recognize a structure object even if `:predicate` was used. In this package, `typep` simply looks for a function called `typename-p`, so it will work for structure types only if they used the default predicate name.

`:include`

This option implements a very limited form of C++-style inheritance. The argument is the name of another structure type previously created with `defstruct`. The effect is to cause the new structure type to inherit all of the included structure's slots (plus, of course, any new slots described by this struct's slot descriptors). The new structure is considered a "specialization" of the included one. In fact, the predicate and slot accessors for the included type will also accept objects of the new type.

If there are extra arguments to the `:include` option after the included-structure name, these options are treated as replacement slot descriptors for slots in the included structure, possibly with modified default values. Borrowing an example from Steele:

```
(defstruct person name (age 0) sex)
     => person
(defstruct (astronaut (:include person (age 45)))
  helmet-size
  (favorite-beverage 'tang))
     => astronaut

(setq joe (make-person :name "Joe"))
     => [cl-struct-person "Joe" 0 nil]
(setq buzz (make-astronaut :name "Buzz"))
     => [cl-struct-astronaut "Buzz" 45 nil nil tang]

(list (person-p joe) (person-p buzz))
     => (t t)
(list (astronaut-p joe) (astronaut-p buzz))
     => (nil t)

(person-name buzz)
     => "Buzz"
(astronaut-name joe)
     => error: "astronaut-name accessing a non-astronaut"
```

Thus, if `astronaut` is a specialization of `person`, then every `astronaut` is also a `person` (but not the other way around). Every `astronaut` includes all the slots of a `person`, plus extra

slots that are specific to astronauts. Operations that work on people (like `person-name`) wo astronauts just like other people.

`:print-function`

In full Common Lisp, this option allows you to specify a function which is called to print an instance of the structure type. The Emacs Lisp system offers no hooks into the Lisp printer which would allow for such a feature, so this package simply ignores `:print-function`.

`:type`

The argument should be one of the symbols `vector` or `list`. This tells which underlying Lisp data type should be used to implement the new structure type. Vectors are used by default, but `(:type list)` will cause structure objects to be stored as lists instead.

The vector representation for structure objects has the advantage that all structure slots can be accessed quickly, although creating vectors is a bit slower in Emacs Lisp. Lists are easier to create, but take a relatively long time accessing the later slots.

`:named`

This option, which takes no arguments, causes a characteristic "tag" symbol to be stored at the front of the structure object. Using `:type` without also using `:named` will result in a structure type stored as plain vectors or lists with no identifying features.

The default, if you don't specify `:type` explicitly, is to use named vectors. Therefore, `:named` is only useful in conjunction with `:type`.

```
(defstruct (person1) name age sex)
(defstruct (person2 (:type list) :named) name age sex)
(defstruct (person3 (:type list)) name age sex)

(setq p1 (make-person1))
     => [cl-struct-person1 nil nil nil]
(setq p2 (make-person2))
     => (person2 nil nil nil)
(setq p3 (make-person3))
     => (nil nil nil)

(person1-p p1)
     => t
(person2-p p2)
     => t
(person3-p p3)
     => error: function person3-p undefined
```

Since unnamed structures don't have tags, `defstruct` is not able to make a useful predicate for recognizing them. Also, accessors like `person3-name` will be generated but they will not be able to do any type checking. The `person3-name` function, for example, will simply be a synonym for `car` in this case. By contrast, `person2-name` is able to verify that its argument is indeed a `person2` object before proceeding.

`:initial-offset`

The argument must be a nonnegative integer. It specifies a number of slots to be left "empty" at the front of the structure. If the structure is named, the tag appears at the specified position in the list or vector; otherwise, the first slot appears at that position. Earlier positions are filled with `nil` by the constructors and ignored otherwise. If the type `:includes` another type, then `:initial-offset` specifies a number of slots to be skipped between the last slot of the included type and the first new slot.

Except as noted, the `defstruct` facility of this package is entirely compatible with that of Common Lisp.

Go to the previous, next section.

Assertions and Errors

This section describes two macros that test assertions, i.e., conditions which must be true if the program is operating correctly. Assertions never add to the behavior of a Lisp program; they simply make "sanity checks" to make sure everything is as it should be.

If the optimization property `speed` has been set to 3, and `safety` is less than 3, then the byte-compiler will optimize away the following assertions. Because assertions might be optimized away, it is a bad idea for them to include side-effects.

Special Form: **assert** *test-form [show-args string args...]*

This form verifies that test-form is true (i.e., evaluates to a non-`nil` value). If so, it returns `nil`. If the test is not satisfied, `assert` signals an error.

A default error message will be supplied which includes test-form. You can specify a different error message by including a string argument plus optional extra arguments. Those arguments are simply passed to `error` to signal the error.

If the optional second argument show-args is `t` instead of `nil`, then the error message (with or without string) will also include all non-constant arguments of the top-level form. For example:

```
(assert (> x 10) t "x is too small: %d")
```

This usage of show-args is an extension to Common Lisp. In true Common Lisp, the second argument gives a list of places which can be `setf`'d by the user before continuing from the error. Since Emacs Lisp does not support continuable errors, it makes no sense to specify places.

Special Form: **check-type** *form type [string]*

This form verifies that form evaluates to a value of type type. If so, it returns `nil`. If not, `check-type` signals a `wrong-type-argument` error. The default error message lists the erroneous value along with type and form themselves. If string is specified, it is included in the error message in place of type. For example:

```
(check-type x (integer 1 *) "a positive integer")
```

See section Type Predicates, for a description of the type specifiers that may be used for type.

Note that in Common Lisp, the first argument to `check-type` must be a place suitable for use by `setf`, because `check-type` signals a continuable error that allows the user to modify place.

The following error-related macro is also defined:

Special Form: **ignore-errors** *forms...*

This executes forms exactly like a `progn`, except that errors are ignored during the forms. More precisely, if an error is signaled then `ignore-errors` immediately aborts execution of the forms and returns `nil`. If the forms complete successfully, `ignore-errors` returns the result of the last form.

Go to the previous, next section.

Go to the previous, next section.

Efficiency Concerns

Macros

Many of the advanced features of this package, such as `defun*`, `loop`, and `setf`, are implemented as Lisp macros. In byte-compiled code, these complex notations will be expanded into equivalent Lisp code which is simple and efficient. For example, the forms

```
(incf i n)
(push x (car p))
```

are expanded at compile-time to the Lisp forms

```
(setq i (+ i n))
(setcar p (cons x (car p)))
```

which are the most efficient ways of doing these respective operations in Lisp. Thus, there is no performance penalty for using the more readable `incf` and `push` forms in your compiled code.

Interpreted code, on the other hand, must expand these macros every time they are executed. For this reason it is strongly recommended that code making heavy use of macros be compiled. (The features labeled "Special Form" instead of "Function" in this manual are macros.) A loop using `incf` a hundred times will execute considerably faster if compiled, and will also garbage-collect less because the macro expansion will not have to be generated, used, and thrown away a hundred times.

You can find out how a macro expands by using the `cl-prettyexpand` function.

Function: **cl-prettyexpand** *form &optional full*

This function takes a single Lisp form as an argument and inserts a nicely formatted copy of it in the current buffer (which must be in Lisp mode so that indentation works properly). It also expands all Lisp macros which appear in the form. The easiest way to use this function is to go to the `*scratch*` buffer and type, say,

```
(cl-prettyexpand '(loop for x below 10 collect x))
```

and type C-x C-e immediately after the closing parenthesis; the expansion

```
(block nil
  (let* ((x 0)
         (G1004 nil))
    (while (< x 10)
      (setq G1004 (cons x G1004))
```

```
    (setq x (+ x 1)))
  (nreverse G1004)))
```

will be inserted into the buffer. (The `block` macro is expanded differently in the interpreter and compiler, so `cl-prettyexpand` just leaves it alone. The temporary variable `G1004` was created by `gensym`.)

If the optional argument full is true, then *all* macros are expanded, including `block`, `eval-when`, and compiler macros. Expansion is done as if form were a top-level form in a file being compiled. For example,

```
(cl-prettyexpand '(pushnew 'x list))
     -| (setq list (adjoin 'x list))
(cl-prettyexpand '(pushnew 'x list) t)
     -| (setq list (if (memq 'x list) list (cons 'x list)))
(cl-prettyexpand '(caddr (member* 'a list)) t)
     -| (car (cdr (cdr (memq 'a list))))
```

Note that `adjoin`, `caddr`, and `member*` all have built-in compiler macros to optimize them in common cases.

Error Checking

Common Lisp compliance has in general not been sacrificed for the sake of efficiency. A few exceptions have been made for cases where substantial gains were possible at the expense of marginal incompatibility. One example is the use of `memq` (which is treated very efficiently by the byte-compiler) to scan for keyword arguments; this can become confused in rare cases when keyword symbols are used as both keywords and data values at once. This is extremely unlikely to occur in practical code, and the use of `memq` allows functions with keyword arguments to be nearly as fast as functions that use `&optional` arguments.

The Common Lisp standard (as embodied in Steele's book) uses the phrase "it is an error if" to indicate a situation which is not supposed to arise in complying programs; implementations are strongly encouraged but not required to signal an error in these situations. This package sometimes omits such error checking in the interest of compactness and efficiency. For example, `do` variable specifiers are supposed to be lists of one, two, or three forms; extra forms are ignored by this package rather than signaling a syntax error. The `endp` function is simply a synonym for `null` in this package. Functions taking keyword arguments will accept an odd number of arguments, treating the trailing keyword as if it were followed by the value `nil`.

Argument lists (as processed by `defun*` and friends) *are* checked rigorously except for the minor point just mentioned; in particular, keyword arguments are checked for validity, and `&allow-other-keys` and `:allow-other-keys` are fully implemented. Keyword validity checking is slightly time consuming (though not too bad in byte-compiled code); you can use `&allow-other-keys` to omit this check. Functions defined in this package such as `find` and `member*` do check their keyword arguments for validity.

Optimizing Compiler

The byte-compiler that comes with Emacs 18 normally fails to expand macros that appear in top-level positions in the file (i.e., outside of `defun`s or other enclosing forms). This would have disastrous consequences to programs that used such top-level macros as `defun*`, `eval-when`, and `defstruct`. To work around this problem, the CL package patches the Emacs 18 compiler to expand top-level macros. This patch will apply to your own macros, too, if they are used in a top-level context. The patch will not harm versions of the Emacs 18 compiler which have already had a similar patch applied, nor will it affect the optimizing Emacs 19 byte-compiler written by Jamie Zawinski and Hallvard Furuseth. The patch is applied to the byte compiler's code in Emacs' memory, *not* to the `` `bytecomp.elc' `` file stored on disk.

The Emacs 19 compiler (for Emacs 18) is available from various Emacs Lisp archive sites such as `archive.cis.ohio-state.edu`. Its use is highly recommended; many of the Common Lisp macros emit code which can be improved by optimization. In particular, `block`s (whether explicit or implicit in constructs like `defun*` and `loop`) carry a fair run-time penalty; the optimizing compiler removes `block`s which are not actually referenced by `return` or `return-from` inside the block.

Go to the previous, next section.

Go to the previous, next section.

Common Lisp Compatibility

Following is a list of all known incompatibilities between this package and Common Lisp as documented in Steele (2nd edition).

Certain function names, such as `member`, `assoc`, and `floor`, were already taken by (incompatible) Emacs Lisp functions; this package appends `*' to the names of its Common Lisp versions of these functions.

The word `defun*` is required instead of `defun` in order to use extended Common Lisp argument lists in a function. Likewise, `defmacro*` and `function*` are versions of those forms which understand full-featured argument lists. The `&whole` keyword does not work in `defmacro` argument lists (except inside recursive argument lists).

In order to allow an efficient implementation, keyword arguments use a slightly cheesy parser which may be confused if a keyword symbol is passed as the *value* of another keyword argument. (Specifically, `(memq :keyword rest-of-arguments)` is used to scan for `:keyword` among the supplied keyword arguments.)

The `eql` and `equal` predicates do not distinguish between IEEE floating-point plus and minus zero. The `equalp` predicate has several differences with Common Lisp; see section Predicates.

The `setf` mechanism is entirely compatible, except that setf-methods return a list of five values rather than five values directly. Also, the new "`setf` function" concept (typified by `(defun (setf foo) ...)`) is not implemented.

The `do-all-symbols` form is the same as `do-symbols` with no obarray argument. In Common Lisp, this form would iterate over all symbols in all packages. Since Emacs obarrays are not a first-class package mechanism, there is no way for `do-all-symbols` to locate any but the default obarray.

The `loop` macro is complete except that `loop-finish` and type specifiers are unimplemented.

The multiple-value return facility treats lists as multiple values, since Emacs Lisp cannot support multiple return values directly. The macros will be compatible with Common Lisp if `values` or `values-list` is always used to return to a `multiple-value-bind` or other multiple-value receiver; if `values` is used without `multiple-value-...` or vice-versa the effect will be different from Common Lisp.

Many Common Lisp declarations are ignored, and others match the Common Lisp standard in concept but not in detail. For example, local `special` declarations, which are purely advisory in Emacs Lisp, do not rigorously obey the scoping rules set down in Steele's book.

The variable `*gensym-counter*` starts out with a pseudo-random value rather than with zero. This is to cope with the fact that generated symbols become interned when they are written to and loaded back from a file.

The `defstruct` facility is compatible, except that structures are of type `:type vector :name` by default rather than some special, distinct type. Also, the `:type` slot option is ignored.

The second argument of `check-type` is treated differently.

Go to the previous, next section.

Go to the previous, next section.

Old CL Compatibility

Following is a list of all known incompatibilities between this package and the older Quiroz `cl.el' package.

This package's emulation of multiple return values in functions is incompatible with that of the older package. That package attempted to come as close as possible to true Common Lisp multiple return values; unfortunately, it could not be 100% reliable and so was prone to occasional surprises if used freely. This package uses a simpler method, namely replacing multiple values with lists of values, which is more predictable though more noticeably different from Common Lisp.

The `defkeyword` form and `keywordp` function are not implemented in this package.

The `member`, `floor`, `ceiling`, `truncate`, `round`, `mod`, and `rem` functions are suffixed by `*' in this package to avoid collision with existing functions in Emacs 18 or Emacs 19. The older package simply redefined these functions, overwriting the built-in meanings and causing serious portability problems with Emacs 19. (Some more recent versions of the Quiroz package changed the names to `cl-member`, etc.; this package defines the latter names as aliases for `member*`, etc.)

Certain functions in the old package which were buggy or inconsistent with the Common Lisp standard are incompatible with the conforming versions in this package. For example, `eql` and `member` were synonyms for `eq` and `memq` in that package, `setf` failed to preserve correct order of evaluation of its arguments, etc.

Finally, unlike the older package, this package is careful to prefix all of its internal names with `cl-`. Except for a few functions which are explicitly defined as additional features (such as `floatp-safe` and `letf`), this package does not export any non-`cl-' symbols which are not also part of Common Lisp.

The `cl-compat` package

The CL package includes emulations of some features of the old `cl.el', in the form of a compatibility package `cl-compat`. To use it, put `(require 'cl-compat)` in your program.

The old package defined a number of internal routines without `cl-` prefixes or other annotations. Call to these routines may have crept into existing Lisp code. `cl-compat` provides emulations of the following internal routines: `pair-with-newsyms`, `zip-lists`, `unzip-lists`, `reassemble-arglists`, `duplicate-symbols-p`, `safe-idiv`.

Some `setf` forms translated into calls to internal functions that user code might call directly. The functions `setnth`, `setnthcdr`, and `setelt` fall in this category; they are defined by `cl-compat`, but the best fix is to change to use `setf` properly.

The `cl-compat` file defines the keyword functions `keywordp`, `keyword-of`, and `defkeyword`, which are not defined by the new CL package because the use of keywords as data is discouraged.

The `build-klist` mechanism for parsing keyword arguments is emulated by `cl-compat`; the `with-keyword-args` macro is not, however, and in any case it's best to change to use the more natural keyword argument processing offered by `defun*`.

Multiple return values are treated differently by the two Common Lisp packages. The old package's method was more compatible with true Common Lisp, though it used heuristics that caused it to report spurious multiple return values in certain cases. The `cl-compat` package defines a set of multiple-value macros that are compatible with the old CL package; again, they are heuristic in nature, but they are guaranteed to work in any case where the old package's macros worked. To avoid name collision with the "official" multiple-value facilities, the ones in `cl-compat` have capitalized names: `Values`, `Values-list`, `Multiple-value-bind`, etc.

The functions `cl-floor`, `cl-ceiling`, `cl-truncate`, and `cl-round` are defined by `cl-compat` to use the old-style multiple-value mechanism, just as they did in the old package. The newer `floor*` and friends return their two results in a list rather than as multiple values. Note that older versions of the old package used the unadorned names `floor`, `ceiling`, etc.; `cl-compat` cannot use these names because they conflict with Emacs 19 built-ins.

Porting Common Lisp

This package is meant to be used as an extension to Emacs Lisp, not as an Emacs implementation of true Common Lisp. Some of the remaining differences between Emacs Lisp and Common Lisp make it difficult to port large Common Lisp applications to Emacs. For one, some of the features in this package are not fully compliant with ANSI or Steele; see section Common Lisp Compatibility. But there are also quite a few features that this package does not provide at all. Here are some major omissions that you will want watch out for when bringing Common Lisp code into Emacs.

- Case-insensitivity. Symbols in Common Lisp are case-insensitive by default. Some programs refer to a function or variable as `foo` in one place and `Foo` or `FOO` in another. Emacs Lisp will treat these as three distinct symbols.

  Some Common Lisp code is written in all upper-case. While Emacs is happy to let the program's own functions and variables use this convention, calls to Lisp builtins like `if` and `defun` will have to be changed to lower-case.

- Lexical scoping. In Common Lisp, function arguments and `let` bindings apply only to references physically within their bodies (or within macro expansions in their bodies). Emacs Lisp, by contrast, uses dynamic scoping wherein a binding to a variable is visible even inside functions called from the body.

  Variables in Common Lisp can be made dynamically scoped by declaring them `special` or using `defvar`. In Emacs Lisp it is as if all variables were declared `special`.

  Often you can use code that was written for lexical scoping even in a dynamically scoped Lisp, but not always. Here is an example of a Common Lisp code fragment that would fail in Emacs Lisp:

```
(defun map-odd-elements (func list)
  (loop for x in list
        for flag = t then (not flag)
        collect (if flag x (funcall func x))))

(defun add-odd-elements (list x)
  (map-odd-elements (function (lambda (a) (+ a x))) list))
```

  In Common Lisp, the two functions' usages of `x` are completely independent. In Emacs Lisp, the binding to `x` made by `add-odd-elements` will have been hidden by the binding in `map-odd-elements` by the time the `(+ a x)` function is called.

  (This package avoids such problems in its own mapping functions by using names like `cl-x` instead of `x` internally; as long as you don't use the `cl-` prefix for your own variables no collision can occur.)

  See section Lexical Bindings, for a description of the `lexical-let` form which establishes a Common Lisp-style lexical binding, and some examples of how it differs from Emacs' regular `let`.

- Common Lisp allows the shorthand `#'x` to stand for `(function x)`, just as `'x` stands for `(quote x)`. In Common Lisp, one traditionally uses `#'` notation when referring to the name of a function. In

Emacs Lisp, it works just as well to use a regular quote:

```
(loop for x in y by #'cddr collect (mapcar #'plusp x))  ; Common Lisp
(loop for x in y by 'cddr collect (mapcar 'plusp x))    ; Emacs Lisp
```

When `#'` introduces a `lambda` form, it is best to write out `(function ...)` longhand in Emacs Lisp. You can use a regular quote, but then the byte-compiler won't know that the `lambda` expression is code that can be compiled.

```
(mapcar #'(lambda (x) (* x 2)) list)            ; Common Lisp
(mapcar (function (lambda (x) (* x 2))) list)   ; Emacs Lisp
```

Lucid Emacs supports `#'` notation starting with version 19.8.

- The "backquote" feature uses a different syntax in Emacs Lisp.

```
(defmacro foo (v &rest body) `(let ((,v 0)) @,body))  ; Common Lisp
(defmacro foo (v &rest body) (` (let (((, v) 0)) (@, body)))  ; Emacs
```

- Reader macros. Common Lisp includes a second type of macro that works at the level of individual characters. For example, Common Lisp implements the quote notation by a reader macro called `'`, whereas Emacs Lisp's parser just treats quote as a special case. Some Lisp packages use reader macros to create special syntaxes for themselves, which the Emacs parser is incapable of reading.

  The lack of reader macros, incidentally, is the reason behind Emacs Lisp's unusual backquote syntax. Since backquotes are implemented as a Lisp package and not built-in to the Emacs parser, they are forced to use a regular macro named ` which is used with the standard function/macro call notation.

- Other syntactic features. Common Lisp provides a number of notations beginning with # that the Emacs Lisp parser won't understand. For example, `#| ... |#' is an alternate comment notation, and `#+lucid (foo)' tells the parser to ignore the `(foo)` except in Lucid Common Lisp.

- Packages. In Common Lisp, symbols are divided into packages. Symbols that are Lisp built-ins are typically stored in one package; symbols that are vendor extensions are put in another, and each application program would have a package for its own symbols. Certain symbols are "exported" by a package and others are internal; certain packages "use" or import the exported symbols of other packages. To access symbols that would not normally be visible due to this importing and exporting, Common Lisp provides a syntax like `package:symbol` or `package::symbol`.

  Emacs Lisp has a single namespace for all interned symbols, and then uses a naming convention of putting a prefix like `cl-` in front of the name. Some Emacs packages adopt the Common Lisp-like convention of using `cl:` or `cl::` as the prefix. However, the Emacs parser does not understand colons and just treats them as part of the symbol name. Thus, while `mapcar` and `lisp:mapcar` may refer to the same symbol in Common Lisp, they are totally distinct in Emacs Lisp. Common Lisp programs which refer to a symbol by the full name sometimes and the short name other times will not port cleanly to Emacs.

  Emacs Lisp does have a concept of "obarrays," which are package-like collections of symbols, but this feature is not strong enough to be used as a true package mechanism.

- Keywords. The notation `:test-not` in Common Lisp really is a shorthand for `keyword:test-not`; keywords are just symbols in a built-in `keyword` package with the special

property that all its symbols are automatically self-evaluating. Common Lisp programs often use keywords liberally to avoid having to use quotes.

In Emacs Lisp a keyword is just a symbol whose name begins with a colon; since the Emacs parser does not treat them specially, they have to be explicitly made self-evaluating by a statement like `(setq :test-not ':test-not)`. This package arranges to execute such a statement whenever `defun*` or some other form sees a keyword being used as an argument. Common Lisp code that assumes that a symbol `:mumble` will be self-evaluating even though it was never introduced by a `defun*` will have to be fixed.

- The `format` function is quite different between Common Lisp and Emacs Lisp. It takes an additional "destination" argument before the format string. A destination of `nil` means to format to a string as in Emacs Lisp; a destination of `t` means to write to the terminal (similar to `message` in Emacs). Also, format control strings are utterly different; `~` is used instead of `%` to introduce format codes, and the set of available codes is much richer. There are no notations like `\n` for string literals; instead, `format` is used with the "newline" format code, `~%`. More advanced formatting codes provide such features as paragraph filling, case conversion, and even loops and conditionals.

  While it would have been possible to implement most of Common Lisp `format` in this package (under the name `format*`, of course), it was not deemed worthwhile. It would have required a huge amount of code to implement even a decent subset of `format*`, yet the functionality it would provide over Emacs Lisp's `format` would rarely be useful.
- Vector constants use square brackets in Emacs Lisp, but `#(a b c)` notation in Common Lisp. To further complicate matters, Emacs 19 introduces its own `#(` notation for something entirely different--strings with properties.
- Characters are distinct from integers in Common Lisp. The notation for character constants is also different: `#\A` instead of `?A`. Also, `string=` and `string-equal` are synonyms in Emacs Lisp whereas the latter is case-insensitive in Common Lisp.
- Data types. Some Common Lisp data types do not exist in Emacs Lisp. Rational numbers and complex numbers are not present, nor are large integers (all integers are "fixnums"). All arrays are one-dimensional. There are no readtables or pathnames; streams are a set of existing data types rather than a new data type of their own. Hash tables, random-states, structures, and packages (obarrays) are built from Lisp vectors or lists rather than being distinct types.
- The Common Lisp Object System (CLOS) is not implemented, nor is the Common Lisp Condition System.
- Common Lisp features that are completely redundant with Emacs Lisp features of a different name generally have not been implemented. For example, Common Lisp writes `defconstant` where Emacs Lisp uses `defconst`. Similarly, `make-list` takes its arguments in different ways in the two Lisps but does exactly the same thing, so this package has not bothered to implement a Common Lisp-style `make-list`.
- A few more notable Common Lisp features not included in this package: `compiler-let`, `tagbody`, `prog`, `ldb/dpb`, `parse-integer`, `cerror`.
- Recursion. While recursion works in Emacs Lisp just like it does in Common Lisp, various details of the Emacs Lisp system and compiler make recursion much less efficient than it is in most Lisps. Some schools of thought prefer to use recursion in Lisp over other techniques; they would sum a list of numbers using something like

```
(defun sum-list (list)
  (if list
      (+ (car list) (sum-list (cdr list)))
    0))
```

where a more iteratively-minded programmer might write one of these forms:

```
(let ((total 0)) (dolist (x my-list) (incf total x)) total)
(loop for x in my-list sum x)
```

While this would be mainly a stylistic choice in most Common Lisps, in Emacs Lisp you should be aware that the iterative forms are much faster than recursion. Also, Lisp programmers will want to note that the current Emacs Lisp compiler does not optimize tail recursion.

The C Preprocessor

Last revised July 1992

for GCC version 2

Richard M. Stallman

The C Preprocessor

Transformations Made Globally

Most C preprocessor features are inactive unless you give specific commands to request their use. (Preprocessor commands are lines starting with `#'; see section Preprocessor Commands). But there are three transformations that the preprocessor always makes on all the input it receives, even in the absence of commands.

- All C comments are replaced with single spaces.
- Backslash-Newline sequences are deleted, no matter where. This feature allows you to break long lines for cosmetic purposes without changing their meaning.
- Predefined macro names are replaced with their expansions (see section Predefined Macros).

The first two transformations are done *before* nearly all other parsing and before preprocessor commands are recognized. Thus, for example, you can split a line cosmetically with Backslash-Newline anywhere (except when trigraphs are in use; see below).

```
/*
*/ # /*
*/ defi\
ne FO\
O 10\
20
```

is equivalent into `#define FOO 1020'. You can split even an escape sequence with Backslash-Newline. For example, you can split `"foo\bar"` between the `\' and the `b' to get

```
"foo\\
bar"
```

This behavior is unclean: in all other contexts, a Backslash can be inserted in a string constant as an ordinary character by writing a double Backslash, and this creates an exception. But the ANSI C standard requires it. (Strict ANSI C does not allow Newlines in string constants, so they do not consider this a problem.)

But there are a few exceptions to all three transformations.

- C comments and predefined macro names are not recognized inside a `#include' command in which the file name is delimited with `<' and `>'.
- C comments and predefined macro names are never recognized within a character or string constant. (Strictly speaking, this is the rule, not an exception, but it is worth noting here anyway.)
- Backslash-Newline may not safely be used within an ANSI "trigraph". Trigraphs are converted before Backslash-Newline is deleted. If you write what looks like a trigraph with a Backslash-Newline inside, the Backslash-Newline is deleted as usual, but it is then too late to

recognize the trigraph.

This exception is relevant only if you use the `-trigraphs' option to enable trigraph processing. See section Invoking the C Preprocessor.

Preprocessor Commands

Most preprocessor features are active only if you use preprocessor commands to request their use.

Preprocessor commands are lines in your program that start with `#'. The `#' is followed by an identifier that is the command name. For example, `#define' is the command that defines a macro. Whitespace is also allowed before and after the `#'.

The set of valid command names is fixed. Programs cannot define new preprocessor commands.

Some command names require arguments; these make up the rest of the command line and must be separated from the command name by whitespace. For example, `#define' must be followed by a macro name and the intended expansion of the macro.

A preprocessor command cannot be more than one line in normal circumstances. It may be split cosmetically with Backslash-Newline, but that has no effect on its meaning. Comments containing Newlines can also divide the command into multiple lines, but the comments are changed to Spaces before the command is interpreted. The only way a significant Newline can occur in a preprocessor command is within a string constant or character constant. Note that most C compilers that might be applied to the output from the preprocessor do not accept string or character constants containing Newlines.

The `#' and the command name cannot come from a macro expansion. For example, if `foo' is defined as a macro expanding to `define', that does not make `#foo' a valid preprocessor command.

Header Files

A header file is a file containing C declarations and macro definitions (see section Macros) to be shared between several source files. You request the use of a header file in your program with the C preprocessor command `#include'.

Uses of Header Files

Header files serve two kinds of purposes.

- System header files declare the interfaces to parts of the operating system. You include them in your program to supply the definitions and declarations you need to invoke system calls and libraries.
- Your own header files contain declarations for interfaces between the source files of your program. Each time you have a group of related declarations and macro definitions all or most of which are needed in several different source files, it is a good idea to create a header file for them.

Including a header file produces the same results in C compilation as copying the header file into each source file that needs it. But such copying would be time-consuming and error-prone. With a header the related declarations appear in only one place. If they need to be changed, they can be changed in one place, and programs that include the header file will automatically use the new version when next recompiled. The header file eliminates the labor of finding and changing all the copies as well as the risk that a failure to find one copy will result in inconsistencies within a program.

The usual convention is to give header files names that end with `.h'.

The `#include' Command

Both user and system header files are included using the preprocessor command `#include'. It has three variants:

`#include <file>`

This variant is used for system header files. It searches for a file named file in a list of directories specified by you, then in a standard list of system directories. You specify directories to search for header files with the command option `-I' (see section Invoking the C Preprocessor). The option `-nostdinc' inhibits searching the standard system directories; in this case only the directories you specify are searched.

The parsing of this form of `#include' is slightly special because comments are not recognized within the `<...>'. Thus, in `#include <x/*y>' the `/*' does not start a comment and the command specifies inclusion of a system header file named `x/*y'. Of course, a header file with such a name is unlikely to exist on Unix, where shell wildcard features would make it hard to manipulate.

The argument file may not contain a `>' character. It may, however, contain a `<' character.

`#include "file"`

This variant is used for header files of your own program. It searches for a file named file first in the current directory, then in the same directories used for system header files. The current directory is the directory of the current input file. It is tried first because it is presumed to be the location of the files that the current input file refers to. (If the `-I-' option is used, the special treatment of the current directory is inhibited.)

The argument file may not contain `"' characters. If backslashes occur within file, they are considered ordinary text characters, not escape characters. None of the character escape sequences appropriate to string constants in C are processed. Thus, `#include "x\n\\y"' specifies a filename containing three backslashes. It is not clear why this behavior is ever useful, but the ANSI standard specifies it.

`#include anything else`

This variant is called a computed #include. Any `#include' command whose argument does not fit the above two forms is a computed include. The text anything else is checked for macro calls, which are expanded (see section Macros). When this is done, the result must fit one of the above two variants--in particular, the expanded text must in the end be surrounded by either quotes or angle braces.

This feature allows you to define a macro which controls the file name to be used at a later pc
the program. One application of this is to allow a site-configuration file for your program to
specify the names of the system include files to be used. This can help in porting the program to
various operating systems in which the necessary system header files are found in different places.

How `#include' Works

The `#include' command works by directing the C preprocessor to scan the specified file as input before continuing with the rest of the current file. The output from the preprocessor contains the output already generated, followed by the output resulting from the included file, followed by the output that comes from the text after the `#include' command. For example, given two files as follows:

```
/* File program.c */
int x;
#include "header.h"

main ()
{
  printf (test ());
}

/* File header.h */
char *test ();
```

the output generated by the C preprocessor for `program.c' as input would be

```
int x;
char *test ();

main ()
{
  printf (test ());
}
```

Included files are not limited to declarations and macro definitions; those are merely the typical uses. Any fragment of a C program can be included from another file. The include file could even contain the beginning of a statement that is concluded in the containing file, or the end of a statement that was started in the including file. However, a comment or a string or character constant may not start in the included file and finish in the including file. An unterminated comment, string constant or character constant in an included file is considered to end (with an error message) at the end of the file.

The line following the `#include' command is always treated as a separate line by the C preprocessor even if the included file lacks a final newline.

Once-Only Include Files

Very often, one header file includes another. It can easily result that a certain header file is included more than once. This may lead to errors, if the header file defines structure types or typedefs, and is certainly wasteful. Therefore, we often wish to prevent multiple inclusion of a header file.

The standard way to do this is to enclose the entire real contents of the file in a conditional, like this:

```
#ifndef __FILE_FOO_SEEN__
#define __FILE_FOO_SEEN__

the entire file

#endif /* __FILE_FOO_SEEN__ */
```

The macro `__FILE_FOO_SEEN__` indicates that the file has been included once already; its name should begin with `__' to avoid conflicts with user programs, and it should contain the name of the file and some additional text, to avoid conflicts with other header files.

The GNU C preprocessor is programmed to notice when a header file uses this particular construct and handle it efficiently. If a header file is contained entirely in a `#ifndef' conditional, then it records that fact. If a subsequent `#include' specifies the same file, and the macro in the `#ifndef' is already defined, then the file is entirely skipped, without even reading it.

There is also an explicit command to tell the preprocessor that it need not include a file more than once. This is called `#pragma once', and was used *in addition to* the `#ifndef' conditional around the contents of the header file. `#pragma once' is now obsolete and should not be used at all.

In the Objective C language, there is a variant of `#include' called `#import' which includes a file, but does so at most once. If you use `#import' *instead of* `#include', then you don't need the conditionals inside the header file to prevent multiple execution of the contents.

`#import' is obsolete because it is not a well-designed feature. It requires the users of a header file--the applications programmers--to know that a certain header file should only be included once. It is much better for the header file's implementor to write the file so that users don't need to know this. Using `#ifndef' accomplishes this goal.

Inheritance and Header Files

Inheritance is what happens when one object or file derives some of its contents by virtual copying from another object or file. In the case of C header files, inheritance means that one header file includes another header file and then replaces or adds something.

If the inheriting header file and the base header file have different names, then inheritance is straightforward: simply write `#include "base"' in the inheriting file.

Sometimes it is necessary to give the inheriting file the same name as the base file. This is less

straightforward.

For example, suppose an application program uses the system header file `sys/signal.h', but the version of `/usr/include/sys/signal.h' on a particular system doesn't do what the application program expects. It might be convenient to define a "local" version, perhaps under the name `/usr/local/include/sys/signal.h', to override or add to the one supplied by the system.

You can do this by using the option `-I.' for compilation, and writing a file `sys/signal.h' that does what the application program expects. But making this file include the standard `sys/signal.h' is not so easy--writing `#include <sys/signal.h>' in that file doesn't work, because it includes your own version of the file, not the standard system version. Used in that file itself, this leads to an infinite recursion and a fatal error in compilation.

`#include </usr/include/sys/signal.h>' would find the proper file, but that is not clean, since it makes an assumption about where the system header file is found. This is bad for maintenance, since it means that any change in where the system's header files are kept requires a change somewhere else.

The clean way to solve this problem is to use `#include_next', which means, "Include the *next* file with this name." This command works like `#include' except in searching for the specified file: it starts searching the list of header file directories *after* the directory in which the current file was found.

Suppose you specify `-I /usr/local/include', and the list of directories to search also includes `/usr/include'; and suppose that both directories contain a file named `sys/signal.h'. Ordinary `#include <sys/signal.h>' finds the file under `/usr/local/include'. If that file contains `#include_next <sys/signal.h>', it starts searching after that directory, and finds the file in `/usr/include'.

Macros

A macro is a sort of abbreviation which you can define once and then use later. There are many complicated features associated with macros in the C preprocessor.

Simple Macros

A simple macro is a kind of abbreviation. It is a name which stands for a fragment of code. Some people refer to these as manifest constants.

Before you can use a macro, you must define it explicitly with the `#define' command. `#define' is followed by the name of the macro and then the code it should be an abbreviation for. For example,

```
#define BUFFER_SIZE 1020
```

defines a macro named `BUFFER_SIZE' as an abbreviation for the text `1020'. Therefore, if somewhere after this `#define' command there comes a C statement of the form

```
foo = (char *) xmalloc (BUFFER_SIZE);
```

then the C preprocessor will recognize and expand the macro `BUFFER_SIZE', resulting in

```
foo = (char *) xmalloc (1020);
```

the definition must be a single line; however, it may not end in the middle of a multi-line string constant or character constant.

The use of all upper case for macro names is a standard convention. Programs are easier to read when it is possible to tell at a glance which names are macros.

Normally, a macro definition must be a single line, like all C preprocessor commands. (You can split a long macro definition cosmetically with Backslash-Newline.) There is one exception: Newlines can be included in the macro definition if within a string or character constant. By the same token, it is not possible for a macro definition to contain an unbalanced quote character; the definition automatically extends to include the matching quote character that ends the string or character constant. Comments within a macro definition may contain Newlines, which make no difference since the comments are entirely replaced with Spaces regardless of their contents.

Aside from the above, there is no restriction on what can go in a macro body. Parentheses need not balance. The body need not resemble valid C code. (Of course, you might get error messages from the C compiler when you use the macro.)

The C preprocessor scans your program sequentially, so macro definitions take effect at the place you write them. Therefore, the following input to the C preprocessor

```
foo = X;
#define X 4
bar = X;
```

produces as output

```
foo = X;

bar = 4;
```

After the preprocessor expands a macro name, the macro's definition body is appended to the front of the remaining input, and the check for macro calls continues. Therefore, the macro body can contain calls to other macros. For example, after

```
#define BUFSIZE 1020
#define TABLESIZE BUFSIZE
```

the name `TABLESIZE' when used in the program would go through two stages of expansion, resulting ultimately in `1020'.

This is not at all the same as defining `TABLESIZE' to be `1020'. The `#define' for `TABLESIZE' uses exactly the body you specify--in this case, `BUFSIZE'---and does not check to see whether it too is the name of a macro. It's only when you *use* `TABLESIZE' that the result of its expansion is checked for

more macro names. See section Cascaded Use of Macros.

Macros with Arguments

A simple macro always stands for exactly the same text, each time it is used. Macros can be more flexible when they accept arguments. Arguments are fragments of code that you supply each time the macro is used. These fragments are included in the expansion of the macro according to the directions in the macro definition.

To define a macro that uses arguments, you write a `#define' command with a list of argument names in parentheses after the name of the macro. The argument names may be any valid C identifiers, separated by commas and optionally whitespace. The open-parenthesis must follow the macro name immediately, with no space in between.

For example, here is a macro that computes the minimum of two numeric values, as it is defined in many C programs:

```
#define min(X, Y)  ((X) < (Y) ? (X) : (Y))
```

(This is not the best way to define a "minimum" macro in GNU C. See section Duplication of Side Effects, for more information.)

To use a macro that expects arguments, you write the name of the macro followed by a list of actual arguments in parentheses, separated by commas. The number of actual arguments you give must match the number of arguments the macro expects. Examples of use of the macro `min' include `min (1, 2)' and `min (x + 28, *p)'.

The expansion text of the macro depends on the arguments you use. Each of the argument names of the macro is replaced, throughout the macro definition, with the corresponding actual argument. Using the same macro `min' defined above, `min (1, 2)' expands into

```
((1) < (2) ? (1) : (2))
```

where `1' has been substituted for `X' and `2' for `Y'.

Likewise, `min (x + 28, *p)' expands into

```
((x + 28) < (*p) ? (x + 28) : (*p))
```

Parentheses in the actual arguments must balance; a comma within parentheses does not end an argument. However, there is no requirement for brackets or braces to balance, and they do not prevent a comma from separating arguments. Thus,

```
macro (array[x = y, x + 1])
```

passes two arguments to `macro`: `array[x = y' and `x + 1]'. If you want to supply `array[x = y, x + 1]' as an argument, you must write it as `array[(x = y, x + 1)]', which is equivalent C code.

After the actual arguments are substituted into the macro body, the entire result is appended to the fr of the remaining input, and the check for macro calls continues. Therefore, the actual arguments can contain calls to other macros, either with or without arguments, or even to the same macro. The macro body can also contain calls to other macros. For example, `min (min (a, b), c)' expands into this text:

```
((((a) < (b) ? (a) : (b))) < (c)
 ? (((a) < (b) ? (a) : (b)))
 : (c))
```

(Line breaks shown here for clarity would not actually be generated.)

If a macro `foo` takes one argument, and you want to supply an empty argument, you must write at least some whitespace between the parentheses, like this: `foo ( )'. Just `foo ()' is providing no arguments, which is an error if `foo` expects an argument. But `foo0 ()' is the correct way to call a macro defined to take zero arguments, like this:

```
#define foo0() ...
```

If you use the macro name followed by something other than an open-parenthesis (after ignoring any spaces, tabs and comments that follow), it is not a call to the macro, and the preprocessor does not change what you have written. Therefore, it is possible for the same name to be a variable or function in your program as well as a macro, and you can choose in each instance whether to refer to the macro (if an actual argument list follows) or the variable or function (if an argument list does not follow).

Such dual use of one name could be confusing and should be avoided except when the two meanings are effectively synonymous: that is, when the name is both a macro and a function and the two have similar effects. You can think of the name simply as a function; use of the name for purposes other than calling it (such as, to take the address) will refer to the function, while calls will expand the macro and generate better but equivalent code. For example, you can use a function named `min' in the same source file that defines the macro. If you write `&min' with no argument list, you refer to the function. If you write `min (x, bb)', with an argument list, the macro is expanded. If you write `(min) (a, bb)', where the name `min' is not followed by an open-parenthesis, the macro is not expanded, so you wind up with a call to the function `min'.

You may not define the same name as both a simple macro and a macro with arguments.

In the definition of a macro with arguments, the list of argument names must follow the macro name immediately with no space in between. If there is a space after the macro name, the macro is defined as taking no arguments, and all the rest of the line is taken to be the expansion. The reason for this is that it is often useful to define a macro that takes no arguments and whose definition begins with an identifier in parentheses. This rule about spaces makes it possible for you to do either this:

```
#define FOO(x) - 1 / (x)
```

(which defines `FOO' to take an argument and expand into minus the reciprocal of that argument) or this:

```
#define BAR (x) - 1 / (x)
```

(which defines `BAR' to take no argument and always expand into `(x) - 1 / (x)').

Note that the *uses* of a macro with arguments can have spaces before the left parenthesis; it's the *definition* where it matters whether there is a space.

Predefined Macros

Several simple macros are predefined. You can use them without giving definitions for them. They fall into two classes: standard macros and system-specific macros.

Standard Predefined Macros

The standard predefined macros are available with the same meanings regardless of the machine or operating system on which you are using GNU C. Their names all start and end with double underscores. Those preceding `__GNUC__` in this table are standardized by ANSI C; the rest are GNU C extensions.

`__FILE__`

This macro expands to the name of the current input file, in the form of a C string constant. The precise name returned is the one that was specified in `#include' or as the input file name argument.

`__LINE__`

This macro expands to the current input line number, in the form of a decimal integer constant. While we call it a predefined macro, it's a pretty strange macro, since its "definition" changes with each new line of source code.

This and `__FILE__' are useful in generating an error message to report an inconsistency detected by the program; the message can state the source line at which the inconsistency was detected. For example,

```
fprintf (stderr, "Internal error: "
                 "negative string length "
                 "%d at %s, line %d.",
         length, __FILE__, __LINE__);
```

A `#include' command changes the expansions of `__FILE__' and `__LINE__' to correspond to the included file. At the end of that file, when processing resumes on the input file that contained the `#include' command, the expansions of `__FILE__' and `__LINE__' revert to the values they had before the `#include' (but `__LINE__' is then incremented by one as processing moves to the line after the `#include').

The expansions of both `__FILE__' and `__LINE__' are altered if a `#line' command is used. See section Combining Source Files.

`__INCLUDE_LEVEL__`

This macro expands to a decimal integer constant that represents the depth of nesting in include files. The value of this macro is incremented on every `#include' command and decremented at every end of file.

`__DATE__`

This macro expands to a string constant that describes the date on which the preprocessor is being run. The string constant contains eleven characters and looks like `"Jan 29 1987"' or `"Apr 1 1905"'.

`__TIME__`

This macro expands to a string constant that describes the time at which the preprocessor is being run. The string constant contains eight characters and looks like `"23:59:01"'.

`__STDC__`

This macro expands to the constant 1, to signify that this is ANSI Standard C. (Whether that is actually true depends on what C compiler will operate on the output from the preprocessor.)

`__GNUC__`

This macro is defined if and only if this is GNU C. This macro is defined only when the entire GNU C compiler is in use; if you invoke the preprocessor directly, `__GNUC__' is undefined.

`__GNUG__`

The GNU C compiler defines this when the compilation language is C++; use `__GNUG__' to distinguish between GNU C and GNU C++.

`__cplusplus`

The draft ANSI standard for C++ used to require predefining this variable. Though it is no longer required, GNU C++ continues to define it, as do other popular C++ compilers. You can use `__cplusplus' to test whether a header is compiled by a C compiler or a C++ compiler.

`__STRICT_ANSI__`

This macro is defined if and only if the `-ansi' switch was specified when GNU C was invoked. Its definition is the null string. This macro exists primarily to direct certain GNU header files not to define certain traditional Unix constructs which are incompatible with ANSI C.

`__BASE_FILE__`

This macro expands to the name of the main input file, in the form of a C string constant. This is the source file that was specified as an argument when the C compiler was invoked.

`__VERSION__`

This macro expands to a string which describes the version number of GNU C. The string is normally a sequence of decimal numbers separated by periods, such as `"1.18"'. The only reasonable use of this macro is to incorporate it into a string constant.

`__OPTIMIZE__`

This macro is defined in optimizing compilations. It causes certain GNU header files to define alternative macro definitions for some system library functions. It is unwise to refer to or test the definition of this macro unless you make very sure that programs will execute with the same effect regardless.

`__CHAR_UNSIGNED__`

This macro is defined if and only if the data type `char` is unsigned on the target machine. It exists to cause the standard header file `limit.h' to work correctly. It is bad practice to refer to this macro yourself; instead, refer to the standard macros defined in `limit.h'. The preprocessor

uses this macro to determine whether or not to sign-extend large character constants written in octal; see section The `#if' Command.

Nonstandard Predefined Macros

The C preprocessor normally has several predefined macros that vary between machines because their purpose is to indicate what type of system and machine is in use. This manual, being for all systems and machines, cannot tell you exactly what their names are; instead, we offer a list of some typical ones. You can use `cpp -dM' to see the values of predefined macros; see section Invoking the C Preprocessor.

Some nonstandard predefined macros describe the operating system in use, with more or less specificity. For example,

`unix`

`unix' is normally predefined on all Unix systems.

`BSD`

`BSD' is predefined on recent versions of Berkeley Unix (perhaps only in version 4.3).

Other nonstandard predefined macros describe the kind of CPU, with more or less specificity. For example,

`vax`

`vax' is predefined on Vax computers.

`mc68000`

`mc68000' is predefined on most computers whose CPU is a Motorola 68000, 68010 or 68020.

`m68k`

`m68k' is also predefined on most computers whose CPU is a 68000, 68010 or 68020; however, some makers use `mc68000' and some use `m68k'. Some predefine both names. What happens in GNU C depends on the system you are using it on.

`M68020`

`M68020' has been observed to be predefined on some systems that use 68020 CPUs--in addition to `mc68000' and `m68k', which are less specific.

`_AM29K`

`_AM29000`

Both `_AM29K' and `_AM29000' are predefined for the AMD 29000 CPU family.

`ns32000`

`ns32000' is predefined on computers which use the National Semiconductor 32000 series CPU.

Yet other nonstandard predefined macros describe the manufacturer of the system. For example,

`sun`

`sun' is predefined on all models of Sun computers.

`pyr`

`pyr' is predefined on all models of Pyramid computers.

`sequent`

`sequent' is predefined on all models of Sequent computers.

These predefined symbols are not only nonstandard, they are contrary to the ANSI standard because their names do not start with underscores. Therefore, the option `-ansi' inhibits the definition of these symbols.

This tends to make `-ansi' useless, since many programs depend on the customary nonstandard predefined symbols. Even system header files check them and will generate incorrect declarations if they do not find the names that are expected. You might think that the header files supplied for the Uglix computer would not need to test what machine they are running on, because they can simply assume it is the Uglix; but often they do, and they do so using the customary names. As a result, very few C programs will compile with `-ansi'. We intend to avoid such problems on the GNU system.

What, then, should you do in an ANSI C program to test the type of machine it will run on?

GNU C offers a parallel series of symbols for this purpose, whose names are made from the customary ones by adding `__' at the beginning and end. Thus, the symbol `__vax__` would be available on a Vax, and so on.

The set of nonstandard predefined names in the GNU C preprocessor is controlled (when `cpp` is itself compiled) by the macro `CPP_PREDEFINES', which should be a string containing `-D' options, separated by spaces. For example, on the Sun 3, we use the following definition:

```
#define CPP_PREDEFINES "-Dmc68000 -Dsun -Dunix -Dm68k"
```

This macro is usually specified in `tm.h'.

Stringification

Stringification means turning a code fragment into a string constant whose contents are the text for the code fragment. For example, stringifying `foo (z)' results in `"foo (z)"'.

In the C preprocessor, stringification is an option available when macro arguments are substituted into the macro definition. In the body of the definition, when an argument name appears, the character `#' before the name specifies stringification of the corresponding actual argument when it is substituted at that point in the definition. The same argument may be substituted in other places in the definition without stringification if the argument name appears in those places with no `#'.

Here is an example of a macro definition that uses stringification:

```
#define WARN_IF(EXP) \
do { if (EXP) \
        fprintf (stderr, "Warning: " #EXP "\n"); } \
while (0)
```

Here the actual argument for `EXP' is substituted once as given, into the `if' statement, and once as stringified, into the argument to `fprintf'. The `do' and `while (0)' are a kludge to make it possible to write `WARN_IF (arg);', which the resemblance of `WARN_IF' to a function would make C programmers

want to do; see section Swallowing the Semicolon).

The stringification feature is limited to transforming one macro argument into one string constant: there is no way to combine the argument with other text and then stringify it all together. But the example above shows how an equivalent result can be obtained in ANSI Standard C using the feature that adjacent string constants are concatenated as one string constant. The preprocessor stringifies the actual value of `EXP' into a separate string constant, resulting in text like

```
do { if (x == 0) \
        fprintf (stderr, "Warning: " "x == 0" "\n"); } \
while (0)
```

but the C compiler then sees three consecutive string constants and concatenates them into one, producing effectively

```
do { if (x == 0) \
        fprintf (stderr, "Warning: x == 0\n"); } \
while (0)
```

Stringification in C involves more than putting doublequote characters around the fragment; it is necessary to put backslashes in front of all doublequote characters, and all backslashes in string and character constants, in order to get a valid C string constant with the proper contents. Thus, stringifying `p = "foo\n";' results in `"p = \"foo\\n\";"'. However, backslashes that are not inside of string or character constants are not duplicated: `\n' by itself stringifies to `"\n"'.

Whitespace (including comments) in the text being stringified is handled according to precise rules. All leading and trailing whitespace is ignored. Any sequence of whitespace in the middle of the text is converted to a single space in the stringified result.

Concatenation

Concatenation means joining two strings into one. In the context of macro expansion, concatenation refers to joining two lexical units into one longer one. Specifically, an actual argument to the macro can be concatenated with another actual argument or with fixed text to produce a longer name. The longer name might be the name of a function, variable or type, or a C keyword; it might even be the name of another macro, in which case it will be expanded.

When you define a macro, you request concatenation with the special operator `##' in the macro body. When the macro is called, after actual arguments are substituted, all `##' operators are deleted, and so is any whitespace next to them (including whitespace that was part of an actual argument). The result is to concatenate the syntactic tokens on either side of the `##'.

Consider a C program that interprets named commands. There probably needs to be a table of commands, perhaps an array of structures declared as follows:

```
struct command
{
```

```
  char *name;
  void (*function) ();
};

struct command commands[] =
{
  { "quit", quit_command},
  { "help", help_command},
  ...
};
```

It would be cleaner not to have to give each command name twice, once in the string constant and once in the function name. A macro which takes the name of a command as an argument can make this unnecessary. The string constant can be created with stringification, and the function name by concatenating the argument with `_command'. Here is how it is done:

```
#define COMMAND(NAME)  { #NAME, NAME ## _command }

struct command commands[] =
{
  COMMAND (quit),
  COMMAND (help),
  ...
};
```

The usual case of concatenation is concatenating two names (or a name and a number) into a longer name. But this isn't the only valid case. It is also possible to concatenate two numbers (or a number and a name, such as `1.5' and `e3') into a number. Also, multi-character operators such as `+=' can be formed by concatenation. In some cases it is even possible to piece together a string constant. However, two pieces of text that don't together form a valid lexical unit cannot be concatenated. For example, concatenation with `x' on one side and `+' on the other is not meaningful because those two characters can't fit together in any lexical unit of C. The ANSI standard says that such attempts at concatenation are undefined, but in the GNU C preprocessor it is well defined: it puts the `x' and `+' side by side with no particular special results.

Keep in mind that the C preprocessor converts comments to whitespace before macros are even considered. Therefore, you cannot create a comment by concatenating `/' and `*': the `/*' sequence that starts a comment is not a lexical unit, but rather the beginning of a "long" space character. Also, you can freely use comments next to a `##' in a macro definition, or in actual arguments that will be concatenated, because the comments will be converted to spaces at first sight, and concatenation will later discard the spaces.

Undefining Macros

To undefine a macro means to cancel its definition. This is done with the `#undef' command. `#undef' is followed by the macro name to be undefined.

Like definition, undefinition occurs at a specific point in the source file, and it applies starting from that point. The name ceases to be a macro name, and from that point on it is treated by the preprocessor as if it had never been a macro name.

For example,

```
#define FOO 4
x = FOO;
#undef FOO
x = FOO;
```

expands into

```
x = 4;

x = FOO;
```

In this example, `FOO' had better be a variable or function as well as (temporarily) a macro, in order for the result of the expansion to be valid C code.

The same form of `#undef' command will cancel definitions with arguments or definitions that don't expect arguments. The `#undef' command has no effect when used on a name not currently defined as a macro.

Redefining Macros

Redefining a macro means defining (with `#define') a name that is already defined as a macro.

A redefinition is trivial if the new definition is transparently identical to the old one. You probably wouldn't deliberately write a trivial redefinition, but they can happen automatically when a header file is included more than once (see section Header Files), so they are accepted silently and without effect.

Nontrivial redefinition is considered likely to be an error, so it provokes a warning message from the preprocessor. However, sometimes it is useful to change the definition of a macro in mid-compilation. You can inhibit the warning by undefining the macro with `#undef' before the second definition.

In order for a redefinition to be trivial, the new definition must exactly match the one already in effect, with two possible exceptions:

- Whitespace may be added or deleted at the beginning or the end.
- Whitespace may be changed in the middle (but not inside strings). However, it may not be eliminated entirely, and it may not be added where there was no whitespace at all.

Recall that a comment counts as whitespace.

Pitfalls and Subtleties of Macros

In this section we describe some special rules that apply to macros and macro expansion, and point out certain cases in which the rules have counterintuitive consequences that you must watch out for.

Improperly Nested Constructs

Recall that when a macro is called with arguments, the arguments are substituted into the macro body and the result is checked, together with the rest of the input file, for more macro calls.

It is possible to piece together a macro call coming partially from the macro body and partially from the actual arguments. For example,

```
#define double(x) (2*(x))
#define call_with_1(x) x(1)
```

would expand `call_with_1 (double)' into `(2*(1))'.

Macro definitions do not have to have balanced parentheses. By writing an unbalanced open parenthesis in a macro body, it is possible to create a macro call that begins inside the macro body but ends outside of it. For example,

```
#define strange(file) fprintf (file, "%s %d",
...
strange(stderr) p, 35)
```

This bizarre example expands to `fprintf (stderr, "%s %d", p, 35)'!

Unintended Grouping of Arithmetic

You may have noticed that in most of the macro definition examples shown above, each occurrence of a macro argument name had parentheses around it. In addition, another pair of parentheses usually surround the entire macro definition. Here is why it is best to write macros that way.

Suppose you define a macro as follows,

```
#define ceil_div(x, y) (x + y - 1) / y
```

whose purpose is to divide, rounding up. (One use for this operation is to compute how many `int' objects are needed to hold a certain number of `char' objects.) Then suppose it is used as follows:

```
a = ceil_div (b & c, sizeof (int));
```

This expands into

```
a = (b & c + sizeof (int) - 1) / sizeof (int);
```

which does not do what is intended. The operator-precedence rules of C make it equivalent to this:

```
a = (b & (c + sizeof (int) - 1)) / sizeof (int);
```

But what we want is this:

```
a = ((b & c) + sizeof (int) - 1)) / sizeof (int);
```

Defining the macro as

```
#define ceil_div(x, y) ((x) + (y) - 1) / (y)
```

provides the desired result.

However, unintended grouping can result in another way. Consider `sizeof ceil_div(1, 2)'. That has the appearance of a C expression that would compute the size of the type of `ceil_div (1, 2)', but in fact it means something very different. Here is what it expands to:

```
sizeof ((1) + (2) - 1) / (2)
```

This would take the size of an integer and divide it by two. The precedence rules have put the division outside the `sizeof' when it was intended to be inside.

Parentheses around the entire macro definition can prevent such problems. Here, then, is the recommended way to define `ceil_div':

```
#define ceil_div(x, y) (((x) + (y) - 1) / (y))
```

Swallowing the Semicolon

Often it is desirable to define a macro that expands into a compound statement. Consider, for example, the following macro, that advances a pointer (the argument `p' says where to find it) across whitespace characters:

```
#define SKIP_SPACES (p, limit)  \
{ register char *lim = (limit); \
  while (p != lim) {            \
    if (*p++ != ' ') {          \
      p--; break; }}}
```

Here Backslash-Newline is used to split the macro definition, which must be a single line, so that it resembles the way such C code would be laid out if not part of a macro definition.

A call to this macro might be `SKIP_SPACES (p, lim)'. Strictly speaking, the call expands to a compound statement, which is a complete statement with no need for a semicolon to end it. But it looks like a function call. So it minimizes confusion if you can use it like a function call, writing a semicolon

afterward, as in `SKIP_SPACES (p, lim);'

But this can cause trouble before `else' statements, because the semicolon is actually a null statement. Suppose you write

```
if (*p != 0)
  SKIP_SPACES (p, lim);
else ...
```

The presence of two statements--the compound statement and a null statement--in between the `if' condition and the `else' makes invalid C code.

The definition of the macro `SKIP_SPACES' can be altered to solve this problem, using a `do ... while' statement. Here is how:

```
#define SKIP_SPACES (p, limit)     \
do { register char *lim = (limit); \
     while (p != lim) {            \
       if (*p++ != ' ') {          \
         p--; break; }}}           \
while (0)
```

Now `SKIP_SPACES (p, lim);' expands into

```
do {...} while (0);
```

which is one statement.

Duplication of Side Effects

Many C programs define a macro `min', for "minimum", like this:

```
#define min(X, Y)  ((X) < (Y) ? (X) : (Y))
```

When you use this macro with an argument containing a side effect, as shown here,

```
next = min (x + y, foo (z));
```

it expands as follows:

```
next = ((x + y) < (foo (z)) ? (x + y) : (foo (z)));
```

where `x + y' has been substituted for `X' and `foo (z)' for `Y'.

The function `foo' is used only once in the statement as it appears in the program, but the expression `foo (z)' has been substituted twice into the macro expansion. As a result, `foo' might be called two times when the statement is executed. If it has side effects or if it takes a long time to compute, the results might not be what you intended. We say that `min' is an unsafe macro.

The best solution to this problem is to define `min' in a way that computes the value of `foo (z)' only once. The C language offers no standard way to do this, but it can be done with GNU C extensions as follows:

```
#define min(X, Y)                       \
({ typeof (X) __x = (X), __y = (Y);   \
   (__x < __y) ? __x : __y; })
```

If you do not wish to use GNU C extensions, the only solution is to be careful when *using* the macro `min'. For example, you can calculate the value of `foo (z)', save it in a variable, and use that variable in `min':

```
#define min(X, Y)  ((X) < (Y) ? (X) : (Y))
...
{
  int tem = foo (z);
  next = min (x + y, tem);
}
```

(where we assume that `foo' returns type `int').

Self-Referential Macros

A self-referential macro is one whose name appears in its definition. A special feature of ANSI Standard C is that the self-reference is not considered a macro call. It is passed into the preprocessor output unchanged.

Let's consider an example:

```
#define foo (4 + foo)
```

where `foo' is also a variable in your program.

Following the ordinary rules, each reference to `foo' will expand into `(4 + foo)'; then this will be rescanned and will expand into `(4 + (4 + foo))'; and so on until it causes a fatal error (memory full) in the preprocessor.

However, the special rule about self-reference cuts this process short after one step, at `(4 + foo)'. Therefore, this macro definition has the possibly useful effect of causing the program to add 4 to the value of `foo' wherever `foo' is referred to.

In most cases, it is a bad idea to take advantage of this feature. A person reading the program who sees that `foo' is a variable will not expect that it is a macro as well. The reader will come across the identifier `foo' in the program and think its value should be that of the variable `foo', whereas in fact the value is four greater.

The special rule for self-reference applies also to indirect self-reference. This is the case where a macro x expands to use a macro `y', and the expansion of `y' refers to the macro `x'. The resulting reference to `x'

comes indirectly from the expansion of `x', so it is a self-reference and is not further expanded. Thus, after

```
#define x (4 + y)
#define y (2 * x)
```

`x' would expand into `(4 + (2 * x))'. Clear?

But suppose `y' is used elsewhere, not from the definition of `x'. Then the use of `x' in the expansion of `y' is not a self-reference because `x' is not "in progress". So it does expand. However, the expansion of `x' contains a reference to `y', and that is an indirect self-reference now because `y' is "in progress". The result is that `y' expands to `(2 * (4 + y))'.

It is not clear that this behavior would ever be useful, but it is specified by the ANSI C standard, so you may need to understand it.

Separate Expansion of Macro Arguments

We have explained that the expansion of a macro, including the substituted actual arguments, is scanned over again for macro calls to be expanded.

What really happens is more subtle: first each actual argument text is scanned separately for macro calls. Then the results of this are substituted into the macro body to produce the macro expansion, and the macro expansion is scanned again for macros to expand.

The result is that the actual arguments are scanned *twice* to expand macro calls in them.

Most of the time, this has no effect. If the actual argument contained any macro calls, they are expanded during the first scan. The result therefore contains no macro calls, so the second scan does not change it. If the actual argument were substituted as given, with no prescan, the single remaining scan would find the same macro calls and produce the same results.

You might expect the double scan to change the results when a self-referential macro is used in an actual argument of another macro (see section Self-Referential Macros): the self-referential macro would be expanded once in the first scan, and a second time in the second scan. But this is not what happens. The self-references that do not expand in the first scan are marked so that they will not expand in the second scan either.

The prescan is not done when an argument is stringified or concatenated. Thus,

```
#define str(s) #s
#define foo 4
str (foo)
```

expands to `"foo"'. Once more, prescan has been prevented from having any noticeable effect.

More precisely, stringification and concatenation use the argument as written, in un-prescanned form. The same actual argument would be used in prescanned form if it is substituted elsewhere without stringification or concatenation.

```
#define str(s) #s lose(s)
#define foo 4
str (foo)
```

expands to `"foo" lose(4)'.

You might now ask, "Why mention the prescan, if it makes no difference? And why not skip it and make the preprocessor faster?" The answer is that the prescan does make a difference in three special cases:

- Nested calls to a macro.
- Macros that call other macros that stringify or concatenate.
- Macros whose expansions contain unshielded commas.

We say that nested calls to a macro occur when a macro's actual argument contains a call to that very macro. For example, if `f' is a macro that expects one argument, `f (f (1))' is a nested pair of calls to `f'. The desired expansion is made by expanding `f (1)' and substituting that into the definition of `f'. The prescan causes the expected result to happen. Without the prescan, `f (1)' itself would be substituted as an actual argument, and the inner use of `f' would appear during the main scan as an indirect self-reference and would not be expanded. Here, the prescan cancels an undesirable side effect (in the medical, not computational, sense of the term) of the special rule for self-referential macros.

But prescan causes trouble in certain other cases of nested macro calls. Here is an example:

```
#define foo  a,b
#define bar(x) lose(x)
#define lose(x) (1 + (x))

bar(foo)
```

We would like `bar(foo)' to turn into `(1 + (foo))', which would then turn into `(1 + (a,b))'. But instead, `bar(foo)' expands into `lose(a,b)', and you get an error because `lose` requires a single argument. In this case, the problem is easily solved by the same parentheses that ought to be used to prevent misnesting of arithmetic operations:

```
#define foo (a,b)
#define bar(x) lose((x))
```

The problem is more serious when the operands of the macro are not expressions; for example, when they are statements. Then parentheses are unacceptable because they would make for invalid C code:

```
#define foo { int a, b; ... }
```

In GNU C you can shield the commas using the `({...})' construct which turns a compound statement into an expression:

```
#define foo ({ int a, b; ... })
```

Or you can rewrite the macro definition to avoid such commas:

```
#define foo { int a; int b; ... }
```

There is also one case where prescan is useful. It is possible to use prescan to expand an argument and then stringify it--if you use two levels of macros. Let's add a new macro `xstr' to the example shown above:

```
#define xstr(s) str(s)
#define str(s) #s
#define foo 4
xstr (foo)
```

This expands into `"4"', not `"foo"'. The reason for the difference is that the argument of `xstr' is expanded at prescan (because `xstr' does not specify stringification or concatenation of the argument). The result of prescan then forms the actual argument for `str'. `str' uses its argument without prescan because it performs stringification; but it cannot prevent or undo the prescanning already done by `xstr'.

Cascaded Use of Macros

A cascade of macros is when one macro's body contains a reference to another macro. This is very common practice. For example,

```
#define BUFSIZE 1020
#define TABLESIZE BUFSIZE
```

This is not at all the same as defining `TABLESIZE' to be `1020'. The `#define' for `TABLESIZE' uses exactly the body you specify--in this case, `BUFSIZE'---and does not check to see whether it too is the name of a macro.

It's only when you *use* `TABLESIZE' that the result of its expansion is checked for more macro names.

This makes a difference if you change the definition of `BUFSIZE' at some point in the source file. `TABLESIZE', defined as shown, will always expand using the definition of `BUFSIZE' that is currently in effect:

```
#define BUFSIZE 1020
#define TABLESIZE BUFSIZE
#undef BUFSIZE
#define BUFSIZE 37
```

Now `TABLESIZE' expands (in two stages) to `37'.

Newlines in Macro Arguments

Traditional macro processing carries forward all newlines in macro arguments into the expansion of the macro. This means that, if some of the arguments are substituted more than once, or not at all, or out of order, newlines can be duplicated, lost, or moved around within the expansion. If the expansion consists of multiple statements, then the effect is to distort the line numbers of some of these statements. The result can be incorrect line numbers, in error messages or displayed in a debugger.

The GNU C preprocessor operating in ANSI C mode adjusts appropriately for multiple use of an argument--the first use expands all the newlines, and subsequent uses of the same argument produce no newlines. But even in this mode, it can produce incorrect line numbering if arguments are used out of order, or not used at all.

Here is an example illustrating this problem:

```
#define ignore_second_arg(a,b,c) a; c

ignore_second_arg (foo (),
                   ignored (),
                   syntax error);
```

The syntax error triggered by the tokens `syntax error' results in an error message citing line four, even though the statement text comes from line five.

Conditionals

In a macro processor, a conditional is a command that allows a part of the program to be ignored during compilation, on some conditions. In the C preprocessor, a conditional can test either an arithmetic expression or whether a name is defined as a macro.

A conditional in the C preprocessor resembles in some ways an `if' statement in C, but it is important to understand the difference between them. The condition in an `if' statement is tested during the execution of your program. Its purpose is to allow your program to behave differently from run to run, depending on the data it is operating on. The condition in a preprocessor conditional command is tested when your program is compiled. Its purpose is to allow different code to be included in the program depending on the situation at the time of compilation.

Why Conditionals are Used

Generally there are three kinds of reason to use a conditional.

- A program may need to use different code depending on the machine or operating system it is to run on. In some cases the code for one operating system may be erroneous on another operating system; for example, it might refer to library routines that do not exist on the other system. When this happens, it is not enough to avoid executing the invalid code: merely having it in the program makes it impossible to link the program and run it. With a preprocessor conditional, the offending

code can be effectively excised from the program when it is not valid.

- You may want to be able to compile the same source file into two different programs. Sometimes the difference between the programs is that one makes frequent time-consuming consistency checks on its intermediate data while the other does not.
- A conditional whose condition is always false is a good way to exclude code from the program but keep it as a sort of comment for future reference.

Most simple programs that are intended to run on only one machine will not need to use preprocessor conditionals.

Syntax of Conditionals

A conditional in the C preprocessor begins with a conditional command: `#if', `#ifdef' or `#ifndef'. See section Conditionals and Macros, for information on `#ifdef' and `#ifndef'; only `#if' is explained here.

The `#if' Command

The `#if' command in its simplest form consists of

```
#if expression
controlled text
#endif /* expression */
```

The comment following the `#endif' is not required, but it is a good practice because it helps people match the `#endif' to the corresponding `#if'. Such comments should always be used, except in short conditionals that are not nested. In fact, you can put anything at all after the `#endif' and it will be ignored by the GNU C preprocessor, but only comments are acceptable in ANSI Standard C.

expression is a C expression of integer type, subject to stringent restrictions. It may contain

- Integer constants, which are all regarded as `long` or `unsigned long`.
- Character constants, which are interpreted according to the character set and conventions of the machine and operating system on which the preprocessor is running. The GNU C preprocessor uses the C data type `char' for these character constants; therefore, whether some character codes are negative is determined by the C compiler used to compile the preprocessor. If it treats `char' as signed, then character codes large enough to set the sign bit will be considered negative; otherwise, no character code is considered negative.
- Arithmetic operators for addition, subtraction, multiplication, division, bitwise operations, shifts, comparisons, and `&&' and `||'.
- Identifiers that are not macros, which are all treated as zero(!).
- Macro calls. All macro calls in the expression are expanded before actual computation of the expression's value begins.

Note that `sizeof' operators and `enum`-type values are not allowed. `enum`-type values, like all other identifiers that are not taken as macro calls and expanded, are treated as zero.

The controlled text inside of a conditional can include preprocessor commands. Then the commands inside the conditional are obeyed only if that branch of the conditional succeeds. The text can also contain other conditional groups. However, the `#if' and `#endif' commands must balance.

The `#else' Command

The `#else' command can be added to a conditional to provide alternative text to be used if the condition is false. This is what it looks like:

```
#if expression
text-if-true
#else /* Not expression */
text-if-false
#endif /* Not expression */
```

If expression is nonzero, and thus the text-if-true is active, then `#else' acts like a failing conditional and the text-if-false is ignored. Contrariwise, if the `#if' conditional fails, the text-if-false is considered included.

The `#elif' Command

One common case of nested conditionals is used to check for more than two possible alternatives. For example, you might have

```
#if X == 1
...
#else /* X != 1 */
#if X == 2
...
#else /* X != 2 */
...
#endif /* X != 2 */
#endif /* X != 1 */
```

Another conditional command, `#elif', allows this to be abbreviated as follows:

```
#if X == 1
...
#elif X == 2
...
#else /* X != 2 and X != 1*/
...
#endif /* X != 2 and X != 1*/
```

`#elif' stands for "else if". Like `#else', it goes in the middle of a `#if'-`#endif' pair and subdivides it; it does not require a matching `#endif' of its own. Like `#if', the `#elif' command includes an expression to

be tested.

The text following the `#elif' is processed only if the original `#if'-condition failed and the `#elif' condition succeeds. More than one `#elif' can go in the same `#if'-`#endif' group. Then the text after each `#elif' is processed only if the `#elif' condition succeeds after the original `#if' and any previous `#elif' commands within it have failed. `#else' is equivalent to `#elif 1', and `#else' is allowed after any number of `#elif' commands, but `#elif' may not follow `#else'.

Keeping Deleted Code for Future Reference

If you replace or delete a part of the program but want to keep the old code around as a comment for future reference, the easy way to do this is to put `#if 0' before it and `#endif' after it.

This works even if the code being turned off contains conditionals, but they must be entire conditionals (balanced `#if' and `#endif').

Conditionals and Macros

Conditionals are useful in connection with macros or assertions, because those are the only ways that an expression's value can vary from one compilation to another. A `#if' command whose expression uses no macros or assertions is equivalent to `#if 1' or `#if 0'; you might as well determine which one, by computing the value of the expression yourself, and then simplify the program.

For example, here is a conditional that tests the expression `BUFSIZE == 1020', where `BUFSIZE' must be a macro.

```
#if BUFSIZE == 1020
  printf ("Large buffers!\n");
#endif /* BUFSIZE is large */
```

(Programmers often wish they could test the size of a variable or data type in `#if', but this does not work. The preprocessor does not understand `sizeof`, or typedef names, or even the type keywords such as `int`.)

The special operator `defined' is used in `#if' expressions to test whether a certain name is defined as a macro. Either `defined name' or `defined (name)' is an expression whose value is 1 if name is defined as macro at the current point in the program, and 0 otherwise. For the `defined' operator it makes no difference what the definition of the macro is; all that matters is whether there is a definition. Thus, for example,

```
#if defined (vax) || defined (ns16000)
```

would include the following code if either of the names `vax' and `ns16000' is defined as a macro. You can test the same condition using assertions (see section Assertions), like this:

```
#if #cpu (vax) || #cpu (ns16000)
```

If a macro is defined and later undefined with `#undef', subsequent use of the `defined' operator retur because the name is no longer defined. If the macro is defined again with another `#define', `defined' recommence returning 1.

Conditionals that test just the definedness of one name are very common, so there are two special short conditional commands for this case.

`#ifdef name`

is equivalent to `#if defined (name)'.

`#ifndef name`

is equivalent to `#if ! defined (name)'.

Macro definitions can vary between compilations for several reasons.

- Some macros are predefined on each kind of machine. For example, on a Vax, the name `vax' is a predefined macro. On other machines, it would not be defined.
- Many more macros are defined by system header files. Different systems and machines define different macros, or give them different values. It is useful to test these macros with conditionals to avoid using a system feature on a machine where it is not implemented.
- Macros are a common way of allowing users to customize a program for different machines or applications. For example, the macro `BUFSIZE' might be defined in a configuration file for your program that is included as a header file in each source file. You would use `BUFSIZE' in a preprocessor conditional in order to generate different code depending on the chosen configuration.
- Macros can be defined or undefined with `-D' and `-U' command options when you compile the program. You can arrange to compile the same source file into two different programs by choosing a macro name to specify which program you want, writing conditionals to test whether or how this macro is defined, and then controlling the state of the macro with compiler command options. See section Invoking the C Preprocessor.

Assertions

Assertions are a more systematic alternative to macros in writing conditionals to test what sort of computer or system the compiled program will run on. Assertions are usually predefined, but you can define them with preprocessor commands or command-line options.

The macros traditionally used to describe the type of target are not classified in any way according to which question they answer; they may indicate a hardware architecture, a particular hardware model, an operating system, a particular version of an operating system, or specific configuration options. These are jumbled together in a single namespace. In contrast, each assertion consists of a named question and an answer. The question is usually called the predicate. An assertion looks like this:

```
#predicate (answer)
```

You must use a properly formed identifier for predicate. The value of answer can be any sequence of words; all characters are significant except for leading and trailing whitespace, and differences in internal whitespace sequences are ignored. Thus, `x + y' is different from `x+y' but equivalent to `x + y'. `)' is not

allowed in an answer.

Here is a conditional to test whether the answer answer is asserted for the predicate predicate:

```
#if #predicate (answer)
```

There may be more than one answer asserted for a given predicate. If you omit the answer, you can test whether *any* answer is asserted for predicate:

```
#if #predicate
```

Most of the time, the assertions you test will be predefined assertions. GNU C provides three predefined predicates: `system`, `cpu`, and `machine`. `system` is for assertions about the type of software, `cpu` describes the type of computer architecture, and `machine` gives more information about the computer. For example, on a GNU system, the following assertions would be true:

```
#system (gnu)
#system (mach)
#system (mach 3)
#system (mach 3.subversion)
#system (hurd)
#system (hurd version)
```

and perhaps others. The alternatives with more or less version information let you ask more or less detailed questions about the type of system software.

On a Unix system, you would find `#system (unix)` and perhaps one of: `#system (aix)`, `#system (bsd)`, `#system (hpux)`, `#system (lynx)`, `#system (mach)`, `#system (posix)`, `#system (svr3)`, `#system (svr4)`, or `#system (xpg4)` with possible version numbers following.

Other values for `system` are `#system (mvs)` and `#system (vms)`.

Portability note: Many Unix C compilers provide only one answer for the `system` assertion: `#system (unix)`, if they support assertions at all. This is less than useful.

An assertion with a multi-word answer is completely different from several assertions with individual single-word answers. For example, the presence of `system (mach 3.0)` does not mean that `system (3.0)` is true. It also does not directly imply `system (mach)`, but in GNU C, that last will normally be asserted as well.

The current list of possible assertion values for `cpu` is: `#cpu (a29k)`, `#cpu (alpha)`, `#cpu (arm)`, `#cpu (clipper)`, `#cpu (convex)`, `#cpu (elxsi)`, `#cpu (tron)`, `#cpu (h8300)`, `#cpu (i370)`, `#cpu (i386)`, `#cpu (i860)`, `#cpu (i960)`, `#cpu (m68k)`, `#cpu (m88k)`, `#cpu (mips)`, `#cpu (ns32k)`, `#cpu (hppa)`, `#cpu (pyr)`, `#cpu (ibm032)`, `#cpu (rs6000)`, `#cpu (sh)`, `#cpu (sparc)`, `#cpu (spur)`, `#cpu (tahoe)`, `#cpu (vax)`, `#cpu (we32000)`.

You can create assertions within a C program using `#assert', like this:

```
#assert predicate (answer)
```

(Note the absence of a `#' before predicate.)

Each time you do this, you assert a new true answer for predicate. Asserting one answer does not invalidate previously asserted answers; they all remain true. The only way to remove an assertion is with `#unassert'. `#unassert' has the same syntax as `#assert'. You can also remove all assertions about predicate like this:

```
#unassert predicate
```

You can also add or cancel assertions using command options when you run `gcc` or `cpp`. See section Invoking the C Preprocessor.

The `#error' and `#warning' Commands

The command `#error' causes the preprocessor to report a fatal error. The rest of the line that follows `#error' is used as the error message.

You would use `#error' inside of a conditional that detects a combination of parameters which you know the program does not properly support. For example, if you know that the program will not run properly on a Vax, you might write

```
#ifdef vax
#error Won't work on Vaxen.  See comments at get_last_object.
#endif
```

See section Nonstandard Predefined Macros, for why this works.

If you have several configuration parameters that must be set up by the installation in a consistent way, you can use conditionals to detect an inconsistency and report it with `#error'. For example,

```
#if HASH_TABLE_SIZE % 2 == 0 || HASH_TABLE_SIZE % 3 == 0 \
    || HASH_TABLE_SIZE % 5 == 0
#error HASH_TABLE_SIZE should not be divisible by a small prime
#endif
```

The command `#warning' is like the command `#error', but causes the preprocessor to issue a warning and continue preprocessing. The rest of the line that follows `#warning' is used as the warning message.

You might use `#warning' in obsolete header files, with a message directing the user to the header file which should be used instead.

Combining Source Files

One of the jobs of the C preprocessor is to inform the C compiler of where each line of C code came from: which source file and which line number.

C code can come from multiple source files if you use `#include'; both `#include' and the use of conditionals and macros can cause the line number of a line in the preprocessor output to be different from the line's number in the original source file. You will appreciate the value of making both the C compiler (in error messages) and symbolic debuggers such as GDB use the line numbers in your source file.

The C preprocessor builds on this feature by offering a command by which you can control the feature explicitly. This is useful when a file for input to the C preprocessor is the output from another program such as the `bison` parser generator, which operates on another file that is the true source file. Parts of the output from `bison` are generated from scratch, other parts come from a standard parser file. The rest are copied nearly verbatim from the source file, but their line numbers in the `bison` output are not the same as their original line numbers. Naturally you would like compiler error messages and symbolic debuggers to know the original source file and line number of each line in the `bison` input.

`bison` arranges this by writing `#line' commands into the output file. `#line' is a command that specifies the original line number and source file name for subsequent input in the current preprocessor input file. `#line' has three variants:

`#line linenum`

> Here linenum is a decimal integer constant. This specifies that the line number of the following line of input, in its original source file, was linenum.

`#line linenum filename`

> Here linenum is a decimal integer constant and filename is a string constant. This specifies that the following line of input came originally from source file filename and its line number there was linenum. Keep in mind that filename is not just a file name; it is surrounded by doublequote characters so that it looks like a string constant.

`#line anything else`

> anything else is checked for macro calls, which are expanded. The result should be a decimal integer constant followed optionally by a string constant, as described above.

`#line' commands alter the results of the `__FILE__' and `__LINE__' predefined macros from that point on. See section Standard Predefined Macros.

The output of the preprocessor (which is the input for the rest of the compiler) contains commands that look much like `#line' commands. They start with just `#' instead of `#line', but this is followed by a line number and file name as in `#line'. See section C Preprocessor Output.

Miscellaneous Preprocessor Commands

This section describes three additional preprocessor commands. They are not very useful, but are mentioned for completeness.

The null command consists of a `#' followed by a Newline, with only whitespace (including comments) in between. A null command is understood as a preprocessor command but has no effect on the preprocessor output. The primary significance of the existence of the null command is that an input line consisting of just a `#' will produce no output, rather than a line of output containing just a `#'. Supposedly some old C programs contain such lines.

The ANSI standard specifies that the `#pragma' command has an arbitrary, implementation-defined effect. In the GNU C preprocessor, `#pragma' commands are not used, except for `#pragma once' (see section Once-Only Include Files). However, they are left in the preprocessor output, so they are available to the compilation pass.

The `#ident' command is supported for compatibility with certain other systems. It is followed by a line of text. On some systems, the text is copied into a special place in the object file; on most systems, the text is ignored and this command has no effect. Typically `#ident' is only used in header files supplied with those systems where it is meaningful.

C Preprocessor Output

The output from the C preprocessor looks much like the input, except that all preprocessor command lines have been replaced with blank lines and all comments with spaces. Whitespace within a line is not altered; however, a space is inserted after the expansions of most macro calls.

Source file name and line number information is conveyed by lines of the form

```
# linenum filename flags
```

which are inserted as needed into the middle of the input (but never within a string or character constant). Such a line means that the following line originated in file filename at line linenum.

After the file name comes zero or more flags, which are `1', `2' or `3'. If there are multiple flags, spaces separate them. Here is what the flags mean:

`1'
: This indicates the start of a new file.

`2'
: This indicates returning to a file (after having included another file).

`3'
: This indicates that the following text comes from a system header file, so certain warnings should be suppressed.

Invoking the C Preprocessor

Most often when you use the C preprocessor you will not have to invoke it explicitly: the C compiler will do so automatically. However, the preprocessor is sometimes useful individually.

The C preprocessor expects two file names as arguments, infile and outfile. The preprocessor reads infile together with any other files it specifies with `#include'. All the output generated by the combined input files is written in outfile.

Either infile or outfile may be `-', which as infile means to read from standard input and as outfile means to write to standard output. Also, if outfile or both file names are omitted, the standard output and standard input are used for the omitted file names.

Here is a table of command options accepted by the C preprocessor. These options can also be given when compiling a C program; they are passed along automatically to the preprocessor when it is invoked by the compiler.

`-P'

Inhibit generation of `#'-lines with line-number information in the output from the preprocessor (see section C Preprocessor Output). This might be useful when running the preprocessor on something that is not C code and will be sent to a program which might be confused by the `#'-lines.

`-C'

Do not discard comments: pass them through to the output file. Comments appearing in arguments of a macro call will be copied to the output before the expansion of the macro call.

`-traditional'

Try to imitate the behavior of old-fashioned C, as opposed to ANSI C.

`'

Traditional macro expansion pays no attention to singlequote or doublequote characters; macro argument symbols are replaced by the argument values even when they appear within apparent string or character constants.

`'

Traditionally, it is permissible for a macro expansion to end in the middle of a string or character constant. The constant continues into the text surrounding the macro call.

`'

However, traditionally the end of the line terminates a string or character constant, with no error.

`'

In traditional C, a comment is equivalent to no text at all. (In ANSI C, a comment counts as whitespace.)

`'

Traditional C does not have the concept of a "preprocessing number". It considers `1.0e+4' to be three tokens: `1.0e', `+', and `4'.

`'

A macro is not suppressed within its own definition, in traditional C. Thus, any macro that is used recursively inevitably causes an error.

`'

The character `#' has no special meaning within a macro definition in traditional C.

`'

In traditional C, the text at the end of a macro expansion can run together with the text after the macro call, to produce a single token. (This is impossible in ANSI C.)

`'

Traditionally, `\' inside a macro argument suppresses the syntactic significance of the following character.

`-trigraphs'

Process ANSI standard trigraph sequences. These are three-character sequences, all starting with `??', that are defined by ANSI C to stand for single characters. For example, `??/' stands for `\', so `'??/n" is a character constant for a newline. Strictly speaking, the GNU C preprocessor does not support all programs in ANSI Standard C unless `-trigraphs' is used, but if you ever notice the difference it will be with relief.

You don't want to know any more about trigraphs.

`-pedantic'

Issue warnings required by the ANSI C standard in certain cases such as when text other than a comment follows `#else' or `#endif'.

`-pedantic-errors'

Like `-pedantic', except that errors are produced rather than warnings.

`-Wtrigraphs'

Warn if any trigraphs are encountered (assuming they are enabled).

`-Wcomment'

Warn whenever a comment-start sequence `/*' appears in a comment.

`-Wall'

Requests both `-Wtrigraphs' and `-Wcomment' (but not `-Wtraditional').

`-Wtraditional'

Warn about certain constructs that behave differently in traditional and ANSI C.

`-I directory'

Add the directory directory to the end of the list of directories to be searched for header files (see section The `#include' Command). This can be used to override a system header file, substituting your own version, since these directories are searched before the system header file directories. If you use more than one `-I' option, the directories are scanned in left-to-right order; the standard system directories come after.

`-I-'

Any directories specified with `-I' options before the `-I-' option are searched only for the case of `#include "file"'; they are not searched for `#include <file>'.

If additional directories are specified with `-I' options after the `-I-', these directories are searched for all `#include' commands.

In addition, the `-I-' option inhibits the use of the current directory as the first search directory for `#include "file"'. Therefore, the current directory is searched only if it is requested explicitly with `-I.'. Specifying both `-I-' and `-I.' allows you to control precisely which directories are searched before the current one and which are searched after.

`-nostdinc'

Do not search the standard system directories for header files. Only the directories you have specified with `-I' options (and the current directory, if appropriate) are searched.

`-nostdinc++'

Do not search for header files in the C++-specific standard directories, but do still search the other standard directories. (This option is used when building libg++.)

`-D name'

Predefine name as a macro, with definition `1'.

`-D name=definition'

Predefine name as a macro, with definition definition. There are no restrictions on the contents of definition, but if you are invoking the preprocessor from a shell or shell-like program you may need to use the shell's quoting syntax to protect characters such as spaces that have a meaning in the shell syntax. If you use more than one `-D' for the same name, the rightmost definition takes effect.

`-U name'

Do not predefine name. If both `-U' and `-D' are specified for one name, the `-U' beats the `-D' and the name is not predefined.

`-undef'

Do not predefine any nonstandard macros.

`-A predicate(answer)'

Make an assertion with the predicate predicate and answer answer. See section Assertions.

You can use `-A-' to disable all predefined assertions; it also undefines all predefined macros that identify the type of target system.

`-dM'

Instead of outputting the result of preprocessing, output a list of `#define' commands for all the macros defined during the execution of the preprocessor, including predefined macros. This gives you a way of finding out what is predefined in your version of the preprocessor; assuming you have no file `foo.h', the command

```
touch foo.h; cpp -dM foo.h
```

will show the values of any predefined macros.

`-dD'

Like `-dM' except in two respects: it does *not* include the predefined macros, and it outputs *both* the `#define' commands and the result of preprocessing. Both kinds of output go to the standard output file.

`-M'

Instead of outputting the result of preprocessing, output a rule suitable for `make` describing the dependencies of the main source file. The preprocessor outputs one `make` rule containing the object file name for that source file, a colon, and the names of all the included files. If there are many included files then the rule is split into several lines using `\'-newline.

This feature is used in automatic updating of makefiles.

`-MM'

Like `-M' but mention only the files included with `#include "file"'. System header files included with `#include <file>' are omitted.

`-MD'

Like `-M' but the dependency information is written to files with names made by replacing `.c' with `.d' at the end of the input file names. This is in addition to compiling the file as specified---`-MD' does not inhibit ordinary compilation the way `-M' does.

In Mach, you can use the utility `md` to merge the `.d' files into a single dependency file suitable for using with the `make' command.

`-MMD'

Like `-MD' except mention only user header files, not system header files.

`-H'

Print the name of each header file used, in addition to other normal activities.

`-imacros file'

Process file as input, discarding the resulting output, before processing the regular input file. Because the output generated from file is discarded, the only effect of `-imacros file' is to make the macros defined in file available for use in the main input.

`-include file'

Process file as input, and include all the resulting output, before processing the regular input file.

`-idirafter dir'

Add the directory dir to the second include path. The directories on the second include path are searched when a header file is not found in any of the directories in the main include path (the one that `-I' adds to).

`-iprefix prefix'

Specify prefix as the prefix for subsequent `-iwithprefix' options.

`-iwithprefix dir'

Add a directory to the second include path. The directory's name is made by concatenating prefix and dir, where prefix was specified previously with `-iprefix'.

`-lang-c'

`-lang-c++'

`-lang-objc'

`-lang-objc++'

Specify the source language. `-lang-c++' makes the preprocessor handle C++ comment syntax (comments may begin with `//', in which case they end at end of line), and includes extra default include directories for C++; and `-lang-objc' enables the Objective C `#import' command. `-lang-c' explicitly turns off both of these extensions, and `-lang-objc++' enables both.

These options are generated by the compiler driver `gcc`, but not passed from the `gcc' command line.

`-lint'

Look for commands to the program checker `lint` embedded in comments, and emit them preceded by `#pragma lint'. For example, the comment `/* NOTREACHED */' becomes `#pragma lint NOTREACHED'.

This option is available only when you call `cpp` directly; `gcc` will not pass it from its command line.

`-$'

Forbid the use of `$' in identifiers. This is required for ANSI conformance. `gcc` automatically supplies this option to the preprocessor if you specify `-ansi', but `gcc` doesn't recognize the `-$' option itself--to use it without the other effects of `-ansi', you must call the preprocessor directly.

Go to the next section.

Transformations Made Globally

Most C preprocessor features are inactive unless you give specific directives to request their use. (Preprocessing directives are lines starting with `#'; see section Preprocessing Directives). But there are three transformations that the preprocessor always makes on all the input it receives, even in the absence of directives.

- All C comments are replaced with single spaces.
- Backslash-Newline sequences are deleted, no matter where. This feature allows you to break long lines for cosmetic purposes without changing their meaning.
- Predefined macro names are replaced with their expansions (see section Predefined Macros).

The first two transformations are done *before* nearly all other parsing and before preprocessing directives are recognized. Thus, for example, you can split a line cosmetically with Backslash-Newline anywhere (except when trigraphs are in use; see below).

```
/*
*/ # /*
*/ defi\
ne FO\
O 10\
20
```

is equivalent into `#define FOO 1020'. You can split even an escape sequence with Backslash-Newline. For example, you can split `"foo\bar"` between the `\' and the `b' to get

```
"foo\\
bar"
```

This behavior is unclean: in all other contexts, a Backslash can be inserted in a string constant as an ordinary character by writing a double Backslash, and this creates an exception. But the ANSI C standard requires it. (Strict ANSI C does not allow Newlines in string constants, so they do not consider this a problem.)

But there are a few exceptions to all three transformations.

- C comments and predefined macro names are not recognized inside a `#include' directive in which the file name is delimited with `<' and `>'.
- C comments and predefined macro names are never recognized within a character or string constant. (Strictly speaking, this is the rule, not an exception, but it is worth noting here anyway.)
- Backslash-Newline may not safely be used within an ANSI "trigraph". Trigraphs are converted before Backslash-Newline is deleted. If you write what looks like a trigraph with a Backslash-Newline inside, the Backslash-Newline is deleted as usual, but it is then too late to recognize the trigraph.

This exception is relevant only if you use the `-trigraphs' option to enable trigraph processing section Invoking the C Preprocessor.

Preprocessing Directives

Most preprocessor features are active only if you use preprocessing directives to request their use.

Preprocessing directives are lines in your program that start with `#'. The `#' is followed by an identifier that is the directive name. For example, `#define' is the directive that defines a macro. Whitespace is also allowed before and after the `#'.

The set of valid directive names is fixed. Programs cannot define new preprocessing directives.

Some directive names require arguments; these make up the rest of the directive line and must be separated from the directive name by whitespace. For example, `#define' must be followed by a macro name and the intended expansion of the macro. See section Simple Macros.

A preprocessing directive cannot be more than one line in normal circumstances. It may be split cosmetically with Backslash-Newline, but that has no effect on its meaning. Comments containing Newlines can also divide the directive into multiple lines, but the comments are changed to Spaces before the directive is interpreted. The only way a significant Newline can occur in a preprocessing directive is within a string constant or character constant. Note that most C compilers that might be applied to the output from the preprocessor do not accept string or character constants containing Newlines.

The `#' and the directive name cannot come from a macro expansion. For example, if `foo' is defined as a macro expanding to `define', that does not make `#foo' a valid preprocessing directive.

Header Files

A header file is a file containing C declarations and macro definitions (see section Macros) to be shared between several source files. You request the use of a header file in your program with the C preprocessing directive `#include'.

Uses of Header Files

Header files serve two kinds of purposes.

- System header files declare the interfaces to parts of the operating system. You include them in your program to supply the definitions and declarations you need to invoke system calls and libraries.
- Your own header files contain declarations for interfaces between the source files of your program. Each time you have a group of related declarations and macro definitions all or most of which are needed in several different source files, it is a good idea to create a header file for them.

Including a header file produces the same results in C compilation as copying the header file into each

source file that needs it. But such copying would be time-consuming and error-prone. With a header the related declarations appear in only one place. If they need to be changed, they can be changed in place, and programs that include the header file will automatically use the new version when next recompiled. The header file eliminates the labor of finding and changing all the copies as well as the risk that a failure to find one copy will result in inconsistencies within a program.

The usual convention is to give header files names that end with `.h'. Avoid unusual characters in header file names, as they reduce portability.

The `#include' Directive

Both user and system header files are included using the preprocessing directive `#include'. It has three variants:

`#include <file>`

This variant is used for system header files. It searches for a file named file in a list of directories specified by you, then in a standard list of system directories. You specify directories to search for header files with the command option `-I' (see section Invoking the C Preprocessor). The option `-nostdinc' inhibits searching the standard system directories; in this case only the directories you specify are searched.

The parsing of this form of `#include' is slightly special because comments are not recognized within the `<...>'. Thus, in `#include <x/*y>' the `/*' does not start a comment and the directive specifies inclusion of a system header file named `x/*y'. Of course, a header file with such a name is unlikely to exist on Unix, where shell wildcard features would make it hard to manipulate.

The argument file may not contain a `>' character. It may, however, contain a `<' character.

`#include "file"`

This variant is used for header files of your own program. It searches for a file named file first in the current directory, then in the same directories used for system header files. The current directory is the directory of the current input file. It is tried first because it is presumed to be the location of the files that the current input file refers to. (If the `-I-' option is used, the special treatment of the current directory is inhibited.)

The argument file may not contain `"' characters. If backslashes occur within file, they are considered ordinary text characters, not escape characters. None of the character escape sequences appropriate to string constants in C are processed. Thus, `#include "x\n\\y"' specifies a filename containing three backslashes. It is not clear why this behavior is ever useful, but the ANSI standard specifies it.

`#include anything else`

This variant is called a computed #include. Any `#include' directive whose argument does not fit the above two forms is a computed include. The text anything else is checked for macro calls, which are expanded (see section Macros). When this is done, the result must fit one of the above two variants--in particular, the expanded text must in the end be surrounded by either quotes or angle braces.

This feature allows you to define a macro which controls the file name to be used at a later poi the program. One application of this is to allow a site-specific configuration file for your progr to specify the names of the system include files to be used. This can help in porting the program to various operating systems in which the necessary system header files are found in different places.

How `#include' Works

The `#include' directive works by directing the C preprocessor to scan the specified file as input before continuing with the rest of the current file. The output from the preprocessor contains the output already generated, followed by the output resulting from the included file, followed by the output that comes from the text after the `#include' directive. For example, given a header file `header.h' as follows,

```
char *test ();
```

and a main program called `program.c' that uses the header file, like this,

```
int x;
#include "header.h"

main ()
{
  printf (test ());
}
```

the output generated by the C preprocessor for `program.c' as input would be

```
int x;
char *test ();

main ()
{
  printf (test ());
}
```

Included files are not limited to declarations and macro definitions; those are merely the typical uses. Any fragment of a C program can be included from another file. The include file could even contain the beginning of a statement that is concluded in the containing file, or the end of a statement that was started in the including file. However, a comment or a string or character constant may not start in the included file and finish in the including file. An unterminated comment, string constant or character constant in an included file is considered to end (with an error message) at the end of the file.

It is possible for a header file to begin or end a syntactic unit such as a function definition, but that would be very confusing, so don't do it.

The line following the `#include' directive is always treated as a separate line by the C preprocessor even if the included file lacks a final newline.

Once-Only Include Files

Very often, one header file includes another. It can easily result that a certain header file is included more than once. This may lead to errors, if the header file defines structure types or typedefs, and is certainly wasteful. Therefore, we often wish to prevent multiple inclusion of a header file.

The standard way to do this is to enclose the entire real contents of the file in a conditional, like this:

```
#ifndef FILE_FOO_SEEN
#define FILE_FOO_SEEN

the entire file

#endif /* FILE_FOO_SEEN */
```

The macro `FILE_FOO_SEEN` indicates that the file has been included once already. In a user header file, the macro name should not begin with `_'. In a system header file, this name should begin with `__' to avoid conflicts with user programs. In any kind of header file, the macro name should contain the name of the file and some additional text, to avoid conflicts with other header files.

The GNU C preprocessor is programmed to notice when a header file uses this particular construct and handle it efficiently. If a header file is contained entirely in a `#ifndef' conditional, then it records that fact. If a subsequent `#include' specifies the same file, and the macro in the `#ifndef' is already defined, then the file is entirely skipped, without even reading it.

There is also an explicit directive to tell the preprocessor that it need not include a file more than once. This is called `#pragma once', and was used *in addition to* the `#ifndef' conditional around the contents of the header file. `#pragma once' is now obsolete and should not be used at all.

In the Objective C language, there is a variant of `#include' called `#import' which includes a file, but does so at most once. If you use `#import' *instead of* `#include', then you don't need the conditionals inside the header file to prevent multiple execution of the contents.

`#import' is obsolete because it is not a well designed feature. It requires the users of a header file--the applications programmers--to know that a certain header file should only be included once. It is much better for the header file's implementor to write the file so that users don't need to know this. Using `#ifndef' accomplishes this goal.

Inheritance and Header Files

Inheritance is what happens when one object or file derives some of its contents by virtual copying from another object or file. In the case of C header files, inheritance means that one header file includes another header file and then replaces or adds something.

If the inheriting header file and the base header file have different names, then inheritance is straightforward: simply write `#include "base"' in the inheriting file.

Sometimes it is necessary to give the inheriting file the same name as the base file. This is less

straightforward.

For example, suppose an application program uses the system header file `sys/signal.h', but the version of `/usr/include/sys/signal.h' on a particular system doesn't do what the application program expects. It might be convenient to define a "local" version, perhaps under the name `/usr/local/include/sys/signal.h', to override or add to the one supplied by the system.

You can do this by using the option `-I.' for compilation, and writing a file `sys/signal.h' that does what the application program expects. But making this file include the standard `sys/signal.h' is not so easy--writing `#include <sys/signal.h>' in that file doesn't work, because it includes your own version of the file, not the standard system version. Used in that file itself, this leads to an infinite recursion and a fatal error in compilation.

`#include </usr/include/sys/signal.h>' would find the proper file, but that is not clean, since it makes an assumption about where the system header file is found. This is bad for maintenance, since it means that any change in where the system's header files are kept requires a change somewhere else.

The clean way to solve this problem is to use `#include_next', which means, "Include the *next* file with this name." This directive works like `#include' except in searching for the specified file: it starts searching the list of header file directories *after* the directory in which the current file was found.

Suppose you specify `-I /usr/local/include', and the list of directories to search also includes `/usr/include'; and suppose that both directories contain a file named `sys/signal.h'. Ordinary `#include <sys/signal.h>' finds the file under `/usr/local/include'. If that file contains `#include_next <sys/signal.h>', it starts searching after that directory, and finds the file in `/usr/include'.

Macros

A macro is a sort of abbreviation which you can define once and then use later. There are many complicated features associated with macros in the C preprocessor.

Simple Macros

A simple macro is a kind of abbreviation. It is a name which stands for a fragment of code. Some people refer to these as manifest constants.

Before you can use a macro, you must define it explicitly with the `#define' directive. `#define' is followed by the name of the macro and then the code it should be an abbreviation for. For example,

```
#define BUFFER_SIZE 1020
```

defines a macro named `BUFFER_SIZE' as an abbreviation for the text `1020'. If somewhere after this `#define' directive there comes a C statement of the form

```
foo = (char *) xmalloc (BUFFER_SIZE);
```

then the C preprocessor will recognize and expand the macro `BUFFER_SIZE', resulting in

```
foo = (char *) xmalloc (1020);
```

The use of all upper case for macro names is a standard convention. Programs are easier to read when it is possible to tell at a glance which names are macros.

Normally, a macro definition must be a single line, like all C preprocessing directives. (You can split a long macro definition cosmetically with Backslash-Newline.) There is one exception: Newlines can be included in the macro definition if within a string or character constant. This is because it is not possible for a macro definition to contain an unbalanced quote character; the definition automatically extends to include the matching quote character that ends the string or character constant. Comments within a macro definition may contain Newlines, which make no difference since the comments are entirely replaced with Spaces regardless of their contents.

Aside from the above, there is no restriction on what can go in a macro body. Parentheses need not balance. The body need not resemble valid C code. (But if it does not, you may get error messages from the C compiler when you use the macro.)

The C preprocessor scans your program sequentially, so macro definitions take effect at the place you write them. Therefore, the following input to the C preprocessor

```
foo = X;
#define X 4
bar = X;
```

produces as output

```
foo = X;

bar = 4;
```

After the preprocessor expands a macro name, the macro's definition body is appended to the front of the remaining input, and the check for macro calls continues. Therefore, the macro body can contain calls to other macros. For example, after

```
#define BUFSIZE 1020
#define TABLESIZE BUFSIZE
```

the name `TABLESIZE' when used in the program would go through two stages of expansion, resulting ultimately in `1020'.

This is not at all the same as defining `TABLESIZE' to be `1020'. The `#define' for `TABLESIZE' uses exactly the body you specify--in this case, `BUFSIZE'---and does not check to see whether it too is the name of a macro. It's only when you *use* `TABLESIZE' that the result of its expansion is checked for more macro names. See section Cascaded Use of Macros.

Macros with Arguments

A simple macro always stands for exactly the same text, each time it is used. Macros can be more flexible when they accept arguments. Arguments are fragments of code that you supply each time the macro is used. These fragments are included in the expansion of the macro according to the directions in the macro definition. A macro that accepts arguments is called a function-like macro because the syntax for using it looks like a function call.

To define a macro that uses arguments, you write a `#define' directive with a list of argument names in parentheses after the name of the macro. The argument names may be any valid C identifiers, separated by commas and optionally whitespace. The open-parenthesis must follow the macro name immediately, with no space in between.

For example, here is a macro that computes the minimum of two numeric values, as it is defined in many C programs:

```
#define min(X, Y)  ((X) < (Y) ? (X) : (Y))
```

(This is not the best way to define a "minimum" macro in GNU C. See section Duplication of Side Effects, for more information.)

To use a macro that expects arguments, you write the name of the macro followed by a list of actual arguments in parentheses, separated by commas. The number of actual arguments you give must match the number of arguments the macro expects. Examples of use of the macro `min' include `min (1, 2)' and `min (x + 28, *p)'.

The expansion text of the macro depends on the arguments you use. Each of the argument names of the macro is replaced, throughout the macro definition, with the corresponding actual argument. Using the same macro `min' defined above, `min (1, 2)' expands into

```
((1) < (2) ? (1) : (2))
```

where `1' has been substituted for `X' and `2' for `Y'.

Likewise, `min (x + 28, *p)' expands into

```
((x + 28) < (*p) ? (x + 28) : (*p))
```

Parentheses in the actual arguments must balance; a comma within parentheses does not end an argument. However, there is no requirement for brackets or braces to balance, and they do not prevent a comma from separating arguments. Thus,

```
macro (array[x = y, x + 1])
```

passes two arguments to `macro`: `array[x = y' and `x + 1]'. If you want to supply `array[x = y, x + 1]' as an argument, you must write it as `array[(x = y, x + 1)]', which is equivalent C code.

After the actual arguments are substituted into the macro body, the entire result is appended to the front

of the remaining input, and the check for macro calls continues. Therefore, the actual arguments can contain calls to other macros, either with or without arguments, or even to the same macro. The macro body can also contain calls to other macros. For example, `min (min (a, b), c)' expands into this text:

```
((((a) < (b) ? (a) : (b))) < (c)
 ? (((a) < (b) ? (a) : (b)))
 : (c))
```

(Line breaks shown here for clarity would not actually be generated.)

If a macro `foo` takes one argument, and you want to supply an empty argument, you must write at least some whitespace between the parentheses, like this: `foo ( )'. Just `foo ()' is providing no arguments, which is an error if `foo` expects an argument. But `foo0 ()' is the correct way to call a macro defined to take zero arguments, like this:

```
#define foo0() ...
```

If you use the macro name followed by something other than an open-parenthesis (after ignoring any spaces, tabs and comments that follow), it is not a call to the macro, and the preprocessor does not change what you have written. Therefore, it is possible for the same name to be a variable or function in your program as well as a macro, and you can choose in each instance whether to refer to the macro (if an actual argument list follows) or the variable or function (if an argument list does not follow).

Such dual use of one name could be confusing and should be avoided except when the two meanings are effectively synonymous: that is, when the name is both a macro and a function and the two have similar effects. You can think of the name simply as a function; use of the name for purposes other than calling it (such as, to take the address) will refer to the function, while calls will expand the macro and generate better but equivalent code. For example, you can use a function named `min' in the same source file that defines the macro. If you write `&min' with no argument list, you refer to the function. If you write `min (x, bb)', with an argument list, the macro is expanded. If you write `(min) (a, bb)', where the name `min' is not followed by an open-parenthesis, the macro is not expanded, so you wind up with a call to the function `min'.

You may not define the same name as both a simple macro and a macro with arguments.

In the definition of a macro with arguments, the list of argument names must follow the macro name immediately with no space in between. If there is a space after the macro name, the macro is defined as taking no arguments, and all the rest of the line is taken to be the expansion. The reason for this is that it is often useful to define a macro that takes no arguments and whose definition begins with an identifier in parentheses. This rule about spaces makes it possible for you to do either this:

```
#define FOO(x) - 1 / (x)
```

(which defines `FOO' to take an argument and expand into minus the reciprocal of that argument) or this:

```
#define BAR (x) - 1 / (x)
```

(which defines `BAR' to take no argument and always expand into `(x) - 1 / (x)').

Note that the *uses* of a macro with arguments can have spaces before the left parenthesis; it's the *definition* where it matters whether there is a space.

Predefined Macros

Several simple macros are predefined. You can use them without giving definitions for them. They fall into two classes: standard macros and system-specific macros.

Standard Predefined Macros

The standard predefined macros are available with the same meanings regardless of the machine or operating system on which you are using GNU C. Their names all start and end with double underscores. Those preceding `__GNUC__` in this table are standardized by ANSI C; the rest are GNU C extensions.

`__FILE__`

This macro expands to the name of the current input file, in the form of a C string constant. The precise name returned is the one that was specified in `#include' or as the input file name argument.

`__LINE__`

This macro expands to the current input line number, in the form of a decimal integer constant. While we call it a predefined macro, it's a pretty strange macro, since its "definition" changes with each new line of source code.

This and `__FILE__' are useful in generating an error message to report an inconsistency detected by the program; the message can state the source line at which the inconsistency was detected. For example,

```
fprintf (stderr, "Internal error: "
                 "negative string length "
                 "%d at %s, line %d.",
         length, __FILE__, __LINE__);
```

A `#include' directive changes the expansions of `__FILE__' and `__LINE__' to correspond to the included file. At the end of that file, when processing resumes on the input file that contained the `#include' directive, the expansions of `__FILE__' and `__LINE__' revert to the values they had before the `#include' (but `__LINE__' is then incremented by one as processing moves to the line after the `#include').

The expansions of both `__FILE__' and `__LINE__' are altered if a `#line' directive is used. See section Combining Source Files.

`__DATE__`

This macro expands to a string constant that describes the date on which the preprocessor is being run. The string constant contains eleven characters and looks like `"Jan 29 1987"' or `"Apr 1 1905"'.

`__TIME__`

This macro expands to a string constant that describes the time at which the preprocessor is being run. The string constant contains eight characters and looks like `'"23:59:01"'.

`__STDC__`

This macro expands to the constant 1, to signify that this is ANSI Standard C. (Whether that is actually true depends on what C compiler will operate on the output from the preprocessor.)

`__STDC_VERSION__`

This macro expands to the C Standard's version number, a long integer constant of the form `yyyymmL' where yyyy and mm are the year and month of the Standard version. This signifies which version of the C Standard the preprocessor conforms to. Like `__STDC__', whether this version number is accurate for the entire implementation depends on what C compiler will operate on the output from the preprocessor.

`__GNUC__`

This macro is defined if and only if this is GNU C. This macro is defined only when the entire GNU C compiler is in use; if you invoke the preprocessor directly, `__GNUC__' is undefined. The value identifies the major version number of GNU CC (`1' for GNU CC version 1, which is now obsolete, and `2' for version 2).

`__GNUC_MINOR__`

The macro contains the minor version number of the compiler. This can be used to work around differences between different releases of the compiler (for example, if gcc 2.6.3 is known to support a feature, you can test for `__GNUC__ > 2 || (__GNUC__ == 2 && __GNUC_MINOR__ >= 6)`). The last number, `3' in the example above, denotes the bugfix level of the compiler; no macro contains this value.

`__GNUG__`

The GNU C compiler defines this when the compilation language is C++; use `__GNUG__' to distinguish between GNU C and GNU C++.

`__cplusplus`

The draft ANSI standard for C++ used to require predefining this variable. Though it is no longer required, GNU C++ continues to define it, as do other popular C++ compilers. You can use `__cplusplus' to test whether a header is compiled by a C compiler or a C++ compiler.

`__STRICT_ANSI__`

This macro is defined if and only if the `-ansi' switch was specified when GNU C was invoked. Its definition is the null string. This macro exists primarily to direct certain GNU header files not to define certain traditional Unix constructs which are incompatible with ANSI C.

`__BASE_FILE__`

This macro expands to the name of the main input file, in the form of a C string constant. This is the source file that was specified as an argument when the C compiler was invoked.

`__INCLUDE_LEVEL__`

This macro expands to a decimal integer constant that represents the depth of nesting in include files. The value of this macro is incremented on every `#include' directive and decremented at every end of file. For input files specified by command line arguments, the nesting level is zero.

`__VERSION__`

This macro expands to a string which describes the version number of GNU C. The string is normally a sequence of decimal numbers separated by periods, such as `"2.6.0"'. The only reasonable use of this macro is to incorporate it into a string constant.

`__OPTIMIZE__`

This macro is defined in optimizing compilations. It causes certain GNU header files to define alternative macro definitions for some system library functions. It is unwise to refer to or test the definition of this macro unless you make very sure that programs will execute with the same effect regardless.

`__CHAR_UNSIGNED__`

This macro is defined if and only if the data type `char` is unsigned on the target machine. It exists to cause the standard header file `` `limit.h' `` to work correctly. It is bad practice to refer to this macro yourself; instead, refer to the standard macros defined in `` `limit.h' ``. The preprocessor uses this macro to determine whether or not to sign-extend large character constants written in octal; see section The `#if' Directive.

`__REGISTER_PREFIX__`

This macro expands to a string describing the prefix applied to cpu registers in assembler code. It can be used to write assembler code that is usable in multiple environments. For example, in the `m68k-aout' environment it expands to the string `"", but in the `m68k-coff' environment it expands to the string `"%"'.

`__USER_LABEL_PREFIX__`

This macro expands to a string describing the prefix applied to user generated labels in assembler code. It can be used to write assembler code that is usable in multiple environments. For example, in the `m68k-aout' environment it expands to the string `"_"', but in the `m68k-coff' environment it expands to the string `""'.

Nonstandard Predefined Macros

The C preprocessor normally has several predefined macros that vary between machines because their purpose is to indicate what type of system and machine is in use. This manual, being for all systems and machines, cannot tell you exactly what their names are; instead, we offer a list of some typical ones. You can use `cpp -dM' to see the values of predefined macros; see section Invoking the C Preprocessor.

Some nonstandard predefined macros describe the operating system in use, with more or less specificity. For example,

`unix`

`unix' is normally predefined on all Unix systems.

`BSD`

`BSD' is predefined on recent versions of Berkeley Unix (perhaps only in version 4.3).

Other nonstandard predefined macros describe the kind of CPU, with more or less specificity. For example,

`vax`

`vax' is predefined on Vax computers.

`mc68000`

`mc68000' is predefined on most computers whose CPU is a Motorola 68000, 68010 or 68020.

`m68k`

`m68k' is also predefined on most computers whose CPU is a 68000, 68010 or 68020; however, some makers use `mc68000' and some use `m68k'. Some predefine both names. What happens in GNU C depends on the system you are using it on.

`M68020`

`M68020' has been observed to be predefined on some systems that use 68020 CPUs--in addition to `mc68000' and `m68k', which are less specific.

`_AM29K`

`_AM29000`

Both `_AM29K' and `_AM29000' are predefined for the AMD 29000 CPU family.

`ns32000`

`ns32000' is predefined on computers which use the National Semiconductor 32000 series CPU.

Yet other nonstandard predefined macros describe the manufacturer of the system. For example,

`sun`

`sun' is predefined on all models of Sun computers.

`pyr`

`pyr' is predefined on all models of Pyramid computers.

`sequent`

`sequent' is predefined on all models of Sequent computers.

These predefined symbols are not only nonstandard, they are contrary to the ANSI standard because their names do not start with underscores. Therefore, the option `-ansi' inhibits the definition of these symbols.

This tends to make `-ansi' useless, since many programs depend on the customary nonstandard predefined symbols. Even system header files check them and will generate incorrect declarations if they do not find the names that are expected. You might think that the header files supplied for the Uglix computer would not need to test what machine they are running on, because they can simply assume it is the Uglix; but often they do, and they do so using the customary names. As a result, very few C programs will compile with `-ansi'. We intend to avoid such problems on the GNU system.

What, then, should you do in an ANSI C program to test the type of machine it will run on?

GNU C offers a parallel series of symbols for this purpose, whose names are made from the customary ones by adding `__' at the beginning and end. Thus, the symbol `__vax__` would be available on a Vax, and so on.

The set of nonstandard predefined names in the GNU C preprocessor is controlled (when `cpp` is itself compiled) by the macro `CPP_PREDEFINES', which should be a string containing `-D' options,

separated by spaces. For example, on the Sun 3, we use the following definition:

```
#define CPP_PREDEFINES "-Dmc68000 -Dsun -Dunix -Dm68k"
```

This macro is usually specified in `tm.h'.

Stringification

Stringification means turning a code fragment into a string constant whose contents are the text for the code fragment. For example, stringifying `foo (z)' results in `"foo (z)"'.

In the C preprocessor, stringification is an option available when macro arguments are substituted into the macro definition. In the body of the definition, when an argument name appears, the character `#' before the name specifies stringification of the corresponding actual argument when it is substituted at that point in the definition. The same argument may be substituted in other places in the definition without stringification if the argument name appears in those places with no `#'.

Here is an example of a macro definition that uses stringification:

```
#define WARN_IF(EXP) \
do { if (EXP) \
        fprintf (stderr, "Warning: " #EXP "\n"); } \
while (0)
```

Here the actual argument for `EXP' is substituted once as given, into the `if' statement, and once as stringified, into the argument to `fprintf'. The `do' and `while (0)' are a kludge to make it possible to write `WARN_IF (arg);', which the resemblance of `WARN_IF' to a function would make C programmers want to do; see section Swallowing the Semicolon.

The stringification feature is limited to transforming one macro argument into one string constant: there is no way to combine the argument with other text and then stringify it all together. But the example above shows how an equivalent result can be obtained in ANSI Standard C using the feature that adjacent string constants are concatenated as one string constant. The preprocessor stringifies the actual value of `EXP' into a separate string constant, resulting in text like

```
do { if (x == 0) \
        fprintf (stderr, "Warning: " "x == 0" "\n"); } \
while (0)
```

but the C compiler then sees three consecutive string constants and concatenates them into one, producing effectively

```
do { if (x == 0) \
        fprintf (stderr, "Warning: x == 0\n"); } \
while (0)
```

Stringification in C involves more than putting doublequote characters around the fragment; it is

necessary to put backslashes in front of all doublequote characters, and all backslashes in string and character constants, in order to get a valid C string constant with the proper contents. Thus, stringifying `p = "foo\n";' results in `"p = \"foo\\n\";"'. However, backslashes that are not inside of string or character constants are not duplicated: `\n' by itself stringifies to `"\n"'.

Whitespace (including comments) in the text being stringified is handled according to precise rules. All leading and trailing whitespace is ignored. Any sequence of whitespace in the middle of the text is converted to a single space in the stringified result.

Concatenation

Concatenation means joining two strings into one. In the context of macro expansion, concatenation refers to joining two lexical units into one longer one. Specifically, an actual argument to the macro can be concatenated with another actual argument or with fixed text to produce a longer name. The longer name might be the name of a function, variable or type, or a C keyword; it might even be the name of another macro, in which case it will be expanded.

When you define a macro, you request concatenation with the special operator `##' in the macro body. When the macro is called, after actual arguments are substituted, all `##' operators are deleted, and so is any whitespace next to them (including whitespace that was part of an actual argument). The result is to concatenate the syntactic tokens on either side of the `##'.

Consider a C program that interprets named commands. There probably needs to be a table of commands, perhaps an array of structures declared as follows:

```
struct command
{
  char *name;
  void (*function) ();
};

struct command commands[] =
{
  { "quit", quit_command},
  { "help", help_command},
  ...
};
```

It would be cleaner not to have to give each command name twice, once in the string constant and once in the function name. A macro which takes the name of a command as an argument can make this unnecessary. The string constant can be created with stringification, and the function name by concatenating the argument with `_command'. Here is how it is done:

```
#define COMMAND(NAME)  { #NAME, NAME ## _command }

struct command commands[] =
```

```
{
  COMMAND (quit),
  COMMAND (help),
  ...
};
```

The usual case of concatenation is concatenating two names (or a name and a number) into a longer name. But this isn't the only valid case. It is also possible to concatenate two numbers (or a number and a name, such as `1.5' and `e3') into a number. Also, multi-character operators such as `+=' can be formed by concatenation. In some cases it is even possible to piece together a string constant. However, two pieces of text that don't together form a valid lexical unit cannot be concatenated. For example, concatenation with `x' on one side and `+' on the other is not meaningful because those two characters can't fit together in any lexical unit of C. The ANSI standard says that such attempts at concatenation are undefined, but in the GNU C preprocessor it is well defined: it puts the `x' and `+' side by side with no particular special results.

Keep in mind that the C preprocessor converts comments to whitespace before macros are even considered. Therefore, you cannot create a comment by concatenating `/' and `*': the `/*' sequence that starts a comment is not a lexical unit, but rather the beginning of a "long" space character. Also, you can freely use comments next to a `##' in a macro definition, or in actual arguments that will be concatenated, because the comments will be converted to spaces at first sight, and concatenation will later discard the spaces.

Undefining Macros

To undefine a macro means to cancel its definition. This is done with the `#undef' directive. `#undef' is followed by the macro name to be undefined.

Like definition, undefinition occurs at a specific point in the source file, and it applies starting from that point. The name ceases to be a macro name, and from that point on it is treated by the preprocessor as if it had never been a macro name.

For example,

```
#define FOO 4
x = FOO;
#undef FOO
x = FOO;
```

expands into

```
x = 4;

x = FOO;
```

In this example, `FOO' had better be a variable or function as well as (temporarily) a macro, in order for the result of the expansion to be valid C code.

The same form of `#undef' directive will cancel definitions with arguments or definitions that don't expect arguments. The `#undef' directive has no effect when used on a name not currently defined as a macro.

Redefining Macros

Redefining a macro means defining (with `#define') a name that is already defined as a macro.

A redefinition is trivial if the new definition is transparently identical to the old one. You probably wouldn't deliberately write a trivial redefinition, but they can happen automatically when a header file is included more than once (see section Header Files), so they are accepted silently and without effect.

Nontrivial redefinition is considered likely to be an error, so it provokes a warning message from the preprocessor. However, sometimes it is useful to change the definition of a macro in mid-compilation. You can inhibit the warning by undefining the macro with `#undef' before the second definition.

In order for a redefinition to be trivial, the new definition must exactly match the one already in effect, with two possible exceptions:

- Whitespace may be added or deleted at the beginning or the end.
- Whitespace may be changed in the middle (but not inside strings). However, it may not be eliminated entirely, and it may not be added where there was no whitespace at all.

Recall that a comment counts as whitespace.

Pitfalls and Subtleties of Macros

In this section we describe some special rules that apply to macros and macro expansion, and point out certain cases in which the rules have counterintuitive consequences that you must watch out for.

Improperly Nested Constructs

Recall that when a macro is called with arguments, the arguments are substituted into the macro body and the result is checked, together with the rest of the input file, for more macro calls.

It is possible to piece together a macro call coming partially from the macro body and partially from the actual arguments. For example,

```
#define double(x) (2*(x))
#define call_with_1(x) x(1)
```

would expand `call_with_1 (double)' into `(2*(1))'.

Macro definitions do not have to have balanced parentheses. By writing an unbalanced open parenthesis in a macro body, it is possible to create a macro call that begins inside the macro body but ends outside of it. For example,

```
#define strange(file) fprintf (file, "%s %d",
```

```
...
strange(stderr) p, 35)
```

This bizarre example expands to `fprintf (stderr, "%s %d", p, 35)'!

Unintended Grouping of Arithmetic

You may have noticed that in most of the macro definition examples shown above, each occurrence of a macro argument name had parentheses around it. In addition, another pair of parentheses usually surround the entire macro definition. Here is why it is best to write macros that way.

Suppose you define a macro as follows,

```
#define ceil_div(x, y) (x + y - 1) / y
```

whose purpose is to divide, rounding up. (One use for this operation is to compute how many `int' objects are needed to hold a certain number of `char' objects.) Then suppose it is used as follows:

```
a = ceil_div (b & c, sizeof (int));
```

This expands into

```
a = (b & c + sizeof (int) - 1) / sizeof (int);
```

which does not do what is intended. The operator-precedence rules of C make it equivalent to this:

```
a = (b & (c + sizeof (int) - 1)) / sizeof (int);
```

But what we want is this:

```
a = ((b & c) + sizeof (int) - 1)) / sizeof (int);
```

Defining the macro as

```
#define ceil_div(x, y) ((x) + (y) - 1) / (y)
```

provides the desired result.

However, unintended grouping can result in another way. Consider `sizeof ceil_div(1, 2)'. That has the appearance of a C expression that would compute the size of the type of `ceil_div (1, 2)', but in fact it means something very different. Here is what it expands to:

```
sizeof ((1) + (2) - 1) / (2)
```

This would take the size of an integer and divide it by two. The precedence rules have put the division outside the `sizeof' when it was intended to be inside.

Parentheses around the entire macro definition can prevent such problems. Here, then, is the

recommended way to define `ceil_div':

```
#define ceil_div(x, y) (((x) + (y) - 1) / (y))
```

Swallowing the Semicolon

Often it is desirable to define a macro that expands into a compound statement. Consider, for example, the following macro, that advances a pointer (the argument `p' says where to find it) across whitespace characters:

```
#define SKIP_SPACES (p, limit)  \
{ register char *lim = (limit); \
  while (p != lim) {            \
    if (*p++ != ' ') {          \
      p--; break; }}}
```

Here Backslash-Newline is used to split the macro definition, which must be a single line, so that it resembles the way such C code would be laid out if not part of a macro definition.

A call to this macro might be `SKIP_SPACES (p, lim)'. Strictly speaking, the call expands to a compound statement, which is a complete statement with no need for a semicolon to end it. But it looks like a function call. So it minimizes confusion if you can use it like a function call, writing a semicolon afterward, as in `SKIP_SPACES (p, lim);'

But this can cause trouble before `else' statements, because the semicolon is actually a null statement. Suppose you write

```
if (*p != 0)
  SKIP_SPACES (p, lim);
else ...
```

The presence of two statements--the compound statement and a null statement--in between the `if' condition and the `else' makes invalid C code.

The definition of the macro `SKIP_SPACES' can be altered to solve this problem, using a `do ... while' statement. Here is how:

```
#define SKIP_SPACES (p, limit)     \
do { register char *lim = (limit); \
     while (p != lim) {            \
       if (*p++ != ' ') {          \
         p--; break; }}}           \
while (0)
```

Now `SKIP_SPACES (p, lim);' expands into

```
do {...} while (0);
```

which is one statement.

Duplication of Side Effects

Many C programs define a macro `min', for "minimum", like this:

```
#define min(X, Y)  ((X) < (Y) ? (X) : (Y))
```

When you use this macro with an argument containing a side effect, as shown here,

```
next = min (x + y, foo (z));
```

it expands as follows:

```
next = ((x + y) < (foo (z)) ? (x + y) : (foo (z)));
```

where `x + y' has been substituted for `X' and `foo (z)' for `Y'.

The function `foo' is used only once in the statement as it appears in the program, but the expression `foo (z)' has been substituted twice into the macro expansion. As a result, `foo' might be called two times when the statement is executed. If it has side effects or if it takes a long time to compute, the results might not be what you intended. We say that `min' is an unsafe macro.

The best solution to this problem is to define `min' in a way that computes the value of `foo (z)' only once. The C language offers no standard way to do this, but it can be done with GNU C extensions as follows:

```
#define min(X, Y)                       \
({ typeof (X) __x = (X), __y = (Y);   \
   (__x < __y) ? __x : __y; })
```

If you do not wish to use GNU C extensions, the only solution is to be careful when *using* the macro `min'. For example, you can calculate the value of `foo (z)', save it in a variable, and use that variable in `min':

```
#define min(X, Y)  ((X) < (Y) ? (X) : (Y))
...
{
  int tem = foo (z);
  next = min (x + y, tem);
}
```

(where we assume that `foo' returns type `int').

Self-Referential Macros

A self-referential macro is one whose name appears in its definition. A special feature of ANSI Standard

C is that the self-reference is not considered a macro call. It is passed into the preprocessor output unchanged.

Let's consider an example:

```
#define foo (4 + foo)
```

where `foo' is also a variable in your program.

Following the ordinary rules, each reference to `foo' will expand into `(4 + foo)'; then this will be rescanned and will expand into `(4 + (4 + foo))'; and so on until it causes a fatal error (memory full) in the preprocessor.

However, the special rule about self-reference cuts this process short after one step, at `(4 + foo)'. Therefore, this macro definition has the possibly useful effect of causing the program to add 4 to the value of `foo' wherever `foo' is referred to.

In most cases, it is a bad idea to take advantage of this feature. A person reading the program who sees that `foo' is a variable will not expect that it is a macro as well. The reader will come across the identifier `foo' in the program and think its value should be that of the variable `foo', whereas in fact the value is four greater.

The special rule for self-reference applies also to indirect self-reference. This is the case where a macro x expands to use a macro `y', and the expansion of `y' refers to the macro `x'. The resulting reference to `x' comes indirectly from the expansion of `x', so it is a self-reference and is not further expanded. Thus, after

```
#define x (4 + y)
#define y (2 * x)
```

`x' would expand into `(4 + (2 * x))'. Clear?

But suppose `y' is used elsewhere, not from the definition of `x'. Then the use of `x' in the expansion of `y' is not a self-reference because `x' is not "in progress". So it does expand. However, the expansion of `x' contains a reference to `y', and that is an indirect self-reference now because `y' is "in progress". The result is that `y' expands to `(2 * (4 + y))'.

It is not clear that this behavior would ever be useful, but it is specified by the ANSI C standard, so you may need to understand it.

Separate Expansion of Macro Arguments

We have explained that the expansion of a macro, including the substituted actual arguments, is scanned over again for macro calls to be expanded.

What really happens is more subtle: first each actual argument text is scanned separately for macro calls. Then the results of this are substituted into the macro body to produce the macro expansion, and the macro expansion is scanned again for macros to expand.

The result is that the actual arguments are scanned *twice* to expand macro calls in them.

Most of the time, this has no effect. If the actual argument contained any macro calls, they are expanded during the first scan. The result therefore contains no macro calls, so the second scan does not change it. If the actual argument were substituted as given, with no prescan, the single remaining scan would find the same macro calls and produce the same results.

You might expect the double scan to change the results when a self-referential macro is used in an actual argument of another macro (see section Self-Referential Macros): the self-referential macro would be expanded once in the first scan, and a second time in the second scan. But this is not what happens. The self-references that do not expand in the first scan are marked so that they will not expand in the second scan either.

The prescan is not done when an argument is stringified or concatenated. Thus,

```
#define str(s) #s
#define foo 4
str (foo)
```

expands to `"foo"'. Once more, prescan has been prevented from having any noticeable effect.

More precisely, stringification and concatenation use the argument as written, in un-prescanned form. The same actual argument would be used in prescanned form if it is substituted elsewhere without stringification or concatenation.

```
#define str(s) #s lose(s)
#define foo 4
str (foo)
```

expands to `"foo" lose(4)'.

You might now ask, "Why mention the prescan, if it makes no difference? And why not skip it and make the preprocessor faster?" The answer is that the prescan does make a difference in three special cases:

- Nested calls to a macro.
- Macros that call other macros that stringify or concatenate.
- Macros whose expansions contain unshielded commas.

We say that nested calls to a macro occur when a macro's actual argument contains a call to that very macro. For example, if `f' is a macro that expects one argument, `f (f (1))' is a nested pair of calls to `f'. The desired expansion is made by expanding `f (1)' and substituting that into the definition of `f'. The prescan causes the expected result to happen. Without the prescan, `f (1)' itself would be substituted as an actual argument, and the inner use of `f' would appear during the main scan as an indirect self-reference and would not be expanded. Here, the prescan cancels an undesirable side effect (in the medical, not computational, sense of the term) of the special rule for self-referential macros.

But prescan causes trouble in certain other cases of nested macro calls. Here is an example:

```
#define foo  a,b
#define bar(x) lose(x)
#define lose(x) (1 + (x))

bar(foo)
```

We would like `bar(foo)' to turn into `(1 + (foo))', which would then turn into `(1 + (a,b))'. But instead, `bar(foo)' expands into `lose(a,b)', and you get an error because `lose` requires a single argument. In this case, the problem is easily solved by the same parentheses that ought to be used to prevent misnesting of arithmetic operations:

```
#define foo (a,b)
#define bar(x) lose((x))
```

The problem is more serious when the operands of the macro are not expressions; for example, when they are statements. Then parentheses are unacceptable because they would make for invalid C code:

```
#define foo { int a, b; ... }
```

In GNU C you can shield the commas using the `({...})' construct which turns a compound statement into an expression:

```
#define foo ({ int a, b; ... })
```

Or you can rewrite the macro definition to avoid such commas:

```
#define foo { int a; int b; ... }
```

There is also one case where prescan is useful. It is possible to use prescan to expand an argument and then stringify it--if you use two levels of macros. Let's add a new macro `xstr' to the example shown above:

```
#define xstr(s) str(s)
#define str(s) #s
#define foo 4
xstr (foo)
```

This expands into `"4"', not `"foo"'. The reason for the difference is that the argument of `xstr' is expanded at prescan (because `xstr' does not specify stringification or concatenation of the argument). The result of prescan then forms the actual argument for `str'. `str' uses its argument without prescan because it performs stringification; but it cannot prevent or undo the prescanning already done by `xstr'.

Cascaded Use of Macros

A cascade of macros is when one macro's body contains a reference to another macro. This is very common practice. For example,

```
#define BUFSIZE 1020
#define TABLESIZE BUFSIZE
```

This is not at all the same as defining `TABLESIZE' to be `1020'. The `#define' for `TABLESIZE' uses exactly the body you specify--in this case, `BUFSIZE'---and does not check to see whether it too is the name of a macro.

It's only when you *use* `TABLESIZE' that the result of its expansion is checked for more macro names.

This makes a difference if you change the definition of `BUFSIZE' at some point in the source file. `TABLESIZE', defined as shown, will always expand using the definition of `BUFSIZE' that is currently in effect:

```
#define BUFSIZE 1020
#define TABLESIZE BUFSIZE
#undef BUFSIZE
#define BUFSIZE 37
```

Now `TABLESIZE' expands (in two stages) to `37'. (The `#undef' is to prevent any warning about the nontrivial redefinition of `BUFSIZE'.)

Newlines in Macro Arguments

Traditional macro processing carries forward all newlines in macro arguments into the expansion of the macro. This means that, if some of the arguments are substituted more than once, or not at all, or out of order, newlines can be duplicated, lost, or moved around within the expansion. If the expansion consists of multiple statements, then the effect is to distort the line numbers of some of these statements. The result can be incorrect line numbers, in error messages or displayed in a debugger.

The GNU C preprocessor operating in ANSI C mode adjusts appropriately for multiple use of an argument--the first use expands all the newlines, and subsequent uses of the same argument produce no newlines. But even in this mode, it can produce incorrect line numbering if arguments are used out of order, or not used at all.

Here is an example illustrating this problem:

```
#define ignore_second_arg(a,b,c) a; c

ignore_second_arg (foo (),
                   ignored (),
                   syntax error);
```

The syntax error triggered by the tokens `syntax error' results in an error message citing line four, even though the statement text comes from line five.

Conditionals

In a macro processor, a conditional is a directive that allows a part of the program to be ignored during compilation, on some conditions. In the C preprocessor, a conditional can test either an arithmetic expression or whether a name is defined as a macro.

A conditional in the C preprocessor resembles in some ways an `if' statement in C, but it is important to understand the difference between them. The condition in an `if' statement is tested during the execution of your program. Its purpose is to allow your program to behave differently from run to run, depending on the data it is operating on. The condition in a preprocessing conditional directive is tested when your program is compiled. Its purpose is to allow different code to be included in the program depending on the situation at the time of compilation.

Why Conditionals are Used

Generally there are three kinds of reason to use a conditional.

- A program may need to use different code depending on the machine or operating system it is to run on. In some cases the code for one operating system may be erroneous on another operating system; for example, it might refer to library routines that do not exist on the other system. When this happens, it is not enough to avoid executing the invalid code: merely having it in the program makes it impossible to link the program and run it. With a preprocessing conditional, the offending code can be effectively excised from the program when it is not valid.
- You may want to be able to compile the same source file into two different programs. Sometimes the difference between the programs is that one makes frequent time-consuming consistency checks on its intermediate data, or prints the values of those data for debugging, while the other does not.
- A conditional whose condition is always false is a good way to exclude code from the program but keep it as a sort of comment for future reference.

Most simple programs that are intended to run on only one machine will not need to use preprocessing conditionals.

Syntax of Conditionals

A conditional in the C preprocessor begins with a conditional directive: `#if', `#ifdef' or `#ifndef'. See section Conditionals and Macros, for information on `#ifdef' and `#ifndef'; only `#if' is explained here.

The `#if' Directive

The `#if' directive in its simplest form consists of

```
#if expression
controlled text
#endif /* expression */
```

The comment following the `#endif' is not required, but it is a good practice because it helps people match the `#endif' to the corresponding `#if'. Such comments should always be used, except in short conditionals that are not nested. In fact, you can put anything at all after the `#endif' and it will be ignored by the GNU C preprocessor, but only comments are acceptable in ANSI Standard C.

expression is a C expression of integer type, subject to stringent restrictions. It may contain

- Integer constants, which are all regarded as `long` or `unsigned long`.
- Character constants, which are interpreted according to the character set and conventions of the machine and operating system on which the preprocessor is running. The GNU C preprocessor uses the C data type `char' for these character constants; therefore, whether some character codes are negative is determined by the C compiler used to compile the preprocessor. If it treats `char' as signed, then character codes large enough to set the sign bit will be considered negative; otherwise, no character code is considered negative.
- Arithmetic operators for addition, subtraction, multiplication, division, bitwise operations, shifts, comparisons, and logical operations (`&&' and `||').
- Identifiers that are not macros, which are all treated as zero(!).
- Macro calls. All macro calls in the expression are expanded before actual computation of the expression's value begins.

Note that `sizeof' operators and `enum`-type values are not allowed. `enum`-type values, like all other identifiers that are not taken as macro calls and expanded, are treated as zero.

The controlled text inside of a conditional can include preprocessing directives. Then the directives inside the conditional are obeyed only if that branch of the conditional succeeds. The text can also contain other conditional groups. However, the `#if' and `#endif' directives must balance.

The `#else' Directive

The `#else' directive can be added to a conditional to provide alternative text to be used if the condition is false. This is what it looks like:

```
#if expression
text-if-true
#else /* Not expression */
text-if-false
#endif /* Not expression */
```

If expression is nonzero, and thus the text-if-true is active, then `#else' acts like a failing conditional and the text-if-false is ignored. Contrariwise, if the `#if' conditional fails, the text-if-false is considered included.

The `#elif' Directive

One common case of nested conditionals is used to check for more than two possible alternatives. For example, you might have

```
#if X == 1
...
#else /* X != 1 */
#if X == 2
...
#else /* X != 2 */
...
#endif /* X != 2 */
#endif /* X != 1 */
```

Another conditional directive, `#elif', allows this to be abbreviated as follows:

```
#if X == 1
...
#elif X == 2
...
#else /* X != 2 and X != 1*/
...
#endif /* X != 2 and X != 1*/
```

`#elif' stands for "else if". Like `#else', it goes in the middle of a `#if'-`#endif' pair and subdivides it; it does not require a matching `#endif' of its own. Like `#if', the `#elif' directive includes an expression to be tested.

The text following the `#elif' is processed only if the original `#if'-condition failed and the `#elif' condition succeeds. More than one `#elif' can go in the same `#if'-`#endif' group. Then the text after each `#elif' is processed only if the `#elif' condition succeeds after the original `#if' and any previous `#elif' directives within it have failed. `#else' is equivalent to `#elif 1', and `#else' is allowed after any number of `#elif' directives, but `#elif' may not follow `#else'.

Keeping Deleted Code for Future Reference

If you replace or delete a part of the program but want to keep the old code around as a comment for future reference, the easy way to do this is to put `#if 0' before it and `#endif' after it. This is better than using comment delimiters `/*' and `*/' since those won't work if the code already contains comments (C comments do not nest).

This works even if the code being turned off contains conditionals, but they must be entire conditionals (balanced `#if' and `#endif').

Conversely, do not use `#if 0' for comments which are not C code. Use the comment delimiters `/*' and `*/' instead. The interior of `#if 0' must consist of complete tokens; in particular, singlequote characters must balance. But comments often contain unbalanced singlequote characters (known in English as apostrophes). These confuse `#if 0'. They do not confuse `/*'.

Conditionals and Macros

Conditionals are useful in connection with macros or assertions, because those are the only ways that an expression's value can vary from one compilation to another. A `#if' directive whose expression uses no macros or assertions is equivalent to `#if 1' or `#if 0'; you might as well determine which one, by computing the value of the expression yourself, and then simplify the program.

For example, here is a conditional that tests the expression `BUFSIZE == 1020', where `BUFSIZE' must be a macro.

```
#if BUFSIZE == 1020
  printf ("Large buffers!\n");
#endif /* BUFSIZE is large */
```

(Programmers often wish they could test the size of a variable or data type in `#if', but this does not work. The preprocessor does not understand `sizeof`, or typedef names, or even the type keywords such as `int`.)

The special operator `defined' is used in `#if' expressions to test whether a certain name is defined as a macro. Either `defined name' or `defined (name)' is an expression whose value is 1 if name is defined as macro at the current point in the program, and 0 otherwise. For the `defined' operator it makes no difference what the definition of the macro is; all that matters is whether there is a definition. Thus, for example,

```
#if defined (vax) || defined (ns16000)
```

would succeed if either of the names `vax' and `ns16000' is defined as a macro. You can test the same condition using assertions (see section Assertions), like this:

```
#if #cpu (vax) || #cpu (ns16000)
```

If a macro is defined and later undefined with `#undef', subsequent use of the `defined' operator returns 0, because the name is no longer defined. If the macro is defined again with another `#define', `defined' will recommence returning 1.

Conditionals that test whether just one name is defined are very common, so there are two special short conditional directives for this case.

`#ifdef name`

is equivalent to `#if defined (name)'.

`#ifndef name`

is equivalent to `#if ! defined (name)'.

Macro definitions can vary between compilations for several reasons.

- Some macros are predefined on each kind of machine. For example, on a Vax, the name `vax' is a predefined macro. On other machines, it would not be defined.

- Many more macros are defined by system header files. Different systems and machines define different macros, or give them different values. It is useful to test these macros with conditionals to avoid using a system feature on a machine where it is not implemented.
- Macros are a common way of allowing users to customize a program for different machines or applications. For example, the macro `BUFSIZE' might be defined in a configuration file for your program that is included as a header file in each source file. You would use `BUFSIZE' in a preprocessing conditional in order to generate different code depending on the chosen configuration.
- Macros can be defined or undefined with `-D' and `-U' command options when you compile the program. You can arrange to compile the same source file into two different programs by choosing a macro name to specify which program you want, writing conditionals to test whether or how this macro is defined, and then controlling the state of the macro with compiler command options. See section Invoking the C Preprocessor.

Assertions

Assertions are a more systematic alternative to macros in writing conditionals to test what sort of computer or system the compiled program will run on. Assertions are usually predefined, but you can define them with preprocessing directives or command-line options.

The macros traditionally used to describe the type of target are not classified in any way according to which question they answer; they may indicate a hardware architecture, a particular hardware model, an operating system, a particular version of an operating system, or specific configuration options. These are jumbled together in a single namespace. In contrast, each assertion consists of a named question and an answer. The question is usually called the predicate. An assertion looks like this:

```
#predicate (answer)
```

You must use a properly formed identifier for predicate. The value of answer can be any sequence of words; all characters are significant except for leading and trailing whitespace, and differences in internal whitespace sequences are ignored. Thus, `x + y' is different from `x+y' but equivalent to `x + y'. `)' is not allowed in an answer.

Here is a conditional to test whether the answer answer is asserted for the predicate predicate:

```
#if #predicate (answer)
```

There may be more than one answer asserted for a given predicate. If you omit the answer, you can test whether *any* answer is asserted for predicate:

```
#if #predicate
```

Most of the time, the assertions you test will be predefined assertions. GNU C provides three predefined predicates: `system`, `cpu`, and `machine`. `system` is for assertions about the type of software, `cpu` describes the type of computer architecture, and `machine` gives more information about the computer. For example, on a GNU system, the following assertions would be true:

```
#system (gnu)
#system (mach)
#system (mach 3)
#system (mach 3.subversion)
#system (hurd)
#system (hurd version)
```

and perhaps others. The alternatives with more or less version information let you ask more or less detailed questions about the type of system software.

On a Unix system, you would find `#system (unix)` and perhaps one of: `#system (aix)`, `#system (bsd)`, `#system (hpux)`, `#system (lynx)`, `#system (mach)`, `#system (posix)`, `#system (svr3)`, `#system (svr4)`, or `#system (xpg4)` with possible version numbers following.

Other values for `system` are `#system (mvs)` and `#system (vms)`.

Portability note: Many Unix C compilers provide only one answer for the `system` assertion: `#system (unix)`, if they support assertions at all. This is less than useful.

An assertion with a multi-word answer is completely different from several assertions with individual single-word answers. For example, the presence of `system (mach 3.0)` does not mean that `system (3.0)` is true. It also does not directly imply `system (mach)`, but in GNU C, that last will normally be asserted as well.

The current list of possible assertion values for `cpu` is: `#cpu (a29k)`, `#cpu (alpha)`, `#cpu (arm)`, `#cpu (clipper)`, `#cpu (convex)`, `#cpu (elxsi)`, `#cpu (tron)`, `#cpu (h8300)`, `#cpu (i370)`, `#cpu (i386)`, `#cpu (i860)`, `#cpu (i960)`, `#cpu (m68k)`, `#cpu (m88k)`, `#cpu (mips)`, `#cpu (ns32k)`, `#cpu (hppa)`, `#cpu (pyr)`, `#cpu (ibm032)`, `#cpu (rs6000)`, `#cpu (sh)`, `#cpu (sparc)`, `#cpu (spur)`, `#cpu (tahoe)`, `#cpu (vax)`, `#cpu (we32000)`.

You can create assertions within a C program using `#assert', like this:

```
#assert predicate (answer)
```

(Note the absence of a `#' before predicate.)

Each time you do this, you assert a new true answer for predicate. Asserting one answer does not invalidate previously asserted answers; they all remain true. The only way to remove an assertion is with `#unassert'. `#unassert' has the same syntax as `#assert'. You can also remove all assertions about predicate like this:

```
#unassert predicate
```

You can also add or cancel assertions using command options when you run `gcc` or `cpp`. See section Invoking the C Preprocessor.

The `#error' and `#warning' Directives

The directive `#error' causes the preprocessor to report a fatal error. The rest of the line that follows `#error' is used as the error message.

You would use `#error' inside of a conditional that detects a combination of parameters which you know the program does not properly support. For example, if you know that the program will not run properly on a Vax, you might write

```
#ifdef __vax__
#error Won't work on Vaxen.  See comments at get_last_object.
#endif
```

See section Nonstandard Predefined Macros, for why this works.

If you have several configuration parameters that must be set up by the installation in a consistent way, you can use conditionals to detect an inconsistency and report it with `#error'. For example,

```
#if HASH_TABLE_SIZE % 2 == 0 || HASH_TABLE_SIZE % 3 == 0 \
    || HASH_TABLE_SIZE % 5 == 0
#error HASH_TABLE_SIZE should not be divisible by a small prime
#endif
```

The directive `#warning' is like the directive `#error', but causes the preprocessor to issue a warning and continue preprocessing. The rest of the line that follows `#warning' is used as the warning message.

You might use `#warning' in obsolete header files, with a message directing the user to the header file which should be used instead.

Combining Source Files

One of the jobs of the C preprocessor is to inform the C compiler of where each line of C code came from: which source file and which line number.

C code can come from multiple source files if you use `#include'; both `#include' and the use of conditionals and macros can cause the line number of a line in the preprocessor output to be different from the line's number in the original source file. You will appreciate the value of making both the C compiler (in error messages) and symbolic debuggers such as GDB use the line numbers in your source file.

The C preprocessor builds on this feature by offering a directive by which you can control the feature explicitly. This is useful when a file for input to the C preprocessor is the output from another program such as the `bison` parser generator, which operates on another file that is the true source file. Parts of the output from `bison` are generated from scratch, other parts come from a standard parser file. The rest are copied nearly verbatim from the source file, but their line numbers in the `bison` output are not the same as their original line numbers. Naturally you would like compiler error messages and symbolic

debuggers to know the original source file and line number of each line in the `bison` input.

`bison` arranges this by writing `#line' directives into the output file. `#line' is a directive that specifies the original line number and source file name for subsequent input in the current preprocessor input file. `#line' has three variants:

`#line linenum`

Here linenum is a decimal integer constant. This specifies that the line number of the following line of input, in its original source file, was linenum.

`#line linenum filename`

Here linenum is a decimal integer constant and filename is a string constant. This specifies that the following line of input came originally from source file filename and its line number there was linenum. Keep in mind that filename is not just a file name; it is surrounded by doublequote characters so that it looks like a string constant.

`#line anything else`

anything else is checked for macro calls, which are expanded. The result should be a decimal integer constant followed optionally by a string constant, as described above.

`#line' directives alter the results of the `__FILE__' and `__LINE__' predefined macros from that point on. See section Standard Predefined Macros.

The output of the preprocessor (which is the input for the rest of the compiler) contains directives that look much like `#line' directives. They start with just `#' instead of `#line', but this is followed by a line number and file name as in `#line'. See section C Preprocessor Output.

Miscellaneous Preprocessing Directives

This section describes three additional preprocessing directives. They are not very useful, but are mentioned for completeness.

The null directive consists of a `#' followed by a Newline, with only whitespace (including comments) in between. A null directive is understood as a preprocessing directive but has no effect on the preprocessor output. The primary significance of the existence of the null directive is that an input line consisting of just a `#' will produce no output, rather than a line of output containing just a `#'. Supposedly some old C programs contain such lines.

The ANSI standard specifies that the `#pragma' directive has an arbitrary, implementation-defined effect. In the GNU C preprocessor, `#pragma' directives are not used, except for `#pragma once' (see section Once-Only Include Files). However, they are left in the preprocessor output, so they are available to the compilation pass.

The `#ident' directive is supported for compatibility with certain other systems. It is followed by a line of text. On some systems, the text is copied into a special place in the object file; on most systems, the text is ignored and this directive has no effect. Typically `#ident' is only used in header files supplied with those systems where it is meaningful.

C Preprocessor Output

The output from the C preprocessor looks much like the input, except that all preprocessing directive lines have been replaced with blank lines and all comments with spaces. Whitespace within a line is not altered; however, a space is inserted after the expansions of most macro calls.

Source file name and line number information is conveyed by lines of the form

```
# linenum filename flags
```

which are inserted as needed into the middle of the input (but never within a string or character constant). Such a line means that the following line originated in file filename at line linenum.

After the file name comes zero or more flags, which are `1', `2' or `3'. If there are multiple flags, spaces separate them. Here is what the flags mean:

`1'

This indicates the start of a new file.

`2'

This indicates returning to a file (after having included another file).

`3'

This indicates that the following text comes from a system header file, so certain warnings should be suppressed.

Invoking the C Preprocessor

Most often when you use the C preprocessor you will not have to invoke it explicitly: the C compiler will do so automatically. However, the preprocessor is sometimes useful on its own.

The C preprocessor expects two file names as arguments, infile and outfile. The preprocessor reads infile together with any other files it specifies with `#include'. All the output generated by the combined input files is written in outfile.

Either infile or outfile may be `-', which as infile means to read from standard input and as outfile means to write to standard output. Also, if outfile or both file names are omitted, the standard output and standard input are used for the omitted file names.

Here is a table of command options accepted by the C preprocessor. These options can also be given when compiling a C program; they are passed along automatically to the preprocessor when it is invoked by the compiler.

`-P'

Inhibit generation of `#'-lines with line-number information in the output from the preprocessor (see section C Preprocessor Output). This might be useful when running the preprocessor on something that is not C code and will be sent to a program which might be confused by the `#'-lines.

`-C'

Do not discard comments: pass them through to the output file. Comments appearing in arguments of a macro call will be copied to the output before the expansion of the macro call.

`-traditional'

Try to imitate the behavior of old-fashioned C, as opposed to ANSI C.

`'

Traditional macro expansion pays no attention to singlequote or doublequote characters; macro argument symbols are replaced by the argument values even when they appear within apparent string or character constants.

`'

Traditionally, it is permissible for a macro expansion to end in the middle of a string or character constant. The constant continues into the text surrounding the macro call.

`'

However, traditionally the end of the line terminates a string or character constant, with no error.

`'

In traditional C, a comment is equivalent to no text at all. (In ANSI C, a comment counts as whitespace.)

`'

Traditional C does not have the concept of a "preprocessing number". It considers `1.0e+4' to be three tokens: `1.0e', `+', and `4'.

`'

A macro is not suppressed within its own definition, in traditional C. Thus, any macro that is used recursively inevitably causes an error.

`'

The character `#' has no special meaning within a macro definition in traditional C.

`'

In traditional C, the text at the end of a macro expansion can run together with the text after the macro call, to produce a single token. (This is impossible in ANSI C.)

`'

Traditionally, `\' inside a macro argument suppresses the syntactic significance of the following character.

`-trigraphs'

Process ANSI standard trigraph sequences. These are three-character sequences, all starting with `??', that are defined by ANSI C to stand for single characters. For example, `??/' stands for `\', so `'??/n" is a character constant for a newline. Strictly speaking, the GNU C preprocessor does not support all programs in ANSI Standard C unless `-trigraphs' is used, but if you ever notice the difference it will be with relief.

You don't want to know any more about trigraphs.

`-pedantic'

Issue warnings required by the ANSI C standard in certain cases such as when text other than a comment follows `#else' or `#endif'.

`-pedantic-errors'

Like `-pedantic', except that errors are produced rather than warnings.

`-Wtrigraphs'

Warn if any trigraphs are encountered (assuming they are enabled).

`-Wcomment'

Warn whenever a comment-start sequence `/*' appears in a comment.

`-Wall'

Requests both `-Wtrigraphs' and `-Wcomment' (but not `-Wtraditional').

`-Wtraditional'

Warn about certain constructs that behave differently in traditional and ANSI C.

`-I directory'

Add the directory directory to the head of the list of directories to be searched for header files (see section The `#include' Directive). This can be used to override a system header file, substituting your own version, since these directories are searched before the system header file directories. If you use more than one `-I' option, the directories are scanned in left-to-right order; the standard system directories come after.

`-I-'

Any directories specified with `-I' options before the `-I-' option are searched only for the case of `#include "file"'; they are not searched for `#include <file>'.

If additional directories are specified with `-I' options after the `-I-', these directories are searched for all `#include' directives.

In addition, the `-I-' option inhibits the use of the current directory as the first search directory for `#include "file"'. Therefore, the current directory is searched only if it is requested explicitly with `-I.'. Specifying both `-I-' and `-I.' allows you to control precisely which directories are searched before the current one and which are searched after.

`-nostdinc'

Do not search the standard system directories for header files. Only the directories you have specified with `-I' options (and the current directory, if appropriate) are searched.

`-nostdinc++'

Do not search for header files in the C++-specific standard directories, but do still search the other standard directories. (This option is used when building libg++.)

`-D name'

Predefine name as a macro, with definition `1'.

`-D name=definition'

Predefine name as a macro, with definition definition. There are no restrictions on the contents of

definition, but if you are invoking the preprocessor from a shell or shell-like program you may need to use the shell's quoting syntax to protect characters such as spaces that have a meaning in the shell syntax. If you use more than one `-D' for the same name, the rightmost definition takes effect.

`-U name'

Do not predefine name. If both `-U' and `-D' are specified for one name, the `-U' beats the `-D' and the name is not predefined.

`-undef'

Do not predefine any nonstandard macros.

`-A predicate(answer)'

Make an assertion with the predicate predicate and answer answer. See section Assertions.

You can use `-A-' to disable all predefined assertions; it also undefines all predefined macros that identify the type of target system.

`-dM'

Instead of outputting the result of preprocessing, output a list of `#define' directives for all the macros defined during the execution of the preprocessor, including predefined macros. This gives you a way of finding out what is predefined in your version of the preprocessor; assuming you have no file `foo.h', the command

```
touch foo.h; cpp -dM foo.h
```

will show the values of any predefined macros.

`-dD'

Like `-dM' except in two respects: it does *not* include the predefined macros, and it outputs *both* the `#define' directives and the result of preprocessing. Both kinds of output go to the standard output file.

`-M [-MG]'

Instead of outputting the result of preprocessing, output a rule suitable for `make` describing the dependencies of the main source file. The preprocessor outputs one `make` rule containing the object file name for that source file, a colon, and the names of all the included files. If there are many included files then the rule is split into several lines using `\'-newline.

`-MG' says to treat missing header files as generated files and assume they live in the same directory as the source file. It must be specified in addition to `-M'.

This feature is used in automatic updating of makefiles.

`-MM [-MG]'

Like `-M' but mention only the files included with `#include "file"'. System header files included with `#include <file>' are omitted.

`-MD file'

Like `-M' but the dependency information is written to file. This is in addition to compiling the file as specified---`-MD' does not inhibit ordinary compilation the way `-M' does.

When invoking gcc, do not specify the file argument. Gcc will create file names made by replacing ".c" with ".d" at the end of the input file names.

In Mach, you can use the utility `md` to merge multiple dependency files into a single dependency file suitable for using with the `make' command.

`-MMD file'

Like `-MD' except mention only user header files, not system header files.

`-H'

Print the name of each header file used, in addition to other normal activities.

`-imacros file'

Process file as input, discarding the resulting output, before processing the regular input file. Because the output generated from file is discarded, the only effect of `-imacros file' is to make the macros defined in file available for use in the main input.

`-include file'

Process file as input, and include all the resulting output, before processing the regular input file.

`-idirafter dir'

Add the directory dir to the second include path. The directories on the second include path are searched when a header file is not found in any of the directories in the main include path (the one that `-I' adds to).

`-iprefix prefix'

Specify prefix as the prefix for subsequent `-iwithprefix' options.

`-iwithprefix dir'

Add a directory to the second include path. The directory's name is made by concatenating prefix and dir, where prefix was specified previously with `-iprefix'.

`-isystem dir'

Add a directory to the beginning of the second include path, marking it as a system directory, so that it gets the same special treatment as is applied to the standard system directories.

`-lang-c'

`-lang-c++'

`-lang-objc'

`-lang-objc++'

Specify the source language. `-lang-c++' makes the preprocessor handle C++ comment syntax (comments may begin with `//', in which case they end at end of line), and includes extra default include directories for C++; and `-lang-objc' enables the Objective C `#import' directive. `-lang-c' explicitly turns off both of these extensions, and `-lang-objc++' enables both.

These options are generated by the compiler driver `gcc`, but not passed from the `gcc' command line.

`-lint'

Look for commands to the program checker `lint` embedded in comments, and emit them

preceded by `#pragma lint'. For example, the comment `/* NOTREACHED */' becomes `#pragma lint NOTREACHED'.

This option is available only when you call `cpp` directly; `gcc` will not pass it from its command line.

`-$'

Forbid the use of `$' in identifiers. This is required for ANSI conformance. `gcc` automatically supplies this option to the preprocessor if you specify `-ansi', but `gcc` doesn't recognize the `-$' option itself--to use it without the other effects of `-ansi', you must call the preprocessor directly.

Version Management

with

CVS

for CVS 1.8.1

Per Cederqvist et al

About this manual

Up to this point, one of the weakest parts of CVS has been the documentation. CVS is a complex program. Previous versions of the manual were written in the manual page format, which is not really well suited for such a complex program.

When writing this manual, I had several goals in mind:

- No knowledge of RCS should be necessary.
- No previous knowledge of revision control software should be necessary. All terms, such as revision numbers, revision trees and merging are explained as they are introduced.
- The manual should concentrate on the things CVS users want to do, instead of what the CVS commands can do. The first part of this manual leads you through things you might want to do while doing development, and introduces the relevant CVS commands as they are needed.
- Information should be easy to find. In the reference manual in the appendices almost all information about every CVS command is gathered together. There is also an extensive index, and a lot of cross references.

This manual was contributed by Signum Support AB in Sweden. Signum is yet another in the growing list of companies that support free software. You are free to copy both this manual and the CVS program. See section GNU GENERAL PUBLIC LICENSE, for the details. Signum Support offers support

contracts and binary distribution for many programs, such as CVS, GNU Emacs, the GNU C compi and others. Write to us for more information.

```

Another company selling support for CVS is Cyclic Software, web: `http://www.cyclic.com/`, email: `info@cyclic.com`.

Checklist for the impatient reader

CVS is a complex system. You will need to read the manual to be able to use all of its capabilities. There are dangers that can easily be avoided if you know about them, and this manual tries to warn you about them. This checklist is intended to help you avoid the dangers without reading the entire manual. If you intend to read the entire manual you can skip this table.

Binary files

> CVS can handle binary files, but you must have RCS release 5.5 or later and a release of GNU diff that supports the `-a' flag (release 1.15 and later are OK). You must also configure both RCS and CVS to handle binary files when you install them.
>
> Keword substitution can be a source of trouble with binary files. See section Keyword substitution, for solutions.

The `admin` command

> Uncareful use of the `admin` command can cause CVS to cease working. See section admin--Administration front end for rcs, before trying to use it.

Credits

Roland Pesch, Cygnus Support <`pesch@cygnus.com`> wrote the manual pages which were distributed with CVS 1.3. Appendix A and B contain much text that was extracted from them. He also read an early draft of this manual and contributed many ideas and corrections.

The mailing-list `info-cvs` is sometimes informative. I have included information from postings made by the following persons: David G. Grubbs <`dgg@think.com`>.

Some text has been extracted from the man pages for RCS.

The CVS FAQ (see section What is CVS?) by David G. Grubbs has been used as a check-list to make

sure that this manual is as complete as possible. (This manual does however not include all of the material in the FAQ). The FAQ contains a lot of useful information.

In addition, the following persons have helped by telling me about mistakes I've made: Roxanne Brunskill <rbrunski@datap.ca>, Kathy Dyer <dyer@phoenix.ocf.llnl.gov>, Karl Pingle <pingle@acuson.com>, Thomas A Peterson <tap@src.honeywell.com>, Inge Wallin <ingwa@signum.se>, Dirk Koschuetzki <koschuet@fmi.uni-passau.de> and Michael Brown <brown@wi.extrel.com>.

BUGS

This manual is known to have room for improvement. Here is a list of known deficiencies:

- In the examples, the output from CVS is sometimes displayed, sometimes not.
- The input that you are supposed to type in the examples should have a different font than the output from the computer.
- This manual should be clearer about what file permissions you should set up in the repository, and about setuid/setgid.
- Some of the chapters are not yet complete. They are noted by comments in the `cvs.texinfo' file.
- This list is not complete. If you notice any error, omission, or something that is unclear, please send mail to bug-cvs@prep.ai.mit.edu.

I hope that you will find this manual useful, despite the above-mentioned shortcomings.

What is CVS?

CVS is a version control system. Using it, you can record the history of your source files.

For example, bugs sometimes creep in when software is modified, and you might not detect the bug until a long time after you make the modification. With CVS, you can easily retrieve old versions to see exactly which change caused the bug. This can sometimes be a big help.

You could of course save every version of every file you have ever created. This would however waste an enormous amount of disk space. CVS stores all the versions of a file in a single file in a clever way that only stores the differences between versions.

CVS also helps you if you are part of a group of people working on the same project. It is all too easy to overwrite each others' changes unless you are extremely careful. Some editors, like GNU Emacs, try to make sure that the same file is never modified by two people at the same time. Unfortunately, if someone is using another editor, that safeguard will not work. CVS solves this problem by insulating the different developers from each other. Every developer works in his own directory, and CVS merges the work when each developer is done.

CVS started out as a bunch of shell scripts written by Dick Grune, posted to `comp.sources.unix` in the volume 6 release of December, 1986. While no actual code from these shell scripts is present in the current version of CVS much of the CVS conflict resolution algorithms come from them.

In April, 1989, Brian Berliner designed and coded CVS. Jeff Polk later helped Brian with the design of the CVS module and vendor branch support.

You can get CVS via anonymous ftp from a number of sites, for instance `prep.ai.mit.edu` in `` `pub/gnu' ``.

There is a mailing list for CVS where bug reports can be sent, questions can be asked, an FAQ is posted, and discussion about future enhancements to CVS take place. To submit a message to the list, write to <`info-cvs@prep.ai.mit.edu`>. To subscribe or unsubscribe, write to <`info-cvs-request@prep.ai.mit.edu`>. Please be specific about your email address.

CVS is not...

CVS can do a lot of things for you, but it does not try to be everything for everyone.

CVS is not a build system.

> Though the structure of your repository and modules file interact with your build system (e.g. `` `Makefile' ``s), they are essentially independent.
>
> CVS does not dictate how you build anything. It merely stores files for retrieval in a tree structure you devise.

CVS does not dictate how to use disk space in the checked out working directories. If you wr:t your `Makefile's or scripts in every directory so they have to know the relative positions o everything else, you wind up requiring the entire repository to be checked out. That's simply bad planning.

If you modularize your work, and construct a build system that will share files (via links, mounts, VPATH in `Makefile's, etc.), you can arrange your disk usage however you like.

But you have to remember that *any* such system is a lot of work to construct and maintain. CVS does not address the issues involved. You must use your brain and a collection of other tools to provide a build scheme to match your plans.

Of course, you should place the tools created to support such a build system (scripts, `Makefile's, etc) under CVS.

CVS is not a substitute for management.

Your managers and project leaders are expected to talk to you frequently enough to make certain you are aware of schedules, merge points, branch names and release dates. If they don't, CVS can't help.

CVS is an instrument for making sources dance to your tune. But you are the piper and the composer. No instrument plays itself or writes its own music.

CVS is not a substitute for developer communication.

When faced with conflicts within a single file, most developers manage to resolve them without too much effort. But a more general definition of "conflict" includes problems too difficult to solve without communication between developers.

CVS cannot determine when simultaneous changes within a single file, or across a whole collection of files, will logically conflict with one another. Its concept of a conflict is purely textual, arising when two changes to the same base file are near enough to spook the merge (i.e. diff3) command.

CVS does not claim to help at all in figuring out non-textual or distributed conflicts in program logic.

For example: Say you change the arguments to function X defined in file `A'. At the same time, someone edits file `B', adding new calls to function X using the old arguments. You are outside the realm of CVS's competence.

Acquire the habit of reading specs and talking to your peers.

CVS is not a configuration management system.

CVS is a source control system. The phrase "configuration management" is a marketing term, not an industry-recognized set of functions.

A true "configuration management system" would contain elements of the following:

Source control.

Dependency tracking.

Build systems (i.e. What to build and how to find things during a build. What is shared? What is local?)

Bug tracking.

Automated Testing procedures.

Release Engineering documentation and procedures.

Tape Construction.

Customer Installation.

A way for users to run different versions of the same software on the same host at the same time.

CVS provides only the first.

This section is taken from release 2.3 of the CVS FAQ.

Go to the previous, next section.

Go to the previous, next section.

Basic concepts

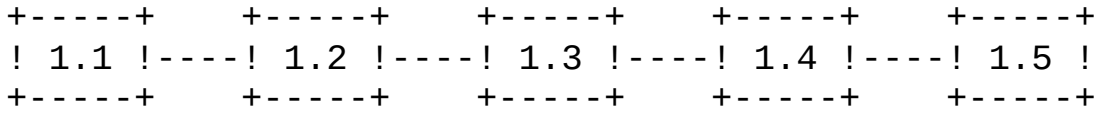
CVS stores all files in a centralized repository: a directory (such as `/usr/local/cvsroot' or `user@remotehost:/usr/local/cvsroot') which is populated with a hierarchy of files and directories. (see section Remote repositories for information about keeping the repository on a remote machine.)

Normally, you never access any of the files in the repository directly. Instead, you use CVS commands to get your own copy of the files, and then work on that copy. When you've finished a set of changes, you check (or commit) them back into the repository.

The files in the repository are organized in modules. Each module is made up of one or more files, and can include files from several directories. A typical usage is to define one module per project.

Revision numbers

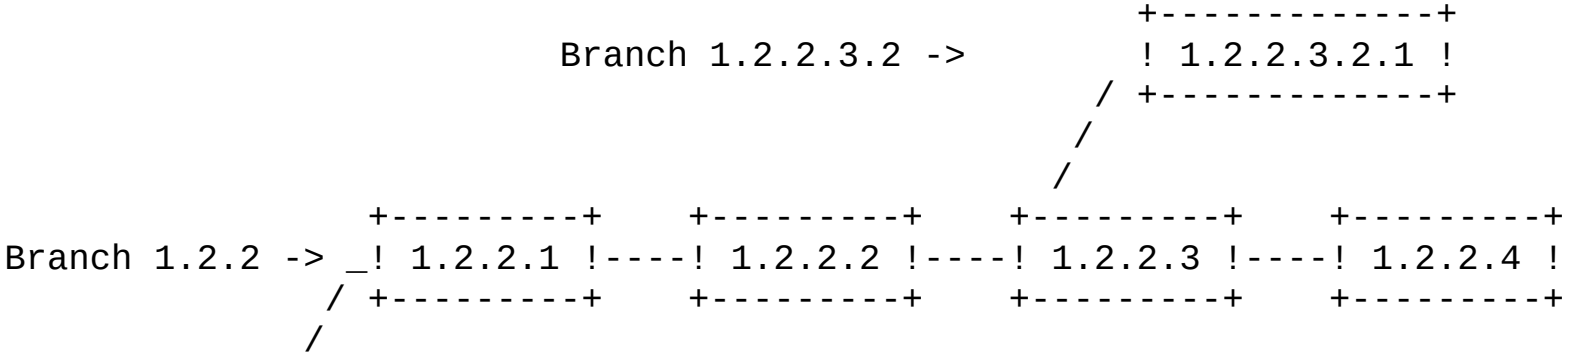
Each version of a file has a unique revision number. Revision numbers look like `1.1', `1.2', `1.3.2.2' or even `1.3.2.2.4.5'. A revision number always has an even number of period-separated decimal integers. By default revision 1.1 is the first revision of a file. Each successive revision is given a new number by increasing the rightmost number by one. The following figure displays a few revisions, with newer revisions to the right.

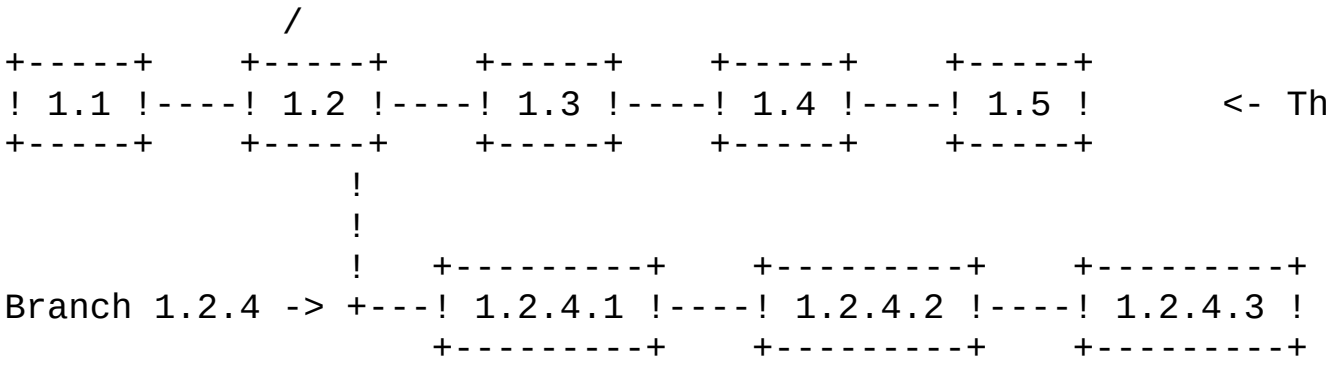


CVS is not limited to linear development. The revision tree can be split into branches, where each branch is a self-maintained line of development. Changes made on one branch can easily be moved back to the main trunk.

Each branch has a branch number, consisting of an odd number of period-separated decimal integers. The branch number is created by appending an integer to the revision number where the corresponding branch forked off. Having branch numbers allows more than one branch to be forked off from a certain revision.

All revisions on a branch have revision numbers formed by appending an ordinal number to the branch number. The following figure illustrates branching with an example.





The exact details of how the branch number is constructed is not something you normally need to be concerned about, but here is how it works: When CVS creates a branch number it picks the first unused even integer, starting with 2. So when you want to create a branch from revision 6.4 it will be numbered 6.4.2. All branch numbers ending in a zero (such as 6.4.0) are used internally by CVS (see section Magic branch numbers). The branch 1.1.1 has a special meaning. See section Tracking third-party sources.

Versions, revisions and releases

A file can have several versions, as described above. Likewise, a software product can have several versions. A software product is often given a version number such as `4.1.1'.

Versions in the first sense are called revisions in this document, and versions in the second sense are called releases. To avoid confusion, the word version is almost never used in this document.

Go to the previous, next section.

Go to the previous, next section.

A sample session

This section describes a typical work-session using CVS. It assumes that a repository is set up (see section The Repository).

Suppose you are working on a simple compiler. The source consists of a handful of C files and a `Makefile'. The compiler is called `tc' (Trivial Compiler), and the repository is set up so that there is a module called `tc'.

Getting the source

The first thing you must do is to get your own working copy of the source for `tc'. For this, you use the `checkout` command:

```
$ cvs checkout tc
```

This will create a new directory called `tc' and populate it with the source files.

```
$ cd tc
$ ls tc
CVS         Makefile    backend.c   driver.c    frontend.c  parser.c
```

The `CVS' directory is used internally by CVS. Normally, you should not modify or remove any of the files in it.

You start your favorite editor, hack away at `backend.c', and a couple of hours later you have added an optimization pass to the compiler. A note to RCS and SCCS users: There is no need to lock the files that you want to edit. See section Multiple developers for an explanation.

Committing your changes

When you have checked that the compiler is still compilable you decide to make a new version of `backend.c'.

```
$ cvs commit backend.c
```

CVS starts an editor, to allow you to enter a log message. You type in "Added an optimization pass.", save the temporary file, and exit the editor.

The environment variable `$CVSEDITOR` determines which editor is started. If `$CVSEDITOR` is not set, then if the environment variable `$EDITOR` is set, it will be used. If both `$CVSEDITOR` and `$EDITOR` are not set then the editor defaults to `vi`. If you want to avoid the overhead of starting an editor you can

specify the log message on the command line using the `-m' flag instead, like this:

```
$ cvs commit -m "Added an optimization pass" backend.c
```

Cleaning up

Before you turn to other tasks you decide to remove your working copy of tc. One acceptable way to do that is of course

```
$ cd ..
$ rm -r tc
```

but a better way is to use the `release` command (see section release--Indicate that a Module is no longer in use):

```
$ cd ..
$ cvs release -d tc
M driver.c
? tc
You have [1] altered files in this repository.
Are you sure you want to release (and delete) module `tc': n
** `release' aborted by user choice.
```

The `release` command checks that all your modifications have been committed. If history logging is enabled it also makes a note in the history file. See section The history file.

When you use the `-d' flag with `release`, it also removes your working copy.

In the example above, the `release` command wrote a couple of lines of output. `? tc' means that the file `` `tc' `` is unknown to CVS. That is nothing to worry about: `` `tc' `` is the executable compiler, and it should not be stored in the repository. See section Ignoring files via cvsignore, for information about how to make that warning go away. See section release output, for a complete explanation of all possible output from `release`.

`M driver.c' is more serious. It means that the file `` `driver.c' `` has been modified since it was checked out.

The `release` command always finishes by telling you how many modified files you have in your working copy of the sources, and then asks you for confirmation before deleting any files or making any note in the history file.

You decide to play it safe and answer n RET when `release` asks for confirmation.

Viewing differences

You do not remember modifying `driver.c', so you want to see what has happened to that file.

```
$ cd tc
$ cvs diff driver.c
```

This command runs `diff` to compare the version of `driver.c' that you checked out with your working copy. When you see the output you remember that you added a command line option that enabled the optimization pass. You check it in, and release the module.

```
$ cvs commit -m "Added an optimization pass" driver.c
Checking in driver.c;
/usr/local/cvsroot/tc/driver.c,v  <--  driver.c
new revision: 1.2; previous revision: 1.1
done
$ cd ..
$ cvs release -d tc
? tc
You have [0] altered files in this repository.
Are you sure you want to release (and delete) module `tc': y
```

Go to the previous, next section.

Go to the previous, next section.

The Repository

Figure 3 below shows a typical setup of a repository. Only directories are shown below.

```
/usr
 |
 +--local
 |   |
 |   +--cvsroot
 |   |    |
 |   |    +--CVSROOT
 |   |    |      (administrative files)
 |   |    |
 |   |    +--gnu
 |   |    |   |
 |   |    |   +--diff
 |   |    |   |   (source code to GNU diff)
 |   |    |   |
 |   |    |   +--rcs
 |   |    |   |   (source code to RCS)
 |   |    |   |
 |   |    |   +--cvs
 |   |    |       (source code to CVS)
 |   |    |
 |   |    +--yoyodyne
 |   |        |
 |   |        +--tc
 |   |        |    |
 |   |        |    +--man
 |   |        |    |
 |   |        |    +--testing
 |   |        |
 |   |        +--(other Yoyodyne software)
```

There are a couple of different ways to tell CVS where to find the repository. You can name the repository on the command line explicitly, with the `-d` (for "directory") option:

```
cvs -d /usr/local/cvsroot checkout yoyodyne/tc
```

Or you can set the `$CVSROOT` environment variable to an absolute path to the root of the repository, `` `/usr/local/cvsroot' `` in this example. To set `$CVSROOT`, all `csh` and `tcsh` users should have this line in their `` `.cshrc' `` or `` `.tcshrc' `` files:

```
setenv CVSROOT /usr/local/cvsroot
```

`sh` and `bash` users should instead have these lines in their `.profile' or `.bashrc':

```
CVSROOT=/usr/local/cvsroot
export CVSROOT
```

A repository specified with `-d` will override the `$CVSROOT` environment variable. Once you've checked a working copy out from the repository, it will remember where its repository is (the information is recorded in the `CVS/Root' file in the working copy).

The `-d` option and the `CVS/Root' file both override the `$CVSROOT` environment variable; however, CVS will complain if the `-d' argument and the `CVS/Root' file disagree.

There is nothing magical about the name `/usr/local/cvsroot'. You can choose to place the repository anywhere you like. See section Remote repositories to learn how the repository can be on a different machine than your working copy of the sources.

The repository is split in two parts. `$CVSROOT/CVSROOT' contains administrative files for CVS. The other directories contain the actual user-defined modules.

User modules

```
$CVSROOT
  |
  +--yoyodyne
  |   |
  |   +--tc
  |   |   |
          +--Makefile,v
          +--backend.c,v
          +--driver.c,v
          +--frontend.c,v
          +--parser.c,v
          +--man
          |    |
          |    +--tc.1,v
          |
          +--testing
               |
               +--testpgm.t,v
               +--test2.t,v
```

The figure above shows the contents of the `tc' module inside the repository. As you can see all file names end in `,v'. The files are history files. They contain, among other things, enough information to recreate any revision of the file, a log of all commit messages and the user-name of the person who committed the revision. CVS uses the facilities of RCS, a simpler version control system, to maintain these files. For a full description of the file format, see the `man` page rcsfile(5).

File permissions

All `,v' files are created read-only, and you should not change the permission of those files. The directories inside the repository should be writable by the persons that have permission to modify the files in each directory. This normally means that you must create a UNIX group (see group(5)) consisting of the persons that are to edit the files in a project, and set up the repository so that it is that group that owns the directory.

This means that you can only control access to files on a per-directory basis.

CVS tries to set up reasonable file permissions for new directories that are added inside the tree, but you must fix the permissions manually when a new directory should have different permissions than its parent directory.

Since CVS was not written to be run setuid, it is unsafe to try to run it setuid. You cannot use the setuid features of RCS together with CVS.

The administrative files

The directory `$CVSROOT/CVSROOT' contains some administrative files. See section Reference manual for the Administrative files, for a complete description. You can use CVS without any of these files, but some commands work better when at least the `modules' file is properly set up.

The most important of these files is the `modules' file. It defines all modules in the repository. This is a sample `modules' file.

```
CVSROOT         CVSROOT
modules         CVSROOT modules
cvs             gnu/cvs
rcs             gnu/rcs
diff            gnu/diff
tc              yoyodyne/tc
```

The `modules' file is line oriented. In its simplest form each line contains the name of the module, whitespace, and the directory where the module resides. The directory is a path relative to $CVSROOT. The last for lines in the example above are examples of such lines.

The line that defines the module called `modules' uses features that are not explained here. See section The modules file, for a full explanation of all the available features.

Editing administrative files

You edit the administrative files in the same way that you would edit any other module. Use `cvs checkout CVSROOT' to get a working copy, edit it, and commit your changes in the normal way.

It is possible to commit an erroneous administrative file. You can often fix the error and check in a new revision, but sometimes a particularly bad error in the administrative file makes it impossible to commit new revisions.

Multiple repositories

In some situations it is a good idea to have more than one repository, for instance if you have two development groups that work on separate projects without sharing any code. All you have to do to have several repositories is to specify the appropriate repository, using the `CVSROOT` environment variable, the `-d' option to CVS, or (once you have checked out a working directories) by simply allowing CVS to use the repository that was used to check out the working directory (see section The Repository).

Notwithstanding, it can be confusing to have two or more repositories.

None of the examples in this manual show multiple repositories.

Creating a repository

See the instructions in the `INSTALL' file in the CVS distribution.

Remote repositories

Your working copy of the sources can be on a different machine than the repository. Generally, using a remote repository is just like using a local one, except that the format of the repository name is:

```
user@hostname:/path/to/repository
```

The details of exactly what needs to be set up depend on how you are connecting to the server.

Connecting with rsh

CVS uses the `rsh' protocol to perform these operations, so the remote user host needs to have a `.rhosts' file which grants access to the local user.

For example, suppose you are the user `mozart' on the local machine `anklet.grunge.com', and the server machine is `chainsaw.brickyard.com'. On chainsaw, put the following line into the file `.rhosts' in `bach''s home directory:

```
anklet.grunge.com  mozart
```

Then test that `rsh` is working with

```
rsh -l bach chainsaw.brickyard.com echo $PATH
```

Next you have to make sure that `rsh` will be able to find the server. Make sure that the path which `rsh` printed in the above example includes the directory containing a program named `cvs` which is the server. You need to set the path in `.bashrc', `.cshrc', etc., not `.login' or `.profile'. Alternately, you can set the environment variable `CVS_SERVER` on the client machine to the filename of the server you want to use, for example `/usr/local/bin/cvs-1.6'.

There is no need to edit `inetd.conf` or start a CVS server daemon.

Continuing our example, supposing you want to access the module `foo' in the repository `/usr/local/cvsroot/', on machine `chainsaw.brickyard.com', you are ready to go:

```
cvs -d bach@chainsaw.brickyard.com:/user/local/cvsroot checkout foo
```

(The `bach@' can be omitted if the username is the same on both the local and remote hosts.)

Direct connection with password authentication

The CVS client can also connect to the server using a password protocol. This is particularly useful if using `rsh` is not feasible (for example, the server is behind a firewall), and Kerberos also is not available.

To use this method, it is necessary to make some adjustments on both the server and client sides.

Setting up the server for password authentication

On the server side, the file `/etc/inetd.conf' needs to be edited so `inetd` knows to run the command `cvs pserver` when it receives a connection on the right port. By default, the port number is 2401; it would be different if your client were compiled with `CVS_AUTH_PORT` defined to something else, though.

If your `inetd` allows raw port numbers in `/etc/inetd.conf', then the following (all on a single line in `inetd.conf') should be sufficient:

```
2401  stream  tcp  nowait  root  /usr/local/bin/cvs
cvs -b /usr/local/bin pserver
```

The `-b' option specifies the directory which contains the RCS binaries on the server.

If your `inetd` wants a symbolic service name instead of a raw port number, then put this in `/etc/services':

```
cvspserver      2401/tcp
```

and put `cvspserver` instead of `2401` in `inetd.conf'.

Once the above is taken care of, restart your `inetd`, or do whatever is necessary to force it to reread its initialization files.

Because the client stores and transmits passwords in cleartext (almost--see section Security considerations with password authentication for details), a separate CVS password file may be used, so people don't compromise their regular passwords when they access the repository. This file is `$CVSROOT/CVSROOT/passwd' (see section The administrative files). Its format is similar to `/etc/passwd', except that it only has two fields, username and password. For example:

```
bach:ULtgRLXo7NRxs
cwang:1sOp854gDF3DY
```

The password is encrypted according to the standard Unix `crypt()` function, so it is possible to paste in passwords directly from regular Unix `passwd' files.

When authenticating a password, the server first checks for the user in the CVS `passwd' file. If it finds the

user, it compares against that password. If it does not find the user, or if the CVS `passwd' file does not, then the server tries to match the password using the system's user-lookup routine. When using the CVS `passwd' file, the server runs under as the username specified in the the third argument in the entry, or as the first argument if there is no third argument (in this way CVS allows imaginary usernames provided the CVS `passwd' file indicates corresponding valid system usernames). In any case, CVS will have no privileges which the (valid) user would not have.

Right now, the only way to put a password in the CVS `passwd' file is to paste it there from somewhere else. Someday, there may be a `cvs passwd` command.

Using the client with password authentication

Before connecting to the server, the client must log in with the command `cvs login`. Logging in verifies a password with the server, and also records the password for later transactions with the server. The `cvs login` command needs to know the username, server hostname, and full repository path, and it gets this information from the repository argument or the `CVSROOT` environment variable.

`cvs login` is interactive -- it prompts for a password:

```
cvs -d bach@chainsaw.brickyard.com:/usr/local/cvsroot login
CVS password:
```

The password is checked with the server; if it is correct, the `login` succeeds, else it fails, complaining that the password was incorrect.

Once you have logged in, you can force CVS to connect directly to the server and authenticate with the stored password by prefixing the repository with `:pserver:':

```
cvs -d :pserver:bach@chainsaw.brickyard.com:/usr/local/cvsroot checkout foo
```

The `:pserver:' is necessary because without it, CVS will assume it should use `rsh` to connect with the server (see section Connecting with rsh). (Once you have a working copy checked out and are running CVS commands from within it, there is no longer any need to specify the repository explicitly, because CVS records it in the working copy's `CVS' subdirectory.)

Passwords are stored by default in the file `$HOME/.cvspass'. Its format is human-readable, but don't edit it unless you know what you are doing. The passwords are not stored in cleartext, but are trivially encoded to protect them from "innocent" compromise (i.e., inadvertently being seen by a system administrator who happens to look at that file).

The `CVS_PASSFILE` environment variable overrides this default. If you use this variable, make sure you set it *before* `cvs login` is run. If you were to set it after running `cvs login`, then later CVS commands would be unable to look up the password for transmission to the server.

The `CVS_PASSWORD` environment variable overrides *all* stored passwords. If it is set, CVS will use it for all password-authenticated connections.

Security considerations with password authentication

The passwords are stored on the client side in a trivial encoding of the cleartext, and transmitted in the same encoding. The encoding is done only to prevent inadvertent password compromises (i.e., a system administrator

accidentally looking at the file), and will not prevent even a naive attacker from gaining the password.

The separate CVS password file (see section Setting up the server for password authentication) allows people to use a different password for repository access than for login access. On the other hand, once a user has access to the repository, she can execute programs on the server system through a variety of means. Thus, repository access implies fairly broad system access as well. It might be possible to modify CVS to prevent that, but no one has done so as of this writing. Furthermore, there may be other ways in which having access to CVS allows people to gain more general access to the system; noone has done a careful audit.

In summary, anyone who gets the password gets repository access, and some measure of general system access as well. The password is available to anyone who can sniff network packets or read a protected (i.e., user read-only) file. If you want real security, get Kerberos.

Direct connection with kerberos

The main disadvantage of using rsh is that all the data needs to pass through additional programs, so it may be slower. So if you have kerberos installed you can connect via a direct TCP connection, authenticating with kerberos (note that the data transmitted is *not* encrypted).

To do this, CVS needs to be compiled with kerberos support; when configuring CVS it tries to detect whether kerberos is present or you can use the `--with-krb4' flag to configure.

You need to edit `inetd.conf` on the server machine to run `cvs kserver`. The client uses port 1999 by default; if you want to use another port specify it in the `CVS_CLIENT_PORT` environment variable on the client. Set `CVS_CLIENT_PORT` to `-1' to force an rsh connection.

When you want to use CVS, get a ticket in the usual way (generally `kinit`); it must be a ticket which allows you to log into the server machine. Then you are ready to go:

```
cvs -d chainsaw.brickyard.com:/user/local/cvsroot checkout foo
```

If CVS fails to connect, it will fall back to trying rsh.

Go to the previous, next section.

Go to the previous, next section.

Starting a project with CVS

Since CVS 1.x is bad at renaming files and moving them between directories, the first thing you do when you start a new project should be to think through your file organization. It is not impossible--just awkward--to rename or move files. See section Moving and renaming files.

What to do next depends on the situation at hand.

Setting up the files

The first step is to create the files inside the repository. This can be done in a couple of different ways.

Creating a module from a number of files

When you begin using CVS, you will probably already have several projects that can be put under CVS control. In these cases the easiest way is to use the `import` command. An example is probably the easiest way to explain how to use it. If the files you want to install in CVS reside in `dir', and you want them to appear in the repository as `$CVSROOT/yoyodyne/dir', you can do this:

```
$ cd dir
$ cvs import -m "Imported sources" yoyodyne/dir yoyo start
```

Unless you supply a log message with the `-m' flag, CVS starts an editor and prompts for a message. The string `yoyo' is a vendor tag, and `start' is a release tag. They may fill no purpose in this context, but since CVS requires them they must be present. See section Tracking third-party sources, for more information about them.

You can now verify that it worked, and remove your original source directory.

```
$ cd ..
$ mv dir dir.orig
$ cvs checkout yoyodyne/dir       # Explanation below
$ ls -R yoyodyne
$ rm -r dir.orig
```

Erasing the original sources is a good idea, to make sure that you do not accidentally edit them in dir, bypassing CVS. Of course, it would be wise to make sure that you have a backup of the sources before you remove them.

The `checkout` command can either take a module name as argument (as it has done in all previous examples) or a path name relative to `$CVSROOT`, as it did in the example above.

It is a good idea to check that the permissions CVS sets on the directories inside `$CVSROOT' are

reasonable, and that they belong to the proper groups. See section File permissions.

Creating Files From Other Version Control Systems

If you have a project which you are maintaining with another version control system, such as RCS, you may wish to put the files from that project into CVS, and preserve the revision history of the files.

From RCS

> If you have been using RCS, find the RCS files--usually a file named `foo.c' will have its RCS file in `RCS/foo.c,v' (but it could be other places; consult the RCS documentation for details). Then create the appropriate directories in CVS if they do not already exist. Then copy the files into the appropriate directories in the CVS repository (the name in the repository must be the name of the source file with `,v' added; the files go directly in the appopriate directory of the repository, not in an `RCS' subdirectory). This is one of the few times when it is a good idea to access the CVS repository directly, rather than using CVS commands. Then you are ready to check out a new working directory.

From another version control system

> Many version control systems have the ability to export RCS files in the standard format. If yours does, export the RCS files and then follow the above instructions.

From SCCS

> There is a script in the `contrib' directory of the CVS source distribution called `sccs2rcs' which converts SCCS files to RCS files. Note: you must run it on a machine which has both SCCS and RCS installed, and like everything else in contrib it is unsupported (your mileage may vary).

Creating a module from scratch

For a new project, the easiest thing to do is probably to create an empty directory structure, like this:

```
$ mkdir tc
$ mkdir tc/man
$ mkdir tc/testing
```

After that, you use the `import` command to create the corresponding (empty) directory structure inside the repository:

```
$ cd tc
$ cvs import -m "Created directory structure" yoyodyne/dir yoyo start
```

Then, use `add` to add files (and new directories) as they appear.

Check that the permissions CVS sets on the directories inside `$CVSROOT' are reasonable.

Defining the module

The next step is to define the module in the `modules' file. This is not strictly necessary, but modules can be convenient in grouping together related files and directories.

In simple cases these steps are sufficient to define a module.

1. Get a working copy of the modules file.

   ```
   $ cvs checkout modules
   $ cd modules
   ```

2. Edit the file and insert a line that defines the module. See section The administrative files, for an introduction. See section The modules file, for a full description of the modules file. You can use the following line to define the module `tc':

   ```
   tc   yoyodyne/tc
   ```

3. Commit your changes to the modules file.

   ```
   $ cvs commit -m "Added the tc module." modules
   ```

4. Release the modules module.

   ```
   $ cd ..
   $ cvs release -d modules
   ```

Go to the previous, next section.

Go to the previous, next section.

Multiple developers

When more than one person works on a software project things often get complicated. Often, two people try to edit the same file simultaneously. Some other version control systems (including RCS and SCCS) try to solve that particular problem by introducing file locking, so that only one person can edit each file at a time. Unfortunately, file locking can be very counter-productive. If two persons want to edit different parts of a file, there may be no reason to prevent either of them from doing so.

CVS does not use file locking. Instead, it allows many people to edit their own working copy of a file simultaneously. The first person that commits his changes has no automatic way of knowing that another has started to edit it. Others will get an error message when they try to commit the file. They must then use CVS commands to bring their working copy up to date with the repository revision. This process is almost automatic, and explained in this chapter.

There are many ways to organize a team of developers. CVS does not try to enforce a certain organization. It is a tool that can be used in several ways. It is often useful to inform the group of commits you have done. CVS has several ways of automating that process. See section Informing others about commits. See section Revision management, for more tips on how to use CVS.

File status

After you have checked out a file out from CVS, it is in one of these four states:

Up-to-date
: The file is identical with the latest revision in the repository.

Locally modified
: You have edited the file, and not yet committed your changes.

Needing update
: Someone else has committed a newer revision to the repository.

Needing merge
: Someone else have committed a newer revision to the repository, and you have also made modifications to the file.

You can use the `status` command to find out the status of a given file. See section status--Status info on the revisions.

Bringing a file up to date

When you want to update or merge a file, use the `update` command. For files that are not up to date this is roughly equivalent to a `checkout` command: the newest revision of the file is extracted from the repository and put in your working copy of the module.

Your modifications to a file are never lost when you use `update`. If no newer revision exists, running

`update` has no effect. If you have edited the file, and a newer revision is available, CVS will merge all changes into your working copy.

For instance, imagine that you checked out revision 1.4 and started editing it. In the meantime someone else committed revision 1.5, and shortly after that revision 1.6. If you run `update` on the file now, CVS will incorporate all changes between revision 1.4 and 1.6 into your file.

If any of the changes between 1.4 and 1.6 were made too close to any of the changes you have made, an overlap occurs. In such cases a warning is printed, and the resulting file includes both versions of the lines that overlap, delimited by special markers. See section update--Bring work tree in sync with repository, for a complete description of the `update` command.

Conflicts example

Suppose revision 1.4 of `` `driver.c' `` contains this:

```
#include <stdio.h>

void main()
{
    parse();
    if (nerr == 0)
        gencode();
    else
        fprintf(stderr, "No code generated.\n");
    exit(nerr == 0 ? 0 : 1);
}
```

Revision 1.6 of `` `driver.c' `` contains this:

```
#include <stdio.h>

int main(int argc,
         char **argv)
{
    parse();
    if (argc != 1)
    {
        fprintf(stderr, "tc: No args expected.\n");
        exit(1);
    }
    if (nerr == 0)
        gencode();
    else
        fprintf(stderr, "No code generated.\n");
    exit(!!nerr);
}
```

Your working copy of `driver.c', based on revision 1.4, contains this before you run `cvs update':

```
#include <stdlib.h>
#include <stdio.h>

void main()
{
    init_scanner();
    parse();
    if (nerr == 0)
        gencode();
    else
        fprintf(stderr, "No code generated.\n");
    exit(nerr == 0 ? EXIT_SUCCESS : EXIT_FAILURE);
}
```

You run `cvs update':

```
$ cvs update driver.c
RCS file: /usr/local/cvsroot/yoyodyne/tc/driver.c,v
retrieving revision 1.4
retrieving revision 1.6
Merging differences between 1.4 and 1.6 into driver.c
rcsmerge warning: overlaps during merge
cvs update: conflicts found in driver.c
C driver.c
```

CVS tells you that there were some conflicts. Your original working file is saved unmodified in `.#driver.c.1.4'. The new version of `driver.c' contains this:

```
#include <stdlib.h>
#include <stdio.h>

int main(int argc,
         char **argv)
{
    init_scanner();
    parse();
    if (argc != 1)
    {
        fprintf(stderr, "tc: No args expected.\n");
        exit(1);
    }
    if (nerr == 0)
        gencode();
    else
        fprintf(stderr, "No code generated.\n");
<<<<<<< driver.c
```

```
    exit(nerr == 0 ? EXIT_SUCCESS : EXIT_FAILURE);
=======
    exit(!!nerr);
>>>>>>> 1.6
}
```

Note how all non-overlapping modifications are incorporated in your working copy, and that the overlapping section is clearly marked with `<<<<<<<', `=======' and `>>>>>>>'.

You resolve the conflict by editing the file, removing the markers and the erroneous line. Suppose you end up with this file:

```
#include <stdlib.h>
#include <stdio.h>

int main(int argc,
         char **argv)
{
    init_scanner();
    parse();
    if (argc != 1)
    {
        fprintf(stderr, "tc: No args expected.\n");
        exit(1);
    }
    if (nerr == 0)
        gencode();
    else
        fprintf(stderr, "No code generated.\n");
    exit(nerr == 0 ? EXIT_SUCCESS : EXIT_FAILURE);
}
```

You can now go ahead and commit this as revision 1.7.

```
$ cvs commit -m "Initialize scanner. Use symbolic exit values." driver.c
Checking in driver.c;
/usr/local/cvsroot/yoyodyne/tc/driver.c,v  <--  driver.c
new revision: 1.7; previous revision: 1.6
done
```

If you use release 1.04 or later of pcl-cvs (a GNU Emacs front-end for CVS) you can use an Emacs package called emerge to help you resolve conflicts. See the documentation for pcl-cvs.

Informing others about commits

It is often useful to inform others when you commit a new revision of a file. The `-i' option of the `modules' file, or the `loginfo' file, can be used to automate this process. See section The modules file. See section Loginfo. You can use these features of CVS to, for instance, instruct CVS to mail a message to all

developers, or post a message to a local newsgroup.

Several developers simultaneously attempting to run CVS

If several developers try to run CVS at the same time, one may get the following message:

```
[11:43:23] waiting for bach's lock in /usr/local/cvsroot/foo
```

CVS will try again every 30 seconds, and either continue with the operation or print the message again, if it still needs to wait. If a lock seems to stick around for an undue amount of time, find the person holding the lock and ask them about the cvs command they are running. If they aren't running a cvs command, look for and remove files starting with `` `#cvs.tfl' ``, `` `#cvs.rfl' ``, or `` `#cvs.wfl' `` from the repository.

Note that these locks are to protect CVS's internal data structures and have no relationship to the word lock in the sense used by RCS--a way to prevent other developers from working on a particular file.

Any number of people can be reading from a given repository at a time; only when someone is writing do the locks prevent other people from reading or writing.

One might hope for the following property

```
If someone commits some changes in one cvs command,
then an update by someone else will either get all the
changes, or none of them.
```

but CVS does *not* have this property. For example, given the files

```
a/one.c
a/two.c
b/three.c
b/four.c
```

if someone runs

```
cvs ci a/two.c b/three.c
```

and someone else runs `cvs update` at the same time, the person running `update` might get only the change to `` `b/three.c' `` and not the change to `` `a/two.c' ``.

Mechanisms to track who is editing files

For many groups, use of CVS in its default mode is perfectly satisfactory. Users may sometimes go to check in a modification only to find that another modification has intervened, but they deal with it and proceed with their check in. Other groups prefer to be able to know who is editing what files, so that if two people try to edit the same file they can choose to talk about who is doing what when rather than be surprised at check in time. The features in this section allow such coordination, while retaining the ability of two developers to edit the

same file at the same time.

For maximum benefit developers should use `cvs edit` (not `chmod`) to make files read-write to edit them, and `cvs release` (not `rm`) to discard a working directory which is no longer in use, but CVS is not able to enforce this behavior.

Telling CVS to watch certain files

To enable the watch features, you first specify that certain files are to be watched.

Command: **cvs watch on** *[-l] files ...*

Specify that developers should run `cvs edit` before editing files. CVS will create working copies of files read-only, to remind developers to run the `cvs edit` command before working on them.

If files includes the name of a directory, CVS arranges to watch all files added to the corresponding repository directory, and sets a default for files added in the future; this allows the user to set notification policies on a per-directory basis. The contents of the directory are processed recursively, unless the `-l` option is given.

If files is omitted, it defaults to the current directory.

Command: **cvs watch off** *[-l] files ...*

Do not provide notification about work on files. CVS will create working copies of files read-write.

The files and `-l` arguments are processed as for `cvs watch on`.

Telling CVS to notify you

You can tell CVS that you want to receive notifications about various actions taken on a file. You can do this without using `cvs watch on` for the file, but generally you will want to use `cvs watch on`, so that developers use the `cvs edit` command.

Command: **cvs watch add** *[-a action] [-l] files ...*

Add the current user to the list of people to receive notification of work done on files.

The `-a` option specifies what kinds of events CVS should notify the user about. action is one of the following:

`edit`
: Another user has applied the `cvs edit` command (described below) to a file.

`unedit`
: Another user has applied the `cvs unedit` command (described below) or the `cvs release` command to a file, or has deleted the file and allowed `cvs update` to recreate it.

`commit`
: Another user has committed changes to a file.

`all`
: All of the above.

`none`
: None of the above. (This is useful with `cvs edit`, described below.)

The `-a` option may appear more than once, or not at all. If omitted, the action defaults to `all`.

The files and `-l` option are processed as for the `cvs watch` commands.

Command: **cvs watch remove** *[-a action] [-l] files ...*

Remove a notification request established using `cvs watch add`; the arguments are the same. If the `-a` option is present, only watches for the specified actions are removed.

When the conditions exist for notification, CVS calls the `` `notify' `` administrative file, passing it the user to receive the notification and the user who is taking the action which results in notification. Normally `` `notify' `` will just send an email message.

Note that if you set this up in the straightforward way, users receive notifications on the server machine. One could of course write a `` `notify' `` script which directed notifications elsewhere, but to make this easy, CVS allows you to associate a notification address for each user. To do so create a file `` `users' `` in `` `CVSROOT' `` with a line for each user in the format user:value. Then instead of passing the name of the user to be notified to `` `notify' ``, CVS will pass the value (normally an email address on some other machine).

How to edit a file which is being watched

Since a file which is being watched is checked out read-only, you cannot simply edit it. To make it read-write, and inform others that you are planning to edit it, use the `cvs edit` command.

Command: **cvs edit** *[options] files ...*

Prepare to edit the working files files. CVS makes the files read-write, and notifies users who have requested `edit` notification for any of files.

The `cvs edit` command accepts the same options as the `cvs watch add` command, and establishes a temporary watch for the user on files; CVS will remove the watch when files are `unedit`ed or `commit`ted. If the user does not wish to receive notifications, she should specify `-a none`.

The files and `-l` option are processed as for the `cvs watch` commands.

Normally when you are done with a set of changes, you use the `cvs commit` command, which checks in your changes and returns the watched files to their usual read-only state. But if you instead decide to abandon your changes, or not to make any changes, you can use the `cvs unedit` command.

Command: **cvs unedit** *[-l] files ...*

Abandon work on the working files files, and revert them to the repository versions on which they are based. CVS makes those files read-only for which users have requested notification using `cvs watch on`. CVS notifies users who have requested `unedit` notification for any of files.

The files and `-l` option are processed as for the `cvs watch` commands.

When using client/server CVS, you can use the `cvs edit` and `cvs unedit` commands even if CVS is unable to succesfully communicate with the server; the notifications will be sent upon the next successful CVS command.

Information about who is watching and editing

Command: **cvs watchers** *[-l] files ...*

List the users currently watching changes to files. The report includes the files being watched, and the mail address of each watcher.

The files and `-l` arguments are processed as for the `cvs watch` commands.

Command: **cvs editors** *[-l] files ...*

List the users currently working on files. The report includes the mail address of each user, the time when the user began working with the file, and the host and path of the working directory containing the file.

The files and `-l` arguments are processed as for the `cvs watch` commands.

Using watches with old versions of CVS

If you use the watch features on a repository, it creates `` `CVS' `` directories in the repository and stores the information about watches in that directory. If you attempt to use CVS 1.6 or earlier with the repository, you get an error message such as

```
cvs update: cannot open CVS/Entries for reading: No such file or directory
```

and your operation will likely be aborted. To use the watch features, you must upgrade all copies of CVS which use that repository in local or server mode. If you cannot upgrade, use the `watch off` and `watch remove` commands to remove all watches, and that will restore the repository to a state which CVS 1.6 can cope with.

Go to the previous, next section.

Go to the previous, next section.

Branches

So far, all revisions shown in this manual have been on the main trunk of the revision tree, i.e., all revision numbers have been of the form x.y. One useful feature, especially when maintaining several releases of a software product at once, is the ability to make branches on the revision tree. Tags, symbolic names for revisions, will also be introduced in this chapter.

Tags--Symbolic revisions

The revision numbers live a life of their own. They need not have anything at all to do with the release numbers of your software product. Depending on how you use CVS the revision numbers might change several times between two releases. As an example, some of the source files that make up RCS 5.6 have the following revision numbers:

```
ci.c            5.21
co.c            5.9
ident.c         5.3
rcs.c           5.12
rcsbase.h       5.11
rcsdiff.c       5.10
rcsedit.c       5.11
rcsfcmp.c       5.9
rcsgen.c        5.10
rcslex.c        5.11
rcsmap.c        5.2
rcsutil.c       5.10
```

You can use the `tag` command to give a symbolic name to a certain revision of a file. You can use the `-v' flag to the `status` command to see all tags that a file has, and which revision numbers they represent. Tag names can contain uppercase and lowercase letters, digits, `-', and `_'. The two tag names BASE and HEAD are reserved for use by CVS. It is expected that future names which are special to CVS will contain characters such as `%' or `=', rather than being named analogously to BASE and HEAD, to avoid conflicts with actual tag names.

The following example shows how you can add a tag to a file. The commands must be issued inside your working copy of the module. That is, you should issue the command in the directory where `backend.c' resides.

```
$ cvs tag release-0-4 backend.c
T backend.c
$ cvs status -v backend.c
===================================================================
File: backend.c         Status: Up-to-date
```

```
    Version:            1.4     Tue Dec  1 14:39:01 1992
    RCS Version:        1.4     /usr/local/cvsroot/yoyodyne/tc/backend.
    Sticky Tag:         (none)
    Sticky Date:        (none)
    Sticky Options:     (none)

    Existing Tags:
        release-0-4                     (revision: 1.4)
```

There is seldom reason to tag a file in isolation. A more common use is to tag all the files that constitute a module with the same tag at strategic points in the development life-cycle, such as when a release is made.

```
$ cvs tag release-1-0 .
cvs tag: Tagging .
T Makefile
T backend.c
T driver.c
T frontend.c
T parser.c
```

(When you give CVS a directory as argument, it generally applies the operation to all the files in that directory, and (recursively), to any subdirectories that it may contain. See section Recursive behavior.)

The `checkout` command has a flag, `-r', that lets you check out a certain revision of a module. This flag makes it easy to retrieve the sources that make up release 1.0 of the module `tc' at any time in the future:

```
$ cvs checkout -r release-1-0 tc
```

This is useful, for instance, if someone claims that there is a bug in that release, but you cannot find the bug in the current working copy.

You can also check out a module as it was at any given date. See section checkout options.

When you tag more than one file with the same tag you can think about the tag as "a curve drawn through a matrix of filename vs. revision number." Say we have 5 files with the following revisions:

```
        file1   file2   file3   file4   file5

        1.1     1.1     1.1     1.1  /--1.1*      <-*-  TAG
        1.2*-   1.2     1.2    -1.2*-
        1.3  \- 1.3*-   1.3   / 1.3
        1.4         \   1.4  /  1.4
                     \-1.5*-   1.5
                       1.6
```

At some time in the past, the * versions were tagged. You can think of the tag as a handle attached to the curve drawn through the tagged revisions. When you pull on the handle, you get all the tagged revisions. Another way to look at it is that you "sight" through a set of revisions that is "flat" along the tagged revisions,

like this:

```
        file1   file2   file3   file4   file5

                        1.1
                        1.2
                1.1     1.3                      _
        1.1     1.2     1.4     1.1              /
        1.2*----1.3*----1.5*----1.2*----1.1     (--- <--- Look here
        1.3             1.6     1.3              \_
        1.4                     1.4
                                1.5
```

What branches are good for

Suppose that release 1.0 of tc has been made. You are continuing to develop tc, planning to create release 1.1 in a couple of months. After a while your customers start to complain about a fatal bug. You check out release 1.0 (see section Tags--Symbolic revisions) and find the bug (which turns out to have a trivial fix). However, the current revision of the sources are in a state of flux and are not expected to be stable for at least another month. There is no way to make a bugfix release based on the newest sources.

The thing to do in a situation like this is to create a branch on the revision trees for all the files that make up release 1.0 of tc. You can then make modifications to the branch without disturbing the main trunk. When the modifications are finished you can select to either incorporate them on the main trunk, or leave them on the branch.

Creating a branch

The `rtag` command can be used to create a branch. The `rtag` command is much like `tag`, but it does not require that you have a working copy of the module. See section rtag--Add a tag to the RCS file. (You can also use the `tag` command; see section tag--Add a symbolic tag to checked out version of RCS file).

```
$ cvs rtag -b -r release-1-0 release-1-0-patches tc
```

The `-b' flag makes `rtag` create a branch (rather than just a symbolic revision name). `-r release-1-0' says that this branch should be rooted at the node (in the revision tree) that corresponds to the tag `release-1-0'. Note that the numeric revision number that matches `release-1-0' will probably be different from file to file. The name of the new branch is `release-1-0-patches', and the module affected is `tc'.

To fix the problem in release 1.0, you need a working copy of the branch you just created.

```
$ cvs checkout -r release-1-0-patches tc
$ cvs status -v driver.c backend.c
===================================================================
File: driver.c          Status: Up-to-date
```

```
    Version:            1.7     Sat Dec  5 18:25:54 1992
    RCS Version:        1.7     /usr/local/cvsroot/yoyodyne/tc/driver.c
    Sticky Tag:         release-1-0-patches (branch: 1.7.2)
    Sticky Date:        (none)
    Sticky Options:     (none)

    Existing Tags:
        release-1-0-patches             (branch: 1.7.2)
        release-1-0                     (revision: 1.7)

===================================================================
File: backend.c         Status: Up-to-date

    Version:            1.4     Tue Dec  1 14:39:01 1992
    RCS Version:        1.4     /usr/local/cvsroot/yoyodyne/tc/backend.c,v
    Sticky Tag:         release-1-0-patches (branch: 1.4.2)
    Sticky Date:        (none)
    Sticky Options:     (none)

    Existing Tags:
        release-1-0-patches             (branch: 1.4.2)
        release-1-0                     (revision: 1.4)
        release-0-4                     (revision: 1.4)
```

As the output from the `status` command shows the branch number is created by adding a digit at the tail of the revision number it is based on. (If `release-1-0' corresponds to revision 1.4, the branch's revision number will be 1.4.2. For obscure reasons CVS always gives branches even numbers, starting at 2. See section Revision numbers).

Sticky tags

The `-r release-1-0-patches' flag that was given to `checkout` in the previous example is sticky, that is, it will apply to subsequent commands in this directory. If you commit any modifications, they are committed on the branch. You can later merge the modifications into the main trunk. See section Merging.

You can use the `status` command to see what sticky tags or dates are set:

```
$ vi driver.c   # Fix the bugs
$ cvs commit -m "Fixed initialization bug" driver.c
Checking in driver.c;
/usr/local/cvsroot/yoyodyne/tc/driver.c,v  <--  driver.c
new revision: 1.7.2.1; previous revision: 1.7
done
$ cvs status -v driver.c
===================================================================
File: driver.c          Status: Up-to-date
```

```
   Version:            1.7.2.1 Sat Dec  5 19:35:03 1992
   RCS Version:        1.7.2.1 /usr/local/cvsroot/yoyodyne/tc/driver.c,v
   Sticky Tag:         release-1-0-patches (branch: 1.7.2)
   Sticky Date:        (none)
   Sticky Options:     (none)

   Existing Tags:
       release-1-0-patches             (branch: 1.7.2)
       release-1-0                     (revision: 1.7)
```

The sticky tags will remain on your working files until you delete them with `cvs update -A'. The `-A' option retrieves the version of the file from the head of the trunk, and forgets any sticky tags, dates, or options.

Sticky tags are not just for branches. If you check out a certain revision (such as 1.4) it will also become sticky. Subsequent `cvs update' will not retrieve the latest revision until you reset the tag with `cvs update -A'. Likewise, use of the `-D' option to `update` or `checkout` sets a sticky date, which, similarly, causes that date to be used for future retrievals.

Many times you will want to retrieve an old version of a file without setting a sticky tag. The way to do that is with the `-p' option to `checkout` or `update`, which sends the contents of the file to standard output. For example, suppose you have a file named `file1' which existed as revision 1.1, and you then removed it (thus adding a dead revision 1.2). Now suppose you want to add it again, with the same contents it had previously. Here is how to do it:

```
$ cvs update -p -r 1.1 file1 >file1
===================================================================
Checking out file1
RCS:  /tmp/cvs-sanity/cvsroot/first-dir/Attic/file1,v
VERS: 1.1
***************
$ cvs add file1
cvs add: version 1.2 of `file1' will be resurrected
cvs add: use 'cvs commit' to add this file permanently
$ cvs commit -m test
Checking in file1;
/tmp/cvs-sanity/cvsroot/first-dir/file1,v  <--  file1
new revision: 1.3; previous revision: 1.2
done
$
```

Go to the previous, next section.

Go to the previous, next section.

Merging

You can include the changes made between any two revisions into your working copy, by merging. You can then commit that revision, and thus effectively copy the changes onto another branch.

Merging an entire branch

You can merge changes made on a branch into your working copy by giving the `-j branch' flag to the `update` command. With one `-j branch' option it merges the changes made between the point where the branch forked and newest revision on that branch (into your working copy).

The `-j' stands for "join".

Consider this revision tree:

```
+-----+    +-----+    +-----+    +-----+
! 1.1 !----! 1.2 !----! 1.3 !----! 1.4 !      <- The main trunk
+-----+    +-----+    +-----+    +-----+
                !
                !
                !   +---------+    +---------+
Branch R1fix -> +---! 1.2.2.1 !----! 1.2.2.2 !
                    +---------+    +---------+
```

The branch 1.2.2 has been given the tag (symbolic name) `R1fix'. The following example assumes that the module `mod' contains only one file, `m.c'.

```
$ cvs checkout mod                # Retrieve the latest revision, 1.4

$ cvs update -j R1fix m.c         # Merge all changes made on the branch,
                                  # i.e. the changes between revision 1.2
                                  # and 1.2.2.2, into your working copy
                                  # of the file.

$ cvs commit -m "Included R1fix" # Create revision 1.5.
```

A conflict can result from a merge operation. If that happens, you should resolve it before committing the new revision. See section Conflicts example.

The `checkout` command also supports the `-j branch' flag. The same effect as above could be achieved with this:

```
$ cvs checkout -j R1fix mod
$ cvs commit -m "Included R1fix"
```

Merging from a branch several times

Continuing our example, the revision tree now looks like this:

```
+-----+    +-----+    +-----+    +-----+    +-----+
! 1.1 !----! 1.2 !----! 1.3 !----! 1.4 !----! 1.5 !      <- The main trunk
+-----+    +-----+    +-----+    +-----+    +-----+
                !                             *
                !                           *
                !   +---------+    +---------+
Branch R1fix -> +---! 1.2.2.1 !----! 1.2.2.2 !
                    +---------+    +---------+
```

where the starred line represents the merge from the `R1fix' branch to the main trunk, as just discussed.

Now suppose that development continues on the `R1fix' branch:

```
+-----+    +-----+    +-----+    +-----+    +-----+
! 1.1 !----! 1.2 !----! 1.3 !----! 1.4 !----! 1.5 !      <- The main trunk
+-----+    +-----+    +-----+    +-----+    +-----+
                !                             *
                !                           *
                !   +---------+    +---------+    +---------+
Branch R1fix -> +---! 1.2.2.1 !----! 1.2.2.2 !----! 1.2.2.3 !
                    +---------+    +---------+    +---------+
```

and then you want to merge those new changes onto the main trunk. If you just use the `cvs update -j R1fix m.c` command again, CVS will attempt to merge again the changes which you have already merged, which can have undesirable side effects.

So instead you need to specify that you only want to merge the changes on the branch which have not yet been merged into the trunk. To do that you specify two `-j' options, and CVS merges the changes from the first revision to the second revision. For example, in this case the simplest way would be

```
cvs update -j 1.2.2.2 -j R1fix m.c    # Merge changes from 1.2.2.2 to the
                                      # head of the R1fix branch
```

The problem with this is that you need to specify the 1.2.2.2 revision manually. A slightly better approach might be to use the date the last merge was done:

```
cvs update -j R1fix:yesterday -j R1fix m.c
```

Better yet, tag the R1fix branch after every merge into the trunk, and then use that tag for subsequent merges:

```
cvs update -j merged_from_R1fix_to_trunk -j R1fix m.c
```

Merging differences between any two revisions

With two `-j revision' flags, the `update` (and `checkout`) command can merge the differences between any two revisions into your working file.

```
$ cvs update -j 1.5 -j 1.3 backend.c
```

will *remove* all changes made between revision 1.3 and 1.5. Note the order of the revisions!

If you try to use this option when operating on multiple files, remember that the numeric revisions will probably be very different between the various files that make up a module. You almost always use symbolic tags rather than revision numbers when operating on multiple files.

Go to the previous, next section.

Go to the previous, next section.

Recursive behavior

Almost all of the subcommands of CVS work recursively when you specify a directory as an argument. For instance, consider this directory structure:

```
$HOME
  |
  +--tc
  |   |
      +--CVS
      |      (internal CVS files)
      +--Makefile
      +--backend.c
      +--driver.c
      +--frontend.c
      +--parser.c
      +--man
      |    |
      |    +--CVS
      |    |  (internal CVS files)
      |    +--tc.1
      |
      +--testing
           |
           +--CVS
           |  (internal CVS files)
           +--testpgm.t
           +--test2.t
```

If `tc' is the current working directory, the following is true:

- `cvs update testing' is equivalent to `cvs update testing/testpgm.t testing/test2.t'
- `cvs update testing man' updates all files in the subdirectories
- `cvs update .' or just `cvs update' updates all files in the `tc` module

If no arguments are given to `update` it will update all files in the current working directory and all its subdirectories. In other words, `.' is a default argument to `update`. This is also true for most of the CVS subcommands, not only the `update` command.

The recursive behavior of the CVS subcommands can be turned off with the `-l' option.

```
$ cvs update -l         # Don't update files in subdirectories
```

Go to the previous, next section.

Adding files to a module

To add a new file to a module, follow these steps.

- You must have a working copy of the module. See section Getting the source.
- Create the new file inside your working copy of the module.
- Use `cvs add filename' to tell CVS that you want to version control the file.
- Use `cvs commit filename' to actually check in the file into the repository. Other developers cannot see the file until you perform this step.
- If the file contains binary data it might be necessary to change the default keyword substitution. See section Keyword substitution. See section admin examples.

You can also use the `add` command to add a new directory inside a module.

Unlike most other commands, the `add` command is not recursive. You cannot even type `cvs add foo/bar'! Instead, you have to

```
$ cd foo
$ cvs add bar
```

See section add--Add a new file/directory to the repository, for a more complete description of the `add` command.

Go to the previous, next section.

Go to the previous, next section.

Removing files from a module

Modules change. New files are added, and old files disappear. Still, you want to be able to retrieve an exact copy of old releases of the module.

Here is what you can do to remove a file from a module, but remain able to retrieve old revisions:

- Make sure that you have not made any uncommitted modifications to the file. See section Viewing differences, for one way to do that. You can also use the `status` or `update` command. If you remove the file without committing your changes, you will of course not be able to retrieve the file as it was immediately before you deleted it.
- Remove the file from your working copy of the module. You can for instance use `rm`.
- Use `cvs remove filename' to tell CVS that you really want to delete the file.
- Use `cvs commit filename' to actually perform the removal of the file from the repository.

When you commit the removal of the file, CVS records the fact that the file no longer exists. It is possible for a file to exist on only some branches and not on others, or to re-add another file with the same name later. CVS will correctly create or not create the file, based on the `-r' and `-D' options specified to `checkout` or `update`.

Command: **cvs remove** *[-lR] files ...*

Schedule file(s) to be removed from the repository (files which have not already been removed from the working directory are not processed). This command does not actually remove the file from the repository until you commit the removal. The `-R' option (the default) specifies that it will recurse into subdirectories; `-l' specifies that it will not.

Here is an example of removing several files:

```
$ cd test
$ rm ?.c
$ cvs remove
cvs remove: Removing .
cvs remove: scheduling a.c for removal
cvs remove: scheduling b.c for removal
cvs remove: use 'cvs commit' to remove these files permanently
$ cvs ci -m "Removed unneeded files"
cvs commit: Examining .
cvs commit: Committing .
```

If you change your mind you can easily resurrect the file before you commit it, using the `add` command.

```
$ ls
```

```
CVS   ja.h  oj.c
$ rm oj.c
$ cvs remove oj.c
cvs remove: scheduling oj.c for removal
cvs remove: use 'cvs commit' to remove this file permanently
$ cvs add oj.c
U oj.c
cvs add: oj.c, version 1.1.1.1, resurrected
```

If you realize your mistake before you run the `remove` command you can use `update` to resurrect the file:

```
$ rm oj.c
$ cvs update oj.c
cvs update: warning: oj.c was lost
U oj.c
```

Go to the previous, next section.

Go to the previous, next section.

Tracking third-party sources

If you modify a program to better fit your site, you probably want to include your modifications when the next release of the program arrives. CVS can help you with this task.

In the terminology used in CVS, the supplier of the program is called a vendor. The unmodified distribution from the vendor is checked in on its own branch, the vendor branch. CVS reserves branch 1.1.1 for this use.

When you modify the source and commit it, your revision will end up on the main trunk. When a new release is made by the vendor, you commit it on the vendor branch and copy the modifications onto the main trunk.

Use the `import` command to create and update the vendor branch. After a successful `import` the vendor branch is made the `head' revision, so anyone that checks out a copy of the file gets that revision. When a local modification is committed it is placed on the main trunk, and made the `head' revision.

Importing a module for the first time

Use the `import` command to check in the sources for the first time. When you use the `import` command to track third-party sources, the vendor tag and release tags are useful. The vendor tag is a symbolic name for the branch (which is always 1.1.1, unless you use the `-b branch' flag---See section import options). The release tags are symbolic names for a particular release, such as `FSF_0_04'.

Suppose you use `wdiff` (a variant of `diff` that ignores changes that only involve whitespace), and are going to make private modifications that you want to be able to use even when new releases are made in the future. You start by importing the source to your repository:

```
$ tar xfz wdiff-0.04.tar.gz
$ cd wdiff-0.04
$ cvs import -m "Import of FSF v. 0.04" fsf/wdiff FSF_DIST WDIFF_0_04
```

The vendor tag is named `FSF_DIST' in the above example, and the only release tag assigned is `WDIFF_0_04'.

Updating a module with the import command

When a new release of the source arrives, you import it into the repository with the same `import` command that you used to set up the repository in the first place. The only difference is that you specify a different release tag this time.

```
$ tar xfz wdiff-0.05.tar.gz
```

```
$ cd wdiff-0.05
$ cvs import -m "Import of FSF v. 0.05" fsf/wdiff FSF_DIST WDIFF_0_
```

For files that have not been modified locally, the newly created revision becomes the head revision. If you have made local changes, `import` will warn you that you must merge the changes into the main trunk, and tell you to use `checkout -j' to do so.

```
$ cvs checkout -jFSF_DIST:yesterday -jFSF_DIST wdiff
```

The above command will check out the latest revision of `wdiff', merging the changes made on the vendor branch `FSF_DIST' since yesterday into the working copy. If any conflicts arise during the merge they should be resolved in the normal way (see section Conflicts example). Then, the modified files may be committed.

Using a date, as suggested above, assumes that you do not import more than one release of a product per day. If you do, you can always use something like this instead:

```
$ cvs checkout -jWDIFF_0_04 -jWDIFF_0_05 wdiff
```

In this case, the two above commands are equivalent.

Go to the previous, next section.

Go to the previous, next section.

Moving and renaming files

Moving files to a different directory or renaming them is not difficult, but some of the ways in which this works may be non-obvious. (Moving or renaming a directory is even harder. See section Moving and renaming directories).

The examples below assume that the file old is renamed to new.

The Normal way to Rename

The normal way to move a file is to copy old to new, and then issue the normal CVS commands to remove old from the repository, and add new to it. (Both old and new could contain relative paths, for example `foo/bar.c').

```
$ mv old new
$ cvs remove old
$ cvs add new
$ cvs commit -m "Renamed old to new" old new
```

This is the simplest way to move a file, it is not error-prone, and it preserves the history of what was done. Note that to access the history of the file you must specify the old or the new name, depending on what portion of the history you are accessing. For example, `cvs log old` will give the log up until the time of the rename.

When new is committed its revision numbers will start at 1.0 again, so if that bothers you, use the `-r rev' option to commit (see section commit options)

Moving the history file

This method is more dangerous, since it involves moving files inside the repository. Read this entire section before trying it out!

```
$ cd $CVSROOT/module
$ mv old,v new,v
```

Advantages:

- The log of changes is maintained intact.
- The revision numbers are not affected.

Disadvantages:

- Old releases of the module cannot easily be fetched from the repository. (The file will show up as

new even in revisions from the time before it was renamed).

- There is no log information of when the file was renamed.
- Nasty things might happen if someone accesses the history file while you are moving it. Make sure no one else runs any of the CVS commands while you move it.

Copying the history file

This way also involves direct modifications to the repository. It is safe, but not without drawbacks.

```
# Copy the RCS file inside the repository
$ cd $CVSROOT/module
$ cp old,v new,v
# Remove the old file
$ cd ~/module
$ rm old
$ cvs remove old
$ cvs commit old
# Remove all tags from new
$ cvs update new
$ cvs log new              # Remember the tag names
$ cvs tag -d tag1
$ cvs tag -d tag2
...
```

By removing the tags you will be able to check out old revisions of the module.

Advantages:

- Checking out old revisions works correctly, as long as you use `-rtag' and not `-Ddate' to retrieve the revisions.
- The log of changes is maintained intact.
- The revision numbers are not affected.

Disadvantages:

- You cannot easily see the history of the file across the rename.
- Unless you use the `-r rev' (see section commit options) flag when new is committed its revision numbers will start at 1.0 again.

Go to the previous, next section.

Go to the previous, next section.

Moving and renaming directories

If you want to be able to retrieve old versions of the module, you must move each file in the directory with the CVS commands. See section The Normal way to Rename. The old, empty directory will remain inside the repository, but it will not appear in your workspace when you check out the module in the future.

If you really want to rename or delete a directory, you can do it like this:

1. Inform everyone who has a copy of the module that the directory will be renamed. They should commit all their changes, and remove their working copies of the module, before you take the steps below.
2. Rename the directory inside the repository.

   ```
   $ cd $CVSROOT/module
   $ mv old-dir new-dir
   ```
3. Fix the CVS administrative files, if necessary (for instance if you renamed an entire module).
4. Tell everyone that they can check out the module and continue working.

If someone had a working copy of the module the CVS commands will cease to work for him, until he removes the directory that disappeared inside the repository.

It is almost always better to move the files in the directory instead of moving the directory. If you move the directory you are unlikely to be able to retrieve old releases correctly, since they probably depend on the name of the directories.

Go to the previous, next section.

Go to the previous, next section.

History browsing

Once you have used CVS to store a version control history--what files have changed when, how, and by whom, there are a variety of mechanisms for looking through the history.

Log messages

Whenever you commit a file you specify a log message.

To look through the log messages which have been specified for every revision which has been committed, use the `cvs log` command (see section log--Print out 'rlog' information for files).

The history database

You can use the history file (see section The history file) to log various CVS actions. To retrieve the information from the history file, use the `cvs history` command (see section history--Show status of files and users).

User-defined logging

You can customize CVS to log various kinds of actions, in whatever manner you choose. These mechanisms operate by executing a script at various times. The script might append a message to a file listing the information and the programmer who created it, or send mail to a group of developers, or, perhaps, post a message to a particular newsgroup. To log commits, use the `` `loginfo' `` file (see section Loginfo). To log commits, checkouts, exports, and tags, respectively, you can also use the `-i', `-o', `-e', and `-t' options in the modules file. For a more flexible way of giving notifications to various users, which requires less in the way of keeping centralized scripts up to date, use the `cvs watch add` command (see section Telling CVS to notify you); this command is useful even if you are not using `cvs watch on`.

The `` `taginfo' `` file defines programs to execute when someone executes a `tag` or `rtag` command. The `` `taginfo' `` file has the standard form for administrative files (see section Reference manual for the Administrative files), where each line is a regular expression followed by a command to execute. The arguments passed to the command are, in order, the tagname, operation (`add` for `tag`, `mov` for `tag -F`, and `del` for `tag -d`), repository, and any remaining are pairs of filename revision. A non-zero exit of the filter program will cause the tag to be aborted.

Annotate command

Command: **cvs annotate** *[- l] files ...*

For each file in files, print the head revision of the trunk, together with information on the last modification for each line. The `-l` option means to process the local directory only, not to recurse (see section Common command options). For example:

```
$ cvs annotate ssfile
Annotations for ssfile
***************
1.1          (mary     27-Mar-96): ssfile line 1
1.2          (joe      28-Mar-96): ssfile line 2
```

The file `` `ssfile' `` currently contains two lines. The `ssfile line 1` line was checked in by `mary` on March 27. Then, on March 28, `joe` added a line `ssfile line 2`, without modifying the `ssfile line 1` line. This report doesn't tell you anything about lines which have been deleted or replaced; you need to use `cvs diff` for that (see section diff--Run diffs between revisions).

Go to the previous, next section.

Go to the previous, next section.

Keyword substitution

As long as you edit source files inside your working copy of a module you can always find out the state of your files via `cvs status' and `cvs log'. But as soon as you export the files from your development environment it becomes harder to identify which revisions they are.

RCS uses a mechanism known as keyword substitution (or keyword expansion) to help identifying the files. Embedded strings of the form `$keyword$` and `$keyword:...$` in a file are replaced with strings of the form `$keyword:value$` whenever you obtain a new revision of the file.

RCS Keywords

This is a list of the keywords that RCS currently (in release 5.6.0.1) supports:

`$Author$`

The login name of the user who checked in the revision.

`$Date$`

The date and time (UTC) the revision was checked in.

`$Header$`

A standard header containing the full pathname of the RCS file, the revision number, the date (UTC), the author, the state, and the locker (if locked). Files will normally never be locked when you use CVS.

`$Id$`

Same as `$Header$`, except that the RCS filename is without a path.

`$Locker$`

The login name of the user who locked the revision (empty if not locked, and thus almost always useless when you are using CVS).

`$Log$`

The log message supplied during commit, preceded by a header containing the RCS filename, the revision number, the author, and the date (UTC). Existing log messages are *not* replaced. Instead, the new log message is inserted after `$Log:...$`. Each new line is prefixed with a comment leader which RCS guesses from the file name extension. It can be changed with `cvs admin -c`. See section admin options. This keyword is useful for accumulating a complete change log in a source file, but for several reasons it can be problematic. See section Problems with the Log keyword..

`$RCSfile$`

The name of the RCS file without a path.

`$Revision$`

The revision number assigned to the revision.

`$Source$`

The full pathname of the RCS file.

`$State$`

The state assigned to the revision. States can be assigned with `cvs admin -s`---See section admin options.

Using keywords

To include a keyword string you simply include the relevant text string, such as `$Id$`, inside the file, and commit the file. CVS will automatically expand the string as part of the commit operation.

It is common to embed Id string in the C source code. This example shows the first few lines of a typical file, after keyword substitution has been performed:

```
static char *rcsid="$Id: samp.c,v 1.5 1993/10/19 14:57:32 ceder Exp $";
/* The following lines will prevent gcc version 2.x
   from issuing an "unused variable" warning. */
#if __GNUC__ == 2
#define USE(var) static void * use_##var = (&use_##var, (void *) &var)
USE (rcsid);
#endif
```

Even though a clever optimizing compiler could remove the unused variable `rcsid`, most compilers tend to include the string in the binary. Some compilers have a `#pragma` directive to include literal text in the binary.

The `ident` command (which is part of the RCS package) can be used to extract keywords and their values from a file. This can be handy for text files, but it is even more useful for extracting keywords from binary files.

```
$ ident samp.c
samp.c:
     $Id: samp.c,v 1.5 1993/10/19 14:57:32 ceder Exp $
$ gcc samp.c
$ ident a.out
a.out:
     $Id: samp.c,v 1.5 1993/10/19 14:57:32 ceder Exp $
```

SCCS is another popular revision control system. It has a command, `what`, which is very similar to `ident` and used for the same purpose. Many sites without RCS have SCCS. Since `what` looks for the character sequence `@(#)` it is easy to include keywords that are detected by either command. Simply prefix the RCS keyword with the magic SCCS phrase, like this:

```
static char *id="@(#) $Id: ab.c,v 1.5 1993/10/19 14:57:32 ceder Exp $";
```

Avoiding substitution

Keyword substitution has its disadvantages. Sometimes you might want the literal text string `$'Author$ to appear inside a file without RCS interpreting it as a keyword and expanding it into something like `$'Author: ceder $.

There is unfortunately no way to selectively turn off keyword substitution. You can use `-ko' (see section Substitution modes) to turn off keyword substitution entirely.

In many cases you can avoid using RCS keywords in the source, even though they appear in the final product. For example, the source for this manual contains `$@asis{}Author$' whenever the text `$'Author$ should appear. In `nroff` and `troff` you can embed the null-character \& inside the keyword for a similar effect.

Substitution modes

Each file has a stored default substitution mode, and each working directory copy of a file also has a substitution mode. The former is set by the `-k' option to `cvs add` and `cvs admin`; the latter is set by the -k or -A options to `cvs checkout` or `cvs update`. `cvs diff` also has a `-k' option. For some examples, See section Handling binary files.

The modes available are:

`-kkv'

Generate keyword strings using the default form, e.g. $Revision: 5.7 $ for the `Revision` keyword.

`-kkvl'

Like `-kkv', except that a locker's name is always inserted if the given revision is currently locked. This option is normally not useful when CVS is used.

`-kk'

Generate only keyword names in keyword strings; omit their values. For example, for the `Revision` keyword, generate the string $Revision$ instead of $Revision: 5.7 $. This option is useful to ignore differences due to keyword substitution when comparing different revisions of a file.

`-ko'

Generate the old keyword string, present in the working file just before it was checked in. For example, for the `Revision` keyword, generate the string $Revision: 1.1 $ instead of $Revision: 5.7 $ if that is how the string appeared when the file was checked in.

`-kb'

Like `-ko', but also inhibit conversion of line endings between the canonical form in which they are stored in the repository (linefeed only), and the form appropriate to the operating system in use on the client. For systems, like unix, which use linefeed only to terminate lines, this is the same as `-ko'. For more information on binary files, see section Handling binary files.

`-kv'

Generate only keyword values for keyword strings. For example, for the `Revision` keyword, generate the string `5.7` instead of $Revision: 5.7 $. This can help generate files in programming languages where it is hard to strip keyword delimiters like $Revision: $ from a string. However, further keyword substitution cannot be performed once the keyword names are removed, so this option should be used with care.

One often would like to use `-kv' with `cvs export`---see section export--Export sources from CVS, similar to checkout. But be aware that doesn't handle an export containing binary files correctly.

Problems with the Log keyword.

The Log keyword is somewhat controversial. As long as you are working on your development system the information is easily accessible even if you do not use the Log keyword--just do a `cvs log`. Once you export the file the history information might be useless anyhow.

A more serious concern is that RCS is not good at handling Log entries when a branch is merged onto the main trunk. Conflicts often result from the merging operation.

People also tend to "fix" the log entries in the file (correcting spelling mistakes and maybe even factual errors). If that is done the information from `cvs log` will not be consistent with the information inside the file. This may or may not be a problem in real life.

It has been suggested that the Log keyword should be inserted *last* in the file, and not in the files header, if it is to be used at all. That way the long list of change messages will not interfere with everyday source file browsing.

Go to the previous, next section.

Go to the previous, next section.

Handling binary files

There are two issues with using CVS to store binary files. The first is that CVS by default convert line endings between the canonical form in which they are stored in the repository (linefeed only), and the form appropriate to the operating system in use on the client (for example, carriage return followed by line feed for Windows NT).

The second is that a binary file might happen to contain data which looks like a keyword (see section Keyword substitution), so keyword expansion must be turned off.

The `-kb' option available with some CVS commands insures that neither line ending conversion nor keyword expansion will be done. If you are using an old version of RCS without this option, and you are using an operating system, such as unix, which terminates lines with linefeeds only, you can use `-ko' instead; if you are on another operating system, upgrade to a version of RCS, such as 5.7 or later, which supports `-kb'.

Here is an example of how you can create a new file using the `-kb' flag:

```
$ echo '$Id$' > kotest
$ cvs add -kb -m"A test file" kotest
$ cvs ci -m"First checkin; contains a keyword" kotest
```

If a file accidentally gets added without `-kb', one can use the `cvs admin` command to recover. For example:

```
$ echo '$Id$' > kotest
$ cvs add -m"A test file" kotest
$ cvs ci -m"First checkin; contains a keyword" kotest
$ cvs admin -kb kotest
$ cvs update -A kotest
```

When you check in the file `kotest' the keywords are expanded. (Try the above example, and do a `cat kotest` after every command). The `cvs admin -kb` command sets the default keyword substitution method for this file, but it does not alter the working copy of the file that you have. The easiest way to get the unexpanded version of `kotest' is `cvs update -A`.

Go to the previous, next section.

Revision management

If you have read this far, you probably have a pretty good grasp on what CVS can do for you. This chapter talks a little about things that you still have to decide.

If you are doing development on your own using CVS you could probably skip this chapter. The questions this chapter takes up become more important when more than one person is working in a repository.

When to commit?

Your group should decide which policy to use regarding commits. Several policies are possible, and as your experience with CVS grows you will probably find out what works for you.

If you commit files too quickly you might commit files that do not even compile. If your partner updates his working sources to include your buggy file, he will be unable to compile the code. On the other hand, other persons will not be able to benefit from the improvements you make to the code if you commit very seldom, and conflicts will probably be more common.

It is common to only commit files after making sure that they can be compiled. Some sites require that the files pass a test suite. Policies like this can be enforced using the commitinfo file (see section Commitinfo), but you should think twice before you enforce such a convention. By making the development environment too controlled it might become too regimented and thus counter-productive to the real goal, which is to get software written.

Reference manual for CVS commands

This appendix describes how to invoke CVS, and describes in detail those subcommands of CVS which are not fully described elsewhere. To look up a particular subcommand, see section Index.

Overall structure of CVS commands

The first release of CVS consisted of a number of shell-scripts. Today CVS is implemented as a single program that is a front-end to RCS and `diff`. The overall format of all CVS commands is:

```
cvs [ cvs_options ] cvs_command [ command_options ] [ command_args ]
```

`cvs`
: The program that is a front-end to RCS.

`cvs_options`
: Some options that affect all sub-commands of CVS. These are described below.

`cvs_command`
: One of several different sub-commands. Some of the commands have aliases that can be used instead; those aliases are noted in the reference manual for that command. There are only two situations where you may omit `cvs_command': `cvs -H' elicits a list of available commands, and `cvs -v' displays version information on CVS itself.

`command_options`
: Options that are specific for the command.

`command_args`
: Arguments to the commands.

There is unfortunately some confusion between `cvs_options` and `command_options`. `-l', when given as a `cvs_option`, only affects some of the commands. When it is given as a `command_option` is has a different meaning, and is accepted by more commands. In other words, do not take the above categorization too seriously. Look at the documentation instead.

Default options and the ~/.cvsrc file

There are some `command_options` that are used so often that you might have set up an alias or some other means to make sure you always specify that option. One example (the one that drove the implementation of the .cvsrc support, actually) is that many people find the default output of the `diff' command to be very hard to read, and that either context diffs or unidiffs are much easier to understand.

The `~/.cvsrc' file is a way that you can add default options to `cvs_commands` within cvs, instead

of relying on aliases or other shell scripts.

The format of the `~/.cvsrc' file is simple. The file is searched for a line that begins with the same name as the `cvs_command' being executed. If a match is found, then the remainder of the line is split up (at whitespace characters) into separate options and added to the command arguments *before* any options from the command line.

If a command has two names (e.g., `checkout' and `co'), the official name, not necessarily the one used on the command line, will be used to match against the file. So if this is the contents of the user's `~/.cvsrc' file:

```
log -N
diff -u
update -P
co -P
```

the command `cvs checkout foo' would have the `-P' option added to the arguments, as well as `cvs co foo'.

With the example file above, the output from `cvs diff foobar' will be in unidiff format. `cvs diff -c foobar' will provide context diffs, as usual. Getting "old" format diffs would be slightly more complicated, because `diff' doesn't have an option to specify use of the "old" format, so you would need `cvs -f diff foobar'.

In place of the command name you can use `cvs' to specify global options (see section Global options). For example the following line in `.cvsrc'

```
cvs -z6
```

causes CVS to use compression level 6

Global options

The available `cvs_options' (that are given to the left of `cvs_command') are:

`-b bindir`

> Use bindir as the directory where RCS programs are located. Overrides the setting of the `$RCSBIN` environment variable and any precompiled directory. This parameter should be specified as an absolute pathname.

`-d cvs_root_directory`

> Use cvs_root_directory as the root directory pathname of the repository. Overrides the setting of the `$CVSROOT` environment variable. See section The Repository.

`-e editor`

> Use editor to enter revision log information. Overrides the setting of the `$CVSEDITOR` and `$EDITOR` environment variables.

`-f`

Do not read the `~/.cvsrc' file. This option is most often used because of the non-orthogonality of the CVS option set. For example, the `cvs log' option `-N' (turn off display of tag names) does not have a corresponding option to turn the display on. So if you have `-N' in the `~/.cvsrc' entry for `diff', you may need to use `-f' to show the tag names. (1)

`-H`

Display usage information about the specified `cvs_command' (but do not actually execute the command). If you don't specify a command name, `cvs -H' displays a summary of all the commands available.

`-l`

Do not log the cvs_command in the command history (but execute it anyway). See section history--Show status of files and users, for information on command history.

`-n`

Do not change any files. Attempt to execute the `cvs_command', but only to issue reports; do not remove, update, or merge any existing files, or create any new files.

`-Q`

Cause the command to be really quiet; the command will only generate output for serious problems.

`-q`

Cause the command to be somewhat quiet; informational messages, such as reports of recursion through subdirectories, are suppressed.

`-r`

Make new working files files read-only. Same effect as if the $CVSREAD environment variable is set (see section All environment variables which affect CVS). The default is to make working files writable, unless watches are on (see section Mechanisms to track who is editing files).

`-s variable=value`

Set a user variable (see section Expansions in administrative files).

`-t`

Trace program execution; display messages showing the steps of CVS activity. Particularly useful with `-n' to explore the potential impact of an unfamiliar command.

`-v`

Display version and copyright information for CVS.

`-w`

Make new working files read-write. Overrides the setting of the $CVSREAD environment variable. Files are created read-write by default, unless $CVSREAD is set or `-r' is given.

`-z gzip-level`

Set the compression level. Only has an effect on the CVS client.

Common command options

This section describes the `command_options' that are available across several CVS commands. These options are always given to the right of `cvs_command'. Not all commands support all of these options; each option is only supported for commands where it makes sense. However, when a command has one of these options you can almost always count on the same behavior of the option as in other commands. (Other command options, which are listed with the individual commands, may have different behavior from one CVS command to the other).

Warning: the `history' command is an exception; it supports many options that conflict even with these standard options.

`-D date_spec`

Use the most recent revision no later than date_spec. date_spec is a single argument, a date description specifying a date in the past.

The specification is sticky when you use it to make a private copy of a source file; that is, when you get a working file using `-D', CVS records the date you specified, so that further updates in the same directory will use the same date (for more information on sticky tags/dates, see section Sticky tags).

A wide variety of date formats are supported by the underlying RCS facilities, similar to those described in co(1), but not exactly the same. The date_spec is interpreted as being in the local timezone, unless a specific timezone is specified. Examples of valid date specifications include:

```
1 month ago
2 hours ago
400000 seconds ago
last year
last Monday
yesterday
a fortnight ago
3/31/92 10:00:07 PST
January 23, 1987 10:05pm
22:00 GMT
```

`-D' is available with the `checkout`, `diff`, `export`, `history`, `rdiff`, `rtag`, and `update` commands. (The `history` command uses this option in a slightly different way; see section history options).

Remember to quote the argument to the `-D' flag so that your shell doesn't interpret spaces as argument separators. A command using the `-D' flag can look like this:

```
$ cvs diff -D "1 hour ago" cvs.texinfo
```

`-f`

When you specify a particular date or tag to CVS commands, they normally ignore files that do

not contain the tag (or did not exist prior to the date) that you specified. Use the `-f' option if you want files retrieved even when there is no match for the tag or date. (The most recent revision of the file will be used).

`-f' is available with these commands: `checkout`, `export`, `rdiff`, `rtag`, and `update`.

Warning: The `commit` command also has a `-f' option, but it has a different behavior for that command. See section commit options.

`-H`

Help; describe the options available for this command. This is the only option supported for all CVS commands.

`-k kflag`

Alter the default RCS processing of keywords. See section Keyword substitution, for the meaning of kflag. Your kflag specification is sticky when you use it to create a private copy of a source file; that is, when you use this option with the `checkout` or `update` commands, CVS associates your selected kflag with the file, and continues to use it with future update commands on the same file until you specify otherwise.

The `-k' option is available with the `add`, `checkout`, `diff` and `update` commands.

`-l`

Local; run only in current working directory, rather than recursing through subdirectories.

Warning: this is not the same as the overall `cvs -l' option, which you can specify to the left of a cvs command!

Available with the following commands: `checkout`, `commit`, `diff`, `export`, `log`, `remove`, `rdiff`, `rtag`, `status`, `tag`, and `update`.

`-m message`

Use message as log information, instead of invoking an editor.

Available with the following commands: `add`, `commit` and `import`.

`-n`

Do not run any checkout/commit/tag program. (A program can be specified to run on each of these activities, in the modules database (see section The modules file); this option bypasses it).

Warning: this is not the same as the overall `cvs -n' option, which you can specify to the left of a cvs command!

Available with the `checkout`, `commit`, `export`, and `rtag` commands.

`-P`

Prune (remove) directories that are empty after being updated, on `checkout`, or `update`. Normally, an empty directory (one that is void of revision-controlled files) is left alone. Specifying `-P' will cause these directories to be silently removed from your checked-out sources. This does not remove the directory from the repository, only from your checked out copy. Note that this option is implied by the `-r' or `-D' options of `checkout` and `export`.

`-p`

Pipe the files retrieved from the repository to standard output, rather than writing them in the current directory. Available with the `checkout` and `update` commands.

`-W`

Specify file names that should be filtered. You can use this option repeatedly. The spec can be a file name pattern of the same type that you can specify in the `.cvswrappers' file. Avaliable with the following commands: `import`, and `update`.

`-r tag`

Use the revision specified by the tag argument instead of the default head revision. As well as arbitrary tags defined with the `tag` or `rtag` command, two special tags are always available: `HEAD' refers to the most recent version available in the repository, and `BASE' refers to the revision you last checked out into the current working directory.

The tag specification is sticky when you use this option with `checkout` or `update` to make your own copy of a file: CVS remembers the tag and continues to use it on future update commands, until you specify otherwise (for more information on sticky tags/dates, see section Sticky tags). The tag can be either a symbolic or numeric tag. See section Tags--Symbolic revisions.

Specifying the `-q' global option along with the `-r' command option is often useful, to suppress the warning messages when the RCS history file does not contain the specified tag.

Warning: this is not the same as the overall `cvs -r' option, which you can specify to the left of a cvs command!

`-r' is available with the `checkout`, `commit`, `diff`, `history`, `export`, `rdiff`, `rtag`, and `update` commands.

add--Add a new file/directory to the repository

- Synopsis: add [-k kflag] [-m 'message'] files...
- Requires: repository, working directory.
- Changes: working directory.
- Synonym: new

Use the `add` command to create a new file or directory in the source repository. The files or directories specified with `add` must already exist in the current directory (which must have been created with the `checkout` command). To add a whole new directory hierarchy to the source repository (for example, files received from a third-party vendor), use the `import` command instead. See section import--Import sources into CVS, using vendor branches.

If the argument to `add` refers to an immediate sub-directory, the directory is created at the correct place in the source repository, and the necessary CVS administration files are created in your working directory. If the directory already exists in the source repository, `add` still creates the administration files

in your version of the directory. This allows you to use `add` to add a particular directory to your priv sources even if someone else created that directory after your checkout of the sources. You can do th following:

```
$ mkdir new_directory
$ cvs add new_directory
$ cvs update new_directory
```

An alternate approach using `update` might be:

```
$ cvs update -d new_directory
```

(To add any available new directories to your working directory, it's probably simpler to use `checkout` (see section checkout--Check out sources for editing) or `update -d' (see section update--Bring work tree in sync with repository)).

The added files are not placed in the source repository until you use `commit` to make the change permanent. Doing an `add` on a file that was removed with the `remove` command will resurrect the file, unless a `commit` command intervened. See section Removing files from a module, for an example.

Unlike most other commands `add` never recurses down directories. It cannot yet handle relative paths. Instead of

```
$ cvs add foo/bar.c
```

you have to do

```
$ cd foo
$ cvs add bar.c
```

add options

There are only two options you can give to `add':

`-k kflag`

> This option specifies the default way that this file will be checked out. The kflag argument (see section Substitution modes) is stored in the RCS file and can be changed with `admin -k` (see section admin options). See section Handling binary files, for information on using this option for binary files.

`-m description`

> Using this option, you can give a description for the file. This description appears in the history log (if it is enabled, see section The history file). It will also be saved in the RCS history file inside the repository when the file is committed. The `log` command displays this description.
>
> The description can be changed using `admin -t'. See section admin--Administration front end for rcs.

If you omit the `-m description' flag, an empty string will be used. You will not be prompted for a description.

add examples

To add the file `backend.c' to the repository, with a description, the following can be used.

```
$ cvs add -m "Optimizer and code generation passes." backend.c
$ cvs commit -m "Early version. Not yet compilable." backend.c
```

admin--Administration front end for rcs

- Requires: repository, working directory.
- Changes: repository.
- Synonym: rcs

This is the CVS interface to assorted administrative RCS facilities, documented in rcs(1). `admin` simply passes all its options and arguments to the `rcs` command; it does no filtering or other processing. This command *does* work recursively, however, so extreme care should be used.

If there is a group whose name matches a compiled in value which defaults to `cvsadmin`, only members of that group can use `cvs admin`. To disallow `cvs admin` for all users, create a group with no users in it.

admin options

Not all valid `rcs` options are useful together with CVS. Some even makes it impossible to use CVS until you undo the effect!

This description of the available options is based on the `rcs(1)' man page, but modified to suit readers that are more interrested in CVS than RCS.

`-Aoldfile`

Might not work together with CVS. Append the access list of oldfile to the access list of the RCS file.

`-alogins`

Might not work together with CVS. Append the login names appearing in the comma-separated list logins to the access list of the RCS file.

`-b[rev]`

When used with bare RCS, this option sets the default branch to rev; in CVS sticky tags (see section Sticky tags) are a better way to decide which branch you want to work on. With CVS, this option can be used to control behavior with respect to the vendor branch.

`-cstring`

Useful with CVS. Sets the comment leader to string. The comment leader is printed before eve log message line generated by the keyword Log (see section Keyword substitution). This is useful for programming languages without multi-line comments. RCS initially guesses the value of the comment leader from the file name extension when the file is first committed.

`-e[logins]`

Might not work together with CVS. Erase the login names appearing in the comma-separated list logins from the access list of the RCS file. If logins is omitted, erase the entire access list.

`-I`

Run interactively, even if the standard input is not a terminal.

`-i`

Useless with CVS. When using bare RCS, this is used to create and initialize a new RCS file, without depositing a revision.

`-ksubst`

Useful with CVS. Set the default keyword substitution to subst. See section Keyword substitution. Giving an explicit `-k' option to `cvs update`, `cvs export`, or `cvs checkout` overrides this default.

`-l[rev]`

Lock the revision with number rev. If a branch is given, lock the latest revision on that branch. If rev is omitted, lock the latest revision on the default branch.

This can be used in conjunction with the `` `rcslock.pl' `` script in the `` `contrib' `` directory of the CVS source distribution to provide reserved checkouts (where only one user can be editing a given file at a time). See the comments in that file for details (and see the `` `README' `` file in that directory for disclaimers about the unsupported nature of contrib). According to comments in that file, locking must set to strict (which is the default).

`-L`

Set locking to strict. Strict locking means that the owner of an RCS file is not exempt from locking for checkin. For use with CVS, strict locking must be set; see the discussion under the `-l' option above.

`-mrev:msg`

Replace the log message of revision rev with msg.

`-Nname[:[rev]]`

Act like `-n', except override any previous assignment of name.

`-nname[:[rev]]`

Associate the symbolic name name with the branch or revision rev. It is normally better to use `cvs tag' or `cvs rtag' instead. Delete the symbolic name if both `:' and rev are omitted; otherwise, print an error message if name is already associated with another number. If rev is symbolic, it is expanded before association. A rev consisting of a branch number followed by a `.' stands for the current latest revision in the branch. A `:' with an empty rev stands for the current latest revision on the default branch, normally the trunk. For example, `rcs -nname: RCS/*' associates name with the current latest revision of all the named RCS files; this contrasts with `rcs -nname:$ RCS/*' which

associates name with the revision numbers extracted from keyword strings in the correspondin working files.

`-orange`

Potentially useful, but dangerous, with CVS (see below). Deletes (outdates) the revisions given by range. A range consisting of a single revision number means that revision. A range consisting of a branch number means the latest revision on that branch. A range of the form `rev1:rev2' means revisions rev1 to rev2 on the same branch, `:rev' means from the beginning of the branch containing rev up to and including rev, and `rev:' means from revision rev to the end of the branch containing rev. None of the outdated revisions may have branches or locks.

Due to the way CVS handles branches rev cannot be specified symbolically if it is a branch. See section Magic branch numbers, for an explanation.

Make sure that no-one has checked out a copy of the revision you outdate. Strange things will happen if he starts to edit it and tries to check it back in. For this reason, this option is not a good way to take back a bogus commit; commit a new revision undoing the bogus change instead (see section Merging differences between any two revisions).

`-q`

Run quietly; do not print diagnostics.

`-sstate[:rev]`

Useful with CVS. Set the state attribute of the revision rev to state. If rev is a branch number, assume the latest revision on that branch. If rev is omitted, assume the latest revision on the default branch. Any identifier is acceptable for state. A useful set of states is `Exp' (for experimental), `Stab' (for stable), and `Rel' (for released). By default, the state of a new revision is set to `Exp' when it is created. The state is visible in the output from cvs log (see section log--Print out 'rlog' information for files), and in the `$'Log$ and `$'State$ keywords (see section Keyword substitution). Note that CVS uses the `dead` state for its own purposes; to take a file to or from the `dead` state use commands like `cvs remove` and `cvs add`, not `cvs admin -s`.

`-t[file]`

Useful with CVS. Write descriptive text from the contents of the named file into the RCS file, deleting the existing text. The file pathname may not begin with `-'. If file is omitted, obtain the text from standard input, terminated by end-of-file or by a line containing `.' by itself. Prompt for the text if interaction is possible; see `-I'. The descriptive text can be seen in the output from `cvs log' (see section log--Print out 'rlog' information for files).

`-t-string`

Similar to `-tfile'. Write descriptive text from the string into the RCS file, deleting the existing text.

`-U`

Set locking to non-strict. Non-strict locking means that the owner of a file need not lock a revision for checkin. For use with CVS, strict locking must be set; see the discussion under the `-l' option above.

`-u[rev]`

See the option `-l' above, for a discussion of using this option with CVS. Unlock the revision with

number rev. If a branch is given, unlock the latest revision on that branch. If rev is omitted, remove the latest lock held by the caller. Normally, only the locker of a revision may unlock it. Somebody else unlocking a revision breaks the lock. This causes a mail message to be sent to the original locker. The message contains a commentary solicited from the breaker. The commentary is terminated by end-of-file or by a line containing `.` by itself.

`-Vn`

Emulate RCS version n. Use -Vn to make an RCS file acceptable to RCS version n by discarding information that would confuse version n.

`-xsuffixes`

Useless with CVS. Use suffixes to characterize RCS files.

admin examples

Outdating is dangerous

First, an example of how *not* to use the `admin` command. It is included to stress the fact that this command can be quite dangerous unless you know *exactly* what you are doing.

The `-o' option can be used to outdate old revisions from the history file. If you are short on disc this option might help you. But think twice before using it--there is no way short of restoring the latest backup to undo this command!

The next line is an example of a command that you would *not* like to execute.

```
$ cvs admin -o:R_1_02 .
```

The above command will delete all revisions up to, and including, the revision that corresponds to the tag R_1_02. But beware! If there are files that have not changed between R_1_02 and R_1_03 the file will have *the same* numerical revision number assigned to the tags R_1_02 and R_1_03. So not only will it be impossible to retrieve R_1_02; R_1_03 will also have to be restored from the tapes!

Comment leaders

If you use the Log keyword and you do not agree with the guess for comment leader that CVS has done, you can enforce your will with `cvs admin -c`. This might be suitable for `nroff` source:

```
$ cvs admin -c'.\" ' *.man
$ rm *.man
$ cvs update
```

The two last steps are to make sure that you get the versions with correct comment leaders in your working files.

checkout--Check out sources for editing

- Synopsis: checkout [options] modules...
- Requires: repository.
- Changes: working directory.
- Synonyms: co, get

Make a working directory containing copies of the source files specified by modules. You must execute `checkout` before using most of the other CVS commands, since most of them operate on your working directory.

The modules part of the command are either symbolic names for some collection of source directories and files, or paths to directories or files in the repository. The symbolic names are defined in the `modules' file. See section The modules file.

Depending on the modules you specify, `checkout` may recursively create directories and populate them with the appropriate source files. You can then edit these source files at any time (regardless of whether other software developers are editing their own copies of the sources); update them to include new changes applied by others to the source repository; or commit your work as a permanent change to the source repository.

Note that `checkout` is used to create directories. The top-level directory created is always added to the directory where `checkout` is invoked, and usually has the same name as the specified module. In the case of a module alias, the created sub-directory may have a different name, but you can be sure that it will be a sub-directory, and that `checkout` will show the relative path leading to each file as it is extracted into your private work area (unless you specify the `-Q' global option).

The files created by `checkout` are created read-write, unless the `-r' option to CVS (see section Global options) is specified, the `CVSREAD` environment variable is specified (see section All environment variables which affect CVS), or a watch is in effect for that file (see section Mechanisms to track who is editing files).

Running `checkout` on a directory that was already built by a prior `checkout` is also permitted, and has the same effect as specifying the `-d' option to the `update` command, that is, any new directories that have been created in the repository will appear in your work area. See section update--Bring work tree in sync with repository.

checkout options

These standard options are supported by `checkout` (see section Common command options, for a complete description of them):

`-D date`

Use the most recent revision no later than date. This option is sticky, and implies `-P'. See section Sticky tags, for more information on sticky tags/dates.

`-f`

Only useful with the `-D date' or `-r tag' flags. If no matching revision is found, retrieve the most recent revision (instead of ignoring the file).

`-k kflag`

Process RCS keywords according to kflag. See co(1). This option is sticky; future updates of this file in this working directory will use the same kflag. The `status` command can be viewed to see the sticky options. See section status--Status info on the revisions.

`-l`

Local; run only in current working directory.

`-n`

Do not run any checkout program (as specified with the `-o' option in the modules file; see section The modules file).

`-P`

Prune empty directories.

`-p`

Pipe files to the standard output.

`-r tag`

Use revision tag. This option is sticky, and implies `-P'. See section Sticky tags, for more information on sticky tags/dates.

In addition to those, you can use these special command options with `checkout`:

`-A`

Reset any sticky tags, dates, or `-k' options. See section Sticky tags, for more information on sticky tags/dates.

`-c`

Copy the module file, sorted, to the standard output, instead of creating or modifying any files or directories in your working directory.

`-d dir`

Create a directory called dir for the working files, instead of using the module name. Unless you also use `-N', the paths created under dir will be as short as possible.

`-j tag`

With two `-j' options, merge changes from the revision specified with the first `-j' option to the revision specified with the second `j' option, into the working directory.

With one `-j' option, merge changes from the ancestor revision to the revision specified with the `-j' option, into the working directory. The ancestor revision is the common ancestor of the revision which the working directory is based on, and the revision specified in the `-j' option.

In addition, each -j option can contain an optional date specification which, when used with branches, can limit the chosen revision to one within a specific date. An optional date is specified by adding a colon (:) to the tag: `-jSymbolic_Tag:Date_Specifier'.

See section Merging.

`-N`

Only useful together with `-d dir'. With this option, CVS will not shorten module paths in your working directory. (Normally, CVS shortens paths as much as possible when you specify an explicit target directory).

`-s`

Like `-c', but include the status of all modules, and sort it by the status string. See section The modules file, for info about the `-s' option that is used inside the modules file to set the module status.

checkout examples

Get a copy of the module `tc':

```
$ cvs checkout tc
```

Get a copy of the module `tc' as it looked one day ago:

```
$ cvs checkout -D yesterday tc
```

commit--Check files into the repository

- Version 1.3 Synopsis: commit [-lnR] [-m 'log_message' | -f file] [-r revision] [files...]
- Version 1.3.1 Synopsis: commit [-lnRf] [-m 'log_message' | -F file] [-r revision] [files...]
- Requires: working directory, repository.
- Changes: repository.
- Synonym: ci

Warning: The `-f file' option will probably be renamed to `-F file', and `-f' will be given a new behavior in future releases of CVS.

Use `commit` when you want to incorporate changes from your working source files into the source repository.

If you don't specify particular files to commit, all of the files in your working current directory are examined. `commit` is careful to change in the repository only those files that you have really changed. By default (or if you explicitly specify the `-R' option), files in subdirectories are also examined and committed if they have changed; you can use the `-l' option to limit `commit` to the current directory only.

`commit` verifies that the selected files are up to date with the current revisions in the source repository; it will notify you, and exit without committing, if any of the specified files must be made current first with `update` (see section update--Bring work tree in sync with repository). `commit` does not call the

`update` command for you, but rather leaves that for you to do when the time is right.

When all is well, an editor is invoked to allow you to enter a log message that will be written to one or more logging programs (see section The modules file, and see section Loginfo) and placed in the RCS history file inside the repository. This log message can be retrieved with the `log` command; See section log--Print out 'rlog' information for files. You can specify the log message on the command line with the `-m message' option, and thus avoid the editor invocation, or use the `-f file' option to specify that the argument file contains the log message.

commit options

These standard options are supported by `commit` (see section Common command options, for a complete description of them):

`-l`

Local; run only in current working directory.

`-n`

Do not run any module program.

`-R`

Commit directories recursively. This is on by default.

`-r revision`

Commit to revision. revision must be either a branch, or a revision on the main trunk that is higher than any existing revision number. You cannot commit to a specific revision on a branch.

`commit` also supports these options:

`-F file`

This option is present in CVS releases 1.3-s3 and later. Read the log message from file, instead of invoking an editor.

`-f`

This option is present in CVS 1.3-s3 and later releases of CVS. Note that this is not the standard behavior of the `-f' option as defined in See section Common command options.

Force CVS to commit a new revision even if you haven't made any changes to the file. If the current revision of file is 1.7, then the following two commands are equivalent:

```
$ cvs commit -f file
$ cvs commit -r 1.8 file
```

`-f file`

This option is present in CVS releases 1.3, 1.3-s1 and 1.3-s2. Note that this is not the standard behavior of the `-f' option as defined in See section Common command options.

Read the log message from file, instead of invoking an editor.

`-m message`

Use message as the log message, instead of invoking an editor.

commit examples

New major release number

When you make a major release of your product, you might want the revision numbers to track your major release number. You should normally not care about the revision numbers, but this is a thing that many people want to do, and it can be done without doing any harm.

To bring all your files up to the RCS revision 3.0 (including those that haven't changed), you might do:

```
$ cvs commit -r 3.0
```

Note that it is generally a bad idea to try to make the RCS revision number equal to the current release number of your product. You should think of the revision number as an internal number that the CVS package maintains, and that you generally never need to care much about. Using the `tag` and `rtag` commands you can give symbolic names to the releases instead. See section tag--Add a symbolic tag to checked out version of RCS file and See section rtag--Add a tag to the RCS file.

Note that the number you specify with `-r' must be larger than any existing revision number. That is, if revision 3.0 exists, you cannot `cvs commit -r 1.3'.

Committing to a branch

You can commit to a branch revision (one that has an even number of dots) with the `-r' option. To create a branch revision, use the `-b' option of the `rtag` or `tag` commands (see section tag--Add a symbolic tag to checked out version of RCS file or see section rtag--Add a tag to the RCS file). Then, either `checkout` or `update` can be used to base your sources on the newly created branch. From that point on, all `commit` changes made within these working sources will be automatically added to a branch revision, thereby not disturbing main-line development in any way. For example, if you had to create a patch to the 1.2 version of the product, even though the 2.0 version is already under development, you might do:

```
$ cvs rtag -b -r FCS1_2 FCS1_2_Patch product_module
$ cvs checkout -r FCS1_2_Patch product_module
$ cd product_module
[[ hack away ]]
$ cvs commit
```

This works automatically since the `-r' option is sticky.

Creating the branch after editing

Say you have been working on some extremely experimental software, based on whatever revision you happened to checkout last week. If others in your group would like to work on this software with you,

but without disturbing main-line development, you could commit your change to a new branch. Others can then checkout your experimental stuff and utilize the full benefit of CVS conflict resolution. The scenario might look like:

```
[[ hacked sources are present ]]
$ cvs tag -b EXPR1
$ cvs update -r EXPR1
$ cvs commit
```

The `update` command will make the `-r EXPR1' option sticky on all files. Note that your changes to the files will never be removed by the `update` command. The `commit` will automatically commit to the correct branch, because the `-r' is sticky. You could also do like this:

```
[[ hacked sources are present ]]
$ cvs tag -b EXPR1
$ cvs commit -r EXPR1
```

but then, only those files that were changed by you will have the `-r EXPR1' sticky flag. If you hack away, and commit without specifying the `-r EXPR1' flag, some files may accidentally end up on the main trunk.

To work with you on the experimental change, others would simply do

```
$ cvs checkout -r EXPR1 whatever_module
```

diff--Run diffs between revisions

- Synopsis: diff [-l] [rcsdiff_options] [[-r rev1 | -D date1] [-r rev2 | -D date2]] [files...]
- Requires: working directory, repository.
- Changes: nothing.

The `diff` command is used to compare different revisions of files. The default action is to compare your working files with the revisions they were based on, and report any differences that are found.

If any file names are given, only those files are compared. If any directories are given, all files under them will be compared.

The exit status will be 0 if no differences were found, 1 if some differences were found, and 2 if any error occurred.

diff options

These standard options are supported by `diff` (see section Common command options, for a complete description of them):

`-D date`

Use the most recent revision no later than date. See `-r' for how this affects the comparison.

CVS can be configured to pass the `-D' option through to `rcsdiff` (which in turn passes it onto `diff`. GNU diff uses `-D' as a way to put `cpp`-style `#define' statements around the output differences. There is no way short of testing to figure out how CVS was configured. In the default configuration CVS will use the `-D date' option.

`-k kflag`

Process RCS keywords according to kflag. See co(1).

`-l`

Local; run only in current working directory.

`-R`

Examine directories recursively. This option is on by default.

`-r tag`

Compare with revision tag. Zero, one or two `-r' options can be present. With no `-r' option, the working file will be compared with the revision it was based on. With one `-r', that revision will be compared to your current working file. With two `-r' options those two revisions will be compared (and your working file will not affect the outcome in any way).

One or both `-r' options can be replaced by a `-D date' option, described above.

Any other options that are found are passed through to `rcsdiff`, which in turn passes them to `diff`. The exact meaning of the options depends on which `diff` you are using. The long options introduced in GNU diff 2.0 are not yet supported in CVS. See the documentation for your `diff` to see which options are supported.

diff examples

The following line produces a Unidiff (`-u' flag) between revision 1.14 and 1.19 of `` `backend.c' ``. Due to the `-kk' flag no keywords are substituted, so differences that only depend on keyword substitution are ignored.

```
$ cvs diff -kk -u -r 1.14 -r 1.19 backend.c
```

Suppose the experimental branch EXPR1 was based on a set of files tagged RELEASE_1_0. To see what has happened on that branch, the following can be used:

```
$ cvs diff -r RELEASE_1_0 -r EXPR1
```

A command like this can be used to produce a context diff between two releases:

```
$ cvs diff -c -r RELEASE_1_0 -r RELEASE_1_1 > diffs
```

If you are maintaining ChangeLogs, a command like the following just before you commit your changes may help you write the ChangeLog entry. All local modifications that have not yet been committed will be printed.

```
$ cvs diff -u | less
```

export--Export sources from CVS, similar to checkout

- Synopsis: export [-flNn] [-r rev|-D date] [-k subst] [-d dir] module...
- Requires: repository.
- Changes: current directory.

This command is a variant of `checkout`; use it when you want a copy of the source for module without the CVS administrative directories. For example, you might use `export` to prepare source for shipment off-site. This command requires that you specify a date or tag (with `-D' or `-r'), so that you can count on reproducing the source you ship to others.

One often would like to use `-kv' with `cvs export`. This causes any RCS keywords to be expanded such that an import done at some other site will not lose the keyword revision information. But be aware that doesn't handle an export containing binary files correctly. Also be aware that after having used `-kv', one can no longer use the `ident` command (which is part of the RCS suite--see ident(1)) which looks for RCS keyword strings. If you want to be able to use `ident` you must not use `-kv'.

export options

These standard options are supported by `export` (see section Common command options, for a complete description of them):

`-D date`
: Use the most recent revision no later than date.

`-f`
: If no matching revision is found, retrieve the most recent revision (instead of ignoring the file).

`-l`
: Local; run only in current working directory.

`-n`
: Do not run any checkout program.

`-R`
: Export directories recursively. This is on by default.

`-r tag`
: Use revision tag.

In addition, these options (that are common to `checkout` and `export`) are also supported:

`-d dir`
: Create a directory called dir for the working files, instead of using the module name. Unless you

also use `-N', the paths created under dir will be as short as possible.

`-k subst`

Set keyword expansion mode (see section Substitution modes).

`-N`

Only useful together with `-d dir'. With this option, CVS will not shorten module paths in your working directory. (Normally, CVS shortens paths as much as possible when you specify an explicit target directory.)

history--Show status of files and users

- Synopsis: history [-report] [-flags] [-options args] [files...]
- Requires: the file `$CVSROOT/CVSROOT/history'
- Changes: nothing.

CVS can keep a history file that tracks each use of the `checkout`, `commit`, `rtag`, `update`, and `release` commands. You can use `history` to display this information in various formats.

Logging must be enabled by creating the file `$CVSROOT/CVSROOT/history'.

Warning: `history` uses `-f', `-l', `-n', and `-p' in ways that conflict with the normal use inside CVS (see section Common command options).

history options

Several options (shown above as `-report') control what kind of report is generated:

`-c`

Report on each time commit was used (i.e., each time the repository was modified).

`-e`

Everything (all record types); equivalent to specifying `-xMACFROGWUT'.

`-m module`

Report on a particular module. (You can meaningfully use `-m' more than once on the command line.)

`-o`

Report on checked-out modules.

`-T`

Report on all tags.

`-x type`

Extract a particular set of record types type from the CVS history. The types are indicated by single letters, which you may specify in combination.

Certain commands have a single record type:

`F`
: release

`O`
: checkout

`T`
: rtag

One of four record types may result from an update:

`C`
: A merge was necessary but collisions were detected (requiring manual merging).

`G`
: A merge was necessary and it succeeded.

`U`
: A working file was copied from the repository.

`W`
: The working copy of a file was deleted during update (because it was gone from the repository).

One of three record types results from commit:

`A`
: A file was added for the first time.

`M`
: A file was modified.

`R`
: A file was removed.

The options shown as `-flags' constrain or expand the report without requiring option arguments:

`-a`
: Show data for all users (the default is to show data only for the user executing `history`).

`-l`
: Show last modification only.

`-w`
: Show only the records for modifications done from the same working directory where `history` is executing.

The options shown as `-options args' constrain the report based on an argument:

`-b str`
: Show data back to a record containing the string str in either the module name, the file name, or the repository path.

`-D date`

Show data since date. This is slightly different from the normal use of `-D date', which selects newest revision older than date.

`-p repository`

Show data for a particular source repository (you can specify several `-p' options on the same command line).

`-r rev`

Show records referring to revisions since the revision or tag named rev appears in individual RCS files. Each RCS file is searched for the revision or tag.

`-t tag`

Show records since tag tag was last added to the the history file. This differs from the `-r' flag above in that it reads only the history file, not the RCS files, and is much faster.

`-u name`

Show records for user name.

import--Import sources into CVS, using vendor branches

- Synopsis: import [-options] repository vendortag releasetag...
- Requires: Repository, source distribution directory.
- Changes: repository.

Use `import` to incorporate an entire source distribution from an outside source (e.g., a source vendor) into your source repository directory. You can use this command both for initial creation of a repository, and for wholesale updates to the module from the outside source. See section Tracking third-party sources, for a discussion on this subject.

The repository argument gives a directory name (or a path to a directory) under the CVS root directory for repositories; if the directory did not exist, import creates it.

When you use import for updates to source that has been modified in your source repository (since a prior import), it will notify you of any files that conflict in the two branches of development; use `checkout -j' to reconcile the differences, as import instructs you to do.

If CVS decides a file should be ignored (see section Ignoring files via cvsignore), it does not import it and prints `I ' followed by the filename

If the file `$CVSROOT/CVSROOT/cvswrappers' exists, any file whose names match the specifications in that file will be treated as packages and the appropriate filtering will be performed on the file/directory before being imported, See section The cvswrappers file.

The outside source is saved in a first-level RCS branch, by default 1.1.1. Updates are leaves of this branch; for example, files from the first imported collection of source will be revision 1.1.1.1, then files from the first imported update will be revision 1.1.1.2, and so on.

At least three arguments are required. repository is needed to identify the collection of source. vendo is a tag for the entire branch (e.g., for 1.1.1). You must also specify at least one releasetag to identify files at the leaves created each time you execute `import`.

import options

This standard option is supported by `import` (see section Common command options, for a complete description):

`-m message`

Use message as log information, instead of invoking an editor.

There are three additional special options.

`-b branch`

Specify a first-level branch other than 1.1.1. Unless the `-b branch' flag is given, revisions will *always* be made to the branch 1.1.1--even if a vendortag that matches another branch is given! What happens in that case, is that the tag will be reset to 1.1.1. Warning: This behavior might change in the future.

`-k subst`

Indicate the RCS keyword expansion mode desired. This setting will apply to all files created during the import, but not to any files that previously existed in the repository. See section Substitution modes for a list of valid `-k' settings.

`-I name`

Specify file names that should be ignored during import. You can use this option repeatedly. To avoid ignoring any files at all (even those ignored by default), specify `-I !'.

name can be a file name pattern of the same type that you can specify in the `.cvsignore' file. See section Ignoring files via cvsignore.

`-W spec`

Specify file names that should be filtered during import. You can use this option repeatedly.

spec can be a file name pattern of the same type that you can specify in the `.cvswrappers' file. See section The cvswrappers file.

import examples

See section Tracking third-party sources, and See section Creating a module from a number of files.

log--Print out 'rlog' information for files

- Synopsis: log [-l] rlog-options [files...]
- Requires: repository, working directory.
- Changes: nothing.

- Synonym: rlog

Display log information for files. `log` calls the RCS utility `rlog`, which prints all available information about the RCS history file. This includes the location of the RCS file, the head revision (the latest revision on the trunk), all symbolic names (tags) and some other things. For each revision, the revision number, the author, the number of lines added/deleted and the log message are printed. All times are displayed in Coordinated Universal Time (UTC). (Other parts of CVS print times in the local timezone).

log options

Only one option is interpreted by CVS and not passed on to `rlog`:

`-l`

Local; run only in current working directory. (Default is to run recursively).

By default, `rlog` prints all information that is available. All other options (including those that normally behave differently) are passed through to `rlog` and restrict the output. See rlog(1) for a complete description of options. This incomplete list (which is a slightly edited extract from rlog(1)) lists all options that are useful in conjunction with CVS.

Please note: There can be no space between the option and its argument, since `rlog` parses its options in a different way than CVS.

`-b`

Print information about the revisions on the default branch, normally the highest branch on the trunk.

`-ddates`

Print information about revisions with a checkin date/time in the range given by the semicolon-separated list of dates. The following table explains the available range formats:

`d1<d2`

`d2>d1`

Select the revisions that were deposited between d1 and d2 inclusive.

`<d`

`d>`

Select all revisions dated d or earlier.

`d<`

`>d`

Select all revisions dated d or later.

`d`

Select the single, latest revision dated d or earlier.

The date/time strings d, d1, and d2 are in the free format explained in co(1). Quoting is normally necessary, especially for < and >. Note that the separator is a semicolon (;).

- -h Print only the RCS pathname, working pathname, head, default branch, access list, locks, symbolic

names, and suffix.

- -N Do not print the list of tags for this file. This option can be very useful when your site uses a lot of tags, so rather than "more"'ing over 3 pages of tag information, the log information is presented without tags at all.
- -R Print only the name of the RCS history file.
- -rrevisions Print information about revisions given in the comma-separated list revisions of revisions and ranges. The following table explains the available range formats:

`rev1:rev2`

Revisions rev1 to rev2 (which must be on the same branch).

`:rev`

Revisions from the beginning of the branch up to and including rev.

`rev:`

Revisions starting with rev to the end of the branch containing rev.

`branch`

An argument that is a branch means all revisions on that branch. You can unfortunately not specify a symbolic branch here. You must specify the numeric branch number. See section Magic branch numbers, for an explanation.

`branch1:branch2`

A range of branches means all revisions on the branches in that range.

`branch.`

The latest revision in branch.

A bare `-r' with no revisions means the latest revision on the default branch, normally the trunk.

- -sstates Print information about revisions whose state attributes match one of the states given in the comma-separated list states.
- -t Print the same as `-h', plus the descriptive text.
- -wlogins Print information about revisions checked in by users with login names appearing in the comma-separated list logins. If logins is omitted, the user's login is assumed.

`rlog` prints the intersection of the revisions selected with the options `-d', `-l', `-s', and `-w', intersected with the union of the revisions selected by `-b' and `-r'.

log examples

Contributed examples are gratefully accepted.

rdiff---'patch' format diffs between releases

- rdiff [-flags] [-V vn] [-r t|-D d [-r t2|-D d2]] modules...
- Requires: repository.

- Changes: nothing.
- Synonym: patch

Builds a Larry Wall format patch(1) file between two releases, that can be fed directly into the patch program to bring an old release up-to-date with the new release. (This is one of the few CVS commands that operates directly from the repository, and doesn't require a prior checkout.) The diff output is sent to the standard output device.

You can specify (using the standard `-r' and `-D' options) any combination of one or two revisions or dates. If only one revision or date is specified, the patch file reflects differences between that revision or date and the current head revisions in the RCS file.

Note that if the software release affected is contained in more than one directory, then it may be necessary to specify the `-p' option to the patch command when patching the old sources, so that patch is able to find the files that are located in other directories.

rdiff options

These standard options are supported by `rdiff` (see section Common command options, for a complete description of them):

`-D date`
: Use the most recent revision no later than date.

`-f`
: If no matching revision is found, retrieve the most recent revision (instead of ignoring the file).

`-l`
: Local; don't descend subdirectories.

`-r tag`
: Use revision tag.

In addition to the above, these options are available:

`-c`
: Use the context diff format. This is the default format.

`-s`
: Create a summary change report instead of a patch. The summary includes information about files that were changed or added between the releases. It is sent to the standard output device. This is useful for finding out, for example, which files have changed between two dates or revisions.

`-t`
: A diff of the top two revisions is sent to the standard output device. This is most useful for seeing what the last change to a file was.

`-u`
: Use the unidiff format for the context diffs. This option is not available if your diff does not support the unidiff format. Remember that old versions of the `patch` program can't handle the

unidiff format, so if you plan to post this patch to the net you should probably not use `-u'.

`-V vn`

Expand RCS keywords according to the rules current in RCS version vn (the expansion format changed with RCS version 5).

rdiff examples

Suppose you receive mail from `foo@bar.com` asking for an update from release 1.2 to 1.4 of the tc compiler. You have no such patches on hand, but with CVS that can easily be fixed with a command such as this:

```
$ cvs rdiff -c -r FOO1_2 -r FOO1_4 tc | \
$$ Mail -s 'The patches you asked for' foo@bar.com
```

Suppose you have made release 1.3, and forked a branch called `R_1_3fix' for bugfixes. `R_1_3_1' corresponds to release 1.3.1, which was made some time ago. Now, you want to see how much development has been done on the branch. This command can be used:

```
$ cvs patch -s -r R_1_3_1 -r R_1_3fix module-name
cvs rdiff: Diffing module-name
File ChangeLog,v changed from revision 1.52.2.5 to 1.52.2.6
File foo.c,v changed from revision 1.52.2.3 to 1.52.2.4
File bar.h,v changed from revision 1.29.2.1 to 1.2
```

release--Indicate that a Module is no longer in use

- release [-d] directories...
- Requires: Working directory.
- Changes: Working directory, history log.

This command is meant to safely cancel the effect of `cvs checkout'. Since CVS doesn't lock files, it isn't strictly necessary to use this command. You can always simply delete your working directory, if you like; but you risk losing changes you may have forgotten, and you leave no trace in the CVS history file (see section The history file) that you've abandoned your checkout.

Use `cvs release' to avoid these problems. This command checks that no uncommitted changes are present; that you are executing it from immediately above a CVS working directory; and that the repository recorded for your files is the same as the repository defined in the module database.

If all these conditions are true, `cvs release' leaves a record of its execution (attesting to your intentionally abandoning your checkout) in the CVS history log.

release options

The `release` command supports one command option:

`-d`

Delete your working copy of the file if the release succeeds. If this flag is not given your files will remain in your working directory.

Warning: The `release` command uses `rm -r `module'' to delete your file. This has the very serious side-effect that any directory that you have created inside your checked-out sources, and not added to the repository (using the `add` command; see section add--Add a new file/directory to the repository) will be silently deleted--even if it is non-empty!

release output

Before `release` releases your sources it will print a one-line message for any file that is not up-to-date.

Warning: Any new directories that you have created, but not added to the CVS directory hierarchy with the `add` command (see section add--Add a new file/directory to the repository) will be silently ignored (and deleted, if `-d' is specified), even if they contain files.

`U file`

There exists a newer revision of this file in the repository, and you have not modified your local copy of the file.

`A file`

The file has been added to your private copy of the sources, but has not yet been committed to the repository. If you delete your copy of the sources this file will be lost.

`R file`

The file has been removed from your private copy of the sources, but has not yet been removed from the repository, since you have not yet committed the removal. See section commit--Check files into the repository.

`M file`

The file is modified in your working directory. There might also be a newer revision inside the repository.

`? file`

file is in your working directory, but does not correspond to anything in the source repository, and is not in the list of files for CVS to ignore (see the description of the `-I' option, and see section Ignoring files via cvsignore). If you remove your working sources, this file will be lost.

Note that no warning message like this is printed for spurious directories that CVS encounters. The directory, and all its contents, are silently ignored.

release examples

Release the module, and delete your local working copy of the files.

```
$ cd ..          # You must stand immediately above the
                 # sources when you issue `cvs release'.
$ cvs release -d tc
You have [0] altered files in this repository.
Are you sure you want to release (and delete) module `tc': y
$
```

rtag--Add a tag to the RCS file

- rtag [-falnR] [-b] [-d] [-r tag | -Ddate] symbolic_tag modules...
- Requires: repository.
- Changes: repository.
- Synonym: rfreeze

You can use this command to assign symbolic tags to particular, explicitly specified source revisions in the repository. `rtag` works directly on the repository contents (and requires no prior checkout). Use `tag` instead (see section tag--Add a symbolic tag to checked out version of RCS file), to base the selection of revisions on the contents of your working directory.

If you attempt to use a tag name that already exists, CVS will complain and not overwrite that tag. Use the `-F' option to force the new tag value.

rtag options

These standard options are supported by `rtag` (see section Common command options, for a complete description of them):

`-D date`

Tag the most recent revision no later than date.

`-f`

Only useful with the `-D date' or `-r tag' flags. If no matching revision is found, use the most recent revision (instead of ignoring the file).

`-F`

Overwrite an existing tag of the same name on a different revision. This option is new in CVS 1.4. The old behavior is matched by `cvs tag -F'.

`-l`

Local; run only in current working directory.

`-n`

Do not run any tag program that was specified with the `-t' flag inside the `modules' file. (s section The modules file).

`-R`

Commit directories recursively. This is on by default.

`-r tag`

Only tag those files that contain tag. This can be used to rename a tag: tag only the files identified by the old tag, then delete the old tag, leaving the new tag on exactly the same files as the old tag.

In addition to the above common options, these options are available:

`-a`

Use the `-a' option to have `rtag` look in the `Attic' (see section Removing files from a module) for removed files that contain the specified tag. The tag is removed from these files, which makes it convenient to re-use a symbolic tag as development continues (and files get removed from the up-coming distribution).

`-b`

Make the tag a branch tag. See section Branches.

`-d`

Delete the tag instead of creating it.

In general, tags (often the symbolic names of software distributions) should not be removed, but the `-d' option is available as a means to remove completely obsolete symbolic names if necessary (as might be the case for an Alpha release, or if you mistagged a module).

status--Status info on the revisions

- status [-lR] [-v] [files...]
- Requires: working directory, repository.
- Changes: nothing.

Display a brief report on the current status of files with respect to the source repository, including any sticky tags, dates, or `-k' options.

You can also use this command to determine the potential impact of a `cvs update' on your working source directory--but remember that things might change in the repository before you run `update`.

status options

These standard options are supported by `status` (see section Common command options, for a complete description of them):

`-l`

Local; run only in current working directory.

`-R`

Commit directories recursively. This is on by default.

There is one additional option:

`-v`

Verbose. In addition to the information normally displayed, print all symbolic tags, together with the numerical value of the revision or branch they refer to.

tag--Add a symbolic tag to checked out version of RCS file

- tag [-lR] [-b] [-d] symbolic_tag [files...]
- Requires: working directory, repository.
- Changes: repository.
- Synonym: freeze

Use this command to assign symbolic tags to the nearest repository versions to your working sources. The tags are applied immediately to the repository, as with `rtag`, but the versions are supplied implicitly by the CVS records of your working files' history rather than applied explicitly.

One use for tags is to record a snapshot of the current sources when the software freeze date of a project arrives. As bugs are fixed after the freeze date, only those changed sources that are to be part of the release need be re-tagged.

The symbolic tags are meant to permanently record which revisions of which files were used in creating a software distribution. The `checkout` and `update` commands allow you to extract an exact copy of a tagged release at any time in the future, regardless of whether files have been changed, added, or removed since the release was tagged.

This command can also be used to delete a symbolic tag, or to create a branch. See the options section below.

If you attempt to use a tag name that already exists, CVS will complain and not overwrite that tag. Use the `-F' option to force the new tag value.

tag options

These standard options are supported by `tag` (see section Common command options, for a complete description of them):

`-F`

Overwrite an existing tag of the same name on a different revision. This option is new in CVS 1.4. The old behavior is matched by `cvs tag -F'.

`-l`

Local; run only in current working directory.

`-R`

Commit directories recursively. This is on by default.

Two special options are available:

`-b`

The -b option makes the tag a branch tag (see section Branches), allowing concurrent, isolated development. This is most useful for creating a patch to a previously released software distribution.

`-d`

Delete a tag.

If you use `cvs tag -d symbolic_tag', the symbolic tag you specify is deleted instead of being added. Warning: Be very certain of your ground before you delete a tag; doing this permanently discards some historical information, which may later turn out to be valuable.

update--Bring work tree in sync with repository

- update [-AdflPpR] [-d] [-r tag|-D date] files...
- Requires: repository, working directory.
- Changes: working directory.

After you've run checkout to create your private copy of source from the common repository, other developers will continue changing the central source. From time to time, when it is convenient in your development process, you can use the `update` command from within your working directory to reconcile your work with any revisions applied to the source repository since your last checkout or update.

update options

These standard options are available with `update` (see section Common command options, for a complete description of them):

`-D date`

Use the most recent revision no later than date. This option is sticky, and implies `-P'. See section Sticky tags, for more information on sticky tags/dates.

`-f`

Only useful with the `-D date' or `-r tag' flags. If no matching revision is found, retrieve the most recent revision (instead of ignoring the file).

`-k kflag`

Process RCS keywords according to kflag. See co(1). This option is sticky; future updates of this file in this working directory will use the same kflag. The `status` command can be viewed to see the sticky options. See section status--Status info on the revisions.

`-l`

Local; run only in current working directory. See section Recursive behavior.

`-P`

Prune empty directories.

`-p`

Pipe files to the standard output.

`-R`

Operate recursively. This is on by default. See section Recursive behavior.

`-r tag`

Retrieve revision tag. This option is sticky, and implies `-P'. See section Sticky tags, for more information on sticky tags/dates.

These special options are also available with `update`.

`-A`

Reset any sticky tags, dates, or `-k' options. See section Sticky tags, for more information on sticky tags/dates.

`-d`

Create any directories that exist in the repository if they're missing from the working directory. Normally, `update` acts only on directories and files that were already enrolled in your working directory.

This is useful for updating directories that were created in the repository since the initial checkout; but it has an unfortunate side effect. If you deliberately avoided certain directories in the repository when you created your working directory (either through use of a module name or by listing explicitly the files and directories you wanted on the command line), then updating with `-d' will create those directories, which may not be what you want.

`-I name`

Ignore files whose names match name (in your working directory) during the update. You can specify `-I' more than once on the command line to specify several files to ignore. Use `-I !' to avoid ignoring any files at all. See section Ignoring files via cvsignore, for other ways to make CVS ignore some files.

`-Wspec`

Specify file names that should be filtered during update. You can use this option repeatedly.

spec can be a file name pattern of the same type that you can specify in the `.cvswrappers' file. See section The cvswrappers file.

`-jrevision`

With two `-j' options, merge changes from the revision specified with the first `-j' option to the revision specified with the second `j' option, into the working directory.

With one `-j' option, merge changes from the ancestor revision to the revision specified with the `-j' option, into the working directory. The ancestor revision is the common ancestor of the revision which the working directory is based on, and the revision specified in the `-j' option.

In addition, each -j option can contain an optional date specification which, when used with branches, can limit the chosen revision to one within a specific date. An optional date is specified by adding a colon (:) to the tag: `-jSymbolic_Tag:Date_Specifier'.

See section Merging.

update output

`update` keeps you informed of its progress by printing a line for each file, preceded by one character indicating the status of the file:

`U file`

The file was brought up to date with respect to the repository. This is done for any file that exists in the repository but not in your source, and for files that you haven't changed but are not the most recent versions available in the repository.

`A file`

The file has been added to your private copy of the sources, and will be added to the source repository when you run `commit` on the file. This is a reminder to you that the file needs to be committed.

`R file`

The file has been removed from your private copy of the sources, and will be removed from the source repository when you run `commit` on the file. This is a reminder to you that the file needs to be committed.

`M file`

The file is modified in your working directory.

`M' can indicate one of two states for a file you're working on: either there were no modifications to the same file in the repository, so that your file remains as you last saw it; or there were modifications in the repository as well as in your copy, but they were merged successfully, without conflict, in your working directory.

CVS will print some messages if it merges your work, and a backup copy of your working file (as it looked before you ran `update`) will be made. The exact name of that file is printed while `update` runs.

`C file`

A conflict was detected while trying to merge your changes to file with changes from the source repository. file (the copy in your working directory) is now the output of the rcsmerge(1) command on the two revisions; an unmodified copy of your file is also in your working directory, with the name `.#file.revision' where revision is the RCS revision that your modified file started from. (Note that some systems automatically purge files that begin with `.#' if they have not been accessed for a few days. If you intend to keep a copy of your original file, it is a very good idea to rename it.)

`? file`

file is in your working directory, but does not correspond to anything in the source repository, and

is not in the list of files for CVS to ignore (see the description of the `-I' option, and see section Ignoring files via cvsignore).

Note that no warning message like this is printed for spurious directories that CVS encounters. The directory, and all its contents, are silently ignored.

update examples

The following line will display all files which are not up-to-date without actually change anything in your working directory. It can be used to check what has been going on with the project.

```
$ cvs -n -q update
```

Go to the previous, next section.

Go to the previous, next section.

Reference manual for the Administrative files

Inside the repository, in the directory `$CVSROOT/CVSROOT', there are a number of supportive files for CVS. You can use CVS in a limited fashion without any of them, but if they are set up properly they can help make life easier.

The most important of these files is the `modules' file, which defines the modules inside the repository.

The modules file

The `modules' file records your definitions of names for collections of source code. CVS will use these definitions if you use CVS to update the modules file (use normal commands like `add`, `commit`, etc).

The `modules' file may contain blank lines and comments (lines beginning with `#') as well as module definitions. Long lines can be continued on the next line by specifying a backslash (`\') as the last character on the line.

A module definition is a single line of the `modules' file, in either of two formats. In both cases, mname represents the symbolic module name, and the remainder of the line is its definition.

`mname -a aliases...`

This represents the simplest way of defining a module mname. The `-a' flags the definition as a simple alias: CVS will treat any use of mname (as a command argument) as if the list of names aliases had been specified instead. aliases may contain either other module names or paths. When you use paths in aliases, `checkout` creates all intermediate directories in the working directory, just as if the path had been specified explicitly in the CVS arguments.

`mname [ options ] dir [ files... ] [ &module... ]`

In the simplest case, this form of module definition reduces to `mname dir'. This defines all the files in directory dir as module mname. dir is a relative path (from `$CVSROOT`) to a directory of source in the source repository. In this case, on checkout, a single directory called mname is created as a working directory; no intermediate directory levels are used by default, even if dir was a path involving several directory levels.

By explicitly specifying files in the module definition after dir, you can select particular files from directory dir. The sample definition for `modules' is an example of a module defined with a single file from a particular directory. Here is another example:

```
m4test  unsupported/gnu/m4 foreach.m4 forloop.m4
```

With this definition, executing `cvs checkout m4test' will create a single working directory `m4test' containing the two files listed, which both come from a common directory several levels deep in the CVS source repository.

A module definition can refer to other modules by including `&module' in its definition. `checkou` creates a subdirectory for each such module, in your working directory.

`-d name`

Name the working directory something other than the module name.

`-e prog`

Specify a program prog to run whenever files in a module are exported. prog runs with a single argument, the module name.

`-i prog`

Specify a program prog to run whenever files in a module are committed. prog runs with a single argument, the full pathname of the affected directory in a source repository. The `` `commitinfo' ``, `` `loginfo' ``, and `` `editinfo' `` files provide other ways to call a program on commit.

`-o prog`

Specify a program prog to run whenever files in a module are checked out. prog runs with a single argument, the module name.

`-s status`

Assign a status to the module. When the module file is printed with `cvs checkout -s' the modules are sorted according to primarily module status, and secondarily according to the module name. This option has no other meaning. You can use this option for several things besides status: for instance, list the person that is responsible for this module.

`-t prog`

Specify a program prog to run whenever files in a module are tagged with `rtag`. prog runs with two arguments: the module name and the symbolic tag specified to `rtag`. There is no way to specify a program to run when `tag` is executed.

`-u prog`

Specify a program prog to run whenever `cvs update' is executed from the top-level directory of the checked-out module. prog runs with a single argument, the full path to the source repository for this module.

The cvswrappers file

Wrappers allow you to set a hook which transforms files on their way in and out of CVS. Most or all of the wrappers features do not work with client/server CVS.

The file `` `cvswrappers' `` defines the script that will be run on a file when its name matches a regular expresion. There are two scripts that can be run on a file or directory. One script is executed on the file/directory before being checked into the repository (this is denoted with the `-t` flag) and the other when the file is checked out of the repository (this is denoted with the `-f` flag)

The `` `cvswrappers' `` also has a `-m' option to specify the merge methodology that should be used when the file is updated. `MERGE` means the usual CVS behavior: try to merge the files (this generally will not work for binary files). `COPY` means that `cvs update` will merely copy one version over the other, and require the user using mechanisms outside CVS, to insert any necessary changes. The `-m' wrapper option only affects behavior when merging is done on update; it does not affect how files are stored. See See section Handling

binary files, for more on binary files.

The basic format of the file `cvswrappers' is:

```
wildcard     [option value][option value]...

where option is one of
-f           from cvs filter         value: path tofilter
-t           to cvs filter           value: path to filter
-m           update methodology      value: MERGE or COPY

and value is a single-quote delimited value.

*.nib     -f 'unwrap %s' -t 'wrap %s %s' -m 'COPY'
*.c       -t 'indent %s %s'
```

The above example of a `cvswrappers' file states that all files/directories that end with a `.nib' should be filtered with the `wrap' program before checking the file into the repository. The file should be filtered though the `unwrap' program when the file is checked out of the repository. The `cvswrappers' file also states that a `COPY' methodology should be used when updating the files in the repository (that is no merging should be performed).

The last example line says that all files that end with a `*.c' should be filtered with `indent' before being checked into the repository. Unlike the previous example no filtering of the `*.c' file is done when it is checked out of the repository. The `-t' filter is called with two arguments, the first is the name of the file/directory to filter and the second is the pathname to where the resulting filtered file should be placed.

The `-f' filter is called with one argument, which is the name of the file to filter from. The end result of this filter will be a file in the users directory that they can work on as they normally would.

The commit support files

The `-i' flag in the `modules' file can be used to run a certain program whenever files are committed (see section The modules file). The files described in this section provide other, more flexible, ways to run programs whenever something is committed.

There are three kind of programs that can be run on commit. They are specified in files in the repository, as described below. The following table summarizes the file names and the purpose of the corresponding programs.

`commitinfo'
: The program is responsible for checking that the commit is allowed. If it exits with a non-zero exit status the commit will be aborted.

`editinfo'
: The specified program is used to edit the log message, and possibly verify that it contains all required fields. This is most useful in combination with the `rcsinfo' file, which can hold a log message template (see section Rcsinfo).

`loginfo'

The specified program is called when the commit is complete. It receives the log message and some additional information and can store the log message in a file, or mail it to appropriate persons, or maybe post it to a local newsgroup, or... Your imagination is the limit!

The common syntax

The four files `commitinfo', `loginfo', `rcsinfo' and `editinfo' all have a common format. The purpose of the files are described later on. The common syntax is described here.

Each line contains the following:

- A regular expression
- A whitespace separator--one or more spaces and/or tabs.
- A file name or command-line template.

Blank lines are ignored. Lines that start with the character `#' are treated as comments. Long lines unfortunately can *not* be broken in two parts in any way.

The first regular expression that matches the current directory name in the repository is used. The rest of the line is used as a file name or command-line as appropriate.

Commitinfo

The `commitinfo' file defines programs to execute whenever `cvs commit' is about to execute. These programs are used for pre-commit checking to verify that the modified, added and removed files are really ready to be committed. This could be used, for instance, to verify that the changed files conform to to your site's standards for coding practice.

As mentioned earlier, each line in the `commitinfo' file consists of a regular expression and a command-line template. The template can include a program name and any number of arguments you wish to supply to it. The full path to the current source repository is appended to the template, followed by the file names of any files involved in the commit (added, removed, and modified files).

The first line with a regular expression matching the relative path to the module will be used. If the command returns a non-zero exit status the commit will be aborted.

If the repository name does not match any of the regular expressions in this file, the `DEFAULT' line is used, if it is specified.

All occurances of the name `ALL' appearing as a regular expression are used in addition to the first matching regular expression or the name `DEFAULT'.

Note: when CVS is accessing a remote repository, `commitinfo' will be run on the *remote* (i.e., server) side, not the client side (see section Remote repositories).

TOC

Editinfo

If you want to make sure that all log messages look the same way, you can use the `editinfo' file to specify a program that is used to edit the log message. This program could be a custom-made editor that always enforces a certain style of the log message, or maybe a simple shell script that calls an editor, and checks that the entered message contains the required fields.

If no matching line is found in the `editinfo' file, the editor specified in the environment variable $CVSEDITOR is used instead. If that variable is not set, then the environment variable $EDITOR is used instead. If that variable is not set a precompiled default, normally vi, will be used.

The `editinfo' file is often most useful together with the `rcsinfo' file, which can be used to specify a log message template.

Each line in the `editinfo' file consists of a regular expression and a command-line template. The template must include a program name, and can include any number of arguments. The full path to the current log message template file is appended to the template.

One thing that should be noted is that the `ALL' keyword is not supported. If more than one matching line is found, the first one is used. This can be useful for specifying a default edit script in a module, and then overriding it in a subdirectory.

If the repository name does not match any of the regular expressions in this file, the `DEFAULT' line is used, if it is specified.

If the edit script exits with a non-zero exit status, the commit is aborted.

Note: when CVS is accessing a remote repository, `editinfo' will be run on the *remote* (i.e., server) side, not the client side (see section Remote repositories).

Editinfo example

The following is a little silly example of a `editinfo' file, together with the corresponding `rcsinfo' file, the log message template and an editor script. We begin with the log message template. We want to always record a bug-id number on the first line of the log message. The rest of log message is free text. The following template is found in the file `/usr/cvssupport/tc.template'.

```
BugId:
```

The script `/usr/cvssupport/bugid.edit' is used to edit the log message.

```
#!/bin/sh
#
#       bugid.edit filename
#
#  Call $EDITOR on FILENAME, and verify that the
#  resulting file contains a valid bugid on the first
#  line.
if [ "x$EDITOR" = "x" ]; then EDITOR=vi; fi
```

```
if [ "x$CVSEDITOR" = "x" ]; then CVSEDITOR=$EDITOR; fi
$CVSEDITOR $1
until head -1|grep '^BugId:[ ]*[0-9][0-9]*$' < $1
do  echo -n  "No BugId found.  Edit again? ([y]/n)"
    read ans
    case ${ans} in
        n*) exit 1;;
    esac
    $CVSEDITOR $1
done
```

The `editinfo' file contains this line:

```
^tc     /usr/cvssupport/bugid.edit
```

The `rcsinfo' file contains this line:

```
^tc     /usr/cvssupport/tc.template
```

Loginfo

The `loginfo' file is used to control where `cvs commit' log information is sent. The first entry on a line is a regular expression which is tested against the directory that the change is being made to, relative to the $CVSROOT. If a match is found, then the remainder of the line is a filter program that should expect log information on its standard input.

The filter program may use one and only one % modifier (a la printf). If `%s' is specified in the filter program, a brief title is included (enclosed in single quotes) showing the modified file names.

If the repository name does not match any of the regular expressions in this file, the `DEFAULT' line is used, if it is specified.

All occurances of the name `ALL' appearing as a regular expression are used in addition to the first matching regular expression or `DEFAULT'.

The first matching regular expression is used.

See section The commit support files, for a description of the syntax of the `loginfo' file.

Note: when CVS is accessing a remote repository, `loginfo' will be run on the *remote* (i.e., server) side, not the client side (see section Remote repositories).

Loginfo example

The following `loginfo' file, together with the tiny shell-script below, appends all log messages to the file `$CVSROOT/CVSROOT/commitlog', and any commits to the administrative files (inside the `CVSROOT' directory) are also logged in `/usr/adm/cvsroot-log'.

```
ALL             /usr/local/bin/cvs-log $CVSROOT/CVSROOT/commitlog
```

```
^CVSROOT        /usr/local/bin/cvs-log /usr/adm/cvsroot-log
```

The shell-script `/usr/local/bin/cvs-log' looks like this:

```
#!/bin/sh
(echo "------------------------------------------------------------";
 echo -n $USER"  ";
 date;
 echo;
 sed '1s+'${CVSROOT}'++') >> $1
```

Rcsinfo

The `rcsinfo' file can be used to specify a form to edit when filling out the commit log. The `rcsinfo' file has a syntax similar to the `editinfo', `commitinfo' and `loginfo' files. See section The common syntax. Unlike the other files the second part is *not* a command-line template. Instead, the part after the regular expression should be a full pathname to a file containing the log message template.

If the repository name does not match any of the regular expressions in this file, the `DEFAULT' line is used, if it is specified.

All occurances of the name `ALL' appearing as a regular expression are used in addition to the first matching regular expression or `DEFAULT'.

The log message template will be used as a default log message. If you specify a log message with `cvs commit -m message' or `cvs commit -f file' that log message will override the template.

See section Editinfo example, for an example `rcsinfo' file.

When CVS is accessing a remote repository, the contents of `rcsinfo' at the time a directory is first checked out will specify a template which does not then change. If you edit `rcsinfo' or its templates, you may need to check out a new working directory.

Ignoring files via cvsignore

There are certain file names that frequently occur inside your working copy, but that you don't want to put under CVS control. Examples are all the object files that you get while you compile your sources. Normally, when you run `cvs update', it prints a line for each file it encounters that it doesn't know about (see section update output).

CVS has a list of files (or sh(1) file name patterns) that it should ignore while running `update', `import' and `release'. This list is constructed in the following way.

- The list is initialized to include certain file name patterns: names associated with CVS administration, or with other common source control systems; common names for patch files, object files, archive files, and editor backup files; and other names that are usually artifacts of assorted utilities. Currently, the default list of ignored file name patterns is:

```
RCS     SCCS    CVS     CVS.adm
```

```
RCSLOG  cvslog.*
tags    TAGS
.make.state     .nse_depinfo
*~      #*      .#*     ,*      _$*     *$
*.old   *.bak   *.BAK   *.orig  *.rej   .del-*
*.a     *.olb   *.o     *.obj   *.so    *.exe
*.Z     *.elc   *.ln
core
```

- The per-repository list in `$CVSROOT/CVSROOT/cvsignore' is appended to the list, if that file exists.
- The per-user list in `.cvsignore' in your home directory is appended to the list, if it exists.
- Any entries in the environment variable $CVSIGNORE is appended to the list.
- Any `-I' options given to CVS is appended.
- As CVS traverses through your directories, the contents of any `.cvsignore' will be appended to the list. The patterns found in `.cvsignore' are only valid for the directory that contains them, not for any sub-directories.

In any of the 5 places listed above, a single exclamation mark (`!') clears the ignore list. This can be used if you want to store any file which normally is ignored by CVS.

The history file

The file `$CVSROOT/CVSROOT/history' is used to log information for the `history' command (see section history--Show status of files and users). This file must be created to turn on logging. This is done automatically if the `cvs init' command is used to set up the repository (see section Setting up the repository).

The file format of the `history' file is documented only in comments in the CVS source code, but generally programs should use the `cvs history' command to access it anyway, in case the format changes with future releases of CVS.

Setting up the repository

To set up a CVS repository, choose a directory with ample disk space available for the revision history of the source files. It should be accessable (directly or via a networked file system) from all machines which want to use CVS in server or local mode; the client machines need not have any access to it other than via the CVS protocol.

To create a repository, run the `cvs init' command. It will set up an empty repository in the CVS root specified in the usual way (see section The Repository). For example,

```
cvs -d /usr/local/cvsroot init
```

`cvs init' is careful to never overwrite any existing files in the repository, so no harm is done if you run `cvs init' on an already set-up repository.

`cvs init` will enable history logging; if you don't want that, remove the history file after running `cvs init`. See section The history file.

Expansions in administrative files

Sometimes in writing an administrative file, you might want the file to be able to know various things based on environment CVS is running in. There are several mechanisms to do that.

To find the home directory of the user running CVS (from the `HOME` environment variable), use `~' followed by `/' or the end of the line. Likewise for the home directory of user, use `~user'. These variables are expanded on the server machine, and don't get any resonable expansion if pserver (see section Direct connection with password authentication) is in used; therefore user variables (see below) may be a better choice to customize behavior based on the user running CVS.

One may want to know about various pieces of information internal to CVS. A CVS internal variable has the syntax `${variable}`, where variable starts with a letter and consists of alphanumberic characters and `_'. If the character following variable is a non-alphanumeric character other than `_', the `{' and `}' can be omitted. The CVS internal variables are:

`CVSROOT`

This is the value of the CVS root in use. See section The Repository, for a description of the various ways to specify this.

`RCSBIN`

This is the value CVS is using for where to find RCS binaries. See section Global options, for a description of how to specify this.

`CVSEDITOR`

`VISUAL`

`EDITOR`

These all expand to the same value, which is the editor that CVS is using. See section Global options, for how to specify this.

`USER`

Username of the user running CVS (on the CVS server machine).

If you want to pass a value to the administrative files which the user that is running CVS can specify, use a user variable. To expand a user variable, the administrative file contains `${=variable}`. To set a user variable, specify the global option `-s' to CVS, with argument `variable=value`. It may be particularly useful to specify this option via `.cvsrc' (see section Default options and the ~/.cvsrc file).

For example, if you want the administrative file to refer to a test directory you might create a user variable `TESTDIR`. Then if CVS is invoked as `cvs -s TESTDIR=/work/local/tests`, and the administrative file contains `sh ${=TESTDIR}/runtests`, then that string is expanded to `sh /work/local/tests/runtests`.

All other strings containing `$' are reserved; there is no way to quote a `$' character so that `$' represents itself.

Go to the previous, next section.

Go to the previous, next section.

All environment variables which affect CVS

This is a complete list of all environment variables that affect CVS.

`$CVSIGNORE`

A whitespace-separated list of file name patterns that CVS should ignore. See section Ignoring files via cvsignore.

`$CVSWRAPPERS`

A whitespace-separated list of file name patterns that CVS should treat as wrappers. See section The cvswrappers file.

`$CVSREAD`

If this is set, `checkout` and `update` will try hard to make the files in your working directory read-only. When this is not set, the default behavior is to permit modification of your working files.

`$CVSROOT`

Should contain the full pathname to the root of the CVS source repository (where the RCS history files are kept). This information must be available to CVS for most commands to execute; if `$CVSROOT` is not set, or if you wish to override it for one invocation, you can supply it on the command line: `cvs -d cvsroot cvs_command...' Once you have checked out a working directory, CVS stores the appropriate root (in the file `` `CVS/Root' ``), so normally you only need to worry about this when initially checking out a working directory.

`$EDITOR`

`$CVSEDITOR`

Specifies the program to use for recording log messages during commit. If not set, the default is `/usr/ucb/vi'. `$CVSEDITOR` overrides `$EDITOR`. `$CVSEDITOR` does not exist in CVS 1.3, but the next release will probably include it.

`$PATH`

If `$RCSBIN` is not set, and no path is compiled into CVS, it will use `$PATH` to try to find all programs it uses.

`$RCSBIN`

Specifies the full pathname of the location of RCS programs, such as co(1) and ci(1). If not set, a compiled-in value is used, or your `$PATH` is searched.

`$HOME`

`$HOMEPATH`

Used to locate the directory where the `` `.cvsrc' `` file is searched (`$HOMEPATH` is used for Windows-NT). see section Default options and the ~/.cvsrc file

`$CVS_RSH`

Used in client-server mode when accessing a remote repository using RSH. The default value is `rsh`. You can set it to use another program for accssing the remote server (e.g. for HP-UX 9, you should set it to `remsh` because `rsh` invokes the restricted shell). see section Connecting with rsh

`$CVS_SERVER`

Used in client-server mode when accessing a remote repository using RSH. It specifies the name of the program to start on the server side when accessing a remote repository using RSH. The default value is `cvs`. see section Connecting with rsh

`$CVS_PASSFILE`

Used in client-server mode when accessing the `cvs login server`. Default value is `` `$HOME/.cvspass' ``. see section Using the client with password authentication

`$CVS_PASSWORD`

Used in client-server mode when accessing the `cvs login server`. see section Using the client with password authentication

`$CVS_CLIENT_PORT`

Used in client-server mode when accessing the server via Kerberos. see section Direct connection with kerberos

`$CVS_RCMD_PORT`

Used in client-server mode. If set, specifies the port number to be used when accessing the RCMD demon on the server side. (Currently not used for Unix clients).

`$CVS_CLIENT_LOG`

Used for debugging only in client-server mode. If set, everything send to the server is logged into `` `$CVS_CLIENT_LOG.in' `` and everything send from the server is logged into `` `$CVS_CLIENT_LOG.out' ``.

`$CVS_SERVER_SLEEP`

Used only for debugging the server side in client-server mode. If set, delays the start of the server child process the the specified amount of seconds so that you can attach to it with a debugger.

`$CVS_IGNORE_REMOTE_ROOT`

(What is the purpose of this variable?)

`$COMSPEC`

Used under OS/2 only. It specifies the name of the command interpreter and defaults to CMD.EXE.

CVS is a front-end to RCS. The following environment variables affect RCS. Note that if you are using the client/server CVS, these variables need to be set on the server side (which may or not may be possible depending on how you are connecting). There is probably not any need to set any of them, however.

`$LOGNAME`

`$USER`

If set, they affect who RCS thinks you are. If you have trouble checking in files it might be because your login name differs from the setting of e.g. `$LOGNAME`.

`$RCSINIT`

Options prepended to the argument list, separated by spaces. A backslash escapes spaces within an option. The `$RCSINIT` options are prepended to the argument lists of most RCS commands.

`$TMPDIR`

`$TMP`

`$TEMP`

Name of the temporary directory. The environment variables are inspected in the order they appear above and the first value found is taken; if none of them are set, a host-dependent default is used, typically `` `/tmp' ``.

Go to the previous, next section.

Troubleshooting

Magic branch numbers

Externally, branch numbers consist of an odd number of dot-separated decimal integers. See section Revision numbers. That is not the whole truth, however. For efficiency reasons CVS sometimes inserts an extra 0 in the second rightmost position (1.2.3 becomes 1.2.0.3, 8.9.10.11.12 becomes 8.9.10.11.0.12 and so on).

CVS does a pretty good job at hiding these so called magic branches, but in at least four places the hiding is incomplete.

- The magic branch can appear in the output from `cvs status` in vanilla CVS 1.3. This is fixed in CVS 1.3-s2.
- The magic branch number appears in the output from `cvs log`. This is much harder to fix, since `cvs log` runs `rlog` (which is part of the RCS distribution), and modifying `rlog` to know about magic branches would probably break someone's habits (if they use branch 0 for their own purposes).
- You cannot specify a symbolic branch name to `cvs log`.
- You cannot specify a symbolic branch name to `cvs admin`.

You can use the `admin` command to reassign a symbolic name to a branch the way RCS expects it to be. If `R4patches` is assigned to the branch 1.4.2 (magic branch number 1.4.0.2) in file `` `numbers.c' `` you can do this:

```
$ cvs admin -NR4patches:1.4.2 numbers.c
```

It only works if at least one revision is already committed on the branch. Be very careful so that you do not assign the tag to the wrong number. (There is no way to see how the tag was assigned yesterday).

Yes, this really should be fixed, and it's being worked on

Dvips: A DVI-to-PostScript Translator

for version 5.526b

February 1994

Tomas Rokicki (edited for Dvipsk by Karl Berry)

Dvips: A DVI-to-PostScript Translator

@defcodeindex fl @defcodeindex op

This document is based on `dvips.tex' by Tomas Rokicki. It is in the public domain.

Why Use dvips?

The `dvips' program has a number of features that set it apart from other PostScript drivers for TeX. This rather long section describes the advantages of using dvips, and may be skipped if you are just interested in learning how to use the program. See section Installation, for details of compilation and installation.

The dvips driver generates excellent, standard PostScript, that can be included in other documents as figures or printed through a variety of spoolers. The generated PostScript requires very little printer memory, so very complex documents with a lot of fonts can easily be printed even on PostScript printers without much memory, such as the original Apple LaserWriter. The PostScript output is also compact, requiring less disk space to store and making it feasible as a transfer format.

Even those documents that are too complex to print in their entirety on a particular printer can be printed, since dvips will automatically split such documents into pieces, reclaiming the printer memory between each piece.

The dvips program supports graphics in a natural way, allowing PostScript graphics to be included and automatically scaled and positioned in a variety of ways.

Printers with resolutions other than 300 dpi are also supported, even if they have different resolutions in the horizontal and vertical directions. High resolution output is supported for typesetters, including an option that compresses the bitmapped fonts so that typesetter virtual memory is not exhausted. This option also significantly reduces the size of the PostScript file and decoding in the printer is very fast.

Missing fonts can be automatically generated if METAFONT exists on the system, or fonts can be converted from `gf' to `pk' format on demand. If a font cannot be generated, a scaled version of the same font at a different size can be used instead, although dvips will complain loudly about the poor aesthetics of the resulting output.

Users will appreciate features such as collated copies and support for `tpic', `psfig', `emtex', and `METAPOST'; system administrators will love the support for multiple printers, each with their own configuration file, and the ability to pipe the output directly to a program such as `lpr'. Support for MS-DOS, OS/2, and VMS in addition to UNIX is provided in the standard distribution, and porting to other systems is easy.

One of the most important features is the support of virtual fonts, which add an entirely new level of flexibility to TeX. Virtual fonts are used to give dvips its excellent PostScript font support, handling all the font remapping in a natural, portable, elegant, and extensible way. The dvips `afm2tfm' driver even comes with its own `afm2tfm' program that creates the necessary virtual fonts and TeX font metric files automatically from the Adobe font metric files.

Source is provided and freely distributable, so adding a site-specific feature is possible. Adding such features is made easier by the highly modular structure of the program.

There is really no reason to use another driver, and the more people use dvips, the less time will be spent fighting with PostScript and the more time will be available to create beautiful documents. So if you don't use dvips on your system, get it today.

Using dvips

To use dvips, simply type

```
dvips foo
```

where `foo.dvi' is the output of TeX that you want to print. If dvips has been installed correctly, the document should come out of your default printer.

If you use fonts that have not been used on your system before, they may be automatically generated; this process can take a few minutes. The next time that document is printed, these fonts will already exist, so printing will go much faster.

Many options are available; they are described in a later section. For a brief summary of available options, just type

```
dvips
```

Paper Size and Landscape Mode

Most TeX documents at a particular site are designed to use the standard paper size (for example, letter size in the United States or A4 in Europe.) The dvips program defaults to these paper sizes and can be customized for the defaults at each site or on each printer.

But many documents are designed for other paper sizes. For instance, you may want to design a document that has the long edge of the paper horizontal. This can be useful when typesetting booklets, brochures, complex tables, or many other documents. This type of paper orientation is called landscape orientation (the `normal' orientation is portrait). Alternatively, a document might be designed for ledger or A3 paper.

Since the intended paper size is a document design decision, and not a decision that is made at printing time, such information should be given in the TeX file and not on the dvips command line. For this reason, dvips supports a `papersize' special. It is hoped that this special will become standard over time for TeX previewers and other printer drivers.

The format of the `papersize' special is

```
\special{papersize=8.5in,11in}
```

where the dimensions given above are for a standard letter sheet. The first dimension given is the horizontal

size of the page, and the second is the vertical size. The dimensions supported are the same as for TeX; namely, in (inches), cm (centimeters), mm (millimeters), pt (points), sp (scaled points), bp (big points, same as the default PostScript unit), pc (picas), dd (didot points), and cc (ciceros).

For a landscape document, the `papersize' comment would be given as

```
\special{papersize=11in,8.5in}
```

An alternate specification of `landscape' is to have a special of the form

```
\special{landscape}
```

This is supported for backward compatibility, but it is hoped that eventually the `papersize' comment will dominate.

Of course, using such a command only informs dvips of the desired paper size; you must still adjust the `hsize' and `vsize' in your TeX document to actually use the full page.

The `papersize' special must occur somewhere on the first page of the document.

Including PostScript Graphics

Scaling and including PostScript graphics is a breeze--if the PostScript file is correctly formed. Even if it is not, however, the file can usually be accommodated with just a little more work. The most important feature of a good PostScript file--from the standpoint of including it in another document--is an accurate bounding box comment.

The Bounding Box Comment

Every well-formed PostScript file has a comment describing where on the page the graphic is located, and how big that graphic is. This information is given in terms of the lower left and upper right corners of a box just enclosing the graphic, and is thus referred to as a bounding box. These coordinates are given in PostScript units (there are precisely 72 PostScript units to the inch) with respect to the lower left corner of the sheet of paper.

To see if a PostScript file has a bounding box comment, just look at the first few lines of the file. (PostScript is standard ASCII, so you can use any text editor to do this.) If within the first few dozen lines there is a line of the form

```
%%BoundingBox: 0 1 2 3
```

(with any numbers), chances are very good that the file is Encapsulated PostScript and will work easily with dvips. If the file contains instead a line like

```
%%BoundingBox: (atend)
```

the file is still probably Encapsulated PostScript, but the bounding box (that dvips needs to position the graphic) is at the end of the file and should be moved to the position of the line above. This can be done with that same text editor, or with a simple Perl script.

If the document lacks a bounding box altogether, one can easily be added. Simply print the file. Now, take a ruler, and make the following measurements. All measurements should be in PostScript units, so measure it in inches and multiply by 72. Alternatively, the `bbfig' program distributed with dvips in the `contrib' directory can be used to automate this process.

From the left edge of the paper to the leftmost mark on the paper is llx, the first number. From the bottom edge of the paper to the bottommost mark on the paper is lly, the second number. From the left edge of the paper to the rightmost mark on the paper is urx, the third number. The fourth and final number, ury, is the distance from the bottom of the page to the uppermost mark on the paper.

Now, add a comment of the following form as the second line of the document. (The first line should already be a line starting with the two characters `%!'; if it is not, the file probably isn't PostScript.)

```
%%BoundingBox: llx lly urx ury
```

Or, if you don't want to modify the file, you can simply write these numbers down in a convenient place and use them when you import the graphic.

If the document does not have such a bounding box, or if the bounding box is given at the end of the document, please complain to the authors of the software package that generated the file; without such a line, including PostScript graphics can be tedious.

Using the EPSF Macros

Now you are ready to include the graphic into a TeX file. Simply add to the top of your TeX file a line like

@flindex epsf.tex

```
\input epsf
```

(or, if your document is in LaTeX or SliTeX, add the `epsf' style option, as was done to the following line).

```
\documentstyle[12pt,epsf]{article}
```

This only needs to be done once, no matter how many figures you plan to include. Now, at the point you want to include the file, enter a line such as

```
\epsffile{foo.ps}
```

If you are using LaTeX or SliTeX, you may need to add a `\leavevmode' command immediately before the `\epsffile' command to get certain environments to work correctly. If your file did not (or does not currently) have a bounding box comment, you should supply those numbers you wrote down as in the following example:

```
\epsffile[100 100 500 500]{foo.ps}
```

(in the same order they would have been in a normal bounding box comment). Now, save your changes and run TeX and dvips; the output should have your graphic positioned at precisely the point you indicated, with the proper amount of space reserved.

The effect of the `epsffile' macro is to typeset the figure as a TeX `vbox' at the point of the page that the command is executed. By default, the graphic will have its `natural' width (namely, the width of its bounding box). The TeX box will have depth zero and a `natural' height. The graphic will be scaled by any `dvi' magnification in effect at the time.

Any PostScript graphics included by any method in this document (except `bop-hook' and its ilk) are scaled by the current `dvi' magnification. For graphics included with `epsffile' where the size is given in TeX dimensions, this scaling will produce the correct, or expected, results. For compatibility with old PostScript drivers, it is possible to turn this scaling off with the following TeX command:

```
\special{! /magscale false def}
```

Use of this command is not recommended because it will make the `epsffile' graphics the wrong size if global magnification is used in a `dvi' document, and it will cause any PostScript graphics to appear improperly scaled and out of position if a `dvi' to `dvi' program is used to scale or otherwise modify the document.

You can enlarge or reduce the figure by putting

```
\epsfxsize=dimen
```

right before the call to `epsffile'. Then the width of the TeX box will be dimen and its' height will be scaled proportionately. Alternatively you can force the vertical size to a particular size with

```
\epsfysize=dimen
```

in which case the height will be set and the width will be scaled proportionally. If you set both, the aspect ratio of the included graphic will be distorted but both size specifications will be honored.

By default, clipping is disabled for included EPSF images. This is because clipping to the bounding box dimensions often cuts off a small portion of the figure, due to slightly inaccurate bounding box arguments. The problem might be subtle; lines around the boundary of the image might be half their intended width, or the tops or bottoms of some text annotations might be sliced off. If you want to turn clipping on, just use the command

```
\epsfclipon
```

and to turn clipping back off, use

```
\epsfclipoff
```

A more general facility for sizing is available by defining the `epsfsize' macro. You can redefine this macro to do almost anything. This TeX macro is passed two parameters by `epsffile'. The first parameter is the

natural horizontal size of the PostScript graphic, and the second parameter is the natural vertical size. 'I macro is responsible for returning the desired horizontal size of the graph (the same as assigning `epsfx above).

In the definitions given below, only the body is given; it should be inserted in

```
\def\epsfsize#1#2{body}
```

Some common definitions are:

`epsfxsize'

This definition (the default) enables the default features listed above, by setting `epsfxsize' to the same value it had before the macro was called.

`0pt'

This definition forces natural sizes for all graphics by setting the width to zero, which turns on horizontal scaling.

`#1'

This forces natural sizes too, by returning the first parameter only (the natural width) and setting the width to it.

`hsize'

This forces all graphics to be scaled so they are as wide as the current horizontal size. (In LaTeX, use `textwidth' instead of `hsize'.)

`0.5#1'

This scales all figures to half of their natural size.

`\ifnum#1>\hsize\hsize\else#1\fi'

This keeps graphics at their natural size, unless the width would be wider than the current `hsize', in which case the graphic is scaled down to `hsize'.

If you want TeX to report the size of the figure as a message on your terminal when it processes each figure, give the command

```
\epsfverbosetrue
```

Header Files

Often in order to get a particular graphic file to work, a certain header file might need to be sent first. Sometimes this is even desirable, since the size of the header macros can dominate the size of certain PostScript graphics files. The dvips program provides support for this with the `header=' special command. For instance, to ensure that `foo.ps' gets downloaded as part of the header material, the following command should be added to the TeX file:

```
\special{header=foo.ps}
```

The dictionary stack will be at the `userdict' level when these header files are included.

For these and all other header files (including the headers required by dvips itself and any downloaded fonts), the printer VM budget is debited by some value. If the header file has, in its first 1024 bytes, a l of the form

```
%%VMusage: min max
```

then the maximum value is used. If it doesn't, then the total size of the header file in bytes is used as an approximation of the memory requirements.

Literal PostScript

For simple graphics, or just for experimentation, literal PostScript graphics can be included. Simply use a special command that starts with a double quote (`"').

For instance, the following (simple) graphic: was created by typing:

```
\vbox to 100bp{\vss % a bp is the same as a PostScript unit
\special{" newpath 0 0 moveto 100 100 lineto 394 0 lineto
closepath gsave 0.8 setgray fill grestore stroke}}
```

(You are responsible for leaving space for such literal graphics.) Literal graphics are discouraged because of their nonportability.

Literal Headers

Similarly, you can define your own macros for use in such literal graphics through the use of literal macros. Literal macros are defined just like literal graphics, only you begin the special with an exclamation point instead of a double quote. These literal macros are included as part of the header material in a special dictionary called `SDict'. This dictionary is the first one on the PostScript dictionary stack when any PostScript graphic is included, whether by literal inclusion or through the `epsffile' macros.

Other Graphics Support

There are other ways to include graphics with dvips. One is to use an existing package, such as `emtex', `psfig', `tpic', or `METAPOST', all of which `dvips' supports.

Other facilities are available for historical reasons, but their use is discouraged, in hope that some `sane' form of PostScript inclusion shall become standard. The main advantage of the `epsffile' macros is that they can be adapted for whatever form of special eventually becomes standard, and thus only minor modifications to that one file need to be made, rather than revising an entire library of TeX documents.

Most of these specials use a flexible key and value scheme:

```
\special{psfile=filename.ps[key=value]*}
```

This will download the PostScript file called `filename.ps' such that the current point will be the

origin of the PostScript coordinate system. The optional key/value assignments allow you to specify transformations on the PostScript.

The possible keys are:

`hoffset'
: The horizontal offset (default 0)

`voffset'
: The vertical offset (default 0)

`hsize'
: The horizontal clipping size (default 612)

`vsize'
: The vertical clipping size (default 792)

`hscale'
: The horizontal scaling factor (default 100)

`vscale'
: The vertical scaling factor (default 100)

`angle'
: The rotation (default 0)

`clip'
: Enable clipping to the bounding box

The dimension parameters are all given in PostScript units. The `hscale' and `vscale' are given in non-dimensioned percentage units, and the rotation value is specified in degrees. Thus

```
\special{psfile=foo.ps hoffset=72 hscale=90 vscale=90}
```

will shift the graphics produced by file `foo.ps' right by one inch and will draw it at 0.9 times normal size. Offsets are given relative to the point of the special command, and are unaffected by scaling or rotation. Rotation is counterclockwise about the origin. The order of operations is to rotate the figure, scale it, then offset it.

For compatibility with older PostScript drivers, it is possible to change the units that `hscale' and `vscale' are given in. This can be done by redefining `@scaleunit' in `SDict' by a TeX command such as

```
\special{! /@scaleunit 1 def}
```

The `@scaleunit' variable, which is by default 100, is what `hscale' and `vscale' are divided by to yield an absolute scale factor.

All of the methods for including graphics we have described so far enclose the graphic in a PostScript save/restore pair, guaranteeing that the figure will have no effect on the rest of the document. Another type of special command allows literal PostScript instructions to be inserted without enclosing them in this protective shield; users of this feature are supposed to understand what they are doing (and they shouldn't change the PostScript graphics state unless they are willing to take the consequences). This command can

take many forms, because it has had a torturous history; any of the following will work:

```
\special{ps:text}
\special{ps::text}
\special{ps::[begin]text}
\special{ps::[end]text}
```

(with longer forms taking precedence over shorter forms, when they are used). Note that `ps::' and `ps::[end]' do not do any positioning, so they can be used to continue PostScript literals started with `ps:' or `ps::[begin]'. There is also the command

```
\special{ps: plotfile filename}
```

which will copy the commands from filename verbatim into the output (but omitting lines that begin with %). An example of the proper use of literal specials can be found in the file `rotate.tex' which makes it easy to typeset text turned 90 degrees.

To finish off this section, the following examples are presented without explanation:

```
\def\rotninety{\special{ps:currentpoint currentpoint translate 90
rotate neg exch neg exch translate}}\font\huge=cmbx10 at 14.4truept
\setbox0=\hbox to0pt{\huge A\hss}\vskip16truept\centerline{\copy0
\special{ps:gsave}\rotninety\copy0\rotninety\copy0\rotninety
\box0\special{ps:grestore}}\vskip16truept

\vbox to 2truein{\special{ps:gsave 0.3 setgray}\hrule height 2in
width\hsize\vskip-2in\special{ps:grestore}\font\big=cminch\big
\vss\special{ps:gsave 1 setgray}\vbox to 0pt{\vskip2pt
\line{\hss\hskip4pt NEAT\hss}\vss}\special{ps:0 setgray}%
\hbox{\raise2pt\line{\hss NEAT\hss}\special{ps:grestore}}\vss}
```

Some caveats are in order when using the above forms. Make sure that each `gsave' on a page is matched with a `grestore' on the same page. Do not use `save' or `restore'. Use of these macros can interact with the PostScript generated by dvips if care is not taken; try to understand what the above macros are doing before writing your own. The `\rotninety' macro especially has a useful trick that appears again and again.

Dynamic Creation of PostScript Graphics Files

PostScript is an excellent page description language--but it does tend to be rather verbose. Compressing PostScript graphics files can often reduce them by more than a factor of five. For this reason, if the filename parameter to one of the graphics inclusion techniques starts with a backtick (``'), the filename is instead interpreted as a command to execute that will send the actual file to standard output. Thus,

```
\special{psfile="`zcat foo.ps.Z"}
```

will include the uncompressed version of `foo.ps'. Since such a command is not accessible to TeX, if

you use this facility with the `EPSF' macros, you need to supply the bounding box parameter yourself,

```
\epsffile[72 72 540 720]{"`zcat screendump.ps.Z"}
```

to include `screendump.ps'. Of course, the commands to be executed can be anything, including using a file conversion utility such as `tek2ps' or whatever is appropriate.

This extension is not portable to other DVI-to-PostScript translators.

Using PostScript Fonts

Thanks to Donald E. Knuth, the dvips driver now supports PostScript fonts through the virtual font capability. PostScript fonts are (or should be) accompanied by a font metric file such as `Times-Roman.afm', which describes characteristics of a font called Times-Roman. To use such fonts with TeX, we need `tfm' files that contain similar information. These can be generated from `afm' files by running the program `afm2tfm', supplied with dvips. This program also creates virtual fonts with which you can use normal plain TeX conventions. See Donald E. Knuth, TUGboat v. 11, no. 1, Apr. 1990, pp. 13--23, "Virtual Fonts: More Fun for Grand Wizards", for a general introduction to virtual fonts.

Non-resident downloaded PostScript fonts tend to use a great deal of printer virtual memory. PostScript printers typically have between 130,000 and 400,000 bytes of available virtual memory; each downloaded font will require approximately 30,000 bytes of that. For many applications, bitmapped fonts work much better, even at typesetter resolutions (with the `-Z' option).

Even resident PostScript fonts can take a fair amount of memory, but less with this release of dvips than previously. Also, bitmapped fonts tend to image faster than PostScript fonts.

The Afm2tfm Program

In its simplest form, the `afm2tfm' program converts an Adobe `afm' file (e.g., `Times-Roman.afm') into a `raw' TeX TFM file (say, `rptmr.tfm' with the command

```
afm2tfm Times-Roman rptmr
```

This file is raw because it does no character remapping; it simply converts the character information on a one-to-one basis to TeX characters *with the same code*. (It would be better to have eschewed the use of the `r' prefix in favor of using a variant letter to specify the encoding; but we didn't think of that at the time, and it's too late to change existing fonts. See section 'Top' in Filenames for TeX fonts.)

In the following examples, we will use the font Times-Roman to illustrate the conversion process. For the standard 35 LaserWriter fonts, however, it is highly recommended that you use the supplied `tfm' and `vf' files that come with dvips, as these files contain some additional changes that make them work better with TeX than they otherwise would.

Standard PostScript fonts have a different encoding scheme from that of plain TeX. Although both schemes are based on ASCII, special characters such as ligatures and accents are handled quite differently.

Therefore we obtain best results by using a `virtual font' interface, which makes TeX see a standard Te encoding for the PostScript font. Such a virtual font can be obtained, for example, by the command

```
afm2tfm Times-Roman -v ptmr rptmr
```

This produces two files as output, namely the `virtual property list' file `ptmr.vpl', and the raw font metric file `rptmr.tfm'. (The upper case `-V' also produces a `vpl' file, but maps a set of small caps into the lower case alphabet.) To use the font in TeX, you should first run

```
vptovf ptmr.vpl ptmr.vf ptmr.tfm
```

and then install the virtual font file `ptmr.vf' where Dvips will see it, and install `ptmr.tfm' and `rptmr.tfm' where TeX and Dvips will see them.

You can also make more complex virtual fonts by editing `ptmr.vpl' before running `vptovf'; such editing might add the uppercase Greek characters in the standard TeX positions, for instance. (This has already been done for the font files that come with Dvips.) Once this has been done, you're all set. You can use code like this in TeX henceforth:

```
\font\myfont = ptmr at 12pt
\myfont Hello, I am being typeset in 12-point Times-Roman.
```

Thus we have two fonts, one actual (`rptmr', which is analogous to the font in the printer) and one virtual (`ptmr', which has been remapped to the standard TeX encoding (almost), and has typesetting know-how added. You could also say

```
\font\PTR = rptmr at 10pt
```

and typeset directly with that, but then you would have no ligatures or kerning, and you would have to use Adobe character positions for special letters like The virtual font called `ptmr' not only has ligatures and kerning, and most of the standard accent conventions of TeX, it also has a few additional features not present in the Computer Modern fonts. For example, it includes all the Adobe characters (such as the Polish ogonek and the French guillemots). The only things you lose from ordinary TeX text fonts are the dotless `j' (which can be hacked into the VPL file with literal PostScript specials if you have the patience) and uppercase Greek letters (which just don't exist unless you buy them separately).

The remapped `p*` fonts mostly follow plain TeX conventions for accents. The exceptions: the Hungarian umlaut (which is at position `0x7D' in `cmr10', but position `0xCD' in `ptmr'); the dot accent (at positions `0x5F' and `0xC7', respectively); and `\AA', which neds different tweaking. In order to use these accents with PostScript fonts or in math mode when `\textfont0' is a PostScript font, you will need to use the following definitions. These definitions will not work with the Computer Modern fonts for the relevant accents. They are already part of the distributed `psfonts.sty' for use with LaTeX.

```
\def\H#1{{\accent"CD #1}}
\def\.#1{{\accent"C7 #1}}
\def\dot{\mathaccent"70C7 }
\newdimen\aadimen
```

```
\def\AA{\leavevmode\setbox0\hbox{h}\aadimen\ht0
  \advance\aadimen-1ex\setbox0\hbox{A}\rlap{\raise.67\aadimen
  \hbox to \wd0{\hss\char'27\hss}}A}
```

These PostScript fonts can be scaled to any size. Go wild! Using PostScript fonts, however, does use up a great deal of the printer's memory and it does take time. You may find downloading bitmapped fonts to be faster than using the built-in PostScript fonts!

Changing a Font's Encoding

The `afm2tfm' program also allows you to specify a different encoding for a PostScript font. This can be done at two levels.

You can specify a different output encoding with `-t'. This only applies when you are building a virtual font, and it tells `afm2tfm' to attempt to remap the font to match the output encoding as closely as possible. In such an output encoding, you can also specify ligature pairs and kerning information that will be used in addition to the information in the `afm' file.

You can also specify a different PostScript encoding with `-p'. This changes both the raw `tfm' file created by Afm2tfm and the `vf' and `tfm' files created by VPtoVF. It also requires that the encoding file be downloaded as part of any document that uses this font. This is the only way to access characters in a PostScript font that are neither encoded in the `afm' file nor built from other characters (constructed characters). For instance, `Times-Roman' contains the extra characters `trademark' and `registered' (among others) that can only be accessed through such a PostScript reencoding. Any ligature or kern information specified in the PostScript encoding is ignored by `afm2tfm'.

To combine the effects of `-p' and `-t', use `-T'. If you make regular use of a private non-standard reencoding `-T' is usually the better idea, since you can get unexpected inconsistencies in mapping otherwise.

Afm2tfm's encoding files have precisely the same format as an encoding vector in any PostScript font. Specifically:

```
% Comments are ignored, unless the first word after the percent sign
% is LIGKERN -- see below.
/MyEncoding [ /Alpha /Beta /Gamma /Delta ...
     /A /B ... /Z % exactly 256 entries, each with a / at the front
     /wfooaccent /xfooaccent /yfooaccent /zfooaccent ] def
```

Comments, which start with a percent sign and continue until the end of the line, are ignored unless they start with `LIGKERN'. The first `word' of the file must start with a forward slash (a PostScript literal name) and defines the name of the encoding. The next word must be an left bracket `['. Following that must be precisely 256 character names; use `/.notdef' for any that you do not want defined. Finally, there must be a matching right bracket `]'. A final `def' token is optional. All names are case sensitive.

Any ligature or kern information is given in the comments. If the first word after the percent sign is `LIGKERN', then the entire rest of the line is parsed for ligature and kern information. This ligature and kern information is given in groups of words, each group of which must be terminated by a semicolon (with

a space before and after it, unless it occurs at the end of a line.)

In these `LIGKERN' statements, three types of information may be specified. These three types are ligature pairs, kerns to remove or ignore, and the character value of this font's boundary character. Which of the types the particular set of words corresponds to is automatically determined by the allowable syntax.

Throughout a `LIGKERN' statement, the boundary character is specified as `||'.

To set the boundary character value, a command such as `|| = 39 ;' must be used.

To indicate a kern to remove, give the names of the two characters (without the leading slash) separated by `{}', as in `one {} one ;'. This is similar to the way you might use `{}' in a TeX file to turn off ligatures or kerns at a particular location. Either or both of the character names can be given as `*', which is a wild card matching any character; thus, all kerns can be removed with `* {} * ;'.

To specify a ligature, specify the names of the pair of characters, followed by the ligature `operation' (as in METAFONT), followed by the replacing character name. Either (but not both) of the first two characters can be `||' to indicate a word boundary.

Normally the `operation' is `=:' meaning that both characters are removed and replaced by the third character, but by adding `|' characters on either side of the `=:', you can specify which of the two leading characters to retain. In addition, by suffixing the ligature operation with one or two `>' signs, you can indicate that the ligature scanning operation should skip that many characters before proceeding. This works just like in METAFONT. A typical ligature might be specified with `ff i =: ffi ;'. A more convoluted ligature is `one one |=:|>> exclam ;' which indicates that every pair of adjacent `1"s should be separated by an exclamation point, and then two of the resulting characters should be skipped over before continuing searching for ligatures and kerns. You cannot give more `>"s in an ligature operation as you did `|', so there are a total of eight possible ligature operations:

```
=: |=: |=:> =:| =:|> |=:| |=:|> |=:|>>
```

The default set of ligatures and kerns built in to `afm2tfm' can be specified with:

```
% LIGKERN question quoteleft =: questiondown ;
% LIGKERN exclam quoteleft =: exclamdown ;
% LIGKERN hyphen hyphen =: endash ; endash hyphen =: emdash ;
% LIGKERN quoteleft quoteleft =: quotedblleft ;
% LIGKERN quoteright quoteright =: quotedblright ;
% LIGKERN space {} * ; * {} space ; 0 {} * ; * {} 0 ;
% LIGKERN 1 {} * ; * {} 1 ; 2 {} * ; * {} 2 ; 3 {} * ; * {} 3 ;
% LIGKERN 4 {} * ; * {} 4 ; 5 {} * ; * {} 5 ; 6 {} * ; * {} 6 ;
% LIGKERN 7 {} * ; * {} 7 ; 8 {} * ; * {} 8 ; 9 {} * ; * {} 9 ;
```

Special Font Effects

Afm2tfm can do other manipulations as well. For example, to make an obliqued variant of Times Roman:

```
afm2tfm Times-Roman -s .167 -v ptmro rptmro
```

which creates `ptmro.vpl' and `rptmro.tfm'. To use this, put the line

```
rptmro Times-Roman ".167 SlantFont"
```

@flindex psfonts.map into `psfonts.map'. Then `rptmro' (our name for the obliqued Times) will act as if it were a resident font, although it is actually constructed from Times-Roman via the PostScript routine `SlantFont` (which slants everything 1/6 to the right, in this case).

Similarly, you can get an expanded font with

```
afm2tfm Times-Roman -e 1.2 -v ptmrre rptmrre
```

and by recording the pseudo-resident font

```
rptmrre Times-Roman "1.2 ExtendFont"
```

in `psfonts.map'.

You can also create a small caps font with a command such as

```
afm2tfm Times-Roman -V ptmrc rptmrc
```

This will generate a set of small caps mapped into the usual lower case positions and scaled down to 0.8 of the normal cap dimensions. You can also specify the scaling as something other than the default 0.8:

```
afm2tfm Times-Roman -c 0.7 -V ptmrc rptmrc
```

It is unfortunately not possible to increase the width of the small caps independently of the rest of the font. If you want a really professional looking set of small caps you will have to make up a custom pair of ``tfm'' and ``vpl'' files using the `-e' option, change the name and checksum of the D 1 font in `ptmrc.vpl' to match the customized raw `tfm', and replace the small caps at the lower case mappings with the small caps in the customized file. You can then throw away the customized `vpl' file, but not the customized `tfm'. That must be identified with an appropriate line in `psfonts.map'.

If you change the PostScript encoding of a font, you must specify the input file as a header file, as well as give a reencoding command. For instance, let us say we are using Times-Roman reencoded according to the encoding `MyEncoding' (stored in the file `myenc.enc') as `rptmrx'. In this case, our `psfonts.map' entry would look like

```
rptmrx Times-Roman "MyEncoding ReEncodeFont" <myenc.enc
```

The `afm2tfm' program prints out the precise line you need to add to `psfonts.map' to use that font, assuming the font is resident in the printer; if the font is not resident, you must add the header command to download the font yourself. Each identical line only needs to be specified once in the `psfonts.map' file, even though many different fonts (small caps variants, or ones with different output encodings) may be based on it.

Non-Resident PostScript Fonts

If you want to use a non-printer-resident PostScript font for which you have a `pfb' or `pfa' file (an Adobe Type 1 font program), you can make it act like a resident font by putting a `<' sign and the name of the `pfb' or `pfa' file just after the font name in the `psfonts.map' @flindex psfonts.map file entry. For example,

```
rpstrn StoneInformal <StoneInformal.pfb
```

will cause dvips to include `StoneInformal.pfb' in your document as if it were a header file, whenever the pseudo-resident font StoneInformal is used in a document. Similarly, you can generate transformed fonts and include lines like

```
rpstrc StoneInformal <StoneInformal.pfb ".8 ExtendFont"
```

in `psfonts.map', in which case `StoneInformal.pfb' will be loaded whenever StoneInformal-Condensed is used. Each header file is loaded at most once per document.

If you are using a `pfb' file that is also has a different PostScript encoding, you need to download multiple header files in `psfonts.map'. If, for instance, `Optima' was both non-resident and you wanted to reencode it in PostScript with `MyEncoding' stored in `myenc.enc', you need:

```
rpstrnx Optima "MyEncoding ReEncodeFont" <myenc.enc <Optima.pfb
```

When using PFB files, dvips is smart enough to unpack the binary PFB format into printable ASCII so there is no need to perform this conversion yourself. In addition, it will scan the font to determine its memory usage, as it would for any header file.

Here is a brief description of the contents of `psfonts.map'. If a line is empty or begins with a space, asterisk, semicolon, or hash mark, it is ignored. Otherwise, the line is separated into words, where words are separated by spaces or tabs, except that if a word begins with a double quote, it extends until the next double quote or the end of the line. If a word starts with a less than character, it is treated as a font header file (or a downloaded PostScript font). There can be more than one such header for a given font. If a word starts with a double quote, it is a special instruction for generating that font. Otherwise it is a name. The first such name is the TFM file that a virtual font file can refer to. If there is another name, it is used as the PostScript name; if there is only one name, it is used for both the TeX name and the PostScript name.

Invoking Afm2tfm

The command line switches to `afm2tfm' are:

`-c ratio'

See `-V'; overrides the default ratio of 0.8 for the scaling of small caps.

`-e ratio'

All characters are stretched horizontally by the stated ratio; if it is less than 1.0, you get a condensed font.

`-O'

This option forces all character codes in the output `vpl' file be given as octal values; this is useful for symbol or other special-purpose fonts where character names such as `A' have no meaning.

`-p file'

This specifies a file to use for the PostScript encoding of the font. This file must also be mentioned as a header file for the font in `psfonts.map', and that ligature and kern information in this file is ignored.

`-T file'

This option specifies that file is to be used for both the PostScript and target TeX encodings of the font.

`-t file'

This specifies a file to use for the target TeX encoding of the font. Ligature and kern information may also be specified in this file; the file need not be mentioned in `psfonts.map'.

`-s slant'

All characters are slanted to the right by slant. If slant is negative, the letters slope to the left (or they might be upright if you start with an italic font).

`-u'

This option indicates that `afm2tfm' should use only those characters that are required by the output encoding, and no others. Normally, `afm2tfm' tries to include both characters that fit the output encoding and any additional characters that might exist in the font. This option forbids those additional characters from being added.

`-v file'

Generate a virtual property list `vpl' file as well as a `tfm' file.

`-V file'

Same as `-v', but the virtual font generated is a small caps font obtained by scaling uppercase letters by 0.8 to typeset lowercase. This font handles accented letters and retains proper kerning.

Here are the `CODINGSCHEMES' that result from the various possible choices for reencoding.

`default encoding'

```
(CODINGSCHEME TeX text + AdobeStandardEncoding)
```

`-p DC.enc'

```
(CODINGSCHEME TeX text + DCEncoding)
```

`-t DC.enc'

```
(CODINGSCHEME DCEncoding + AdobeStandardEncoding)
```

`-T DC.enc'

```
(CODINGSCHEME DCEncoding + DCEncoding)
```

Command Line Options

The dvips driver has a plethora of command line options. Reading through this section will give a good idea of the capabilities of the driver.

Many of the parameterless options listed here can be turned off by immediately suffixing the option with a zero (0); for instance, to turn off page reversal if it is turned on by default, use `-r0'. The options that can be turned off in this way are `a', `f', `k', `i', `m', `q', `r', `s', `E', `F', `K', `M', `N', `U', and `Z'.

This is a handy summary of the options; it is printed out when you run dvips with no arguments.

```
This is dvipsk version Copyright 1986, 1993 Radical Eye Software
     Usage: dvips [options] filename[.dvi]
 a*  Conserve memory, not time      y # Multiply by dvi magnification
 b # Page copies, for posters e.g.  A   Print only odd (TeX) pages
 c # Uncollated copies              B   Print only even (TeX) pages
 d # Debugging                      C # Collated copies

     # = number   f = file   s = string  * = suffix, `0' to turn off
     c = comma-separated dimension pair (e.g., 3.2in,-32.1cm)
```

`-a'

Conserve memory by making three passes over the `dvi' file instead of two and only loading those characters actually used. Generally only useful on machines with a very limited amount of memory, like some PCs.

`-c num'

Generate num copies of every page. Default is 1. (For collated copies, see the `-C' option below.)

`-b num'

Generate num copies of each page, but duplicating the page body rather than using the `#numcopies'

option. This can be useful in conjunction with a header file setting `\bop-hook' to do color separations or other neat tricks.

`-d num'

Set the debug flags. This is intended only for emergencies or for unusual fact-finding expeditions; it will work only if dvips has been compiled with the `DEBUG' option. See section Debug Options, for the possible values of num. Use a value of `-1' for maximum output.

`-e num'

Make sure that each character is placed at most this many pixels from its `true' resolution-independent position on the page. The default value of this parameter is resolution dependent (it is the number of entries in the list [100, 200, 300, 400, 500, 600, 800, 1000, 1200, 1600, 2000, 2400, 2800, 3200, ...] that are less than or equal to the resolution in dots per inch). Allowing individual characters to `drift' from their correctly rounded positions by a few pixels, while regaining the true position at the beginning of each new word, improves the spacing of letters in words.

`-f'

Run as a filter. Read the `dvi' file from standard input and write the PostScript to standard output. The standard input must be seekable, so it cannot be a pipe. If you must use a pipe, write a shell script that copies the pipe output to a temporary file and then points dvips at this file. This option also disables the automatic reading of the `PRINTER' environment variable, and turns off the automatic sending of control D if it was turned on with the `-F' option or in the configuration file; use `-F' after this option if you want both.

`-h name'

Prepend file name as an additional header file. (However, if the name is simply `-', suppress all header files from the output.) This header file gets added to the PostScript `userdict'.

`-i'

Make each section be a separate file. Under certain circumstances, dvips will split the document up into `sections' to be processed independently; this is most often done for memory reasons. Using this option tells dvips to place each section into a separate file; the new file names are created replacing the suffix of the supplied output file name by a three-digit sequence number. This option is most often used in conjunction with the `-S' option which sets the maximum section length in pages. For instance, some phototypesetters cannot print more than ten or so consecutive pages before running out of steam; these options can be used to automatically split a book into ten-page sections, each to its own file.

`-k'

Print crop marks. This option increases the paper size (which should be specified, either with a paper size special or with the `-T' option) by a half inch in each dimension. It translates each page by a quarter inch and draws cross-style crop marks. It is mostly useful with typesetters that can set the page size automatically.

`-l num'

The last page printed will be the first one numbered num. Default is the last page in the document. If the num is prefixed by an equals sign, then it (and any argument to the `-p' option) is treated as a sequence number, rather than a value to compare with `\count0' values. Thus, using `-l =9' will end with the ninth page of the document, no matter what the pages are actually numbered.

`-m'

Specify manual feed for printer.

`-n num'

At most num pages will be printed. Default is 100000.

`-o name'

The output will be sent to file name. If no file name is given, the default name is `file.ps' where the `dvi' file was called `file.dvi'; if this option isn't given, any default in the configuration file is used. If the first character of the supplied output file name is an exclamation mark, then the remainder will be used as an argument to `popen'; thus, specifying `!lpr' as the output file will automatically queue the file for printing. This option also disables the automatic reading of the `PRINTER' environment variable, and turns off the automatic sending of control D if it was turned on with the `-F' option or in the configuration file; use `-F' after this option if you want both.

`-p num'

The first page printed will be the first one numbered num. Default is the first page in the document. If the num is prefixed by an equals sign, then it (and any argument to the `-l' option) is treated as a sequence number, rather than a value to compare with `\count0' values. Thus, using `-p =3' will start with the third page of the document, no matter what the pages are actually numbered.

`-pp first-last'

@opindex -pp range Print pages first through last; equivalent to `-p first -l last'. The `-' range separator can also be a `:'.

`-q'

Run in quiet mode. Don't chatter about pages converted, etc.; report nothing but errors to standard error.

`-r'

Stack pages in reverse order. Normally, page 1 will be printed first.

`-s'

Causes the entire global output to be enclosed in a save/restore pair. This causes the file to not be truly conformant, and is thus not recommended, but is useful if you are driving the printer directly and don't care too much about the portability of the output.

`-t papertype'

This sets the paper type to papertype. The papertype should be defined in one of the configuration files, along with the appropriate code to select it. See the documentation for `@'in the configuration file option descriptions. You can also specify `-t landscape', which rotates a document by 90 degrees. To rotate a document whose size is not letter, you can use the `-t' option twice, once for the page size, and once for `landscape'. The upper left corner of each page in the `dvi' file is placed one inch from the left and one inch from the top. Use of this option is highly dependent on the configuration file. Note that executing the `letter' or `a4' or other PostScript operators cause the document to be nonconforming and can cause it not to print on certain printers, so the default paper size should not execute such an operator if at all possible.

`-x num'

Set the magnification ratio to num/1000. Overrides the magnification specified in the `dvi' file. Must be between 10 and 100000. It is recommended that you use standard magstep values (1095, 1200,

1440, 1728, 2074, 2488, 2986, and so on) to help reduce the total number of PK files generated.

`-A'

This option prints only the odd pages. This option uses the \TeX\ page numbering rather than the sequence page numbers.

`-B'

This option prints only the even pages. This option uses the \TeX\ page numbering rather than the sequence page numbers.

`-C num'

Create num copies, but collated (by replicating the data in the PostScript file). Slower than the `-c' option, but easier on the hands, and faster than resubmitting the same PostScript file multiple times.

`-D num'

Set the resolution in dpi (dots per inch) to num. This affects the choice of bitmap fonts that are loaded and also the positioning of letters in resident PostScript fonts. Must be between 10 and 10000. This affects both the horizontal and vertical resolution. If a high resolution (something greater than 400 dpi, say) is selected, the `-Z' flag should probably also be used.

`-E'

Makes dvips attempt to generate an EPSF file with a tight bounding box. This only works on one-page files, and it only looks at marks made by characters and rules, not by any included graphics. In addition, it gets the glyph metrics from the `tfm' file, so characters that lie outside their enclosing `tfm' box may confuse it. In addition, the bounding box might be a bit too loose if the character glyph has significant left or right side bearings. Nonetheless, this option works well for creating small EPSF files for equations or tables or the like. (Of course, `dvips' output is resolution dependent and thus does not make very good EPSF files, especially if the images are to be scaled; use these EPSF files with a great deal of care.)

`-F'

Causes Control-D (ASCII code 4) to be appended as the very last character of the PostScript file. This is useful when dvips is driving the printer directly instead of working through a spooler, as is common on extremely small systems. Otherwise, it is not recommended.

`-K'

This option causes comments in included PostScript graphics, font files, and headers to be removed. This is sometimes necessary to get around bugs in spoolers or PostScript post-processing programs. Specifically, the `%%Page' comments, when left in, often cause difficulties. Use of this flag can cause some included graphics to fail, since the PostScript header macros from some software packages read portions of the input stream line by line, searching for a particular comment. This option has been turned off by default because PostScript previewers and spoolers have been getting better.

`-M'

Turns off the automatic font generation facility. If any fonts are missing, commands to generate the fonts are appended to the file `missfont.log' in the current directory; this file can then be executed and deleted to create the missing fonts.

`-N'

Turns off structured comments; this might be necessary on some systems that try to interpret

PostScript comments in weird ways, or on some PostScript printers. Old versions of TranScript i particular cannot handle modern Encapsulated PostScript.

`-O offset'

Move the origin by a certain amount. The offset is a comma-separated pair of dimensions, such as `.1in,-.3cm' (in the same syntax used in the `papersize' special). The origin of the page is shifted from the default position (of one inch down, one inch to the right from the upper left corner of the paper) by this amount.

`-P printername'

Sets up the output for the appropriate printer. This is implemented by reading in `config.printername', which can then set the output pipe (as in, `o !lpr -Pprintername') as well as the font paths and any other defaults for that printer only. It is recommended that all standard defaults go in the one master `config.ps' file and only things that vary printer to printer go in the `config.printername' files. Note that `config.ps' is read before `config.printername'. In addition, another file called `~/.dvipsrc' is searched for immediately after `config.ps'; this file is intended for user defaults. If no `-P' command is given, the environment variable `PRINTER' is checked. If that variable exists, and a corresponding configuration file exists, that configuration file is read in.

`-S num'

Set the maximum number of pages in each `section'. This option is most commonly used with the `-i' option; see that documentation above for more information.

`-T offset'

Set the paper size to the given pair of dimensions. This option takes its arguments in the same style as `-O'. It overrides any paper size special in the `dvi' file.

`-U'

Disable a PostScript virtual memory saving optimization that stores the character metric information in the same string that is used to store the bitmap information. This is only necessary when driving the Xerox 4045 PostScript interpreter. It is caused by a bug in that interpreter that results in `garbage' on the bottom of each character. Not recommended unless you must drive this printer.

`-V'

Download non-resident PostScript fonts as bitmaps. This requires use of `mtpk` or `pstopk` or some combination of the two in order to generate the required bitmap fonts; neither of these programs are supplied with Dvips.

`-X num'

Set the horizontal resolution in dots per inch to num.

`-Y num'

Set the vertical resolution in dots per inch to num.

`-Z'

Causes bitmapped fonts to be compressed before they are downloaded, thereby reducing the size of the PostScript font-downloading information. Especially useful at high resolutions or when very large fonts are used. Will slow down printing somewhat, especially on early 68000-based PostScript printers.

Configuration File Searching

@flindex config.ps

The dvips program has a system of loading configuration files such that parameters can be set globally across the system, on a per-printer basis, or by the user.

When dvips starts up, first the global `config.ps' file is searched for and loaded. This file is looked for along the path for configuration files, which is set in the `Makefile' at compilation. After this master configuration file is loaded, a file by the name of @flindex .dvipsrc `.dvipsrc' is loaded from the current user's home directory, if such a file exists. This file is loaded in exactly the same way as the global configuration file, and it can override any options set in the global file.

Then the command line is read and parsed. If the `-P' option is encountered, at that point in the command line a configuration file for that printer is read in. Thus, the printer configuration file can override anything in the global or user configuration file, and it can also override anything seen in the command line up to the point that the `-P' option was encountered.

After the command line has been completely scanned, if there was no `-P' option selected, and also the `-o' and `-f' command line options were not used, a `PRINTER' environment variable is searched for. If this variable exists, and a configuration file for the printer mentioned in it exists, this configuration file is loaded last of all.

Note that because the printer-specific configuration files are read after the user's configuration file, the user cannot override things in the printer configuration files. On the other hand, the configuration path usually includes the current directory, and can be set to include the user's home directory (or any other directory of the user), so the user can always provide his or her own printer-specific configuration files that will be found before the system global ones.

It is best to give a METAFONT mode as well as a resolution in the printer configuration file. Also make sure that METAFONT knows about the mode, by entering it into your local `mode_def' file. (For example, the file `modes.mf' @flindex modes.mf which is available from `ftp.cs.umb.edu' in `pub/tex/modes.mf'.)

The most common problem in generating fonts with METAFONT is that this file with the mode definitions is not included when creating the `plain.base' file.

Configuration File Options

Most of the configuration file options are similar to the command line options, but there are a few new ones.

Again, many may be turned off by suffixing the letter with a zero (0). These options are `a', `f', `q', `r', `K', `N', `U', and `Z'.

Within a configuration file, any empty line or line starting with a space, asterisk, equal sign, or a pound sign is ignored.

`@ name hsize vsize'

This option is used to set the paper size defaults and options for the particular printer this configuration file describes. There are three formats for this option. If the option is specified on a line by itself, with no parameters, it instructs dvips to discard all other paper size information (possibly from another configuration file) and start fresh. If three parameters are given, as above, with the first parameter being a name and the second and third being a dimension (as in 8.5in or 3.2cc, just like in the `papersize' special), then the option is interpreted as starting a new paper size description, where name is the name and hsize and vsize describe the horizontal and vertical size of the sheet of paper, respectively. If both hsize and vsize are equal to zero (although you must still specify units!) then any page size will match it. If the `@' character is immediately followed by a `+' sign, then the remainder of the line (after skipping any leading blanks) is treated as PostScript code to send to the printer to select that particular paper size. After all that, if the first character of the line is an exclamation point, then the line is put in the initial comments section of the final output file; else, it is put in the setup section of the output file. For instance, a subset of the paper size information supplied in the default `config.ps' looks like

```
@ letterSize 8.5in 11in
@ letter 8.5in 11in
@+ %%BeginPaperSize: Letter
@+ letter
@+ %%EndPaperSize
@ legal 8.5in 14in
@+ ! %%DocumentPaperSizes: Legal
@+ %%BeginPaperSize: Legal
@+ legal
@+ %%EndPaperSize
```

Note that you can even include structured comments in the configuration file! When dvips has a paper format name given on the command line, it looks for a match by the name; when it has a `papersize' special, it looks for a match by dimensions. The first match found (in the order the paper size information is found in the configuration file) is used. If nothing matches, a warning is printed and the first paper size given is used, so the first paper size should always be the default. The dimensions must match within a quarter of an inch. Landscape mode for all of the paper sizes are automatically supported. If your printer has a command to set a special paper size, then give dimensions of `0in 0in'; the PostScript code that sets the paper size can refer to the dimensions the user requested as `hsize' and `vsize'; these will be macros defined in the PostScript that return the requested size in default PostScript units. Note that virtually all of the PostScript commands you use here are device dependent and degrade the portability of the file; that is why the default first paper size entry should not send any PostScript commands down (although a structured comment or two would be okay). Also, some printers want `BeginPaperSize' comments and paper size setting commands; others (such as the NeXT) want `PaperSize' comments and they will handle setting the paper size. There is no solution I could find that works for both (except maybe specifying both.) See the supplied `config.ps' file for a more realistic example.

`a'

Conserve memory by making three passes over the `dvi' file instead of two and only loading those characters actually used. Generally only useful on machines with a very limited amount of memory, like some PCs.

`b num'

Generate num copies of each page, but duplicating the page body rather than using the `#numcopies' option. This can be useful in conjunction with a header file setting `\bop-hook' to do color separations or other neat tricks.

`e num'

Set the maximum drift parameter to num dots (pixels) as explained above.

`f'

Run as a filter by default.

`h name'

Add name as a PostScript header file to be downloaded at the beginning.

`i num'

Make each section be a separate file, and set the maximum number of pages in a given file to num. Under certain circumstances, dvips will split the document into `sections' to be processed independently; this is most often done for memory reasons. Using this option tells dvips to place each section into a separate file; the new file names are created by replacing the suffix of the supplied output file name with a three-digit sequence number. This is essentially a combination of the command line options `-i' and `-S'; see the documentation for these options for more information.

`m num'

The value num is the virtual memory available for fonts and strings in the printer. Default is 180000. This value must be accurate if memory conservation and document splitting is to work correctly. To determine this value, send the following file to the printer:

```
%! Hey, we're PostScript
/Times-Roman findfont 30 scalefont setfont 144 432 moveto
vmstatus exch sub 40 string cvs show pop showpage
```

Note that the number returned by this file is the total memory free; it is often a good idea to tell dvips that the printer has somewhat less memory. This is because many programs download permanent macros that can reduce the memory in the printer. In general, a memory size of about `300000' is plenty, since dvips can automatically split a document if required. It is unfortunate that PostScript printers with much less virtual memory still exist. Some systems or printers can dynamically increase the memory available to a PostScript interpreter, in which case this file might return a ridiculously low number; the NeXT computer is such a machine. For these systems, a value of one million works well.

`o name'

The default output file is set to name. As above, it can be a pipe. Useful in printer-specific configuration files to redirect the output to a particular printer queue.

`p name'

The file to examine for PostScript font aliases is name. It defaults to `psfonts.map'. This option allows different printers to use different resident fonts. If the name starts with a `+' character, then the rest of the name (after any leading spaces) is used as an additional map file; thus, it is possible to have local map files pointed to by local configuration files that append to the global map file.

`q'

Run in quiet mode by default.

`r'

Reverse the order of pages by default.

`s'

Enclose the entire document in a global save/restore pair by default. Not recommended, but useful in some environments; this breaks the conformance of the document to the Adobe PostScript structuring conventions.

`D num'

Set the vertical and horizontal resolution to num dots per inch. Useful in printer-specific configuration files.

`E command'

Executes the command listed; can be used to get the current date into a header file for inclusion, for instance. Possibly dangerous; in many installations this may be disabled, in which case a warning message will be printed if the option is used.

`H path'

The (colon-separated) path to search for PostScript header files is path. The environment variable `DVIPSHEADERS' overrides this.

`K'

Filter comments out of included PostScript files; see the description above for more information.

`M mode'

Set mode as the METAFONT mode to be used when generating fonts. This is passed along to `MakeTeXPK' and overrides mode derivation from the base resolution.

`N'

Disable PostScript comments by default.

`O offset'

Move the origin by a certain amount. The offset is a comma-separated pair of dimensions, such as `.1in,-.3cm' (in the same syntax as used in the `papersize' special). The origin of the page is shifted from the default position (of one inch down, one inch to the right from the upper left corner of the paper) by this amount.

`P path'

The (colon-separated) path to search for bitmap `pk' font files is path. The `PKFONTS', `TEXPKS', `GLYPHFONTS', and `TEXFONTS' environment variables override this. @xref{TeX environment variables, TeX environment variables, kpathsea, Kpathsearch library}.

`R num num ...'

Sets up a list of default resolutions to search for `pk' fonts, if the requested size is not available. The output will then scale the font found using PostScript scaling to the requested size. The resulting output may be ugly, and thus a warning is issued. To turn this off, use a line with just the `R' and no numbers.

`S path'

The path to search for special illustrations (Encapsulated PostScript files or psfiles) is path. The

`TEXPICTS' and then `TEXINPUTS' environment variables override this.

`T path'

The path to search for the `tfm' files is path. The `TEXFONTS' environment variable will override this. This path is used for resident fonts and fonts that can't otherwise be found. It's usually best to make it identical to the path used by TeX.

`U'

Turns off a memory-saving optimization; this is necessary for the Xerox 4045 printer, but not recommended otherwise. See the description above for more information.

`V path'

The path to search for virtual font `vf' files is path. This may be device-dependent if you use virtual fonts to simulate actual fonts on different devices.

`W string'

Sends string to stderr, if a parameter is given; otherwise it cancels another previous message. This is useful in the default configuration file if you want to require the user to specify a printer, for instance, or if you want to notify the user that the resultant output has special characteristics.

`X num'

Set the horizontal resolution to num dots per inch.

`Y num'

Set the vertical resolution to num dots per inch.

`Z'

Compress all downloaded fonts by default, as above.

Automatic Font Generation

One major problem with TeX and the Computer Modern fonts is the huge amount of disk space a full set of high resolution fonts can take. Dvips solves this problem by creating fonts on demand, so only those fonts that are actually used are stored on disk. At a typical site, less than one-fifth of the full set of Computer Modern fonts are used over a long period, so this saves a great deal of disk space.

Furthermore, the addition of dynamic font generation allows fonts to be used at any size, including typesetter resolutions and extremely huge banner sizes. Nothing special needs to be done; the fonts will be automatically created and installed as needed.

The downside is that it does take a certain amount of time to create a new font if it has never been used before. But once a font is created, it will exist on disk, and the next time that document is printed it will print very quickly.

It is the `MakeTeXPK' shell script that is responsible for making these fonts. It *must* echo the filename of the new font (and nothing else) to standard output. Use standard error for commentary. `MakeTeXPK' is passed various arguments, the last of which is the font it's supposed to make. You can override the other argument conventions with environment variables or at compilation time; see the Kpathsea documentation.

The `MakeTeXPK' script supplied invokes Metafont (using the Sauter scripts first, if necessary and if they

are installed) to create the font and then copies the resultant `pk' file to a world-writable font cache area.

`MakeTeXPK' can be customized to do other things to get the font. For instance, if you are installing dvips to replace (or run alongside) an existing PostScript driver, and that driver demands `gf' fonts, you can easily modify `MakeTeXPK' to invoke `gftopk' to convert the `gf' files to `pk' files for dvips. This provides the same space savings listed above.

Because dvips (and thus `MakeTeXPK') is run by a wide variety of users, there must be a system-wide place to put the cached font files. In order for everyone to be able to supply fonts, the directory must be world writable. If your system administrator considers this a security hole, `MakeTeXPK' can write to `/tmp/pk' or some such directory, and periodically the cached fonts can be moved to a more general system area. The cache directory must exist on the `pk' file search path in order for `MakeTeXPK' to work.

Environment Variables

Dvips reads a certain set of environment variables to configure its operation. The path variables are read as needed, after all configuration files are read, so they override values in the configuration files. (Except for the `TEXCONFIG' variable.)

See section 'Path specifications' in Kpathsea library, for details of interpretation of environment variable values, and the common environment variables. Only the environment specific to `dvips' are mentioned here.

`DVIPSFONTS'

Default path to search for all fonts. Overrides all the font-related config file options and other environment variables.

`DVIPSHEADERS'

Default path to search for PostScript header files. Overrides the `H' config file option.

`DVIPSMAKEPK'

Overrides `MakeTeXPK' as the name of the program to invoke to create missing PK fonts. You can change the arguments passed to the `MakeTeXPK' program with the `MAKETEXPK' environment variables; see the Kpathsea documentation.

`DVIPSSIZES'

Last-resort sizes for scaling for unfound fonts. Overrides the `R' definition in config files.

`PRINTER'

This environment variable is read to determine which default printer configuration file to read in. It is the responsibility of the configuration file to send output to the proper print queue, if such functionality is desired.

`TEXCONFIG'

This environment variable sets the directories to search for configuration files, including the system-wide one. Using this single environment variable and the appropriate configuration files, it is possible to set up the program for any environment. (The other path environment variables are thus redundant.)

`TEXPICTS'

Path to search for special illustrations. Overrides the `S' config file option. If not set, `TEXINPU is used.

Other Bells And Whistles

For special effects, if any of the macros `bop-hook', `eop-hook', `start-hook', or `end-hook' are defined in the PostScript `userdict', they will be executed at the beginning of a page, end of a page, start of the document, and end of a document, respectively.

When these macros are executed, the default PostScript coordinate system and origin is in effect. Such macros can be defined in headers added by the `-h' option or the `header=' special, and might be useful for writing, for instance, DRAFT across the entire page, or, with the aid of a shell script, dating the document. These macros are executed outside of the save/restore context of the individual pages, so it is possible for them to accumulate information, but if a document must be divided into sections because of memory constraints, such added information will be lost across section breaks.

The single argument to `bop-hook' is the sequence number of the page in the file; the first page gets zero, the second one, etc. The procedure must leave this number on the stack. None of the other hooks are (currently) given parameters, although this may change in the future.

As an example of what can be done, the following special will write a light DRAFT across each page in the document:

```
\special{!userdict begin /bop-hook{gsave 200 30 translate
65 rotate /Times-Roman findfont 216 scalefont setfont
0 0 moveto 0.7 setgray (DRAFT) show grestore}def end}
```

Note that using `bop-hook' or `eop-hook' in any way that preserves information across pages will break compliance with the Adobe document structuring conventions, so if you use any such tricks, it is recommended that you also use the `-N' option to turn off structured comments.

Several of the above tricks can be used nicely together, and it is not necessary that a `printer configuration file' be used only to set printer defaults. For instance, a `-P' file can be set up to print the date on each page; the particular configuration file will execute a command to put the date into a header file, which is then included with a `h' line in the configuration file. Multiple `-P' options can be used.

MS-DOS

If you have any experience with `dvipsk' under DOS, `karl@cs.umb.edu` would like to hear about it.

Installation

To compile and install Dvipsk:

- Edit the top-level `Makefile.in' if you want to make changes that will have effect across different runs of `configure'; for example, changing the installation directories. Alternatively, override the make variables on the command line when you run make.
- Edit `kpathsea/paths.h.in' to define your local default paths. See section 'System dependencies' in Kpathsea, for more details on changing the paths.
- Run `sh configure' in the top-level directory. This tries to figure out system dependencies and the installation prefix. See section 'The `configure' script' in Kpathsearch library, for options and other information about `configure'.
- @flindex Makefile, editing @flindex c-auto.h, editing If necessary, edit the paths or other definitions in the files `Makefile' and in `dvipsk/c-auto.h' (which `configure' created.)
- Run `make'; e.g., just type `make' in the top-level directory. Barring configuration and compiler bugs, this will compile all the programs. @flindex MACHINES See the `./MACHINES' for possibly helpful system-dependent information.
- @flindex MakeTeXPK, editing Check the paths in `MakeTeXPK', unless you do not want automatic font generation (in which case you need not install `MakeTeXPK' at all). See section Automatic Font Generation. The `MakeTeXPK' in the distribution will overwrite the installed file only if the latter contains the string `original MakeTeXPK --'. Dvipsk, unlike the original dvips, requires `MakeTeXPK' to echo the generated filename (and nothing else) to standard output (standard error can be used for commentary). For more details, or in general if your `MakeTeXPK' fails, see section Unable to Generate Fonts.
- @flindex config.ps, editing Update the device parameters (available memory, resolution, etc.) in `config.ps'. This file is installed as the system-wide configuration file. See section Configuration File Options. The `config.ps' in the distribution will overwrite the installed file only if the latter contains the string `original config.ps --'.
- Install the programs and supporting macros, fonts, and data files with `make install'. If you want to install only the executables, do `make install-exec'; for only the data files, `make install-data'. And if you don't want to install the fonts (perhaps because your directory structure is different from the default), set the Make variable `install_fonts=false'.
- If you want to use more than one device, create configuration files for each and install them in the directory named by the Make variable `configdir'.

See section 'Reporting bugs' in Kpathsea, for the bug reporting address and information.

Diagnosing problems

You've gone through all the trouble of installing dvips, carefully read all the instructions in this manual, and still can't get something to work. This is all too common, and is usually caused by some broken PostScript application out there. The following sections provide some helpful hints if you find yourself in such a situation.

In all cases, you should attempt to find the smallest file that causes the problem. This will not only make debugging easier, it will also reduce the number of possible interactions among different parts of the system.

Debug Options

The `-d' flag to dvips is very useful for helping to track down certain errors. The parameter to this flag is an integer that tells what errors are currently being tracked. To track a certain class of debug messages, simply provide the appropriate number given below; if you wish to track multiple classes, sum the numbers of the classes you wish to track. The classes are:

1
: specials

2
: paths

4
: fonts

8
: pages

16
: headers

32
: font compression

64
: files

128
: memory

No Output At All

If you are not getting any output at all, even from the simplest one-character file (for instance, `\ \bye'), then something is very wrong. Practically any file sent to a PostScript laser printer should generate some output, at the very least a page detailing what error occurred, if any. Talk to your system administrator about downloading a PostScript error handler. (Adobe distributes a good one called `ehandler.ps'.) @flindex

ehandler.ps

It is possible, especially if you are using non-Adobe PostScript, that your PostScript interpreter is broken. Even then it should generate an error message. I've tried to work around as many bugs as possible in common non-Adobe PostScript interpreters, but I'm sure I've missed a few.

If dvips gives any strange error messages, or compilation on your machine generated a lot of warnings, perhaps the dvips program itself is broken. Carefully check the types in `dvips.h' and the declarations in the `Makefile', and try using the debug options to determine where the error occurred.

It is possible your spooler is broken and is misinterpreting the structured comments. Try the `-N' flag to turn off structured comments and see what happens.

Output Too Small or Inverted

If some documents come out inverted or too small, your spooler is not supplying an end of job indicator at the end of each file. (This happens a lot on small machines that don't have spoolers.) You can force dvips to do this with the `-F' flag, but note that this generates files with a binary character (control-D) in them. You can also try using the `-s' flag to enclose the entire job in a save/restore pair.

Error Messages From Printer

If your printer returns error messages, the error message gives very good information on what might be going wrong. One of the most common error messages is `bop undefined'. This is caused by old versions of Transcript and other spoolers that do not properly parse the setup section of the PostScript. To fix this, turn off structured comments with the `-N' option, but make sure you get your spooling software updated.

Another error message is `VM exhausted'. (Some printers indicate this error by locking up; others quietly reset.) This is caused by telling dvips that the printer has more memory than it actually does, and then printing a complicated document. To fix this, try lowering the parameter to `m' in the configuration file; use the debug option to make sure you adjust the correct file.

Other errors may indicate that the graphics you are trying to include don't nest properly in other PostScript documents, or any of a number of other possibilities. Try the output on a QMS PS-810 or other Adobe PostScript printer; it might be a problem with the printer itself.

400 DPI Is Used Instead Of 300 DPI

This common error is caused by not editing the `config.ps' file to reflect the correct resolution for your site. You can use the debug flags (`-d64') to see what files are actually being read.

Long Documents Fail To Print

This is usually caused by incorrectly specifying the amount of memory the printer has in `config.ps'; see the description above.

Including Graphics Fails

The reasons why graphics inclusions fail are too numerous to mention. The most common problem is an incorrect bounding box; read the section on bounding boxes and check your PostScript file. Complain very loudly to whoever wrote the software that generated the file if the bounding box is indeed incorrect.

Another possible problem is that the figure you are trying to include does not nest properly; there are certain rules PostScript applications should follow when generating files to be included. The dvips program includes work-arounds for such errors in Adobe Illustrator and other programs, but there are certainly applications that haven't been tested.

One possible thing to try is the `-K' flag, to strip the comments from an included figure. This might be necessary if the PostScript spooling software does not read the structuring comments correctly. Use of this flag will break graphics from some applications, though, since some applications read the PostScript file from the input stream looking for a particular comment.

Any application which generates graphics output containing raw binary (not ASCII hex) will probably fail with dvips.

Unable to Find Font Files

If dvips complains that it cannot find certain font files, it is possible that the paths haven't been set up correctly for your system. Use the debug flags to determine precisely what fonts are being looked for and make sure these match where the fonts are located on your system.

Unable to Generate Fonts

This happens a lot if either `MakeTeXPK' hasn't been properly edited and installed, or if the local installation of METAFONT isn't correct.

`MakeTeXPK' must echo the generated filename (and nothing else) to standard output. See section Automatic Font Generation.

If METAFONT isn't found when `MakeTeXPK' is running, then you need to install it. Retrieve it from, e.g., `ftp.cs.umb.edu' in `pub/tex/web2c.tar.gz' and `pub/tex/web.tar.gz'.

If METAFONT runs but generates fonts that are too large (and prints out the name of each character as well as just a character number), then your METAFONT base file probably hasn't been made properly. To make a proper `plain.base', assuming the local mode definitions are contained in `modes.mf' type the following command (assuming UNIX):

```
inimf "plain; input modes; dump"
```

Then copy the `plain.base' file from the current directory to where the base files are stored on your system.

By the way, the macros defined in `cmbase' will break fonts that do not use `cmbase'; such fonts include the LaTeX fonts. Loading the `cmbase' macros when they are needed is done automatically and takes less than

a second--an insignificant fraction of the total run time of METAFONT for a font, especially when the possibility of generating incorrect fonts is taken into account. If you create the LaTeX font `circle10', for instance, with the `cmbase' macros loaded, the characters will have incorrect widths.

Using Color with dvips

This new feature of `dvips' is somewhat experimental so your experiences and comments are welcome. Initially added by Jim Hafner, IBM Research, `hafner@almaden.ibm.com', the color support has gone through many changes by Tomas Rokicki. Besides the changes to the source code itself, there are additional TeX macro files: `colordvi.tex' and `blackdvi.tex'. There are also `.sty' versions of these files that can be used with LaTeX and other similar macro packages. This feature adds one-pass multi-color printing of TeX documents on any color PostScript device.

In this section we describe the use of color from the document preparer's point of view and then add some simple instructions on installation for the system administrator.

Macro Files

All the color macro commands are defined in `colordvi.tex' (or `colordvi.sty'). To access these macros simply add to the top of your TeX file the command

```
\input colordvi
```

or, if your document uses style files like LaTeX, add the `colordvi' style option as in

```
\documentstyle[12pt,colordvi]{article}
```

There are basically two kinds of color macros, ones for local color changes to, say, a few words or even one symbol and one for global color changes. Note that all the color names use a mixed case scheme. There are 68 predefined colors, with names taken primarily from the Crayola crayon box of 64 colors, and one pair of macros for the user to set his own color pattern. More on this extra feature later. You can browse the file `colordvi.tex' for a list of the predefined colors. The comments in this file also show a rough correspondence between the crayon names and PANTONEs.

A local color command is in the form

```
\ColorName{this will print in color}
```

Here `ColorName' is the name of a predefined color. As this example shows, this type of command takes one argument which is the text that is to print in the selected color. This can be used for nested color changes since it restores the original color state when it completes. For example, suppose you were writing in green and want to switch temporarily to red, then blue, back to red and restore green. Here is one way that you can do this:

```
This text is green but here we are \Red{switching to red,
```

```
\Blue{nesting blue}, recovering the red} and back to
original green.
```

In principle there is no limit to the nesting level, but it is not advisable to nest too deep lest you loose track of the color history. The global color command has the form

```
\textColorName
```

This macro takes no arguments and immediately changes the default color from that point on to the specified color. This of course can be overriden globally by another such command or locally by local color commands. For example, expanding on the example above, we might have

```
\textGreen
This text is green but here we are \Red{switching to red,
\Blue{nesting blue}, recovering the red} and back to
original green.
\textCyan
The text from here on will be cyan unless
\Yellow{locally changed to yellow}. Now we are back to cyan.
```

The color commands will even work in math mode and across math mode boundaries. This means that if you have a color before going into math mode, the mathematics will be set in that color as well. More importantly however, in alignment environments like `\halign', `tabular' or `eqnarray', local color commands cannot extend beyond the alignment characters. Because local color commands respect only some environment and deliminator changes besides their own, care must be taken in setting their scope. It is best not to have then stretch too far. At the present time there are no macros for color environments in LaTeX which might have a larger range. This is primarily to keep the TeX and LaTeX use compatible.

User Definable Colors

There are two ways for the user to specify colors not already defined. For local changes, there is the command `\Color' which takes two arguments. The first argument is a quadruple of numbers between zero and one and specifies the intensity of cyan, magenta, yellow and black (CMYK) in that order. The second argument is the text that should appear in the given color. For example, suppose you want the words "this color is pretty" to appear in a color which is 50% cyan, 85% magenta, 40% yellow and 20% black. You would use the command

```
\Color{.5 .85 .4 .2}{this color is pretty}
```

For global color changes, there is a command `\textColor' which takes one argument, the CMYK quadruple of relative color intensities. For example, if you want the default color to be as above, then the command

```
\textColor{.5 .85 .4 .2}
The text from now on will be this pretty color
```

will do the trick. Making a global color change in the midst of a nested local colors is highly discouraged. Consequently, dvips will give you warning message and do its best to recover by discarding the current

color history.

Subtleties in Using Color

These color macros are defined by use of specialized `\special' keywords. As such, they are put in the `.dvi' file only as explicit message strings to the driver. The (unpleasant) result is that certain unprotected regions of the text can have unwanted color side effects. For example, if a color region is split by TeX across a page boundary, then the footers of the current page (e.g., the page number) and the headers of the next page can inherit that color. To avoid this effect globally, users should make sure that these special regions of the text are defined with their own local color commands. For example in TeX, to protect the header and footer, use

```
\headline{\Black{My Header}}
\footline{\Black{\hss\tenrm\folio\hss}}
```

This warning also applies to figures and other insertions, so be careful!

Of course, in LaTeX, this is much more difficult to do because of the complexity of the macros that control these regions. This is unfortunate, but is somehow inevitable because TeX and LaTeX were not written with color in mind.

Even when writing your own macros, much care must be taken. The color macros that `colorize' a portion of the text work by prefixing the text with a special command to turn the color on and postfixing it with a different special command to restore the original color. It is often useful to ensure that TeX is in horizontal mode before the first special command is issued; this can be done by prefixing the color command with `\leavevmode'.

Printing in Black/White, after Colorizing

If you have a TeX or LaTeX document written with color macros and you want to print it in black and white there are two options. On all (good) PostScript devices, printing a color file will print in corresponding grey-levels. This is useful since in this way you can get a rough idea of where the colors are changing without using expensive color printing devices. The second option is to replace the call to input `colordvi.tex' with `blackdvi.tex' (and similarly for the `.sty' files). So in the above example, replacing the word `colordvi' with `blackdvi' suffices. This file defines the color macros as no-ops, and so will produce normal black/white printing. By this simple mechanism, the user can switch to all black/white printing without having to ferret out the color commands. Also, some device drivers, particularly non-PostScript ones like screen previewers, will simply ignore the color commands and so print in normal black/white. Hopefully, in the future screen previewers for color displays will be compatible with some form of color support.

Configuring dvips for Color Devices

To configure dvips for a particular color device you need to fine tune the color parameters to match your devices color rendition. To do this, you will need a PANTONE chart for your device. The header file `color.lpro' shows a (rough) correspondence between the Crayola crayon names and the PANTONE numbers and also defines default CMYK values for each of the colors. Note that these colors must be defined in CMYK terms and not RGB as dvips outputs PostScript color commands in CMYK. This header file also defines (if they are not known to the interpreter) the PostScript commands `setcmykcolor' and `currentcmykcolor' in terms of a RGB equivalent so if your device only understands RGB, there should be no problem.

The parameters set in this file were determined by comparing the PANTONE chart of a Tektronics PHASER printer with the actual Crayola Crayons. Because these were defined for a particular device, the actual color rendition on your device may be very different. There are two ways to adjust this. One is to use the PANTONE chart for your device to rewrite `color.lpro' prior to compilation and installation. A better alternative, which supports multiple devices, is to add a header file option in the configuration file for each device that defines, in `userdict', the color parameters for those colors that need redefining.

For example, if you need to change the parameters defining `Goldenrod' (approximately PANTONE 109) for your device `mycolordev', do the following. In the PANTONE chart for your device, find the CMYK values for PANTONE 109. Let's say they are `{\ 0 0.10 0.75 0.03 }'. Then create a header file named `mycolordev.pro' with the commands

```
userdict begin
/Goldenrod { 0 0.10 0.75 0.03 setcmykcolor} bind def
```

Finally, in `config.mycolordev' add the line

```
h mycolordev.pro
```

This will then define `Goldenrod' in your device's CMYK values in `userdict' which is checked before defining it in `TeXdict' by `color.pro'.

This mechanism, together with additions to `colordvi.tex' and `blackdvi.tex' (and the `.sty' files), can also be used to predefine other colors for your users.

Color Support Details

To support color, dvips recognizes a certain set of specials. These specials all start with the keyword `color' or the keyword `background'.

We will describe `background' first, since it is the simplest. The `background' keyword must be followed by a color specification. That color specification is used as a fill color for the background. The last `background' special on a page is the one that gets issued, and it gets issued at the very beginning of the page, before any text or specials are sent. (This is possible because the prescan phase of dvips notices all of the color specials so that the appropriate information can be written out during the second phase.)

Ahh, but what is a color specification? It is one of three things. First, it might be a PostScript procedure defined in a PostScript header file. The `color.pro' file defines 64 of these, including `Maroon'. This PostScript procedure must set the current color to be some value; in this case, `Maroon' is defined as `0.87 0.68 0.32 setcmykcolor'.

The second possibility is the name of a color model (initially, one of `rgb', `hsb', `cmyk', or `gray') followed by the appropriate number of parameters. When dvips encounters such a macro, it sends out the parameters first, followed by the string created by prefixing `TeXcolor' to the color model. Thus, the color specification `rgb 0.3 0.4 0.5' would generate the PostScript code `0.3 0.4 0.5 TeXrgbcolor'. Note that the case of zero arguments is disallowed, as that is handled by the single keyword case above (where no changes to the name are made before it is sent to the PostScript file.)

The third and final type of color specification is a double quote followed by any sequence of PostScript. The double quote is stripped from the output. For instance, the color specification `"AggiePattern setpattern' will set the `color' to the Aggie logo pattern (assuming such exists.)

So those are the three types of color specifications. The same type of specifications are used by both the `background' special and the `color' special. The `color' special itself has three forms. The first is just `color' followed by a color specification. In this case, the current global color is set to that color; the color stack must be empty when such a command is executed.

The second form is `color push' followed by a color specification. This saves the current color on the color stack and sets the color to be that given by the color specification. This is the most common way to set a color.

The final version of the `color' special is just `color pop', with no color specification; this says to pop the color last pushed on the color stack from the color stack and set the current color to be that color.

The `dvips' program correctly handles these color specials across pages, even when the pages are repeated or reversed.

These color specials can be used for things such as patterns or screens as well as simple colors. However, note that in the PostScript, only one `color specification' can be active at a time. For instance, at the beginning of a page, only the bottommost entry on the color stack is sent; also, when a color is `popped', all that is done is that the color specification from the previous stack entry is sent. No `gsave' or `grestore' is used. This means that you cannot easily mix usage of the `color' specials for screens and colors, just one or the other. This may be addressed in the future by adding support for different `categories' of color-like state.

GNU Emacs Lisp Reference Manual

GNU Emacs Version 19

for Unix Users

Edition 2.0, May 1993

by Bil Lewis, Dan LaLiberte, Richard Stallman and the GNU Manual Group

Go to the next section.

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free

use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.

2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

   You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

3. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:

   1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
   2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
   3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

These requirements apply to the modified work as a whole. If identifiable sections of that wor not derived from the Program, and can be reasonably considered independent and separate wo in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for noncommercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

    The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

    If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.

5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so

long as such parties remain in full compliance.

6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on it.
7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

   If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

   It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

   This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.
9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number

of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.

11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the

"copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and an idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or
modify it under the terms of the GNU General Public License
as published by the Free Software Foundation; either version 2
of the License, or (at your option) any later version.

This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details
type `show w'.  This is free software, and you are welcome
to redistribute it under certain conditions; type `show c'
for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright
interest in the program `Gnomovision'
(which makes passes at compilers) written
by James Hacker.

signature of Ty Coon, 1 April 1989
Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License

instead of this License.

Go to the previous, next section.

Introduction

Most of the GNU Emacs text editor is written in the programming language called Emacs Lisp. You can write new code in Emacs Lisp and install it as an extension to the editor. However, Emacs Lisp is more than a mere "extension language"; it is a full computer programming language in its own right. You can use it as you would any other programming language.

Because Emacs Lisp is designed for use in an editor, it has special features for scanning and parsing text as well as features for handling files, buffers, displays, subprocesses, and so on. Emacs Lisp is closely integrated with the editing facilities; thus, editing commands are functions that can also conveniently be called from Lisp programs, and parameters for customization are ordinary Lisp variables.

This manual describes Emacs Lisp, presuming considerable familiarity with the use of Emacs for editing. (See The GNU Emacs Manual, for this basic information.) Generally speaking, the earlier chapters describe features of Emacs Lisp that have counterparts in many programming languages, and later chapters describe features that are peculiar to Emacs Lisp or relate specifically to editing.

This is edition 2.0.

Caveats

This manual has gone through numerous drafts. It is nearly complete but not flawless. There are a few sections which are not included, either because we consider them secondary (such as most of the individual modes) or because they are yet to be written.

Because we are not able to deal with them completely, we have left out several parts intentionally. This includes most references to VMS and all information relating Sunview. (The Free Software Foundation expends no effort on support for Sunview, since we believe users should use the free X window system rather than proprietary window systems.)

The manual should be fully correct in what it does cover, and it is therefore open to criticism on anything it says--from specific examples and descriptive text, to the ordering of chapters and sections. If something is confusing, or you find that you have to look at the sources or experiment to learn something not covered in the manual, then perhaps the manual should be fixed. Please let us know.

As you use the manual, we ask that you mark pages with corrections so you can later look them up and send them in. If you think of a simple, real life example for a function or group of functions, please make an effort to write it up and send it in. Please reference any comments to the chapter name, section name, and function name, as appropriate, since page numbers and chapter and section numbers will change. Also state the number of the edition which you are criticizing.

Please mail comments and corrections to

```
bug-lisp-manual@prep.ai.mit.edu
```

```
--Bil Lewis, Dan LaLiberte, Richard Stallman
```

Lisp History

Lisp (LISt Processing language) was first developed in the late 1950s at the Massachusetts Institute of Technology for research in artificial intelligence. The great power of the Lisp language makes it superior for other purposes as well, such as writing editing commands.

Dozens of Lisp implementations have been built over the years, each with its own idiosyncrasies. Many of them were inspired by Maclisp, which was written in the 1960's at MIT's Project MAC. Eventually the implementors of the descendents of Maclisp came together and developed a standard for Lisp systems, called Common Lisp.

GNU Emacs Lisp is largely inspired by Maclisp, and a little by Common Lisp. If you know Common Lisp, you will notice many similarities. However, many of the features of Common Lisp have been omitted or simplified in order to reduce the memory requirements of GNU Emacs. Sometimes the simplifications are so drastic that a Common Lisp user might be very confused. We will occasionally point out how GNU Emacs Lisp differs from Common Lisp. If you don't know Common Lisp, don't worry about it; this manual is self-contained.

Conventions

This section explains the notational conventions that are used in this manual. You may want to skip this section and refer back to it later.

Some Terms

Throughout this manual, the phrases "the Lisp reader" and "the Lisp printer" are used to refer to those routines in Lisp that convert textual representations of Lisp objects into actual objects, and vice versa. See section Printed Representation and Read Syntax, for more details. You, the person reading this manual, are thought of as "the programmer" and are addressed as "you". "The user" is the person who uses Lisp programs including those you write.

Examples of Lisp code appear in this font or form: `(list 1 2 3)`. Names that represent arguments or metasyntactic variables appear in this font or form: first-number.

`nil` and `t`

In Lisp, the symbol `nil` is overloaded with three meanings: it is a symbol with the name `nil'; it is the logical truth value false; and it is the empty list--the list of zero elements. When used as a variable, `nil` always has the value `nil`.

As far as the Lisp reader is concerned, `()' and `nil' are identical: they stand for the same object, the symbol `nil`. The different ways of writing the symbol are intended entirely for human readers. After the

Lisp reader has read either `()' or `nil', there is no way to determine which representation was actually written by the programmer.

In this manual, we use `()` when we wish to emphasize that it means the empty list, and we use `nil` when we wish to emphasize that it means the truth value false. That is a good convention to use in Lisp programs also.

```
(cons 'foo ())                  ; Emphasize the empty list
(not nil)                       ; Emphasize the truth value false
```

In contexts where a truth value is expected, any non-`nil` value is considered to be true. However, `t` is the preferred way to represent the truth value true. When you need to choose a value which represents true, and there is no other basis for choosing, use `t`. The symbol `t` always has value `t`.

In Emacs Lisp, `nil` and `t` are special symbols that always evaluate to themselves. This is so that you do not need to quote them to use them as constants in a program. An attempt to change their values results in a `setting-constant` error. See section Accessing Variable Values.

Evaluation Notation

A Lisp expression that you can evaluate is called a form. Evaluating a form always produces a result, which is a Lisp object. In the examples in this manual, this is indicated with `=>':

```
(car '(1 2))
     => 1
```

You can read this as "`(car '(1 2))` evaluates to 1".

When a form is a macro call, it expands into a new form for Lisp to evaluate. We show the result of the expansion with `==>'. We may or may not show the actual result of the evaluation of the expanded form.

```
(third '(a b c))
     ==> (car (cdr (cdr '(a b c))))
     => c
```

Sometimes to help describe one form we show another form which produces identical results. The exact equivalence of two forms is indicated with `=='.

```
(make-sparse-keymap) == (list 'keymap)
```

Printing Notation

Many of the examples in this manual print text when they are evaluated. If you execute the code from an example in a Lisp Interaction buffer (such as the buffer `*scratch*'), the printed text is inserted into the buffer. If the example is executed by other means (such as by evaluating the function `eval-region`), the text printed is usually displayed in the echo area. You should be aware that text displayed in the echo

area is truncated to a single line.

In examples that print text, the printed text is indicated with `-|', irrespective of how the form is executed. The value returned by evaluating the form (here `bar') follows on a separate line.

```
(progn (print 'foo) (print 'bar))
     -| foo
     -| bar
     => bar
```

Error Messages

Some examples cause errors to be signaled. In them, the error message (which always appears in the echo area) is shown on a line starting with `error-->'. Note that `error-->' itself does not appear in the echo area.

```
(+ 23 'x)
error--> Wrong type argument: integer-or-marker-p, x
```

Buffer Text Notation

Some examples show modifications to text in a buffer, with "before" and "after" versions of the text. In such cases, the entire contents of the buffer in question are included between two lines of dashes containing the buffer name. In addition, the location of point is shown as `-!-'. (The symbol for point, of course, is not part of the text in the buffer; it indicates the place *between* two characters where point is located.)

```
---------- Buffer: foo ----------
This is the -!-contents of foo.
---------- Buffer: foo ----------

(insert "changed ")
     => nil
---------- Buffer: foo ----------
This is the changed -!-contents of foo.
---------- Buffer: foo ----------
```

Format of Descriptions

Functions, variables, macros, commands, user options, and special forms are described in this manual in a uniform format. The first line of a description contains the name of the item followed by its arguments, if any. The category--function, variable, or whatever--is printed next to the right margin. The description follows on succeeding lines, sometimes with examples.

A Sample Function Description

In a function description, the name of the function being described appears first. It is followed on the same line by a list of parameters. The names used for the parameters are also used in the body of the description.

The appearance of the keyword `&optional` in the parameter list indicates that the arguments for subsequent parameters may be omitted (omitted parameters default to `nil`). Do not write `&optional` when you call the function.

The keyword `&rest` (which will always be followed by a single parameter) indicates that any number of arguments can follow. The value of the single following parameter will be a list of all these arguments. Do not write `&rest` when you call the function.

Here is a description of an imaginary function `foo`:

Function: **foo** *integer1 &optional integer2 &rest integers*

The function `foo` subtracts integer1 from integer2, then adds all the rest of the arguments to the result. If integer2 is not supplied, then the number 19 is used by default.

```
(foo 1 5 3 9)
     => 16
(foo 5)
     => 14
```

More generally,

```
(foo w x y...)
==
(+ (- x w) y...)
```

Any parameter whose name contains the name of a type (e.g., integer, integer1 or buffer) is expected to be of that type. A plural of a type (such as buffers) often means a list of objects of that type. Parameters named object may be of any type. (See section Lisp Data Types, for a list of Emacs object types.) Parameters with other sorts of names (e.g., new-file) are discussed specifically in the description of the function. In some sections, features common to parameters of several functions are described at the beginning.

See section Lambda Expressions, for a more complete description of optional and rest arguments.

Command, macro, and special form descriptions have the same format, but the word `Function' is replaced by `Command', `Macro', or `Special Form', respectively. Commands are simply functions that may be called interactively; macros process their arguments differently from functions (the arguments are not evaluated), but are presented the same way.

Special form descriptions use a more complex notation to specify optional and repeated parameters because they can break the argument list down into separate arguments in more complicated ways. `[optional-arg]' means that optional-arg is optional and `repeated-args...' stands for zero or more arguments. Parentheses are used when several arguments are grouped into additional levels of list

structure. Here is an example:

Special Form: **count-loop** *(var [from to [inc]]) body...*

This imaginary special form implements a loop that executes the body forms and then increments the variable var on each iteration. On the first iteration, the variable has the value from; on subsequent iterations, it is incremented by 1 (or by inc if that is given). The loop exits before executing body if var equals to. Here is an example:

```
(count-loop (i 0 10)
  (prin1 i) (princ " ")
  (prin1 (aref vector i)) (terpri))
```

If from and to are omitted, then var is bound to `nil` before the loop begins, and the loop exits if var is non-`nil` at the beginning of an iteration. Here is an example:

```
(count-loop (done)
  (if (pending)
      (fixit)
    (setq done t)))
```

In this special form, the arguments from and to are optional, but must both be present or both absent. If they are present, inc may optionally be specified as well. These arguments are grouped with the argument var into a list, to distinguish them from body, which includes all remaining elements of the form.

A Sample Variable Description

A variable is a name that can hold a value. Although any variable can be set by the user, certain variables that exist specifically so that users can change them are called user options. Ordinary variables and user options are described using a format like that for functions except that there are no arguments.

Here is a description of the imaginary `electric-future-map` variable.

Variable: **electric-future-map**

The value of this variable is a full keymap used by electric command future mode. The functions in this map will allow you to edit commands you have not yet thought about executing.

User option descriptions have the same format, but `Variable' is replaced by `User Option'.

Acknowledgements

This manual was written by Robert Krawitz, Bil Lewis, Dan LaLiberte, Richard M. Stallman and Chris Welty, the volunteers of the GNU manual group, in an effort extending over several years. Robert J. Chassell helped to review and edit the manual, with the support of the Defense Advanced Research Projects Agency, ARPA Order 6082, arranged by Warren A. Hunt, Jr. of Computational Logic, Inc.

Corrections were supplied by Karl Berry, Jim Blandy, Bard Bloom, David Boyes, Alan Carroll, David A.

Lisp Data Types

A Lisp object is a piece of data used and manipulated by Lisp programs. For our purposes, a type or data type is a set of possible objects.

Every object belongs to at least one type. Objects of the same type have similar structures and may usually be used in the same contexts. Types can overlap, and objects can belong to two or more types. Consequently, we can ask whether an object belongs to a particular type, but not for "the" type of an object.

A few fundamental object types are built into Emacs. These, from which all other types are constructed, are called primitive types. Each object belongs to one and only one primitive type. These types include integer, float, cons, symbol, string, vector, subr, byte-code function, and several special types, such as buffer, that are related to editing. (See section Editing Types.)

Each primitive type has a corresponding Lisp function that checks whether an object is a member of that type.

Note that Lisp is unlike many other languages in that Lisp objects are self-typing: the primitive type of the object is implicit in the object itself. For example, if an object is a vector, it cannot be treated as a number because Lisp knows it is a vector, not a number.

In most languages, the programmer must declare the data type of each variable, and the type is known by the compiler but not represented in the data. Such type declarations do not exist in Emacs Lisp. A Lisp variable can have any type of value, and remembers the type of any value you store in it.

This chapter describes the purpose, printed representation, and read syntax of each of the standard types in GNU Emacs Lisp. Details on how to use these types can be found in later chapters.

Printed Representation and Read Syntax

The printed representation of an object is the format of the output generated by the Lisp printer (the function `print`) for that object. The read syntax of an object is the format of the input accepted by the Lisp reader (the function `read`) for that object. Most objects have more than one possible read syntax. Some types of object have no read syntax; except for these cases, the printed representation of an object is also a read syntax for it.

In other languages, an expression is text; it has no other form. In Lisp, an expression is primarily a Lisp object and only secondarily the text that is the object's read syntax. Often there is no need to emphasize this distinction, but you must keep it in the back of your mind, or you will occasionally be very confused.

Every type has a printed representation. Some types have no read syntax, since it may not make sense to enter objects of these types directly in a Lisp program. For example, the buffer type does not have a read syntax. Objects of these types are printed in hash notation: the characters `#<' followed by a descriptive

string (typically the type name followed by the name of the object), and closed with a matching `>'. I notation cannot be read at all, so the Lisp reader signals the error `invalid-read-syntax` whene a `#<' is encountered.

```
(current-buffer)
     => #<buffer objects.texi>
```

When you evaluate an expression interactively, the Lisp interpreter first reads the textual representation of it, producing a Lisp object, and then evaluates that object (see section Evaluation). However, evaluation and reading are separate activities. Reading returns the Lisp object represented by the text that is read; the object may or may not be evaluated later. See section Input Functions, for a description of `read`, the basic function for reading objects.

Comments

A comment is text that is written in a program only for the sake of humans that read the program, and that has no effect on the meaning of the program. In Lisp, a comment starts with a semicolon (`;') if it is not within a string or character constant, and continues to the end of line. Comments are discarded by the Lisp reader, and do not become part of the Lisp objects which represent the program within the Lisp system.

See section Tips on Writing Comments, for conventions for formatting comments.

Programming Types

There are two general categories of types in Emacs Lisp: those having to do with Lisp programming, and those having to do with editing. The former are provided in many Lisp implementations, in one form or another. The latter are unique to Emacs Lisp.

Integer Type

Integers are the only kind of number in GNU Emacs Lisp, version 18. The range of values for integers is -8388608 to 8388607 (24 bits; i.e., to on most machines, but is 25 or 26 bits on some systems. It is important to note that the Emacs Lisp arithmetic functions do not check for overflow. Thus `(1+ 8388607)` is -8388608 on 24-bit implementations.

The read syntax for numbers is a sequence of (base ten) digits with an optional sign. The printed representation produced by the Lisp interpreter never has a leading `+'.

```
-1              ; The integer -1.
1               ; The integer 1.
+1              ; Also the integer 1.
16777217        ; Also the integer 1!
                ;   (on a 24-bit or 25-bit implementation)
```

See section Numbers, for more information.

Floating Point Type

Emacs version 19 supports floating point numbers, if compiled with the macro `LISP_FLOAT_TYPE` defined. The precise range of floating point numbers is machine-specific.

The printed representation for floating point numbers requires either a decimal point (with at least one digit following), an exponent, or both. For example, `1500.0', `15e2', `15.0e2', `1.5e3', and `.15e4' are five ways of writing a floating point number whose value is 1500. They are all equivalent.

See section Numbers, for more information.

Character Type

A character in Emacs Lisp is nothing more than an integer. In other words, characters are represented by their character codes. For example, the character A is represented as the integer 65.

Individual characters are not often used in programs. It is far more common to work with *strings*, which are sequences composed of characters. See section String Type.

Characters in strings, buffers, and files are currently limited to the range of 0 to 255. If an arbitrary integer is used as a character for those purposes, only the lower eight bits are significant. Characters that represent keyboard input have a much wider range.

Since characters are really integers, the printed representation of a character is a decimal number. This is also a possible read syntax for a character, but writing characters that way in Lisp programs is a very bad idea. You should *always* use the special read syntax formats that Emacs Lisp provides for characters. These syntax formats start with a question mark.

The usual read syntax for alphanumeric characters is a question mark followed by the character; thus, `?A' for the character A, `?B' for the character B, and `?a' for the character a.

For example:

```
?Q => 81

?q => 113
```

You can use the same syntax for punctuation characters, but it is often a good idea to add a `\' to prevent Lisp mode from getting confused. For example, `?\ ' is the way to write the space character. If the character is `\', you *must* use a second `\' to quote it: `?\\'.

You can express the characters control-g, backspace, tab, newline, vertical tab, formfeed, return, and escape as `?\a', `?\b', `?\t', `?\n', `?\v', `?\f', `?\r', `?\e', respectively. Those values are 7, 8, 9, 10, 11, 12, 13, and 27 in decimal. Thus,

```
?\a => 7                 ; C-g
```

```
?\b => 8                ; backspace, BS, C-h
?\t => 9                ; tab, TAB, C-i
?\n => 10               ; newline, LFD, C-j
?\v => 11               ; vertical tab, C-k
?\f => 12               ; formfeed character, C-l
?\r => 13               ; carriage return, RET, C-m
?\e => 27               ; escape character, ESC, C-[
?\\ => 92               ; backslash character, \
```

These sequences which start with backslash are also known as escape sequences, because backslash plays the role of an escape character, but they have nothing to do with the character ESC.

Control characters may be represented using yet another read syntax. This consists of a question mark followed by a backslash, caret, and the corresponding non-control character, in either upper or lower case. For example, either `?\^I' or `?\^i' may be used as the read syntax for the character C-i, the character whose value is 9.

Instead of the `^', you can use `C-'; thus, `?\C-i' is equivalent to `?\^I' and to `?\^i':

```
?\^I => 9

?\C-I => 9
```

For use in strings and buffers, you are limited to the control characters that exist in ASCII, but for keyboard input purposes, you can turn any character into a control character with `C-'. The character codes for these characters include the 2**22 bit as well as the code for the non-control character. Ordinary terminals have no way of generating non-ASCII control characters, but you can generate them straightforwardly using an X terminal.

The DEL key can be considered and written as Control-?:

```
?\^? => 127

?\C-? => 127
```

When you represent control characters to be found in files or strings, we recommend the `^' syntax; but when you refer to keyboard input, we prefer the `C-' syntax. This does not affect the meaning of the program, but may guide the understanding of people who read it.

A meta character is a character typed with the META key. The integer that represents such a character has the 2**23 bit set (which on most machines makes it a negative number). We use high bits for this and other modifiers to make possible a wide range of basic character codes.

In a string, the 2**7 bit indicates a meta character, so the meta characters that can fit in a string have codes in the range from 128 to 255, and are the meta versions of the ordinary ASCII characters. (In Emacs versions 18 and older, this convention was used for characters outside of strings as well.)

The read syntax for meta characters uses `\M-'. For example, `?\M-A' stands for M-A. You can use `\M-'

together with octal codes, `\C-', or any other syntax for a character. Thus, you can write M-A as `?\M-A', or as `?\M-\101'. Likewise, you can write C-M-b as `?\M-\C-b', `?\C-\M-b', or `?\M-\002'.

The shift modifier is used in indicating the case of a character in special circumstances. The case of an ordinary letter is indicated by its character code as part of ASCII, but ASCII has no way to represent whether a control character is upper case or lower case. Emacs uses the 2**21 bit to indicate that the shift key was used for typing a control character. This distinction is possible only when you use X terminals or other special terminals; ordinary terminals do not indicate the distinction to the computer in any way.

The X Window system defines three other modifier bits that can be set in a character: hyper, super and alt. The syntaxes for these bits are `\H-', `\s-' and `\A-'. Thus, `?\H-\M-\A-x' represents Alt-Hyper-Meta-x. Numerically, the bit values are 2**18 for alt, 2**19 for super and 2**20 for hyper.

Finally, the most general read syntax consists of a question mark followed by a backslash and the character code in octal (up to three octal digits); thus, `?\101' for the character A, `?\001' for the character C-a, and `?\002` for the character C-b. Although this syntax can represent any ASCII character, it is preferred only when the precise octal value is more important than the ASCII representation.

```
?\012 => 10          ?\n => 10          ?\C-j => 10

?\101 => 65          ?A => 65
```

A backslash is allowed, and harmless, preceding any character without a special escape meaning; thus, `?\A' is equivalent to `?A'. There is no reason to use a backslash before most such characters. However, any of the characters `()\|;'`"#.,' should be preceded by a backslash to avoid confusing the Emacs commands for editing Lisp code. Whitespace characters such as space, tab, newline and formfeed should also be preceded by a backslash. However, it is cleaner to use one of the easily readable escape sequences, such as `\t', instead of an actual control character such as a tab.

Sequence Types

A sequence is a Lisp object that represents an ordered set of elements. There are two kinds of sequence in Emacs Lisp, lists and arrays. Thus, an object of type list or of type array is also considered a sequence.

Arrays are further subdivided into strings and vectors. Vectors can hold elements of any type, but string elements must be characters in the range from 0 to 255. However, the characters in a string can have text properties; vectors do not support text properties even when their elements happen to be characters.

Lists, strings and vectors are different, but they have important similarities. For example, all have a length l, and all have elements which can be indexed from zero to l minus one. Also, several functions, called sequence functions, accept any kind of sequence. For example, the function `elt` can be used to extract an element of a sequence, given its index. See section Sequences, Arrays, and Vectors.

It is impossible to read the same sequence twice, in the sense of `eq` (see section Equality Predicates), since sequences are always created anew upon reading. There is one exception: the empty list `()` always stands for the same object, `nil`.

List Type

A list is a series of cons cells, linked together. A cons cell is an object comprising two pointers named the CAR and the CDR. Each of them can point to any Lisp object, but when the cons cell is part of a list, the CDR points either to another cons cell or to the empty list. See section Lists, for functions that work on lists.

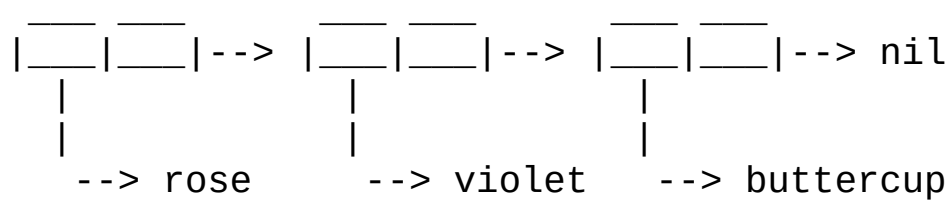
The names CAR and CDR have only historical meaning now. The original Lisp implementation ran on an IBM 704 computer which divided words into two parts, called the "address" part and the "decrement"; CAR was an instruction to extract the contents of the address part of a register, and CDR an instruction to extract the contents of the decrement. By contrast, "cons cells" are named for the function `cons` that creates them, which in turn is named for its purpose, the construction of cells.

Because cons cells are so central to Lisp, we also have a word for "an object which is not a cons cell". These objects are called atoms.

The read syntax and printed representation for lists are identical, and consist of a left parenthesis, an arbitrary number of elements, and a right parenthesis.

Upon reading, any object inside the parentheses is made into an element of the list. That is, a cons cell is made for each element. The CAR of the cons cell points to the element, and its CDR points to the next cons cell which holds the next element in the list. The CDR of the last cons cell is set to point to `nil`.

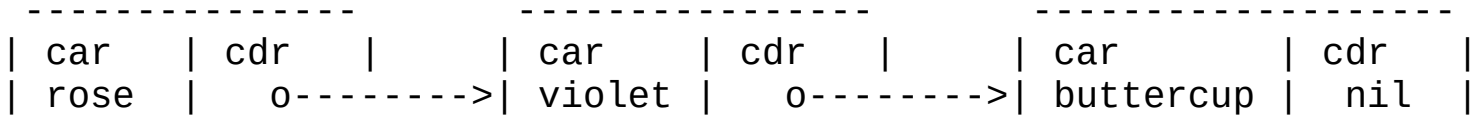
A list can be illustrated by a diagram in which the cons cells are shown as pairs of boxes. (The Lisp reader cannot read such an illustration; unlike the textual notation, which can be understood both humans and computers, the box illustrations can only be understood by humans.) The following represents the three-element list `(rose violet buttercup)`:

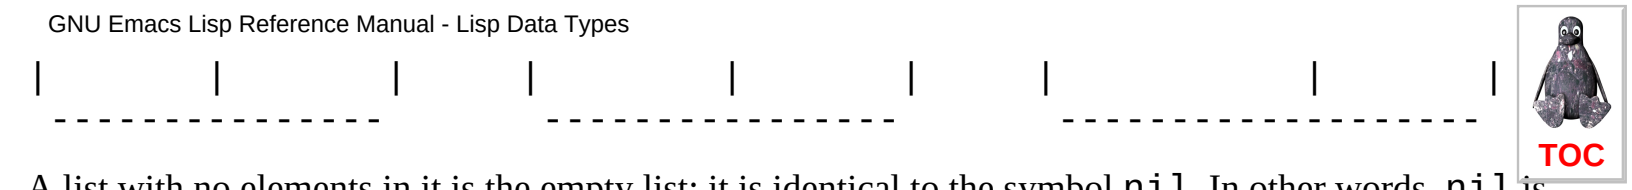


In the diagram, each box represents a slot that can refer to any Lisp object. Each pair of boxes represents a cons cell. Each arrow is a reference to a Lisp object, either an atom or another cons cell.

In this example, the first box, the CAR of the first cons cell, refers to or "contains" `rose` (a symbol). The second box, the CDR of the first cons cell, refers to the next pair of boxes, the second cons cell. The CAR of the second cons cell refers to `violet` and the CDR refers to the third cons cell. The CDR of the third (and last) cons cell refers to `nil`.

Here is another diagram of the same list, `(rose violet buttercup)`, sketched in a different manner:



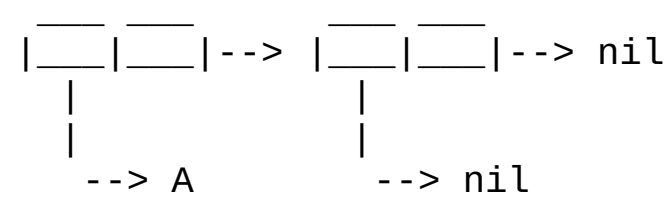


A list with no elements in it is the empty list; it is identical to the symbol `nil`. In other words, `nil` is both a symbol and a list.

Here are examples of lists written in Lisp syntax:

```
(A 2 "A")            ; A list of three elements.
()                   ; A list of no elements (the empty list).
nil                  ; A list of no elements (the empty list).
("A ()")             ; A list of one element: the string "A ()".
(A ())               ; A list of two elements: A and the empty list.
(A nil)              ; Equivalent to the previous.
((A B C))            ; A list of one element
                     ;   (which is a list of three elements).
```

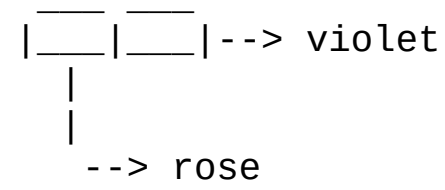
Here is the list `(A ())`, or equivalently `(A nil)`, depicted with boxes and arrows:



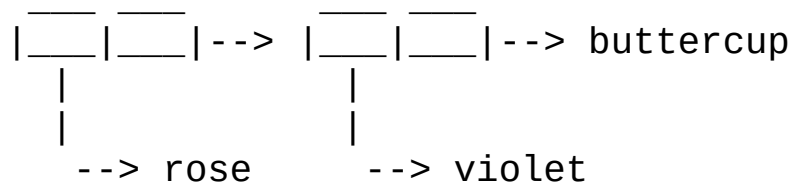
Dotted Pair Notation

Dotted pair notation is an alternative syntax for cons cells that represents the CAR and CDR explicitly. In this syntax, `(a . b)` stands for a cons cell whose CAR is the object a, and whose CDR is the object b. Dotted pair notation is therefore more general than list syntax. In the dotted pair notation, the list `(1 2 3)' is written as `(1 . (2 . (3 . nil)))'. For `nil`-terminated lists, the two notations produce the same result, but list notation is usually clearer and more convenient when it is applicable. When printing a list, the dotted pair notation is only used if the CDR of a cell is not a list.

Box notation can also be used to illustrate what dotted pairs look like. For example, `(rose . violet)` is diagrammed as follows:

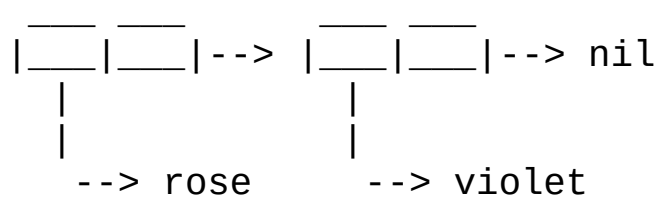


Dotted pair notation can be combined with list notation to represent a chain of cons cells with a non-`nil` final CDR. For example, `(rose violet . buttercup)` is equivalent to `(rose . (violet . buttercup))`. The object looks like this:



These diagrams make it evident that `(rose . violet . buttercup)` must have an invalid syntax since it would require that a cons cell have three parts rather than two.

The list `(rose violet)` is equivalent to `(rose . (violet))` and looks like this:



Similarly, the three-element list `(rose violet buttercup)` is equivalent to `(rose . (violet . (buttercup)))`.

Association List Type

An association list or alist is a specially-constructed list whose elements are cons cells. In each element, the CAR is considered a key, and the CDR is considered an associated value. (In some cases, the associated value is stored in the CAR of the CDR.) Association lists are often used to implement stacks, since new associations may easily be added to or removed from the front of the list.

For example,

```
(setq alist-of-colors
      '((rose . red) (lily . white)  (buttercup . yellow)))
```

sets the variable `alist-of-colors` to an alist of three elements. In the first element, `rose` is the key and `red` is the value.

See section Association Lists, for a further explanation of alists and for functions that work on alists.

Array Type

An array is composed of an arbitrary number of other Lisp objects, arranged in a contiguous block of memory. Any element of an array may be accessed in constant time. In contrast, accessing an element of a list requires time proportional to the position of the element in the list. (Elements at the end of a list take longer to access than elements at the beginning of a list.)

Emacs defines two types of array, strings and vectors. A string is an array of characters and a vector is an array of arbitrary objects. Both are one-dimensional. (Most other programming languages support

multidimensional arrays, but we don't think they are essential in Emacs Lisp.) Each type of array has its own read syntax; see section String Type, and section Vector Type.

An array may have any length up to the largest integer; but once created, it has a fixed size. The first element of an array has index zero, the second element has index 1, and so on. This is called zero-origin indexing. For example, an array of four elements has indices 0, 1, 2, and 3.

The array type is contained in the sequence type and contains both strings and vectors.

String Type

A string is an array of characters. Strings are used for many purposes in Emacs, as can be expected in a text editor; for example, as the names of Lisp symbols, as messages for the user, and to represent text extracted from buffers. Strings in Lisp are constants; evaluation of a string returns the same string.

The read syntax for strings is a double-quote, an arbitrary number of characters, and another double-quote, `"like this"`. The Lisp reader accepts the same formats for reading the characters of a string as it does for reading single characters (without the question mark that begins a character literal). You can enter a nonprinting character such as tab, C-a or M-C-A using the convenient escape sequences, like this: `"\t, \C-a, \M-\C-a"`. You can include a double-quote in a string by preceding it with a backslash; thus, `"\""` is a string containing just a single double-quote character. (See section Character Type, for a description of the read syntax for characters.)

If you use the `\M-' syntax to indicate a meta character in a string constant, this sets the 2**7 bit of the character in the string. This is not the same representation that the meta modifier has in a character regarded as a simple integer. See section Character Type.

Strings cannot hold characters that have the hyper, super or alt modifiers; they can hold ASCII control characters, but no others. They do not distinguish case in ASCII control characters.

In contrast with the C programming language, Emacs Lisp allows newlines in string literals. But an escaped newline--one that is preceded by `\'---does not become part of the string; i.e., the Lisp reader ignores an escaped newline in a string literal.

```
"It is useful to include newlines
in documentation strings,
but the newline is \
ignored if escaped."
     => "It is useful to include newlines
in documentation strings,
but the newline is ignored if escaped."
```

The printed representation of a string consists of a double-quote, the characters it contains, and another double-quote. However, any backslash or double-quote characters in the string are preceded with a backslash like this: `"this \" is an embedded quote"`.

A string can hold properties of the text it contains, in addition to the characters themselves. This enables programs that copy text between strings and buffers to preserve the properties with no special effort. See

section Text Properties. Strings with text properties have a special read and print syntax:

```
#("characters" property-data...)
```

where property-data is zero or more elements in groups of three as follows:

```
beg end plist
```

The elements beg and end are integers, and together specify a portion of the string; plist is the property list for that portion.

See section Strings and Characters, for functions that work on strings.

Vector Type

A vector is a one-dimensional array of elements of any type. It takes a constant amount of time to access any element of a vector. (In a list, the access time of an element is proportional to the distance of the element from the beginning of the list.)

The printed representation of a vector consists of a left square bracket, the elements, and a right square bracket. This is also the read syntax. Like numbers and strings, vectors are considered constants for evaluation.

```
[1 "two" (three)]      ; A vector of three elements.
     => [1 "two" (three)]
```

See section Vectors, for functions that work with vectors.

Symbol Type

A symbol in GNU Emacs Lisp is an object with a name. The symbol name serves as the printed representation of the symbol. In ordinary use, the name is unique--no two symbols have the same name.

A symbol may be used in programs as a variable, as a function name, or to hold a list of properties. Or it may serve only to be distinct from all other Lisp objects, so that its presence in a data structure may be recognized reliably. In a given context, usually only one of these uses is intended.

A symbol name can contain any characters whatever. Most symbol names are written with letters, digits, and the punctuation characters `-+=*/'. Such names require no special punctuation; the characters of the name suffice as long as the name does not look like a number. (If it does, write a `\' at the beginning of the name to force interpretation as a symbol.) The characters `_~!@$%^&:<>{}' are less often used but also require no special punctuation. Any other characters may be included in a symbol's name by escaping them with a backslash. In contrast to its use in strings, however, a backslash in the name of a symbol quotes the single character that follows the backslash, without conversion. For example, in a string, `\t' represents a tab character; in the name of a symbol, however, `\t' merely quotes the letter t. To have a symbol with a tab character in its name, you must actually type an tab (preceded with a backslash). But you would hardly ever do such a thing.

Common Lisp note: in Common Lisp, lower case letters are always "folded" to upper case, unless they are explicitly escaped. This is in contrast to Emacs Lisp, in which upper case and lower case letters are distinct.

Here are several examples of symbol names. Note that the `+' in the fifth example is escaped to prevent it from being read as a number. This is not necessary in the last example because the rest of the name makes it invalid as a number.

```
foo                 ; A symbol named `foo'.
FOO                 ; A symbol named `FOO', different from `foo'.
char-to-string      ; A symbol named `char-to-string'.
1+                  ; A symbol named `1+'
                    ;   (not `+1', which is an integer).
\+1                 ; A symbol named `+1'
                    ;   (not a very readable name).
\(*\ 1\ 2\)         ; A symbol named `(* 1 2)' (a worse name).
+-*/_~!@$%^&=:<>{}  ; A symbol named `+-*/_~!@$%^&=:<>{}'.
                    ;   These characters need not be escaped.
```

Lisp Function Type

Just as functions in other programming languages are executable, Lisp function objects are pieces of executable code. However, functions in Lisp are primarily Lisp objects, and only secondarily the text which represents them. These Lisp objects are lambda expressions: lists whose first element is the symbol `lambda` (see section Lambda Expressions).

In most programming languages, it is impossible to have a function without a name. In Lisp, a function has no intrinsic name. A lambda expression is also called an anonymous function (see section Anonymous Functions). A named function in Lisp is actually a symbol with a valid function in its function cell (see section Defining Named Functions).

Most of the time, functions are called when their names are written in Lisp expressions in Lisp programs. However, a function object found or constructed at run time can be called and passed arguments with the primitive functions `funcall` and `apply`. See section Calling Functions.

Lisp Macro Type

A Lisp macro is a user-defined construct that extends the Lisp language. It is represented as an object much like a function, but with different parameter-passing semantics. A Lisp macro has the form of a list whose first element is the symbol `macro` and whose CDR is a Lisp function object, including the `lambda` symbol.

Lisp macro objects are usually defined with the built-in `defmacro` function, but any list that begins with `macro` is a macro as far as Emacs is concerned. See section Macros, for an explanation of how to write a macro.

Primitive Function Type

A primitive function is a function callable from Lisp but written in the C programming language. Primitive functions are also called subrs or built-in functions. (The word "subr" is derived from "subroutine".) Most primitive functions evaluate all their arguments when they are called. A primitive function that does not evaluate all its arguments is called a special form (see section Special Forms).

It does not matter to the caller of a function whether the function is primitive. However, this does matter if you are trying to substitute a function written in Lisp for a primitive of the same name. The reason is that the primitive function may be called directly from C code. When the redefined function is called from Lisp, the new definition will be used; but calls from C code may still use the old definition.

The term function is used to refer to all Emacs functions, whether written in Lisp or C. See section Lisp Function Type, for information about the functions written in Lisp.

Primitive functions have no read syntax and print in hash notation with the name of the subroutine.

```
(symbol-function 'car)          ; Access the function cell
                                ;   of the symbol.
     => #<subr car>
(subrp (symbol-function 'car))  ; Is this a primitive function?
     => t                       ; Yes.
```

Byte-Code Function Type

The byte compiler produces byte-code function objects. Internally, a byte-code function object is much like a vector; however, the evaluator handles this data type specially when it appears as a function to be called. See section Byte Compilation, for information about the byte compiler.

The printed representation for a byte-code function object is like that for a vector, with an additional `#' before the opening `['.

Autoload Type

An autoload object is a list whose first element is the symbol `autoload`. It is stored as the function definition of a symbol to say that a file of Lisp code should be loaded when necessary to find the true definition of that symbol. The autoload object contains the name of the file, plus some other information about the real definition.

After the file has been loaded, the symbol should have a new function definition that is not an autoload object. The new definition is then called as if it had been there to begin with. From the user's point of view, the function call works as expected, using the function definition in the loaded file.

An autoload object is usually created with the function `autoload`, which stores the object in the function cell of a symbol. See section Autoload, for more details.

Editing Types

The types in the previous section are common to many Lisp-like languages. But Emacs Lisp provides several additional data types for purposes connected with editing.

Buffer Type

A buffer is an object that holds text that can be edited (see section Buffers). Most buffers hold the contents of a disk file (see section Files) so they can be edited, but some are used for other purposes. Most buffers are also meant to be seen by the user, and therefore displayed, at some time, in a window (see section Windows). But a buffer need not be displayed in a window.

The contents of a buffer are much like a string, but buffers are not used like strings in Emacs Lisp, and the available operations are different. For example, text can be inserted into a buffer very quickly, while "inserting" text into a string is accomplished by concatenation and the result is an entirely new string object.

Each buffer has a designated position called point (see section Positions). And one buffer is the current buffer. Most editing commands act on the contents of the current buffer in the neighborhood of point. Many other functions manipulate or test the characters in the current buffer and much of this manual is devoted to describing these functions (see section Text).

Several other data structures are associated with each buffer:

- a local syntax table (see section Syntax Tables);
- a local keymap (see section Keymaps); and,
- a local variable binding list (see section Buffer-Local Variables).

The local keymap and variable list contain entries which individually override global bindings or values. These are used to customize the behavior of programs in different buffers, without actually changing the programs.

Buffers have no read syntax. They print in hash notation with the buffer name.

```
(current-buffer)
     => #<buffer objects.texi>
```

Window Type

A window describes the portion of the terminal screen that Emacs uses to display a buffer. Every window has one associated buffer, whose contents appear in the window. By contrast, a given buffer may appear in one window, no window, or several windows.

Though many windows may exist simultaneously, one window is designated the selected window. This is the window where the cursor is (usually) displayed when Emacs is ready for a command. The selected window usually displays the current buffer, but this is not necessarily the case.

Windows are grouped on the screen into frames; each window belongs to one and only one frame. See section Frame Type.

Windows have no read syntax. They print in hash notation, giving the window number and the name of the buffer being displayed. The window numbers exist to identify windows uniquely, since the buffer displayed in any given window can change frequently.

```
(selected-window)
     => #<window 1 on objects.texi>
```

See section Windows, for a description of the functions that work on windows.

Frame Type

A frame is a rectangle on the screen that contains one or more Emacs windows. A frame initially contains a single main window (plus perhaps a minibuffer window) which you can subdivide vertically or horizontally into smaller windows.

Frames have no read syntax. They print in hash notation, giving the frame's title, plus its address in core (useful to identify the frame uniquely).

```
(selected-frame)
     => #<frame xemacs@mole.gnu.ai.mit.edu 0xdac80>
```

See section Frames, for a description of the functions that work on frames.

Window Configuration Type

A window configuration stores information about the positions and sizes of windows at the time the window configuration is created, so that the screen layout may be recreated later.

Window configurations have no read syntax. They print as `#<window-configuration>'. See section Window Configurations, for a description of several functions related to window configurations.

Marker Type

A marker denotes a position in a specific buffer. Markers therefore have two components: one for the buffer, and one for the position. The position value is changed automatically as necessary as text is inserted into or deleted from the buffer. This is to ensure that the marker always points between the same two characters in the buffer.

Markers have no read syntax. They print in hash notation, giving the current character position and the name of the buffer.

```
(point-marker)
     => #<marker at 10779 in objects.texi>
```

See section Markers, for information on how to test, create, copy, and move markers.

Process Type

The word process means a running program. Emacs itself runs in a process of this sort. However, in Emacs Lisp, a process is a Lisp object that designates a subprocess created by Emacs process. External subprocesses, such as shells, GDB, ftp, and compilers, may be used to extend the processing capability of Emacs.

A process takes input from Emacs and returns output to Emacs for further manipulation. Both text and signals can be communicated between Emacs and a subprocess.

Processes have no read syntax. They print in hash notation, giving the name of the process:

```
(process-list)
     => (#<process shell>)
```

See section Processes, for information about functions that create, delete, return information about, send input or signals to, and receive output from processes.

Stream Type

A stream is an object that can be used as a source or sink for characters--either to supply characters for input or to accept them as output. Many different types can be used this way: markers, buffers, strings, and functions. Most often, input streams (character sources) obtain characters from the keyboard, a buffer, or a file, and output streams (character sinks) send characters to a buffer, such as a `` `*Help*' `` buffer, or to the echo area.

The object `nil`, in addition to its other meanings, may be used as a stream. It stands for the value of the variable `standard-input` or `standard-output`. Also, the object `t` as a stream specifies input using the minibuffer (see section Minibuffers) or output in the echo area (see section The Echo Area).

Streams have no special printed representation or read syntax, and print as whatever primitive type they are.

See section Reading and Printing Lisp Objects, for a description of various functions related to streams, including various parsing and printing functions.

Keymap Type

A keymap maps keys typed by the user to functions. This mapping controls how the user's command input is executed. A keymap is actually a list whose CAR is the symbol `keymap`.

See section Keymaps, for information about creating keymaps, handling prefix keys, local as well as global keymaps, and changing key bindings.

Syntax Table Type

A syntax table is a vector of 256 integers. Each element of the vector defines how one character is interpreted when it appears in a buffer. For example, in C mode (see section Major Modes), the `+' character is punctuation, but in Lisp mode it is a valid character in a symbol. These different interpretations are effected by changing the syntax table entry for `+', i.e., at index 43.

Syntax tables are only used for scanning text in buffers, not for reading Lisp expressions. The table the Lisp interpreter uses to read expressions is built into the Emacs source code and cannot be changed; thus, to change the list delimiters to be `{' and `}' instead of `(' and `)' would be impossible.

See section Syntax Tables, for details about syntax classes and how to make and modify syntax tables.

Display Table Type

A display table specifies how to display each character code. Each buffer and each window can have its own display table. A display table is actually a vector of length 261. See section Display Tables.

Overlay Type

An overlay specifies temporary alteration of the display appearance of a part of a buffer. It contains markers delimiting a range of the buffer, plus a property list (a list whose elements are alternating property names and values). Overlays are used to present parts of the buffer temporarily in a different display style.

See section Overlays, for how to create and use overlays.

Type Predicates

The Emacs Lisp interpreter itself does not perform type checking on the actual arguments passed to functions when they are called. It could not do otherwise, since variables in Lisp are not declared to be of a certain type, as they are in other programming languages. It is therefore up to the individual function to test whether each actual argument belongs to a type that can be used by the function.

All built-in functions do check the types of their actual arguments when appropriate and signal a `wrong-type-argument` error if an argument is of the wrong type. For example, here is what happens if you pass an argument to `+` which it cannot handle:

```
(+ 2 'a)
     error--> Wrong type argument: integer-or-marker-p, a
```

Many functions, called type predicates, are provided to test whether an object is a member of a given type. (Following a convention of long standing, the names of most Emacs Lisp predicates end in `p'.)

Here is a table of predefined type predicates, in alphabetical order, with references to further information.

`atom`

Equality Predicates

Here we describe two functions that test for equality between any two objects. Other functions test equality between objects of specific types, e.g., strings. See the appropriate chapter describing the data type for these predicates.

Function: **eq** *object1 object2*

This function returns `t` if object1 and object2 are the same object, `nil` otherwise. The "same object" means that a change in one will be reflected by the same change in the other.

`eq` returns `t` if object1 and object2 are integers with the same value. Also, since symbol names are normally unique, if the arguments are symbols with the same name, they are `eq`. For other types (e.g., lists, vectors, strings), two arguments with the same contents or elements are not necessarily `eq` to each other: they are `eq` only if they are the same object.

(The `make-symbol` function returns an uninterned symbol that is not interned in the standard `obarray`. When uninterned symbols are in use, symbol names are no longer unique. Distinct symbols with the same name are not `eq`. See section Creating and Interning Symbols.)

```
(eq 'foo 'foo)
     => t

(eq 456 456)
     => t

(eq "asdf" "asdf")
     => nil

(eq '(1 (2 (3))) '(1 (2 (3))))
     => nil

(eq [(1 2) 3] [(1 2) 3])
     => nil

(eq (point-marker) (point-marker))
     => nil
```

Function: **equal** *object1 object2*

This function returns `t` if object1 and object2 have equal components, `nil` otherwise. Whereas `eq` tests if its arguments are the same object, `equal` looks inside nonidentical arguments to see if their elements are the same. So, if two objects are `eq`, they are `equal`, but the converse is not always true.

```
(equal 'foo 'foo)
     => t

(equal 456 456)
     => t

(equal "asdf" "asdf")
     => t
(eq "asdf" "asdf")
```

```
     => nil

(equal '(1 (2 (3))) '(1 (2 (3))))
     => t
(eq '(1 (2 (3))) '(1 (2 (3))))
     => nil

(equal [(1 2) 3] [(1 2) 3])
     => t
(eq [(1 2) 3] [(1 2) 3])
     => nil

(equal (point-marker) (point-marker))
     => t

(eq (point-marker) (point-marker))
     => nil
```

Comparison of strings is case-sensitive.

```
(equal "asdf" "ASDF")
     => nil
```

The test for equality is implemented recursively, and circular lists may therefore cause infinite recursion (leading to an error).

Go to the previous, next section.

Go to the previous, next section.

Numbers

GNU Emacs supports two numeric data types: integers and floating point numbers. Integers are whole numbers such as -3, 0, 7, 13, and 511. Their values are exact. Floating point numbers are numbers with fractional parts, such as -4.5, 0.0, or 2.71828. They can also be expressed in an exponential notation as well: thus, 1.5e2 equals 150; in this example, `e2' stands for ten to the second power, and is multiplied by 1.5. Floating point values are not exact; they have a fixed, limited amount of precision.

Support for floating point numbers is a new feature in Emacs 19, and it is controlled by a separate compilation option, so you may encounter a site where Emacs does not support them.

Integer Basics

The range of values for an integer depends on the machine. The range is -8388608 to 8388607 (24 bits; i.e., to) on most machines, but on others it is -16777216 to 16777215 (25 bits), or -33554432 to 33554431 (26 bits). All of the examples shown below assume an integer has 24 bits.

The Lisp reader reads numbers as a sequence of digits with an optional sign.

```
 1               ; The integer 1.
+1               ; Also the integer 1.
-1               ; The integer -1.
 16777217        ; Also the integer 1, due to overflow.
 0               ; The number 0.
-0               ; The number 0.
 1.              ; The integer 1.
```

To understand how various functions work on integers, especially the bitwise operators (see section Bitwise Operations on Integers), it is often helpful to view the numbers in their binary form.

In 24 bit binary, the decimal integer 5 looks like this:

```
0000 0000  0000 0000  0000 0101
```

(We have inserted spaces between groups of 4 bits, and two spaces between groups of 8 bits, to make the binary integer easier to read.)

The integer -1 looks like this:

```
1111 1111  1111 1111  1111 1111
```

-1 is represented as 24 ones. (This is called two's complement notation.)

The negative integer, -5, is creating by subtracting 4 from -1. In binary, the decimal integer 4 is 100. Consequently, -5 looks like this:

```
1111 1111  1111 1111  1111 1011
```

In this implementation, the largest 24 bit binary integer is the decimal integer 8,388,607. In binary, this number looks like this:

```
0111 1111  1111 1111  1111 1111
```

Since the arithmetic functions do not check whether integers go outside their range, when you add 1 to 8,388,607, the value is negative integer -8,388,608:

```
(+ 1 8388607)
     => -8388608
     => 1000 0000  0000 0000  0000 0000
```

Many of the following functions accept markers for arguments as well as integers. (See section Markers.) More precisely, the actual parameters to such functions may be either integers or markers, which is why we often give these parameters the name int-or-marker. When the actual parameter is a marker, the position value of the marker is used and the buffer of the marker is ignored.

Floating Point Basics

Emacs version 19 supports floating point numbers, if compiled with the macro `LISP_FLOAT_TYPE` defined. The precise range of floating point numbers is machine-specific; it is the same as the range of the C data type `double` on the machine in question.

The printed representation for floating point numbers requires either a decimal point (with at least one digit following), an exponent, or both. For example, `1500.0', `15e2', `15.0e2', `1.5e3', and `.15e4' are five ways of writing a floating point number whose value is 1500. They are all equivalent. You can also use a minus sign to write negative floating point numbers, as in `-1.0'.

You can use `logb` to extract the binary exponent of a floating point number (or estimate the logarithm of an integer):

Function: **logb** *number*

This function returns the binary exponent of number. More precisely, the value is the logarithm of number base 2, rounded down to an integer.

Type Predicates for Numbers

The functions in this section test whether the argument is a number or whether it is a certain sort of number. The functions `integerp` and `floatp` can take any type of Lisp object as argument (the predicates would not be of much use otherwise); but the `zerop` predicate requires a number as its

argument. See also `integer-or-marker-p` and `number-or-marker-p`, in section Predicates on Markers.

Function: **floatp** *object*

This predicate tests whether its argument is a floating point number and returns `t` if so, `nil` otherwise.

`floatp` does not exist in Emacs versions 18 and earlier.

Function: **integerp** *object*

This predicate tests whether its argument is an integer, and returns `t` if so, `nil` otherwise.

Function: **numberp** *object*

This predicate tests whether its argument is a number (either integer or floating point), and returns `t` if so, `nil` otherwise.

Function: **natnump** *object*

The `natnump` predicate (whose name comes from the phrase "natural-number-p") tests to see whether its argument is a nonnegative integer, and returns `t` if so, `nil` otherwise. 0 is considered non-negative.

Markers are not converted to integers, hence `natnump` of a marker is always `nil`.

People have pointed out that this function is misnamed, because the term "natural number" is usually understood as excluding zero. We are open to suggestions for a better name to use in a future version.

Function: **zerop** *number*

This predicate tests whether its argument is zero, and returns `t` if so, `nil` otherwise. The argument must be a number.

These two forms are equivalent: `(zerop x) == (= x 0)`.

Comparison of Numbers

Floating point numbers in Emacs Lisp actually take up storage, and there can be many distinct floating point number objects with the same numeric value. If you use `eq` to compare them, then you test whether two values are the same *object*. If you want to compare just the numeric values, use `=`.

If you use `eq` to compare two integers, it always returns `t` if they have the same value. This is sometimes useful, because `eq` accepts arguments of any type and never causes an error, whereas `=` signals an error if the arguments are not numbers or markers. However, it is a good idea to use `=` if you can, even for comparing integers, just in case we change the representation of integers in a future Emacs version.

There is another wrinkle: because floating point arithmetic is not exact, it is often a bad idea to check for equality of two floating point values. Usually it is better to test for approximate equality. Here's a function to do this:

```
(defvar fuzz-factor 1.0e-6)

(defun approx-equal (x y)
  (< (/ (abs (- x y))
        (max (abs x) (abs y)))
     fuzz-factor))
```

Common Lisp note: because of the way numbers are implemented in Common Lisp, you generally need to use `=' to test for equality between numbers of any kind.

Function: = *number-or-marker1 number-or-marker2*

This function tests whether its arguments are the same number, and returns `t` if so, `nil` otherwise.

Function: /= *number-or-marker1 number-or-marker2*

This function tests whether its arguments are not the same number, and returns `t` if so, `nil` otherwise.

Function: < *number-or-marker1 number-or-marker2*

This function tests whether its first argument is strictly less than its second argument. It returns `t` if so, `nil` otherwise.

Function: <= *number-or-marker1 number-or-marker2*

This function tests whether its first argument is less than or equal to its second argument. It returns `t` if so, `nil` otherwise.

Function: > *number-or-marker1 number-or-marker2*

This function tests whether its first argument is strictly greater than its second argument. It returns `t` if so, `nil` otherwise.

Function: >= *number-or-marker1 number-or-marker2*

This function tests whether its first argument is greater than or equal to its second argument. It returns `t` if so, `nil` otherwise.

Function: **max** *number-or-marker &rest numbers-or-markers*

This function returns the largest of its arguments.

```
(max 20)
     => 20
(max 1 2)
     => 2
(max 1 3 2)
     => 3
```

Function: **min** *number-or-marker &rest numbers-or-markers*

This function returns the smallest of its arguments.

Numeric Conversions

To convert an integer to floating point, use the function `float`.

Function: **float** *number*

This returns number converted to floating point. If number is already a floating point number, `float` returns it unchanged.

There are four functions to convert floating point numbers to integers; they differ in how they round. You can call these functions with an integer argument also; if you do, they return it without change.

Function: **truncate** *number*

This returns number, converted to an integer by rounding towards zero.

Function: **floor** *number*

This returns number, converted to an integer by rounding downward (towards negative infinity).

Function: **ceiling** *number*

This returns number, converted to an integer by rounding upward (towards positive infinity).

Function: **round** *number*

This returns number, converted to an integer by rounding towards the nearest integer.

Arithmetic Operations

Emacs Lisp provides the traditional four arithmetic operations: addition, subtraction, multiplication, and division. A remainder function supplements the (integer) division function. The functions to add or subtract 1 are provided because they are traditional in Lisp and commonly used.

All of these functions except % return a floating point value if any argument is floating.

It is important to note that in GNU Emacs Lisp, arithmetic functions do not check for overflow. Thus `(1+ 8388607)` may equal -8388608, depending on your hardware.

Function: **1+** *number-or-marker*

This function returns number-or-marker plus 1. For example,

```
(setq foo 4)
     => 4
(1+ foo)
     => 5
```

This function is not analogous to the C operator ++---it does not increment a variable. It just computes a

sum. Thus,

```
foo
     => 4
```

If you want to increment the variable, you must use `setq`, like this:

```
(setq foo (1+ foo))
     => 5
```

Function: **1-** *number-or-marker*

This function returns number-or-marker minus 1.

Function: **abs** *number*

This returns the absolute value of number.

Function: **+** *&rest numbers-or-markers*

This function adds its arguments together. When given no arguments, `+` returns 0. It does not check for overflow.

```
(+)
     => 0
(+ 1)
     => 1
(+ 1 2 3 4)
     => 10
```

Function: **-** *&optional number-or-marker &rest other-numbers-or-markers*

The `-` function serves two purposes: negation and subtraction. When `-` has a single argument, the value is the negative of the argument. When there are multiple arguments, each of the other-numbers-or-markers is subtracted from number-or-marker, cumulatively. If there are no arguments, the result is 0. This function does not check for overflow.

```
(- 10 1 2 3 4)
     => 0
(- 10)
     => -10
(-)
     => 0
```

Function: ***** *&rest numbers-or-markers*

This function multiplies its arguments together, and returns the product. When given no arguments, `*` returns 1. It does not check for overflow.

```
(*)
     => 1
(* 1)
     => 1
(* 1 2 3 4)
     => 24
```

Function: / *dividend divisor &rest divisors*

This function divides dividend by divisors and returns the quotient. If there are additional arguments divisors, then dividend is divided by each divisor in turn. Each argument may be a number or a marker.

If all the arguments are integers, then the result is an integer too. This means the result has to be rounded. On most machines, the result is rounded towards zero after each division, but some machines may round differently with negative arguments. This is because the Lisp function `/` is implemented using the C division operator, which has the same possibility for machine-dependent rounding. As a practical matter, all known machines round in the standard fashion.

If you divide by 0, an `arith-error` error is signaled. (See section Errors.)

```
(/ 6 2)
     => 3
(/ 5 2)
     => 2
(/ 25 3 2)
     => 4
(/ -17 6)
     => -2
```

Since the division operator in Emacs Lisp is implemented using the division operator in C, the result of dividing negative numbers may in principle vary from machine to machine, depending on how they round the result. Thus, the result of `(/ -17 6)` could be -3 on some machines. In practice, nearly all machines round the quotient towards 0.

Function: **%** *dividend divisor*

This function returns the value of dividend modulo divisor; in other words, the integer remainder after division of dividend by divisor. The sign of the result is the sign of dividend. The sign of divisor is ignored. The arguments must be integers.

For negative arguments, the value is in principle machine-dependent since the quotient is; but in practice, all known machines behave alike.

An `arith-error` results if divisor is 0.

```
(% 9 4)
     => 1
```

```
(% -9 4)
     => -1
(% 9 -4)
     => 1
(% -9 -4)
     => -1
```

For any two numbers dividend and divisor,

```
(+ (% dividend divisor)
   (* (/ dividend divisor) divisor))
```

always equals dividend.

Bitwise Operations on Integers

In a computer, an integer is represented as a binary number, a sequence of bits (digits which are either zero or one). A bitwise operation acts on the individual bits of such a sequence. For example, shifting moves the whole sequence left or right one or more places, reproducing the same pattern "moved over".

The bitwise operations in Emacs Lisp apply only to integers.

Function: **lsh** *integer1 count*

`lsh`, which is an abbreviation for logical shift, shifts the bits in integer1 to the left count places, or to the right if count is negative. If count is negative, `lsh` shifts zeros into the most-significant bit, producing a positive result even if integer1 is negative. Contrast this with `ash`, below.

Thus, the decimal number 5 is the binary number 00000101. Shifted once to the left, with a zero put in the one's place, the number becomes 00001010, decimal 10.

Here are two examples of shifting the pattern of bits one place to the left. Since the contents of the rightmost place has been moved one place to the left, a value has to be inserted into the rightmost place. With `lsh`, a zero is placed into the rightmost place. (These examples show only the low-order eight bits of the binary pattern; the rest are all zero.)

```
(lsh 5 1)
     => 10

;; Decimal 5 becomes decimal 10.
00000101 => 00001010

(lsh 7 1)
     => 14

;; Decimal 7 becomes decimal 14.
00000111 => 00001110
```

As the examples illustrate, shifting the pattern of bits one place to the left produces a number that is t the value of the previous number.

Note, however that functions do not check for overflow, and a returned value may be negative (and in any case, no more than a 24 bit value) when an integer is sufficiently left shifted.

For example, left shifting 8,388,607 produces -2:

```
(lsh 8388607 1)          ; left shift
     => -2
```

In binary, in the 24 bit implementation, the numbers looks like this:

```
;; Decimal 8,388,607
0111 1111  1111 1111  1111 1111
```

which becomes the following when left shifted:

```
;; Decimal -2
1111 1111  1111 1111  1111 1110
```

Shifting the pattern of bits two places to the left produces results like this (with 8-bit binary numbers):

```
(lsh 3 2)
     => 12

;; Decimal 3 becomes decimal 12.
00000011 => 00001100
```

On the other hand, shifting the pattern of bits one place to the right looks like this:

```
(lsh 6 -1)
     => 3

;; Decimal 6 becomes decimal 3.
00000110 => 00000011

(lsh 5 -1)
     => 2

;; Decimal 5 becomes decimal 2.
00000101 => 00000010
```

As the example illustrates, shifting the pattern of bits one place to the right divides the value of the binary number by two, rounding downward.

Function: **ash** *integer1 count*

`ash` (arithmetic shift) shifts the bits in integer1 to the left count places, or to the right if count is negative.

`ash` gives the same results as `lsh` except when integer1 and count are both negative. In that case, `ash` puts a one in the leftmost position, while `lsh` puts a zero in the leftmost position.

Thus, with `ash`, shifting the pattern of bits one place to the right looks like this:

```
(ash -6 -1)
     => -3

;; Decimal -6
;; becomes decimal -3.

1111 1111  1111 1111  1111 1010
     =>
1111 1111  1111 1111  1111 1101
```

In contrast, shifting the pattern of bits one place to the right with `lsh` looks like this:

```
(lsh -6 -1)
     => 8388605

;; Decimal -6
;; becomes decimal 8,388,605.

1111 1111  1111 1111  1111 1010
     =>
0111 1111  1111 1111  1111 1101
```

In this case, the 1 in the leftmost position is shifted one place to the right, and a zero is shifted into the leftmost position.

Here are other examples:

```
                  ;               24-bit binary values

(lsh 5 2)         ;   5  =  0000 0000  0000 0000  0000 0101
     => 20        ;  20  =  0000 0000  0000 0000  0001 0100
(ash 5 2)
     => 20
(lsh -5 2)        ;  -5  =  1111 1111  1111 1111  1111 1011
     => -20       ; -20  =  1111 1111  1111 1111  1110 1100
(ash -5 2)
     => -20
(lsh 5 -2)        ;   5  =  0000 0000  0000 0000  0000 0101
```

```
     => 1           ;   1  =  0000 0000  0000 0000  0000 0001
(ash 5 -2)
     => 1
(lsh -5 -2)         ;  -5  =  1111 1111  1111 1111  1111 1011
     => 4194302     ;         0011 1111  1111 1111  1111 1110
(ash -5 -2)         ;  -5  =  1111 1111  1111 1111  1111 1011
     => -2          ;  -2  =  1111 1111  1111 1111  1111 1110
```

Function: **logand** *&rest ints-or-markers*

This function returns the "logical and" of the arguments: the nth bit is set in the result if, and only if, the nth bit is set in all the arguments. ("Set" means that the value of the bit is 1 rather than 0.)

For example, using 4-bit binary numbers, the "logical and" of 13 and 12 is 12: 1101 combined with 1100 produces 1100.

In both the binary numbers, the leftmost two bits are set (i.e., they are 1's), so the leftmost two bits of the returned value are set. However, for the rightmost two bits, each is zero in at least one of the arguments, so the rightmost two bits of the returned value are 0's.

Therefore,

```
(logand 13 12)
     => 12
```

If `logand` is not passed any argument, it returns a value of -1. This number is an identity element for `logand` because its binary representation consists entirely of ones. If `logand` is passed just one argument, it returns that argument.

```
                    ;                  24-bit binary values

(logand 14 13)      ; 14  =  0000 0000  0000 0000  0000 1110
                    ; 13  =  0000 0000  0000 0000  0000 1101
     => 12          ; 12  =  0000 0000  0000 0000  0000 1100

(logand 14 13 4)    ; 14  =  0000 0000  0000 0000  0000 1110
                    ; 13  =  0000 0000  0000 0000  0000 1101
                    ;  4  =  0000 0000  0000 0000  0000 0100
     => 4           ;  4  =  0000 0000  0000 0000  0000 0100

(logand)
     => -1          ; -1  =  1111 1111  1111 1111  1111 1111
```

Function: **logior** *&rest ints-or-markers*

This function returns the "inclusive or" of its arguments: the nth bit is set in the result if, and only if, the nth bit is set in at least one of the arguments. If there are no arguments, the result is zero, which is an identity element for this operation. If `logior` is passed just one argument, it returns that argument.

```
                    ;                  24-bit binary values

(logior 12 5)       ; 12  =  0000 0000  0000 0000  0000 1100
                    ;  5  =  0000 0000  0000 0000  0000 0101
     => 13          ; 13  =  0000 0000  0000 0000  0000 1101

(logior 12 5 7)     ; 12  =  0000 0000  0000 0000  0000 1100
                    ;  5  =  0000 0000  0000 0000  0000 0101
                    ;  7  =  0000 0000  0000 0000  0000 0111
     => 15          ; 15  =  0000 0000  0000 0000  0000 1111
```

Function: **logxor** *&rest ints-or-markers*

This function returns the "exclusive or" of its arguments: the nth bit is set in the result if, and only if, the nth bit is set in an odd number of the arguments. If there are no arguments, the result is 0. If `logxor` is passed just one argument, it returns that argument.

```
                    ;                  24-bit binary values

(logxor 12 5)       ; 12  =  0000 0000  0000 0000  0000 1100
                    ;  5  =  0000 0000  0000 0000  0000 0101
     => 9           ;  9  =  0000 0000  0000 0000  0000 1001

(logxor 12 5 7)     ; 12  =  0000 0000  0000 0000  0000 1100
                    ;  5  =  0000 0000  0000 0000  0000 0101
                    ;  7  =  0000 0000  0000 0000  0000 0111
     => 14          ; 14  =  0000 0000  0000 0000  0000 1110
```

Function: **lognot** *integer*

This function returns the logical complement of its argument: the nth bit is one in the result if, and only if, the nth bit is zero in integer, and vice-versa.

```
;;  5  =  0000 0000  0000 0000  0000 0101
;; becomes
;; -6  =  1111 1111  1111 1111  1111 1010

(lognot 5)
     => -6
```

Transcendental Functions

These mathematical functions are available if floating point is supported. They allow integers as well as floating point numbers as arguments.

Function: **sin** *arg*

Function: **cos** *arg*

Function: **tan** *arg*

These are the ordinary trigonometric functions, with argument measured in radians.

Function: **asin** *arg*

The value of `(asin arg)` is a number between - pi / 2 and pi / 2 (inclusive) whose sine is arg; if, however, arg is out of range (outside [-1, 1]), then the result is a NaN.

Function: **acos** *arg*

The value of `(acos arg)` is a number between 0 and pi (inclusive) whose cosine is arg; if, however, arg is out of range (outside [-1, 1]), then the result is a NaN.

Function: **atan** *arg*

The value of `(atan arg)` is a number between - pi / 2 and pi / 2 (exclusive) whose tangent is arg.

Function: **exp** *arg*

This is the exponential function; it returns *e* to the power arg.

Function: **log** *arg &optional base*

This function returns the logarithm of arg, with base base. If you don't specify base, the base e is used. If arg is negative, the result is a NaN.

Function: **log10** *arg*

This function returns the logarithm of arg, with base 10. If arg is negative, the result is a NaN.

Function: **expt** *x y*

This function returns x raised to power y.

Function: **sqrt** *arg*

This returns the square root of arg.

Random Numbers

In a computer, a series of pseudo-random numbers is generated in a deterministic fashion. The numbers are not truly random, but they have certain properties that mimic a random series. For example, all possible values occur equally often in a pseudo-random series.

In Emacs, pseudo-random numbers are generated from a "seed" number. Starting from any given seed, the `random` function always generates the same sequence of numbers. Emacs always starts with the same seed value, so the sequence of values of `random` is actually the same in each Emacs run! For

example, in one operating system, the first call to `(random)` after you start Emacs always returns -1457731, and the second one always returns -7692030. This is helpful for debugging.

If you want truly unpredictable random numbers, execute `(random t)`. This chooses a new seed based on the current time of day and on Emacs' process ID number.

Function: **random** *&optional limit*

This function returns a pseudo-random integer. When called more than once, it returns a series of pseudo-random integers.

If limit is `nil`, then the value may in principle be any integer. If limit is a positive integer, the value is chosen to be nonnegative and less than limit (only in Emacs 19).

If limit is `t`, it means to choose a new seed based on the current time of day and on Emacs's process ID number.

On some machines, any integer representable in Lisp may be the result of `random`. On other machines, the result can never be larger than a certain maximum or less than a certain (negative) minimum.

Strings and Characters

A string in Emacs Lisp is an array that contains an ordered sequence of characters. Strings are used as names of symbols, buffers, and files, to send messages to users, to hold text being copied between buffers, and for many other purposes. Because strings are so important, many functions are provided expressly for manipulating them. Emacs Lisp programs use strings more often than individual characters.

See section Putting Keyboard Events in Strings, for special considerations when using strings of keyboard character events.

Introduction to Strings and Characters

Strings in Emacs Lisp are arrays that contain an ordered sequence of characters. Characters are represented in Emacs Lisp as integers; whether an integer was intended as a character or not is determined only by how it is used. Thus, strings really contain integers.

The length of a string (like any array) is fixed and independent of the string contents, and cannot be altered. Strings in Lisp are *not* terminated by a distinguished character code. (By contrast, strings in C are terminated by a character with ASCII code 0.) This means that any character, including the null character (ASCII code 0), is a valid element of a string.

Since strings are considered arrays, you can operate on them with the general array functions. (See section Sequences, Arrays, and Vectors.) For example, you can access or change individual characters in a string using the functions `aref` and `aset` (see section Functions that Operate on Arrays).

Each character in a string is stored in a single byte. Therefore, numbers not in the range 0 to 255 are truncated when stored into a string. This means that a string takes up much less memory than a vector of the same length.

Sometimes key sequences are represented as strings. When a string is a key sequence, string elements in the range 128 to 255 represent meta characters (which are extremely large integers) rather than keyboard events in the range 128 to 255.

Strings cannot hold characters that have the hyper, super or alt modifiers; they can hold ASCII control characters, but no others. They do not distinguish case in ASCII control characters. See section Character Type, for more information about representation of meta and other modifiers for keyboard input characters.

Like a buffer, a string can contain text properties for the characters in it, as well as the characters themselves. See section Text Properties.

See section Text, for information about functions that display strings or copy them into buffers. See section Character Type, and section String Type, for information about the syntax of characters and

strings.

The Predicates for Strings

For more information about general sequence and array predicates, see section Sequences, Arrays, and Vectors, and section Arrays.

Function: **stringp** *object*

This function returns `t` if object is a string, `nil` otherwise.

Function: **char-or-string-p** *object*

This function returns `t` if object is a string or a character (i.e., an integer), `nil` otherwise.

Creating Strings

The following functions create strings, either from scratch, or by putting strings together, or by taking them apart.

Function: **make-string** *count character*

This function returns a string made up of count repetitions of character. If count is negative, an error is signaled.

```
(make-string 5 ?x)
     => "xxxxx"
(make-string 0 ?x)
     => ""
```

Other functions to compare with this one include `char-to-string` (see section Conversion of Characters and Strings), `make-vector` (see section Vectors), and `make-list` (see section Building Cons Cells and Lists).

Function: **substring** *string start &optional end*

This function returns a new string which consists of those characters from string in the range from (and including) the character at the index start up to (but excluding) the character at the index end. The first character is at index zero.

```
(substring "abcdefg" 0 3)
     => "abc"
```

Here the index for `a' is 0, the index for `b' is 1, and the index for `c' is 2. Thus, three letters, `abc', are copied from the full string. The index 3 marks the character position up to which the substring is copied. The character whose index is 3 is actually the fourth character in the string.

A negative number counts from the end of the string, so that -1 signifies the index of the last character of the string. For example:

```
(substring "abcdefg" -3 -1)
     => "ef"
```

In this example, the index for `e' is -3, the index for `f' is -2, and the index for `g' is -1. Therefore, `e' and `f' are included, and `g' is excluded.

When `nil` is used as an index, it falls after the last character in the string. Thus:

```
(substring "abcdefg" -3 nil)
     => "efg"
```

Omitting the argument end is equivalent to specifying `nil`. It follows that `(substring string 0)` returns a copy of all of string.

```
(substring "abcdefg" 0)
     => "abcdefg"
```

But we recommend `copy-sequence` for this purpose (see section Sequences).

A `wrong-type-argument` error is signaled if either start or end are non-integers. An `args-out-of-range` error is signaled if start indicates a character following end, or if either integer is out of range for string.

Contrast this function with `buffer-substring` (see section Examining Buffer Contents), which returns a string containing a portion of the text in the current buffer. The beginning of a string is at index 0, but the beginning of a buffer is at index 1.

Function: **concat** *&rest sequences*

This function returns a new string consisting of the characters in the arguments passed to it. The arguments may be strings, lists of numbers, or vectors of numbers; they are not themselves changed. If no arguments are passed to `concat`, it returns an empty string.

```
(concat "abc" "-def")
     => "abc-def"
(concat "abc" (list 120 (+ 256 121)) [122])
     => "abcxyz"
(concat "The " "quick brown " "fox.")
     => "The quick brown fox."
(concat)
     => ""
```

The second example above shows how characters stored in strings are taken modulo 256. In other words, each character in the string is stored in one byte.

The `concat` function always constructs a new string that is not `eq` to any existing string.

When an argument is an integer (not a sequence of integers), it is converted to a string of digits making up the decimal printed representation of the integer. This special case exists for compatibility with Mocklisp, and we don't recommend you take advantage of it. If you want to convert an integer in this way, use `format` (see section Formatting Strings) or `int-to-string` (see section Conversion of Characters and Strings).

```
(concat 137)
     => "137"
(concat 54 321)
     => "54321"
```

For information about other concatenation functions, see the description of `mapconcat` in section Mapping Functions, `vconcat` in section Vectors, and `append` in section Building Cons Cells and Lists.

Comparison of Characters and Strings

Function: **char-equal** *character1 character2*

This function returns `t` if the arguments represent the same character, `nil` otherwise. This function ignores differences in case if `case-fold-search` is non-`nil`.

```
(char-equal ?x ?x)
     => t
(char-to-string (+ 256 ?x))
     => "x"
(char-equal ?x  (+ 256 ?x))
     => t
```

Function: **string=** *string1 string2*

This function returns `t` if the characters of the two strings match exactly; case is significant.

```
(string= "abc" "abc")
     => t
(string= "abc" "ABC")
     => nil
(string= "ab" "ABC")
     => nil
```

Function: **string-equal** *string1 string2*

`string-equal` is another name for `string=`.

Function: **string<** *string1 string2*

This function compares two strings a character at a time. First it scans both the strings at once to find the first pair of corresponding characters that do not match. If the lesser character of those two is the character from string1, then string1 is less, and this function returns `t`. If the lesser character is the one from string2, then string1 is greater, and this function returns `nil`. If the two strings match entirely, the value is `nil`.

Pairs of characters are compared by their ASCII codes. Keep in mind that lower case letters have higher numeric values in the ASCII character set than their upper case counterparts; numbers and many punctuation characters have a lower numeric value than upper case letters.

```
(string< "abc" "abd")
     => t
(string< "abd" "abc")
     => nil
(string< "123" "abc")
     => t
```

When the strings have different lengths, and they match up to the length of string1, then the result is `t`. If they match up to the length of string2, the result is `nil`. A string without any characters in it is the smallest possible string.

```
(string< "" "abc")
     => t
(string< "ab" "abc")
     => t
(string< "abc" "")
     => nil
(string< "abc" "ab")
     => nil
(string< "" "")
     => nil
```

Function: **string-lessp** *string1 string2*

`string-lessp` is another name for `string<`.

See `compare-buffer-substrings` in section Comparing Text, for a way to compare text in buffers.

Conversion of Characters and Strings

Characters and strings may be converted into each other and into integers. `format` and `prin1-to-string` (see section Output Functions) may also be used to convert Lisp objects into strings. `read-from-string` (see section Input Functions) may be used to "convert" a string

representation of a Lisp object into an object.

See section Documentation, for a description of functions which return a string representing the Emacs standard notation of the argument character (`single-key-description` and `text-char-description`). These functions are used primarily for printing help messages.

Function: **char-to-string** *character*

This function returns a new string with a length of one character. The value of character, modulo 256, is used to initialize the element of the string.

This function is similar to `make-string` with an integer argument of 1. (See section Creating Strings.) This conversion can also be done with `format` using the `%c' format specification. (See section Formatting Strings.)

```
(char-to-string ?x)
     => "x"
(char-to-string (+ 256 ?x))
     => "x"
(make-string 1 ?x)
     => "x"
```

Function: **string-to-char** *string*

This function returns the first character in string. If the string is empty, the function returns 0. The value is also 0 when the first character of string is the null character, ASCII code 0.

```
(string-to-char "ABC")
     => 65
(string-to-char "xyz")
     => 120
(string-to-char "")
     => 0
(string-to-char "\000")
     => 0
```

This function may be eliminated in the future if it does not seem useful enough to retain.

Function: **number-to-string** *number*

Function: **int-to-string** *number*

This function returns a string consisting of the printed representation of number, which may be an integer or a floating point number. The value starts with a sign if the argument is negative.

```
(int-to-string 256)
     => "256"
(int-to-string -23)
```

```
     => "-23"
(int-to-string -23.5)
     => "-23.5"
```

See also the function `format` in section Formatting Strings.

Function: **string-to-number** *string*

Function: **string-to-int** *string*

This function returns the integer value of the characters in string, read as a number in base ten. It skips spaces at the beginning of string, then reads as much of string as it can interpret as a number. (On some systems it ignores other whitespace at the beginning, not just spaces.) If the first character after the ignored whitespace is not a digit or a minus sign, this function returns 0.

```
(string-to-number "256")
     => 256
(string-to-number "25 is a perfect square.")
     => 25
(string-to-number "X256")
     => 0
(string-to-number "-4.5")
     => -4.5
```

Formatting Strings

Formatting means constructing a string by substitution of computed values at various places in a constant string. This string controls how the other values are printed as well as where they appear; it is called a format string.

Formatting is often useful for computing messages to be displayed. In fact, the functions `message` and `error` provide the same formatting feature described here; they differ from `format` only in how they use the result of formatting.

Function: **format** *string &rest objects*

This function returns a new string that is made by copying string and then replacing any format specification in the copy with encodings of the corresponding objects. The arguments objects are the computed values to be formatted.

A format specification is a sequence of characters beginning with a `%'. Thus, if there is a `%d' in string, the `format` function replaces it with the printed representation of one of the values to be formatted (one of the arguments objects). For example:

```
(format "The value of fill-column is %d." fill-column)
     => "The value of fill-column is 72."
```

If string contains more than one format specification, the format specifications are matched with successive values from objects. Thus, the first format specification in string is matched with the first value, the second format specification is matched with the second such value, and so on. Any extra format specifications (those for which there are no corresponding values) cause unpredictable behavior. Any extra values to be formatted will be ignored.

Certain format specifications require values of particular types. However, no error is signaled if the value actually supplied fails to have the expected type. Instead, the output is likely to be meaningless.

Here is a table of the characters that can follow `%' to make up a format specification:

`s'

Replace the specification with the printed representation of the object, made without quoting. Thus, strings are represented by their contents alone, with no `"' characters, and symbols appear without `\' characters.

If there is no corresponding object, the empty string is used.

`S'

Replace the specification with the printed representation of the object, made with quoting. Thus, strings are enclosed in `"' characters, and `\' characters appear where necessary before special characters.

If there is no corresponding object, the empty string is used.

`o'

Replace the specification with the base-eight representation of an integer.

`d'

Replace the specification with the base-ten representation of an integer.

`x'

Replace the specification with the base-sixteen representation of an integer.

`c'

Replace the specification with the character which is the value given.

`e'

Replace the specification with the exponential notation for a floating point number.

`f'

Replace the specification with the decimal-point notation for a floating point number.

`g'

Replace the specification with notation for a floating point number, using either exponential notation or decimal-point notation whichever is shorter.

`%'

A single `%' is placed in the string. This format specification is unusual in that it does not use a value. For example, `(format "%% %d" 30)` returns `"% 30"`.

Any other format character results in an `Invalid format operation' error.

Here are several examples:

```
(format "The name of this buffer is %s." (buffer-name))
     => "The name of this buffer is strings.texi."

(format "The buffer object prints as %s." (current-buffer))
     => "The buffer object prints as #<buffer strings.texi>."

(format "The octal value of 18 is %o,
         and the hex value is %x." 18 18)
     => "The octal value of 18 is 22,
         and the hex value is 12."
```

All the specification characters allow an optional numeric prefix between the `%' and the character. The optional numeric prefix defines the minimum width for the object. If the printed representation of the object contains fewer characters than this, then it is padded. The padding is on the left if the prefix is positive (or starts with zero) and on the right if the prefix is negative. The padding character is normally a space, but if the numeric prefix starts with a zero, zeros are used for padding.

```
(format "%06d will be padded on the left with zeros" 123)
     => "000123 will be padded on the left with zeros"

(format "%-6d will be padded on the right" 123)
     => "123    will be padded on the right"
```

`format` never truncates an object's printed representation, no matter what width you specify. Thus, you can use a numeric prefix to specify a minimum spacing between columns with no risk of losing information.

In the following three examples, `%7s' specifies a minimum width of 7. In the first case, the string inserted in place of `%7s' has only 3 letters, so 4 blank spaces are inserted for padding. In the second case, the string `"specification"` is 13 letters wide but is not truncated. In the third case, the padding is on the right.

```
(format "The word `%7s' actually has %d letters in it." "foo"
        (length "foo"))
     => "The word `    foo' actually has 3 letters in it."

(format "The word `%7s' actually has %d letters in it."
        "specification"
        (length "specification"))
     => "The word `specification' actually has 13 letters in it."

(format "The word `%-7s' actually has %d letters in it." "foo"
        (length "foo"))
     => "The word `foo    ' actually has 3 letters in it."
```

Character Case

The character case functions change the case of single characters or of the contents of strings. The functions convert only alphabetic characters (the letters `A' through `Z' and `a' through `z'); other characters are not altered. The functions do not modify the strings that are passed to them as arguments.

The examples below use the characters `X' and `x' which have ASCII codes 88 and 120 respectively.

Function: **downcase** *string-or-char*

This function converts a character or a string to lower case.

When the argument to `downcase` is a string, the function creates and returns a new string in which each letter in the argument that is upper case is converted to lower case. When the argument to `downcase` is a character, `downcase` returns the corresponding lower case character. This value is an integer. If the original character is lower case, or is not a letter, then the value equals the original character.

```
(downcase "The cat in the hat")
     => "the cat in the hat"

(downcase ?X)
     => 120
```

Function: **upcase** *string-or-char*

This function converts a character or a string to upper case.

When the argument to `upcase` is a string, the function creates and returns a new string in which each letter in the argument that is lower case is converted to upper case.

When the argument to `upcase` is a character, `upcase` returns the corresponding upper case character. This value is an integer. If the original character is upper case, or is not a letter, then the value equals the original character.

```
(upcase "The cat in the hat")
     => "THE CAT IN THE HAT"

(upcase ?x)
     => 88
```

Function: **capitalize** *string-or-char*

This function capitalizes strings or characters. If string-or-char is a string, the function creates and returns a new string, whose contents are a copy of string-or-char in which each word has been capitalized. This means that the first character of each word is converted to upper case, and the rest are converted to lower case.

The definition of a word is any sequence of consecutive characters that are assigned to the word

TOC

constituent category in the current syntax table (See section Table of Syntax Classes).

When the argument to `capitalize` is a character, `capitalize` has the same result as `upcase`.

```
(capitalize "The cat in the hat")
     => "The Cat In The Hat"

(capitalize "THE 77TH-HATTED CAT")
     => "The 77th-Hatted Cat"

(capitalize ?x)
     => 88
```

The Case Table

You can customize case conversion by installing a special case table. A case table specifies the mapping between upper case and lower case letters. It affects both the string and character case conversion functions (see the previous section) and those that apply to text in the buffer (see section Case Changes). Use case table if you are using a language which has letters that are not the standard ASCII letters.

A case table is a list of this form:

```
(downcase upcase canonicalize equivalences)
```

where each element is either `nil` or a string of length 256. The element downcase says how to map each character to its lower-case equivalent. The element upcase maps each character to its upper-case equivalent. If lower and upper case characters are in one-to-one correspondence, use `nil` for upcase; then Emacs deduces the upcase table from downcase.

For some languages, upper and lower case letters are not in one-to-one correspondence. There may be two different lower case letters with the same upper case equivalent. In these cases, you need to specify the maps for both directions.

The element canonicalize maps each character to a canonical equivalent; any two characters that are related by case-conversion have the same canonical equivalent character.

The element equivalences is a map that cyclicly permutes each equivalence class (of characters with the same canonical equivalent). (For ordinary ASCII, this would map `a' into `A' and `A' into `a', and likewise for each set of equivalent characters.)

You can provide `nil` for both canonicalize and equivalences, in which case both are deduced from downcase and upcase. Normally, that's what you should do, when you construct a case table. But when you look at the case table that's in use, you will find non-`nil` values for those components.

Each buffer has a case table. Emacs also has a standard case table which is copied into each buffer when you create the buffer. (Changing the standard case table doesn't affect any existing buffers.)

Here are the functions for working with case tables:

Function: **case-table-p** *object*

This predicate returns non-`nil` if object is a valid case table.

Function: **set-standard-case-table** *table*

This function makes table the standard case table, so that it will apply to any buffers created subsequently.

Function: **standard-case-table**

This returns the standard case table.

Function: **current-case-table**

This function returns the current buffer's case table.

Function: **set-case-table** *table*

This sets the current buffer's case table to table.

The following three functions are convenient subroutines for packages that define non-ASCII character sets. They modify a string downcase-table provided as an argument; this should be a string to be used as the downcase part of a case table. They also modify two syntax tables, the standard syntax table and the Text mode syntax table. (See section Syntax Tables.)

Function: **set-case-syntax-pair** *uc lc downcase-table*

This function specifies a pair of corresponding letters, one upper case and one lower case.

Function: **set-case-syntax-delims** *l r downcase-table*

This function makes characters l and r a matching pair of case-invariant delimiters.

Function: **set-case-syntax** *char syntax downcase-table*

This function makes char case-invariant, with syntax syntax.

Command: **describe-buffer-case-table**

This command displays a description of the contents of the current buffer's case table.

You can load the library `` `iso-syntax' `` to set up the syntax and case table for the 256 bit ISO Latin 1 character set.

Go to the previous, next section.

Go to the previous, next section.

Lists

A list represents a sequence of zero or more elements (which may be any Lisp objects). The important difference between lists and vectors is that two or more lists can share part of their structure; in addition, you can insert or delete elements in a list without copying the whole list.

Lists and Cons Cells

Lists in Lisp are not a primitive data type; they are built up from cons cells. A cons cell is a data object which represents an ordered pair. It records two Lisp objects, one labeled as the CAR, and the other labeled as the CDR. (These names are traditional.)

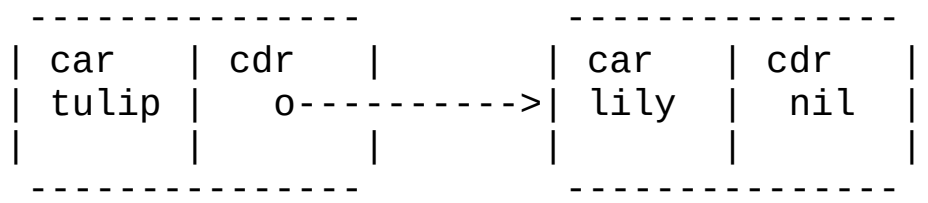
A list is made by chaining cons cells together, one cons cell per element. By convention, the CARs of the cons cells are the elements of the list, and the CDRs are used to chain the list: the CDR of each cons cell is the following cons cell. The CDR of the last cons cell is `nil`. This asymmetry between the CAR and the CDR is entirely a matter of convention; at the level of cons cells, the CAR and CDR slots have the same characteristics.

The symbol `nil` is considered a list as well as a symbol; it is the list with no elements. For convenience, the symbol `nil` is considered to have `nil` as its CDR (and also as its CAR).

The CDR of any nonempty list l is a list containing all the elements of l except the first.

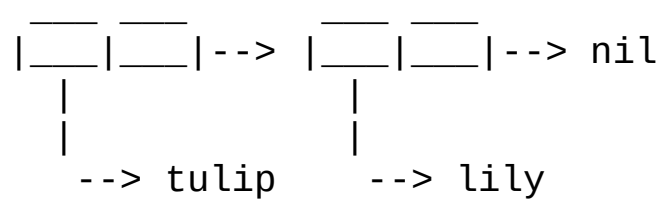
Lists as Linked Pairs of Boxes

A cons cell can be illustrated as a pair of boxes. The first box represents the CAR and the second box represents the CDR. Here is an illustration of the two-element list, `(tulip lily)`, made from two cons cells:

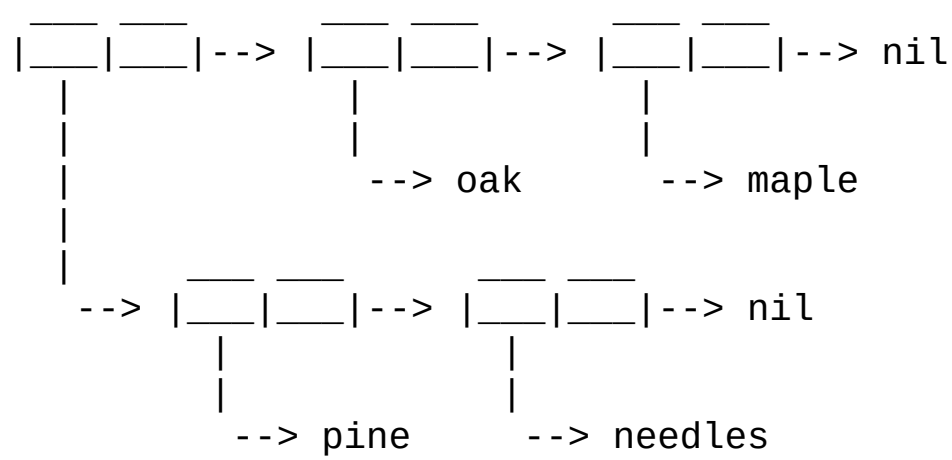


Each pair of boxes represents a cons cell. Each box "refers to", "points to" or "contains" a Lisp object. (These terms are synonymous.) The first box, which is the CAR of the first cons cell, contains the symbol `tulip`. The arrow from the CDR of the first cons cell to the second cons cell indicates that the CDR of the first cons cell points to the second cons cell.

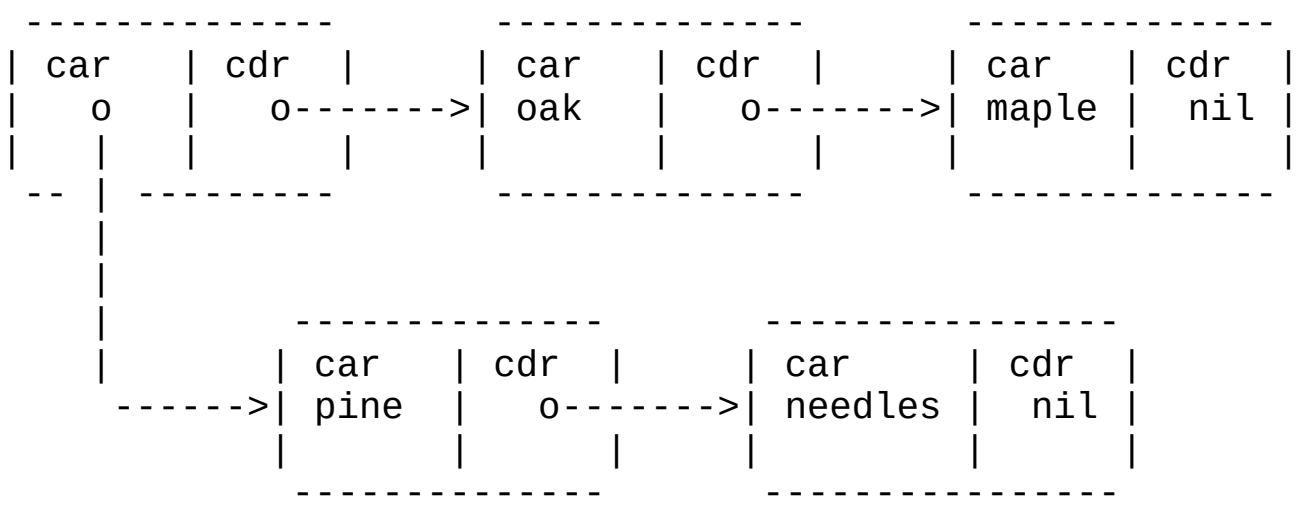
The same list can be illustrated in a different sort of box notation like this:



Here is a more complex illustration, this time of the three-element list, `((pine needles) oak maple)`, the first element of which is a two-element list:



The same list is represented in the first box notation like this:



See section List Type, for the read and print syntax of lists, and for more "box and arrow" illustrations of lists.

Predicates on Lists

The following predicates test whether a Lisp object is an atom, is a cons cell or is a list, or whether it is the distinguished object `nil`. (Many of these tests can be defined in terms of the others, but they are used so often that it is worth having all of them.)

Function: **consp** *object*

This function returns `t` if object is a cons cell, `nil` otherwise. `nil` is not a cons cell, although it *is* a

Function: **atom** *object*

This function returns `t` if object is an atom, `nil` otherwise. All objects except cons cells are atoms. The symbol `nil` is an atom and is also a list; it is the only Lisp object which both.

```
(atom object) == (not (consp object))
```

Function: **listp** *object*

This function returns `t` if object is a cons cell or `nil`. Otherwise, it returns `nil`.

```
(listp '(1))
     => t
(listp '())
     => t
```

Function: **nlistp** *object*

This function is the opposite of `listp`: it returns `t` if object is not a list. Otherwise, it returns `nil`.

```
(listp object) == (not (nlistp object))
```

Function: **null** *object*

This function returns `t` if object is `nil`, and returns `nil` otherwise. This function is identical to `not`, but as a matter of clarity we use `null` when object is considered a list and `not` when it is considered a truth value (see `not` in section Constructs for Combining Conditions).

```
(null '(1))
     => nil
(null '())
     => t
```

Accessing Elements of Lists

Function: **car** *cons-cell*

This function returns the value pointed to by the first pointer of the cons cell cons-cell. Expressed another way, this function returns the CAR of cons-cell.

As a special case, if cons-cell is `nil`, then `car` is defined to return `nil`; therefore, any list is a valid argument for `car`. An error is signaled if the argument is not a cons cell or `nil`.

```
(car '(a b c))
```

```
     => a
(car '())
     => nil
```

Function: **cdr** *cons-cell*

This function returns the value pointed to by the second pointer of the cons cell cons-cell. Expressed another way, this function returns the CDR of cons-cell.

As a special case, if cons-cell is `nil`, then `cdr` is defined to return `nil`; therefore, any list is a valid argument for `cdr`. An error is signaled if the argument is not a cons cell or `nil`.

```
(cdr '(a b c))
     => (b c)
(cdr '())
     => nil
```

Function: **car-safe** *object*

This function lets you take the CAR of a cons cell while avoiding errors for other data types. It returns the CAR of object if object is a cons cell, `nil` otherwise. This is in contrast to `car`, which signals an error if object is not a list.

```
(car-safe object)
==
(let ((x object))
  (if (consp x)
      (car x)
    nil))
```

Function: **cdr-safe** *object*

This function lets you take the CDR of a cons cell while avoiding errors for other data types. It returns the CDR of object if object is a cons cell, `nil` otherwise. This is in contrast to `cdr`, which signals an error if object is not a list.

```
(cdr-safe object)
==
(let ((x object))
  (if (consp x)
      (cdr x)
    nil))
```

Function: **nth** *n list*

This function returns the nth element of list. Elements are numbered starting with zero, so the CAR of list is element number zero. If the length of list is n or less, the value is `nil`.

If n is less than zero, then the first element is returned.

```
(nth 2 '(1 2 3 4))
     => 3
(nth 10 '(1 2 3 4))
     => nil
(nth -3 '(1 2 3 4))
     => 1

(nth n x) == (car (nthcdr n x))
```

Function: **nthcdr** *n list*

This function returns the nth cdr of list. In other words, it removes the first n links of list and returns what follows.

If n is less than or equal to zero, then all of list is returned. If the length of list is n or less, the value is `nil`.

```
(nthcdr 1 '(1 2 3 4))
     => (2 3 4)
(nthcdr 10 '(1 2 3 4))
     => nil
(nthcdr -3 '(1 2 3 4))
     => (1 2 3 4)
```

Building Cons Cells and Lists

Many functions build lists, as lists reside at the very heart of Lisp. `cons` is the fundamental list-building function; however, it is interesting to note that `list` is used more times in the source code for Emacs than `cons`.

Function: **cons** *object1 object2*

This function is the fundamental function used to build new list structure. It creates a new cons cell, making object1 the CAR, and object2 the CDR. It then returns the new cons cell. The arguments object1 and object2 may be any Lisp objects, but most often object2 is a list.

```
(cons 1 '(2))
     => (1 2)
(cons 1 '())
     => (1)
(cons 1 2)
     => (1 . 2)
```

`cons` is often used to add a single element to the front of a list. This is called consing the element onto

the list. For example:

```
(setq list (cons newelt list))
```

Note that there is no conflict between the variable named `list` used in this example and the function named `list` described below; any symbol can serve both functions.

Function: **list** *&rest objects*

This function creates a list with objects as its elements. The resulting list is always `nil`-terminated. If no objects are given, the empty list is returned.

```
(list 1 2 3 4 5)
     => (1 2 3 4 5)
(list 1 2 '(3 4 5) 'foo)
     => (1 2 (3 4 5) foo)
(list)
     => nil
```

Function: **make-list** *length object*

This function creates a list of length length, in which all the elements have the identical value object. Compare `make-list` with `make-string` (see section Creating Strings).

```
(make-list 3 'pigs)
     => (pigs pigs pigs)
(make-list 0 'pigs)
     => nil
```

Function: **append** *&rest sequences*

This function returns a list containing all the elements of sequences. The sequences may be lists, vectors, strings, or integers. All arguments except the last one are copied, so none of them are altered.

The final argument to `append` may be any object but it is typically a list. The final argument is not copied or converted; it becomes part of the structure of the new list.

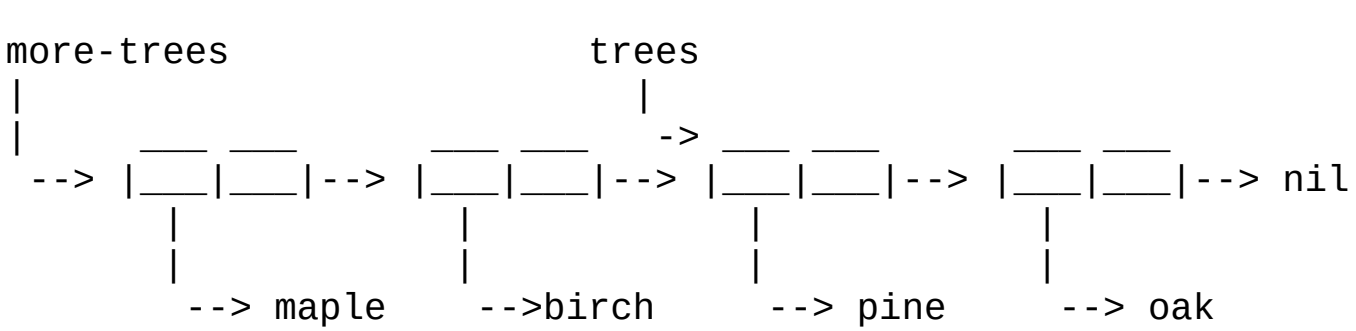
Here is an example:

```
(setq trees '(pine oak))
     => (pine oak)
(setq more-trees (append '(maple birch) trees))
     => (maple birch pine oak)

trees
     => (pine oak)
more-trees
     => (maple birch pine oak)
```

```
(eq trees (cdr (cdr more-trees)))
     => t
```

You can see what happens by looking at a box diagram. The variable `trees` is set to the list `(pine oak)` and then the variable `more-trees` is set to the list `(maple birch pine oak)`. However, the variable `trees` continues to refer to the original list:



An empty sequence contributes nothing to the value returned by `append`. As a consequence of this, a final `nil` argument forces a copy of the previous argument.

```
trees
     => (pine oak)
(setq wood (append trees ()))
     => (pine oak)
wood
     => (pine oak)
(eq wood trees)
     => nil
```

This once was the standard way to copy a list, before the function `copy-sequence` was invented. See section Sequences, Arrays, and Vectors.

With the help of `apply`, we can append all the lists in a list of lists:

```
(apply 'append '((a b c) nil (x y z) nil))
     => (a b c x y z)
```

If no sequences are given, `nil` is returned:

```
(append)
     => nil
```

In the special case where one of the sequences is an integer (not a sequence of integers), it is first converted to a string of digits making up the decimal print representation of the integer. This special case exists for compatibility with Mocklisp, and we don't recommend you take advantage of it. If you want to convert an integer in this way, use `format` (see section Formatting Strings) or `number-to-string` (see section Conversion of Characters and Strings).

```
(setq trees '(pine oak))
     => (pine oak)
(char-to-string 54)
     => "6"
(setq longer-list (append trees 6 '(spruce)))
     => (pine oak 54 spruce)
(setq x-list (append trees 6 6))
     => (pine oak 54 . 6)
```

See `nconc` in section Functions that Rearrange Lists, for another way to join lists without copying.

Function: **reverse** *list*

This function creates a new list whose elements are the elements of list, but in reverse order. The original argument list is *not* altered.

```
(setq x '(1 2 3 4))
     => (1 2 3 4)
(reverse x)
     => (4 3 2 1)
x
     => (1 2 3 4)
```

Modifying Existing List Structure

You can modify the CAR and CDR contents of a cons cell with the primitives `setcar` and `setcdr`.

> **Common Lisp note:** Common Lisp uses functions `rplaca` and `rplacd` to alter list structure; they change structure the same way as `setcar` and `setcdr`, but the Common Lisp functions return the cons cell while `setcar` and `setcdr` return the new CAR or CDR.

Altering List Elements with `setcar`

Changing the CAR of a cons cell is done with `setcar` and replaces one element of a list with a different element.

Function: **setcar** *cons object*

This function stores object as the new CAR of cons, replacing its previous CAR. It returns the value object. For example:

```
(setq x '(1 2))
     => (1 2)
(setcar x '4)
     => 4
x
```

```
     => (4 2)
```

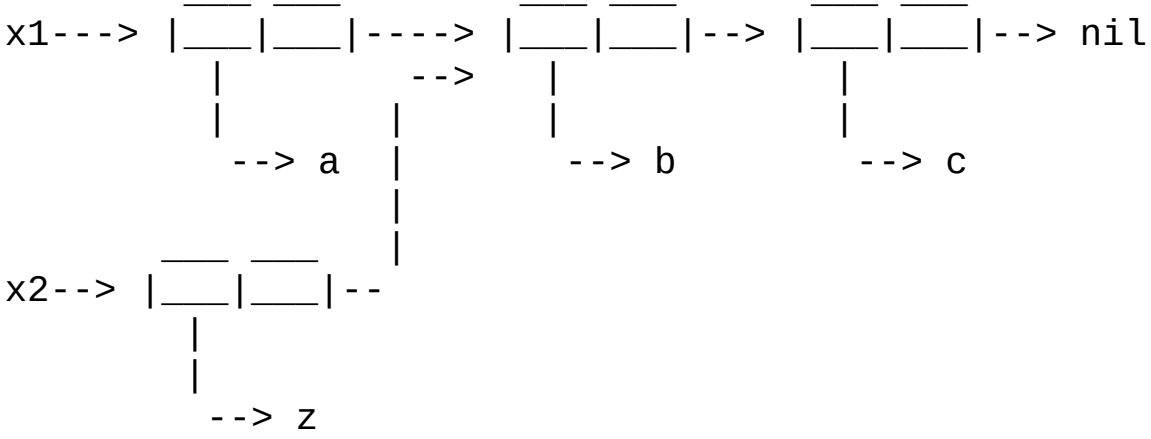
When a cons cell is part of the shared structure of several lists, storing a new CAR into the cons changes one element of each of these lists. Here is an example:

```
;; Create two lists that are partly shared.
(setq x1 '(a b c))
     => (a b c)
(setq x2 (cons 'z (cdr x1)))
     => (z b c)

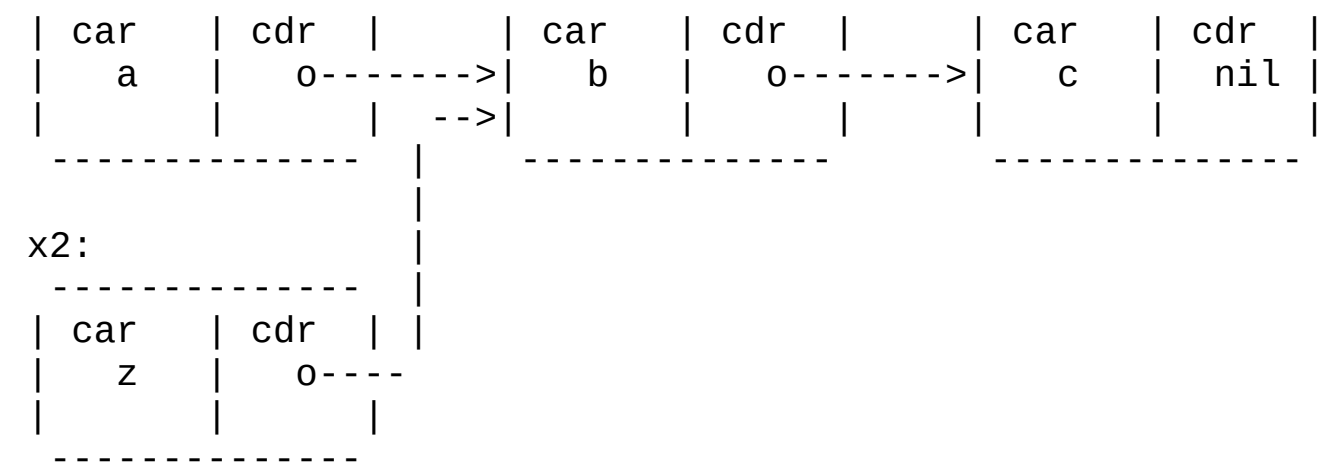
;; Replace the CAR of a shared link.
(setcar (cdr x1) 'foo)
     => foo
x1                              ; Both lists are changed.
     => (a foo c)
x2
     => (z foo c)

;; Replace the CAR of a link that is not shared.
(setcar x1 'baz)
     => baz
x1                              ; Only one list is changed.
     => (baz foo c)
x2
     => (z foo c)
```

Here is a graphical depiction of the shared structure of the two lists x1 and x2, showing why replacing `b` changes them both:



Here is an alternative form of box diagram, showing the same relationship:



Altering the CDR of a List

The lowest-level primitive for modifying a CDR is `setcdr`:

Function: **setcdr** *cons object*

This function stores object into the cdr of cons. The value returned is object, not cons.

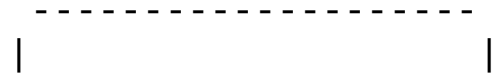
Here is an example of replacing the CDR of a list with a different list. All but the first element of the list are removed in favor of a different sequence of elements. The first element is unchanged, because it resides in the CAR of the list, and is not reached via the CDR.

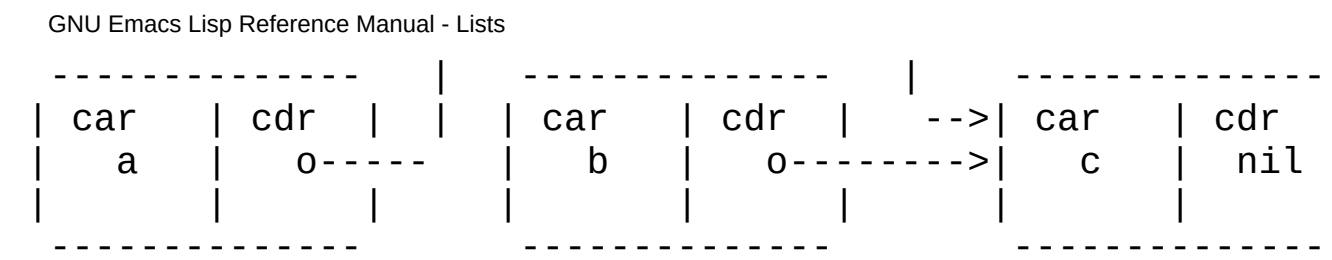
```
(setq x '(1 2 3))
     => (1 2 3)
(setcdr x '(4))
     => (4)
x
     => (1 4)
```

You can delete elements from the middle of a list by altering the CDRs of the cons cells in the list. For example, here we delete the second element, `b`, from the list `(a b c)`, by changing the CDR of the first cell:

```
(setq x1 '(a b c))
     => (a b c)
(setcdr x1 (cdr (cdr x1)))
     => (c)
x1
     => (a c)
```

Here is the result in box notation:



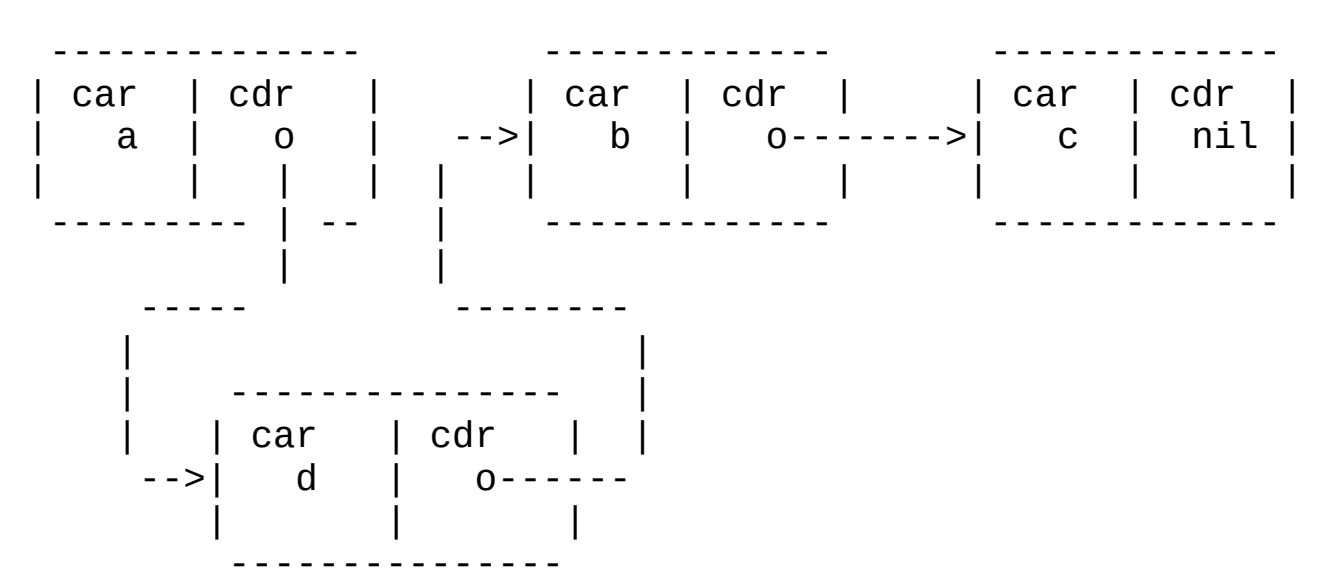


The second cons cell, which previously held the element `b`, still exists and its CAR is still `b`, but it no longer forms part of this list.

It is equally easy to insert a new element by changing CDRs:

```
(setq x1 '(a b c))
     => (a b c)
(setcdr x1 (cons 'd (cdr x1)))
     => (d b c)
x1
     => (a d b c)
```

Here is this result in box notation:



Functions that Rearrange Lists

Here are some functions that rearrange lists "destructively" by modifying the CDRs of their component cons cells. We call these functions "destructive" because the original lists passed as arguments to them are chewed up to produce a new list that is subsequently returned.

Function: **nconc** *&rest lists*

This function returns a list containing all the elements of lists. Unlike `append` (see section Building Cons Cells and Lists), the lists are *not* copied. Instead, the last CDR of each of the lists is changed to refer to the following list. The last of the lists is not altered. For example:

```
(setq x '(1 2 3))
     => (1 2 3)
(nconc x '(4 5))
     => (1 2 3 4 5)
x
     => (1 2 3 4 5)
```

Since the last argument of `nconc` is not itself modified, it is reasonable to use a constant list, such as `'(4 5)`, as is done in the above example. For the same reason, the last argument need not be a list:

```
(setq x '(1 2 3))
     => (1 2 3)
(nconc x 'z)
     => (1 2 3 . z)
x
     => (1 2 3 . z)
```

A common pitfall is to use a quoted constant list as a non-last argument to `nconc`. If you do this, your program will change each time you run it! Here is what happens:

```
(defun add-foo (x)              ; This function should add
  (nconc '(foo) x))             ;   foo to the front of its arg.

(symbol-function 'add-foo)
     => (lambda (x) (nconc (quote (foo)) x))

(setq xx (add-foo '(1 2)))    ; It seems to work.
     => (foo 1 2)
(setq xy (add-foo '(3 4)))    ; What happened?
     => (foo 1 2 3 4)
(eq xx xy)
     => t

(symbol-function 'add-foo)
     => (lambda (x) (nconc (quote (foo 1 2 3 4) x)))
```

Function: **nreverse** *list*

This function reverses the order of the elements of list. Unlike `reverse`, `nreverse` alters its argument destructively by reversing the CDRs in the cons cells forming the list. The cons cell which used to be the last one in list becomes the first cell of the value.

For example:

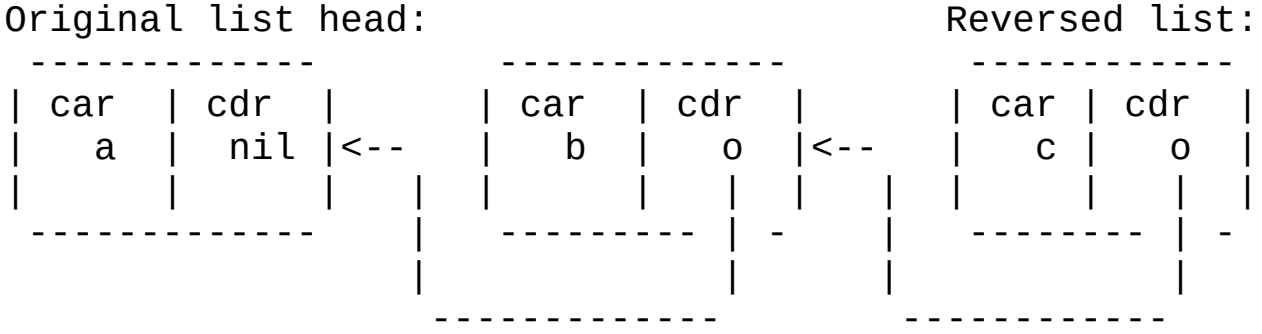
```
(setq x '(1 2 3 4))
     => (1 2 3 4)
x
```

```
     => (1 2 3 4)
(nreverse x)
     => (4 3 2 1)
;; The cell that was first is now last.
x
     => (1)
```

To avoid confusion, we usually store the result of `nreverse` back in the same variable which held the original list:

```
(setq x (nreverse x))
```

Here is the `nreverse` of our favorite example, `(a b c)`, presented graphically:



Function: **sort** *list predicate*

This function sorts list stably, though destructively, and returns the sorted list. It compares elements using predicate. A stable sort is one in which elements with equal sort keys maintain their relative order before and after the sort. Stability is important when successive sorts are used to order elements according to different criteria.

The argument predicate must be a function that accepts two arguments. It is called with two elements of list. To get an increasing order sort, the predicate should return `t` if the first element is "less than" the second, or `nil` if not.

The destructive aspect of `sort` is that it rearranges the cons cells forming list by changing CDRs. A nondestructive sort function would create new cons cells to store the elements in their sorted order. If you wish to sort a list without destroying the original, copy it first with `copy-sequence`.

The CARs of the cons cells are not changed; the cons cell that originally contained the element `a` in list still has `a` in its CAR after sorting, but it now appears in a different position in the list due to the change of CDRs. For example:

```
(setq nums '(1 3 2 6 5 4 0))
     => (1 3 2 6 5 4 0)
(sort nums '<)
     => (0 1 2 3 4 5 6)
nums
```

```
     => (1 2 3 4 5 6)
```

Note that the list in `nums` no longer contains 0; this is the same cons cell that it was before, but it is no longer the first one in the list. Don't assume a variable that formerly held the argument now holds the entire sorted list! Instead, save the result of `sort` and use that. Most often we store the result back into the variable that held the original list:

```
(setq nums (sort nums '<))
```

See section Sorting Text, for more functions that perform sorting. See `documentation` in section Access to Documentation Strings, for a useful example of `sort`.

The function `delq` in the following section is another example of destructive list manipulation.

Using Lists as Sets

A list can represent an unordered mathematical set--simply consider a value an element of a set if it appears in the list, and ignore the order of the list. To form the union of two sets, use `append` (as long as you don't mind having duplicate elements). Other useful functions for sets include `memq` and `delq`, and their `equal` versions, `member` and `delete`.

> **Common Lisp note:** Common Lisp has functions `union` (which avoids duplicate elements) and `intersection` for set operations, but GNU Emacs Lisp does not have them. You can write them in Lisp if you wish.

Function: **memq** *object list*

This function tests to see whether object is a member of list. If it is, `memq` returns a list starting with the first occurrence of object. Otherwise, it returns `nil`. The letter `q' in `memq` says that it uses `eq` to compare object against the elements of the list. For example:

```
(memq 2 '(1 2 3 2 1))
     => (2 3 2 1)
(memq '(2) '((1) (2)))    ; (2) and (2) are not eq.
     => nil
```

Function: **delq** *object list*

This function removes all elements `eq` to object from list. The letter `q' in `delq` says that it uses `eq` to compare object against the elements of the list, like `memq`.

When `delq` deletes elements from the front of the list, it does so simply by advancing down the list and returning a sublist that starts after those elements:

```
(delq 'a '(a b c))
==
(cdr '(a b c))
```

When an element to be deleted appears in the middle of the list, removing it involves changing the C
(see section Altering the CDR of a List).

```
(setq sample-list '(1 2 3 (4)))
     => (1 2 3 (4))
(delq 1 sample-list)
     => (2 3 (4))
sample-list
     => (1 2 3 (4))
(delq 2 sample-list)
     => (1 3 (4))
sample-list
     => (1 3 (4))
```

Note that `(delq 2 sample-list)` modifies `sample-list` to splice out the second element, but `(delq 1 sample-list)` does not splice anything--it just returns a shorter list. Don't assume that a variable which formerly held the argument list now has fewer elements, or that it still holds the original list! Instead, save the result of `delq` and use that. Most often we store the result back into the variable that held the original list:

```
(setq flowers (delq 'rose flowers))
```

In the following example, the `(4)` that `delq` attempts to match and the `(4)` in the `sample-list` are not `eq`:

```
(delq '(4) sample-list)
     => (1 3 (4))
```

The following two functions are like `memq` and `delq` but use `equal` rather than `eq` to compare elements. They are new in Emacs 19.

Function: **member** *object list*

The function `member` tests to see whether object is a member of list, comparing members with object using `equal`. If object is a member, `memq` returns a list starting with its first occurrence in list. Otherwise, it returns `nil`.

Compare this with `memq`:

```
(member '(2) '((1) (2)))  ; (2) and (2) are equal.
     => ((2))
(memq '(2) '((1) (2)))    ; (2) and (2) are not eq.
     => nil
;; Two strings with the same contents are equal.
(member "foo" '("foo" "bar"))
     => ("foo" "bar")
```

Function: **delete** *object list*

This function removes all elements `equal` to object from list. It is to `delq` as `member` is to `memq`: it uses `equal` to compare elements with object, like `member`; when it finds an element that matches, it removes the element just as `delq` would. For example:

```
(delete '(2) '((2) (1) (2)))
     => '((1))
```

Common Lisp note: The functions `member` and `delete` in GNU Emacs Lisp are derived from Maclisp, not Common Lisp. The Common Lisp versions do not use `equal` to compare elements.

Association Lists

An association list, or alist for short, records a mapping from keys to values. It is a list of cons cells called associations: the CAR of each cell is the key, and the CDR is the associated value. (This usage of "key" is not related to the term "key sequence"; it means any object which can be looked up in a table.)

Here is an example of an alist. The key `pine` is associated with the value `cones`; the key `oak` is associated with `acorns`; and the key `maple` is associated with `seeds`.

```
'((pine . cones)
  (oak . acorns)
  (maple . seeds))
```

The associated values in an alist may be any Lisp objects; so may the keys. For example, in the following alist, the symbol `a` is associated with the number `1`, and the string `"b"` is associated with the *list* `(2 3)`, which is the CDR of the alist element:

```
((a . 1) ("b" 2 3))
```

Sometimes it is better to design an alist to store the associated value in the CAR of the CDR of the element. Here is an example:

```
'((rose red) (lily white) (buttercup yellow))
```

Here we regard `red` as the value associated with `rose`. One advantage of this method is that you can store other related information--even a list of other items--in the CDR of the CDR. One disadvantage is that you cannot use `rassq` (see below) to find the element containing a given value. When neither of these considerations is important, the choice is a matter of taste, as long as you are consistent about it for any given alist.

Note that the same alist shown above could be regarded as having the associated value in the CDR of the element; the value associated with `rose` would be the list `(red)`.

Association lists are often used to record information that you might otherwise keep on a stack, since

new associations may be added easily to the front of the list. When searching an association list for an association with a given key, the first one found is returned, if there is more than one.

In Emacs Lisp, it is *not* an error if an element of an association list is not a cons cell. The alist search functions simply ignore such elements. Many other versions of Lisp signal errors in such cases.

Note that property lists are similar to association lists in several respects. A property list behaves like an association list in which each key can occur only once. See section Property Lists, for a comparison of property lists and association lists.

Function: **assoc** *key alist*

This function returns the first association for key in alist. It compares key against the alist elements using `equal` (see section Equality Predicates). It returns `nil` if no association in alist has a CAR `equal` to key. For example:

```
(setq trees '((pine . cones) (oak . acorns) (maple . seeds)))
     => ((pine . cones) (oak . acorns) (maple . seeds))
(assoc 'oak trees)
     => (oak . acorns)
(cdr (assoc 'oak trees))
     => acorns
(assoc 'birch trees)
     => nil
```

Here is another example in which the keys and values are not symbols:

```
(setq needles-per-cluster
      '((2 . ("Austrian Pine" "Red Pine"))
        (3 . "Pitch Pine")
        (5 . "White Pine")))

(cdr (assoc 3 needles-per-cluster))
     => "Pitch Pine"
(cdr (assoc 2 needles-per-cluster))
     => ("Austrian Pine" "Red Pine")
```

Function: **assq** *key alist*

This function is like `assoc` in that it returns the first association for key in alist, but it makes the comparison using `eq` instead of `equal`. `assq` returns `nil` if no association in alist has a CAR `eq` to key. This function is used more often than `assoc`, since `eq` is faster than `equal` and most alists use symbols as keys. See section Equality Predicates.

```
(setq trees '((pine . cones) (oak . acorns) (maple . seeds)))

(assq 'pine trees)
```

```
     => (pine . cones)
```

On the other hand, `assq` is not usually useful in alists where the keys may not be symbols:

```
(setq leaves
      '(("simple leaves" . oak)
        ("compound leaves" . horsechestnut)))

(assq "simple leaves" leaves)
     => nil
(assoc "simple leaves" leaves)
     => ("simple leaves" . oak)
```

Function: **rassq** *alist value*

This function returns the first association with value value in alist. It returns `nil` if no association in alist has a CDR `eq` to value.

`rassq` is like `assq` except that the CDR of the alist associations is tested instead of the CAR. You can think of this as "reverse `assq`", finding the key for a given value.

For example:

```
(setq trees '((pine . cones) (oak . acorns) (maple . seeds)))

(rassq 'acorns trees)
     => (oak . acorns)
(rassq 'spores trees)
     => nil
```

Note that `rassq` cannot be used to search for a value stored in the CAR of the CDR of an element:

```
(setq colors '((rose red) (lily white) (buttercup yellow)))

(rassq 'white colors)
     => nil
```

In this case, the CDR of the association `(lily white)` is not the symbol `white`, but rather the list `(white)`. This can be seen more clearly if the association is written in dotted pair notation:

```
(lily white) == (lily . (white))
```

Function: **copy-alist** *alist*

This function returns a two-level deep copy of alist: it creates a new copy of each association, so that you can alter the associations of the new alist without changing the old one.

```
(setq needles-per-cluster
```

```
      '((2 . ("Austrian Pine" "Red Pine"))
        (3 . "Pitch Pine")
        (5 . "White Pine")))
=>
((2 "Austrian Pine" "Red Pine")
 (3 . "Pitch Pine")
 (5 . "White Pine"))

(setq copy (copy-alist needles-per-cluster))
=>
((2 "Austrian Pine" "Red Pine")
 (3 . "Pitch Pine")
 (5 . "White Pine"))

(eq needles-per-cluster copy)
     => nil
(equal needles-per-cluster copy)
     => t
(eq (car needles-per-cluster) (car copy))
     => nil
(cdr (car (cdr needles-per-cluster)))
     => "Pitch Pine"
(eq (cdr (car (cdr needles-per-cluster)))
    (cdr (car (cdr copy))))
     => t
```

Go to the previous, next section.

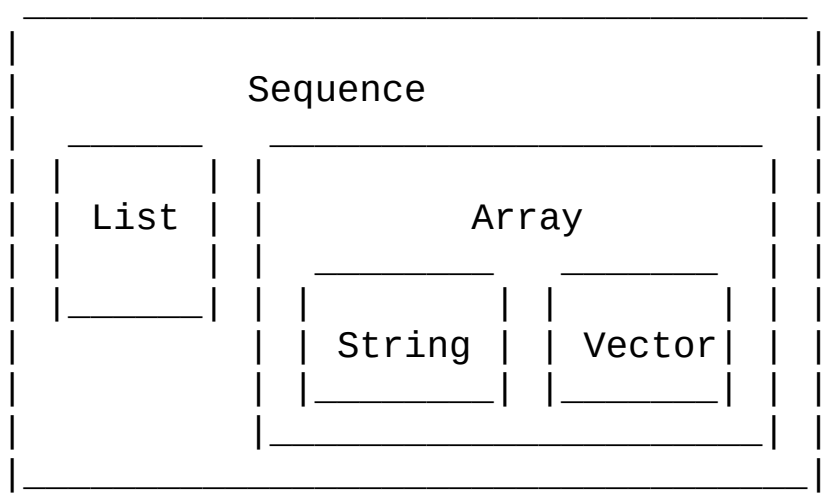
Sequences, Arrays, and Vectors

Recall that the sequence type is the union of three other Lisp types: lists, vectors, and strings. In other words, any list is a sequence, any vector is a sequence, and any string is a sequence. The common property that all sequences have is that each is an ordered collection of elements.

An array is a single primitive object directly containing all its elements. Therefore, all the elements are accessible in constant time. The length of an existing array cannot be changed. Both strings and vectors are arrays. A list is a sequence of elements, but it is not a single primitive object; it is made of cons cells, one cell per element. Therefore, elements farther from the beginning of the list take longer to access, but it is possible to add elements to the list or remove elements. The elements of vectors and lists may be any Lisp objects. The elements of strings are all characters.

The following diagram shows the relationship between these types:



The Relationship between Sequences, Arrays, and Vectors

Sequences

In Emacs Lisp, a sequence is either a list, a vector or a string. The common property that all sequences have is that each is an ordered collection of elements. This section describes functions that accept any kind of sequence.

Function: **sequencep** *object*

Returns `t` if object is a list, vector, or string, `nil` otherwise.

Function: **copy-sequence** *sequence*

Returns a copy of sequence. The copy is the same type of object as the original sequence, and it has the

same elements in the same order.

Storing a new element into the copy does not affect the original sequence, and vice versa. However, the elements of the new sequence are not copies; they are identical (`eq`) to the elements of the original. Therefore, changes made within these elements, as found via the copied sequence, are also visible in the original sequence.

If the sequence is a string with text properties, the property list in the copy is itself a copy, not shared with the original's property list. However, the actual values of the properties are shared. See section Text Properties.

See also `append` in section Building Cons Cells and Lists, `concat` in section Creating Strings, and `vconcat` in section Vectors, for others ways to copy sequences.

```
(setq bar '(1 2))
     => (1 2)
(setq x (vector 'foo bar))
     => [foo (1 2)]
(setq y (copy-sequence x))
     => [foo (1 2)]

(eq x y)
     => nil
(equal x y)
     => t
(eq (elt x 1) (elt y 1))
     => t

;; Replacing an element of one sequence.
(aset x 0 'quux)
x => [quux (1 2)]
y => [foo (1 2)]

;; Modifying the inside of a shared element.
(setcar (aref x 1) 69)
x => [quux (69 2)]
y => [foo (69 2)]
```

Function: **length** *sequence*

Returns the number of elements in sequence. If sequence is a cons cell that is not a list (because the final CDR is not `nil`), a `wrong-type-argument` error is signaled.

```
(length '(1 2 3))
    => 3
(length ())
```

```
    => 0
(length "foobar")
    => 6
(length [1 2 3])
    => 3
```

Function: **elt** *sequence index*

This function returns the element of sequence indexed by index. Legitimate values of index are integers ranging from 0 up to one less than the length of sequence. If sequence is a list, then out-of-range values of index return `nil`; otherwise, they produce an `args-out-of-range` error.

```
(elt [1 2 3 4] 2)
     => 3
(elt '(1 2 3 4) 2)
     => 3
(char-to-string (elt "1234" 2))
     => "3"
(elt [1 2 3 4] 4)
     error-->Args out of range: [1 2 3 4], 4
(elt [1 2 3 4] -1)
     error-->Args out of range: [1 2 3 4], -1
```

This function duplicates `aref` (see section Functions that Operate on Arrays) and `nth` (see section Accessing Elements of Lists), except that it works for any kind of sequence.

Arrays

An array object refers directly to a number of other Lisp objects, called the elements of the array. Any element of an array may be accessed in constant time. In contrast, an element of a list requires access time that is proportional to the position of the element in the list.

When you create an array, you must specify how many elements it has. The amount of space allocated depends on the number of elements. Therefore, it is impossible to change the size of an array once it is created. You cannot add or remove elements. However, you can replace an element with a different value.

Emacs defines two types of array, both of which are one-dimensional: strings and vectors. A vector is a general array; its elements can be any Lisp objects. A string is a specialized array; its elements must be characters (i.e., integers between 0 and 255). Each type of array has its own read syntax. See section String Type, and section Vector Type.

Both kinds of arrays share these characteristics:

- The first element of an array has index zero, the second element has index 1, and so on. This is called zero-origin indexing. For example, an array of four elements has indices 0, 1, 2, and 3.
- The elements of an array may be referenced or changed with the functions `aref` and `aset`,

respectively (see section Functions that Operate on Arrays).

In principle, if you wish to have an array of characters, you could use either a string or a vector. In practice, we always choose strings for such applications, for four reasons:

- They occupy one-fourth the space of a vector of the same elements.
- Strings are printed in a way that shows the contents more clearly as characters.
- Strings can hold text properties. See section Text Properties.
- Many of the specialized editing and I/O facilities of Emacs accept only strings. For example, you cannot insert a vector of characters into a buffer the way you can insert a string. See section Strings and Characters.

Functions that Operate on Arrays

In this section, we describe the functions that accept both strings and vectors.

Function: **arrayp** *object*

This function returns `t` if object is an array (i.e., either a vector or a string).

```
(arrayp [a])
=> t
(arrayp "asdf")
=> t
```

Function: **aref** *array index*

This function returns the indexth element of array. The first element is at index zero.

```
(setq primes [2 3 5 7 11 13])
     => [2 3 5 7 11 13]
(aref primes 4)
     => 11
(elt primes 4)
     => 11

(aref "abcdefg" 1)
     => 98           ; `b' is ASCII code 98.
```

See also the function `elt`, in section Sequences.

Function: **aset** *array index object*

This function sets the indexth element of array to be object. It returns object.

```
(setq w [foo bar baz])
```

```
     => [foo bar baz]
(aset w 0 'fu)
     => fu
w
     => [fu bar baz]

(setq x "asdfasfd")
     => "asdfasfd"
(aset x 3 ?Z)
     => 90
x
     => "asdZasfd"
```

If array is a string and object is not a character, a `wrong-type-argument` error results.

Function: **fillarray** *array object*

This function fills the array array with pointers to object, replacing any previous values. It returns array.

```
(setq a [a b c d e f g])
     => [a b c d e f g]
(fillarray a 0)
     => [0 0 0 0 0 0 0]
a
     => [0 0 0 0 0 0 0]
(setq s "When in the course")
     => "When in the course"
(fillarray s ?-)
     => "------------------"
```

If array is a string and object is not a character, a `wrong-type-argument` error results.

The general sequence functions `copy-sequence` and `length` are often useful for objects known to be arrays. See section Sequences.

Vectors

Arrays in Lisp, like arrays in most languages, are blocks of memory whose elements can be accessed in constant time. A vector is a general-purpose array; its elements can be any Lisp objects. (The other kind of array provided in Emacs Lisp is the string, whose elements must be characters.) The main uses of vectors in Emacs are as syntax tables (vectors of integers) and keymaps (vectors of commands). They are also used internally as part of the representation of a byte-compiled function; if you print such a function, you will see a vector in it.

The indices of the elements of a vector are numbered starting with zero in Emacs Lisp.

Vectors are printed with square brackets surrounding the elements in their order. Thus, a vector

containing the symbols `a`, `b` and `c` is printed as `[a b c]`. You can write vectors in the same way in Lisp input.

A vector, like a string or a number, is considered a constant for evaluation: the result of evaluating it is the same vector. The elements of the vector are not evaluated. See section Self-Evaluating Forms.

Here are examples of these principles:

```
(setq avector [1 two '(three) "four" [five]])
     => [1 two (quote (three)) "four" [five]]
(eval avector)
     => [1 two (quote (three)) "four" [five]]
(eq avector (eval avector))
     => t
```

Here are some functions that relate to vectors:

Function: **vectorp** *object*

This function returns `t` if object is a vector.

```
(vectorp [a])
     => t
(vectorp "asdf")
     => nil
```

Function: **vector** *&rest objects*

This function creates and returns a vector whose elements are the arguments, objects.

```
(vector 'foo 23 [bar baz] "rats")
     => [foo 23 [bar baz] "rats"]
(vector)
     => []
```

Function: **make-vector** *integer object*

This function returns a new vector consisting of integer elements, each initialized to object.

```
(setq sleepy (make-vector 9 'Z))
     => [Z Z Z Z Z Z Z Z Z]
```

Function: **vconcat** *&rest sequences*

This function returns a new vector containing all the elements of the sequences. The arguments sequences may be lists, vectors, or strings. If no sequences are given, an empty vector is returned.

The value is a newly constructed vector that is not `eq` to any existing vector.

```
(setq a (vconcat '(A B C) '(D E F)))
     => [A B C D E F]
(eq a (vconcat a))
     => nil
(vconcat)
     => []
(vconcat [A B C] "aa" '(foo (6 7)))
     => [A B C 97 97 foo (6 7)]
```

When an argument is an integer (not a sequence of integers), it is converted to a string of digits making up the decimal printed representation of the integer. This special case exists for compatibility with Mocklisp, and we don't recommend you take advantage of it. If you want to convert an integer in this way, use `format` (see section Formatting Strings) or `int-to-string` (see section Conversion of Characters and Strings).

For other concatenation functions, see `mapconcat` in section Mapping Functions, `concat` in section Creating Strings, and `append` in section Building Cons Cells and Lists.

The `append` function may be used to convert a vector into a list with the same elements (see section Building Cons Cells and Lists):

```
(setq avector [1 two (quote (three)) "four" [five]])
     => [1 two (quote (three)) "four" [five]]
(append avector nil)
     => (1 two (quote (three)) "four" [five])
```

Symbols

A symbol is an object with a unique name. This chapter describes symbols, their components, and how they are created and interned. Property lists are also described. The uses of symbols as variables and as function names are described in separate chapters; see section Variables, and section Functions. For the precise syntax for symbols, see section Symbol Type.

You can test whether an arbitrary Lisp object is a symbol with `symbolp`:

Function: **symbolp** *object*

This function returns `t` if object is a symbol, `nil` otherwise.

Symbol Components

Each symbol has four components (or "cells"), each of which references another object:

Print name

> The print name cell holds a string which names the symbol for reading and printing. See `symbol-name` in section Creating and Interning Symbols.

Value

> The value cell holds the current value of the symbol as a variable. When a symbol is used as a form, the value of the form is the contents of the symbol's value cell. See `symbol-value` in section Accessing Variable Values.

Function

> The function cell holds the function definition of the symbol. When a symbol is used as a function, its function definition is used in its place. This cell is also used to make a symbol stand for a keymap or a keyboard macro, for editor command execution. Because each symbol has separate value and function cells, variables and function names do not conflict. See `symbol-function` in section Accessing Function Cell Contents.

Property list

> The property list cell holds the property list of the symbol. See `symbol-plist` in section Property Lists.

The print name cell always holds a string, and cannot be changed. The other three cells can be set individually to any specified Lisp object.

The print name cell holds the string that is the name of the symbol. Since symbols are represented textually by their names, it is important not to have two symbols with the same name. The Lisp reader ensures this: every time it reads a symbol, it looks for an existing symbol with the specified name before it creates a new one. (In GNU Emacs Lisp, this is done with a hashing algorithm that uses an obarray; see

section Creating and Interning Symbols.)

In normal usage, the function cell usually contains a function or macro, as that is what the Lisp interpreter expects to see there (see section Evaluation). Keyboard macros (see section Keyboard Macros), keymaps (see section Keymaps) and autoload objects (see section Autoloading) are also sometimes stored in the function cell of symbols. We often refer to "the function `foo`" when we really mean the function stored in the function cell of the symbol `foo`. We make the distinction only when necessary.

Similarly, the property list cell normally holds a correctly formatted property list (see section Property Lists), as a number of functions expect to see a property list there.

The function cell or the value cell may be void, which means that the cell does not reference any object. (This is not the same thing as holding the symbol `void`, nor the same as holding the symbol `nil`.) Examining the value of a cell which is void results in an error, such as `Symbol's value as variable is void'.

The four functions `symbol-name`, `symbol-value`, `symbol-plist`, and `symbol-function` return the contents of the four cells. Here as an example we show the contents of the four cells of the symbol `buffer-file-name`:

```
(symbol-name 'buffer-file-name)
     => "buffer-file-name"
(symbol-value 'buffer-file-name)
     => "/gnu/elisp/symbols.texi"
(symbol-plist 'buffer-file-name)
     => (variable-documentation 29529)
(symbol-function 'buffer-file-name)
     => #<subr buffer-file-name>
```

Because this symbol is the variable which holds the name of the file being visited in the current buffer, the value cell contents we see are the name of the source file of this chapter of the Emacs Lisp Manual. The property list cell contains the list `(variable-documentation 29529)` which tells the documentation functions where to find documentation about `buffer-file-name` in the `DOC'` file. (29529 is the offset from the beginning of the `DOC'` file where the documentation for the function begins.) The function cell contains the function for returning the name of the file. `buffer-file-name` names a primitive function, which has no read syntax and prints in hash notation (see section Primitive Function Type). A symbol naming a function written in Lisp would have a lambda expression (or a byte-code object) in this cell.

Defining Symbols

A definition in Lisp is a special form that announces your intention to use a certain symbol in a particular way. In Emacs Lisp, you can define a symbol as a variable, or define it as a function (or macro), or both independently.

A definition construct typically specifies a value or meaning for the symbol for one kind of use, plus documentation for its meaning when used in this way. Thus, when you define a symbol as a variable, you can supply an initial value for the variable, plus documentation for the variable.

`defvar` and `defconst` are special forms that define a symbol as a global variable. They are documented in detail in section Defining Global Variables.

`defun` defines a symbol as a function, creating a lambda expression and storing it in the function cell of the symbol. This lambda expression thus becomes the function definition of the symbol. (The term "function definition", meaning the contents of the function cell, is derived from the idea that `defun` gives the symbol its definition as a function.) See section Functions.

`defmacro` defines a symbol as a macro. It creates a macro object and stores it in the function cell of the symbol. Note that a given symbol can be a macro or a function, but not both at once, because both macro and function definitions are kept in the function cell, and that cell can hold only one Lisp object at any given time. See section Macros.

In GNU Emacs Lisp, a definition is not required in order to use a symbol as a variable or function. Thus, you can make a symbol a global variable with `setq`, whether you define it first or not. The real purpose of definitions is to guide programmers and programming tools. They inform programmers who read the code that certain symbols are *intended* to be used as variables, or as functions. In addition, utilities such as `` `etags' `` and `` `make-docfile' `` can recognize definitions, and add the appropriate information to tag tables and the `` `emacs/etc/DOC-version' `` file. See section Access to Documentation Strings.

Creating and Interning Symbols

To understand how symbols are created in GNU Emacs Lisp, you must know how Lisp reads them. Lisp must ensure that it finds the same symbol every time it reads the same set of characters. Failure to do so would cause complete confusion.

When the Lisp reader encounters a symbol, it reads all the characters of the name. Then it "hashes" those characters to find an index in a table called an obarray. Hashing is an efficient method of looking something up. For example, instead of searching a telephone book cover to cover when looking up Jan Jones, you start with the J's and go from there. That is a simple version of hashing. Each element of the obarray is a bucket which holds all the symbols with a given hash code; to look for a given name, it is sufficient to look through all the symbols in the bucket for that name's hash code.

If a symbol with the desired name is found, then it is used. If no such symbol is found, then a new symbol is created and added to the obarray bucket. Adding a symbol to an obarray is called interning it, and the symbol is then called an interned symbol. In Emacs Lisp, a symbol may be interned in only one obarray--if you try to intern the same symbol in more than one obarray, you will get unpredictable results.

It is possible for two different symbols to have the same name in different obarrays; these symbols are not `eq` or `equal`. However, this normally happens only as part of abbrev definition (see section Abbrevs And Abbrev Expansion).

Common Lisp note: in Common Lisp, a symbol may be interned in several obarrays at once.

If a symbol is not in the obarray, then there is no way for Lisp to find it when its name is read. Such a symbol is called an uninterned symbol relative to the obarray. An uninterned symbol has all the other characteristics of symbols.

In Emacs Lisp, an obarray is represented as a vector. Each element of the vector is a bucket; its value is either an interned symbol whose name hashes to that bucket, or 0 if the bucket is empty. Each interned symbol has an internal link (invisible to the user) to the next symbol in the bucket. Because these links are invisible, there is no way to scan the symbols in an obarray except using `mapatoms` (below). The order of symbols in a bucket is not significant.

In an empty obarray, every element is 0, and you can create an obarray with `(make-vector length 0)`. **This is the only valid way to create an obarray.** Prime numbers as lengths tend to result in good hashing; lengths one less than a power of two are also good.

Do not try to create an obarray that is not empty. This does not work--only `intern` can enter a symbol in an obarray properly. Also, don't try to put into an obarray of your own a symbol that is already interned in the main obarray, because in Emacs Lisp a symbol cannot be in two obarrays at once.

Most of the functions below take a name and sometimes an obarray as arguments. A `wrong-type-argument` error is signaled if the name is not a string, or if the obarray is not a vector.

Function: **symbol-name** *symbol*

This function returns the string that is symbol's name. For example:

```
(symbol-name 'foo)
     => "foo"
```

Changing the string by substituting characters, etc, does change the name of the symbol, but fails to update the obarray, so don't do it!

Function: **make-symbol** *name*

This function returns a newly-allocated, uninterned symbol whose name is name (which must be a string). Its value and function definition are void, and its property list is `nil`. In the example below, the value of `sym` is not `eq` to `foo` because it is a distinct uninterned symbol whose name is also `foo'.

```
(setq sym (make-symbol "foo"))
     => foo
(eq sym 'foo)
     => nil
```

Function: **intern** *name &optional obarray*

This function returns the interned symbol whose name is name. If there is no such symbol in the obarray, a new one is created, added to the obarray, and returned. If obarray is supplied, it specifies the obarray to

use; otherwise, the value of the global variable `obarray` is used.

```
(setq sym (intern "foo"))
     => foo
(eq sym 'foo)
     => t

(setq sym1 (intern "foo" other-obarray))
     => foo
(eq sym 'foo)
     => nil
```

Function: **intern-soft** *name &optional obarray*

This function returns the symbol whose name is name, or `nil` if a symbol with that name is not found in the obarray. Therefore, you can use `intern-soft` to test whether a symbol with a given name is interned. If obarray is supplied, it specifies the obarray to use; otherwise the value of the global variable `obarray` is used.

```
(intern-soft "frazzle")        ; No such symbol exists.
     => nil
(make-symbol "frazzle")        ; Create an uninterned one.
     => frazzle
(intern-soft "frazzle")        ; That one cannot be found.
     => nil
(setq sym (intern "frazzle"))  ; Create an interned one.
     => frazzle
(intern-soft "frazzle")        ; That one can be found!
     => frazzle
(eq sym 'frazzle)              ; And it is the same one.
     => t
```

Variable: **obarray**

This variable is the standard obarray for use by `intern` and `read`.

Function: **mapatoms** *function &optional obarray*

This function applies function to every symbol in obarray. It returns `nil`. If obarray is not supplied, it defaults to the value of `obarray`, the standard obarray for ordinary symbols.

```
(setq count 0)
     => 0
(defun count-syms (s)
  (setq count (1+ count)))
     => count-syms
(mapatoms 'count-syms)
```

```
     => nil
count
     => 1871
```

See `documentation` in section Access to Documentation Strings, for another example using `mapatoms`.

Property Lists

A property list (plist for short) is a list of paired elements stored in the property list cell of a symbol. Each of the pairs associates a property name (usually a symbol) with a property or value. Property lists are generally used to record information about a symbol, such as how to compile it, the name of the file where it was defined, or perhaps even the grammatical class of the symbol (representing a word) in a language understanding system.

Character positions in a string or buffer can also have property lists. See section Text Properties.

The property names and values in a property list can be any Lisp objects, but the names are usually symbols. They are compared using `eq`. Here is an example of a property list, found on the symbol `progn` when the compiler is loaded:

```
(lisp-indent-function 0 byte-compile byte-compile-progn)
```

Here `lisp-indent-function` and `byte-compile` are property names, and the other two elements are the corresponding values.

Association lists (see section Association Lists) are very similar to property lists. In contrast to association lists, the order of the pairs in the property list is not significant since the property names must be distinct.

Property lists are better than association lists when it is necessary to attach information to various Lisp function names or variables. If all the pairs are recorded in one association list, the program will need to search that entire list each time a function or variable is to be operated on. By contrast, if the information is recorded in the property lists of the function names or variables themselves, each search will scan only the length of one property list, which is usually short. For this reason, the documentation for a variable is recorded in a property named `variable-documentation`. The byte compiler likewise uses properties to record those functions needing special treatment.

However, association lists have their own advantages. Depending on your application, it may be faster to add an association to the front of an association list than to update a property. All properties for a symbol are stored in the same property list, so there is a possibility of a conflict between different uses of a property name. (For this reason, it is a good idea to use property names that are probably unique, such as by including the name of the library in the property name.) An association list may be used like a stack where associations are pushed on the front of the list and later discarded; this is not possible with a property list.

Function: **symbol-plist** *symbol*

This function returns the property list of symbol.

Function: **setplist** *symbol plist*

This function sets symbol's property list to plist. Normally, plist should be a well-formed property list, but this is not enforced.

```
(setplist 'foo '(a 1 b (2 3) c nil))
     => (a 1 b (2 3) c nil)
(symbol-plist 'foo)
     => (a 1 b (2 3) c nil)
```

For symbols in special obarrays, which are not used for ordinary purposes, it may make sense to use the property list cell in a nonstandard fashion; in fact, the abbrev mechanism does so (see section Abbrevs And Abbrev Expansion).

Function: **get** *symbol property*

This function finds the value of the property named property in symbol's property list. If there is no such property, `nil` is returned. Thus, there is no distinction between a value of `nil` and the absence of the property.

The name property is compared with the existing property names using `eq`, so any object is a legitimate property.

See `put` for an example.

Function: **put** *symbol property value*

This function puts value onto symbol's property list under the property name property, replacing any previous value.

```
(put 'fly 'verb 'transitive)
     =>'transitive
(put 'fly 'noun '(a buzzing little bug))
     => (a buzzing little bug)
(get 'fly 'verb)
     => transitive
(symbol-plist 'fly)
     => (verb transitive noun (a buzzing little bug))
```

Go to the previous, next section.

Go to the previous, next section.

Evaluation

The evaluation of expressions in Emacs Lisp is performed by the Lisp interpreter---a program that receives a Lisp object as input and computes its value as an expression. The value is computed in a fashion that depends on the data type of the object, following rules described in this chapter. The interpreter runs automatically to evaluate portions of your program, but can also be called explicitly via the Lisp primitive function `eval`.

A Lisp object which is intended for evaluation is called an expression or a form. The fact that expressions are data objects and not merely text is one of the fundamental differences between Lisp-like languages and typical programming languages. Any object can be evaluated, but in practice only numbers, symbols, lists and strings are evaluated very often.

It is very common to read a Lisp expression and then evaluate the expression, but reading and evaluation are separate activities, and either can be performed alone. Reading per se does not evaluate anything; it converts the printed representation of a Lisp object to the object itself. It is up to the caller of `read` whether this object is a form to be evaluated, or serves some entirely different purpose. See section Input Functions.

Do not confuse evaluation with command key interpretation. The editor command loop translates keyboard input into a command (an interactively callable function) using the active keymaps, and then uses `call-interactively` to invoke the command. The execution of the command itself involves evaluation if the command is written in Lisp, but that is not a part of command key interpretation itself. See section Command Loop.

Evaluation is a recursive process. That is, evaluation of a form may cause `eval` to be called again in order to evaluate parts of the form. For example, evaluation of a function call first evaluates each argument of the function call, and then evaluates each form in the function body. Consider evaluation of the form `(car x)`: the subform `x` must first be evaluated recursively, so that its value can be passed as an argument to the function `car`.

The evaluation of forms takes place in a context called the environment, which consists of the current values and bindings of all Lisp variables.(1) Whenever the form refers to a variable without creating a new binding for it, the value of the binding in the current environment is used. See section Variables.

Evaluation of a form may create new environments for recursive evaluation by binding variables (see section Local Variables). These environments are temporary and will be gone by the time evaluation of the form is complete. The form may also make changes that persist; these changes are called side effects. An example of a form that produces side effects is `(setq foo 1)`.

Finally, evaluation of one particular function call, `byte-code`, invokes the byte-code interpreter on its arguments. Although the byte-code interpreter is not the same as the Lisp interpreter, it uses the same environment as the Lisp interpreter, and may on occasion invoke the Lisp interpreter. (See section Byte Compilation.)

The details of what evaluation means for each kind of form are described below (see section Kinds of Forms).

Eval

Most often, forms are evaluated automatically, by virtue of their occurrence in a program being run. On rare occasions, you may need to write code that evaluates a form that is computed at run time, such as after reading a form from text being edited or getting one from a property list. On these occasions, use the `eval` function.

The functions and variables described in this section evaluate forms, specify limits to the evaluation process, or record recently returned values. Loading a file also does evaluation (see section Loading).

Function: **eval** *form*

This is the basic function for performing evaluation. It evaluates form in the current environment and returns the result. How the evaluation proceeds depends on the type of the object (see section Kinds of Forms).

Since `eval` is a function, the argument expression that appears in a call to `eval` is evaluated twice: once as preparation before `eval` is called, and again by the `eval` function itself. Here is an example:

```
(setq foo 'bar)
     => bar
(setq bar 'baz)
     => baz
;; eval receives argument bar, which is the value of foo
(eval foo)
     => baz
```

The number of currently active calls to `eval` is limited to `max-lisp-eval-depth` (see below).

Command: **eval-current-buffer** *&optional stream*

This function evaluates the forms in the current buffer. It reads forms from the buffer and calls `eval` on them until the end of the buffer is reached, or until an error is signaled and not handled.

If stream is supplied, the variable `standard-output` is bound to stream during the evaluation (see section Output Functions).

`eval-current-buffer` always returns `nil`.

Command: **eval-region** *start end &optional stream*

This function evaluates the forms in the current buffer in the region defined by the positions start and end. It reads forms from the region and calls `eval` on them until the end of the region is reached, or until an error is signaled and not handled.

If stream is supplied, `standard-output` is bound to it for the duration of the command.

`eval-region` always returns `nil`.

Variable: **max-lisp-eval-depth**

This variable defines the maximum depth allowed in calls to `eval`, `apply`, and `funcall` before an error is signaled (with error message `"Lisp nesting exceeds max-lisp-eval-depth"`). `eval` is called recursively to evaluate the arguments of Lisp function calls and to evaluate bodies of functions.

This limit, with the associated error when it is exceeded, is one way that Lisp avoids infinite recursion on an ill-defined function.

The default value of this variable is 200. If you set it to a value less than 100, Lisp will reset it to 100 if the given value is reached.

`max-specpdl-size` provides another limit on nesting. See section Local Variables.

Variable: **values**

The value of this variable is a list of values returned by all expressions which were read from buffers (including the minibuffer), evaluated, and printed. The elements are in order, most recent first.

```
(setq x 1)
     => 1
(list 'A (1+ 2) auto-save-default)
     => (A 3 t)
values
     => ((A 3 t) 1 ...)
```

This variable is useful for referring back to values of forms recently evaluated. It is generally a bad idea to print the value of `values` itself, since this may be very long. Instead, examine particular elements, like this:

```
;; Refer to the most recent evaluation result.
(nth 0 values)
     => (A 3 t)
;; That put a new element on,
;;   so all elements move back one.
(nth 1 values)
     => (A 3 t)
;; This gets the element that was next-to-last
;;   before this example.
(nth 3 values)
     => 1
```

Kinds of Forms

A Lisp object that is intended to be evaluated is called a form. How Emacs evaluates a form depends on its data type. Emacs has three different kinds of form that are evaluated differently: symbols, lists, and "all other types". All three kinds are described in this section, starting with "all other types" which are self-evaluating forms.

Self-Evaluating Forms

A self-evaluating form is any form that is not a list or symbol. Self-evaluating forms evaluate to themselves: the result of evaluation is the same object that was evaluated. Thus, the number 25 evaluates to 25, and the string `"foo"` evaluates to the string `"foo"`. Likewise, evaluation of a vector does not cause evaluation of the elements of the vector--it returns the same vector with its contents unchanged.

```
'123               ; An object, shown without evaluation.
     => 123
123                ; Evaluated as usual--result is the same.
     => 123
(eval '123)        ; Evaluated "by hand"---result is the same.
     => 123
(eval (eval '123)) ; Evaluating twice changes nothing.
     => 123
```

It is common to write numbers, characters, strings, and even vectors in Lisp code, taking advantage of the fact that they self-evaluate. However, it is quite unusual to do this for types that lack a read syntax, because it is inconvenient and not very useful; however, it is possible to put them inside Lisp programs when they are constructed from subexpressions rather than read. Here is an example:

```
;; Build such an expression.
(setq buffer (list 'print (current-buffer)))
     => (print #<buffer eval.texi>)
;; Evaluate it.
(eval buffer)
     -| #<buffer eval.texi>
     => #<buffer eval.texi>
```

Symbol Forms

When a symbol is evaluated, it is treated as a variable. The result is the variable's value, if it has one. If it has none (if its value cell is void), an error is signaled. For more information on the use of variables, see section Variables.

In the following example, we set the value of a symbol with `setq`. When the symbol is later evaluated, that value is returned.

```
(setq a 123)
     => 123
(eval 'a)
     => 123
a
     => 123
```

The symbols `nil` and `t` are treated specially, so that the value of `nil` is always `nil`, and the value of `t` is always `t`. Thus, these two symbols act like self-evaluating forms, even though `eval` treats them like any other symbol.

Classification of List Forms

A form that is a nonempty list is either a function call, a macro call, or a special form, according to its first element. These three kinds of forms are evaluated in different ways, described below. The rest of the list consists of arguments for the function, macro or special form.

The first step in evaluating a nonempty list is to examine its first element. This element alone determines what kind of form the list is and how the rest of the list is to be processed. The first element is *not* evaluated, as it would be in some Lisp dialects including Scheme.

Symbol Function Indirection

If the first element of the list is a symbol then evaluation examines the symbol's function cell, and uses its contents instead of the original symbol. If the contents are another symbol, this process, called symbol function indirection, is repeated until a non-symbol is obtained. See section Naming a Function, for more information about using a symbol as a name for a function stored in the function cell of the symbol.

One possible consequence of this process is an infinite loop, in the event that a symbol's function cell refers to the same symbol. Or a symbol may have a void function cell, causing a `void-function` error. But if neither of these things happens, we eventually obtain a non-symbol, which ought to be a function or other suitable object.

More precisely, we should now have a Lisp function (a lambda expression), a byte-code function, a primitive function, a Lisp macro, a special form, or an autoload object. Each of these types is a case described in one of the following sections. If the object is not one of these types, the error `invalid-function` is signaled.

The following example illustrates the symbol indirection process. We use `fset` to set the function cell of a symbol and `symbol-function` to get the function cell contents (see section Accessing Function Cell Contents). Specifically, we store the symbol `car` into the function cell of `first`, and the symbol `first` into the function cell of `erste`.

```
;; Build this function cell linkage:
;;   -------------       -----        -------        -------
```

```
;;  | #<subr car> | <-- | car |  <-- | first |  <-- | erste |
;;   -------------       -----        -------        -------

(symbol-function 'car)
     => #<subr car>
(fset 'first 'car)
     => car
(fset 'erste 'first)
     => first
(erste '(1 2 3))   ; Call the function referenced by erste.
     => 1
```

By contrast, the following example calls a function without any symbol function indirection, because the first element is an anonymous Lisp function, not a symbol.

```
((lambda (arg) (erste arg))
 '(1 2 3))
     => 1
```

After that function is called, its body is evaluated; this does involve symbol function indirection when calling `erste`.

The built-in function `indirect-function` provides an easy way to perform symbol function indirection explicitly.

Function: **indirect-function** *function*

This function returns the meaning of function as a function. If function is a symbol, then it finds function's function definition and starts over with that value. If function is not a symbol, then it returns function itself.

Here is how you could define `indirect-function` in Lisp:

```
(defun indirect-function (function)
  (if (symbolp function)
      (indirect-function (symbol-function function))
    function))
```

Evaluation of Function Forms

If the first element of a list being evaluated is a Lisp function object, byte-code object or primitive function object, then that list is a function call. For example, here is a call to the function `+`:

```
(+ 1 x)
```

When a function call is evaluated, the first step is to evaluate the remaining elements of the list in the order they appear. The results are the actual argument values, one argument from each element. Then the

function is called with this list of arguments, effectively using the function `apply` (see section Calli Functions). If the function is written in Lisp, the arguments are used to bind the argument variables of the function (see section Lambda Expressions); then the forms in the function body are evaluated in order, and the result of the last one is used as the value of the function call.

Lisp Macro Evaluation

If the first element of a list being evaluated is a macro object, then the list is a macro call. When a macro call is evaluated, the elements of the rest of the list are *not* initially evaluated. Instead, these elements themselves are used as the arguments of the macro. The macro definition computes a replacement form, called the expansion of the macro, which is evaluated in place of the original form. The expansion may be any sort of form: a self-evaluating constant, a symbol or a list. If the expansion is itself a macro call, this process of expansion repeats until some other sort of form results.

Normally, the argument expressions are not evaluated as part of computing the macro expansion, but instead appear as part of the expansion, so they are evaluated when the expansion is evaluated.

For example, given a macro defined as follows:

```
(defmacro cadr (x)
  (list 'car (list 'cdr x)))
```

an expression such as `(cadr (assq 'handler list))` is a macro call, and its expansion is:

```
(car (cdr (assq 'handler list)))
```

Note that the argument `(assq 'handler list)` appears in the expansion.

See section Macros, for a complete description of Emacs Lisp macros.

Special Forms

A special form is a primitive function specially marked so that its arguments are not all evaluated. Special forms define control structures or perform variable bindings--things which functions cannot do.

Each special form has its own rules for which arguments are evaluated and which are used without evaluation. Whether a particular argument is evaluated may depend on the results of evaluating other arguments.

Here is a list, in alphabetical order, of all of the special forms in Emacs Lisp with a reference to where each is described.

`and`

see section Constructs for Combining Conditions

`catch`

see section Explicit Nonlocal Exits: `catch` and `throw`

`cond`
see section Conditionals

`condition-case`
see section Writing Code to Handle Errors

`defconst`
see section Defining Global Variables

`defmacro`
see section Defining Macros

`defun`
see section Defining Named Functions

`defvar`
see section Defining Global Variables

`function`
see section Anonymous Functions

`if`
see section Conditionals

`interactive`
see section Interactive Call

`let`
`let*`
see section Local Variables

`or`
see section Constructs for Combining Conditions

`prog1`
`prog2`
`progn`
see section Sequencing

`quote`
see section Quoting

`save-excursion`
see section Excursions

`save-restriction`
see section Narrowing

`save-window-excursion`
see section Window Configurations

`setq`

see section How to Alter a Variable Value

`setq-default`

see section Creating and Destroying Buffer-local Bindings

`track-mouse`

see section Mouse Tracking

`unwind-protect`

see section Nonlocal Exits

`while`

see section Iteration

`with-output-to-temp-buffer`

see section Temporary Displays

Common Lisp note: here are some comparisons of special forms in GNU Emacs Lisp and Common Lisp. `setq`, `if`, and `catch` are special forms in both Emacs Lisp and Common Lisp. `defun` is a special form in Emacs Lisp, but a macro in Common Lisp. `save-excursion` is a special form in Emacs Lisp, but doesn't exist in Common Lisp. `throw` is a special form in Common Lisp (because it must be able to throw multiple values), but it is a function in Emacs Lisp (which doesn't have multiple values).

Autoloading

The autoload feature allows you to call a function or macro whose function definition has not yet been loaded into Emacs. When an autoload object appears as a symbol's function definition and that symbol is used as a function, Emacs will automatically install the real definition (plus other associated code) and then call that definition. (See section Autoload.)

Quoting

The special form `quote` returns its single argument "unchanged".

Special Form: **quote** *object*

This special form returns object, without evaluating it. This allows symbols and lists, which would normally be evaluated, to be included literally in a program. (It is not necessary to quote numbers, strings, and vectors since they are self-evaluating.)

Because `quote` is used so often in programs, Lisp provides a convenient read syntax for it. An apostrophe character (`'`) followed by a Lisp object (in read syntax) expands to a list whose first element is `quote`, and whose second element is the object. Thus, the read syntax `'x` is an abbreviation for `(quote x)`.

Here are some examples of expressions that use `quote`:

```
(quote (+ 1 2))
     => (+ 1 2)
(quote foo)
     => foo
'foo
     => foo
"foo
     => (quote foo)
'(quote foo)
     => (quote foo)
['foo]
     => [(quote foo)]
```

Other quoting constructs include `function` (see section Anonymous Functions), which causes an anonymous lambda expression written in Lisp to be compiled, and ` (see section Backquote), which is used to quote only part of a list, while computing and substituting other parts.

Go to the previous, next section.

Go to the previous, next section.

Control Structures

A Lisp program consists of expressions or forms (see section Kinds of Forms). We control the order of execution of the forms by enclosing them in control structures. Control structures are special forms which control when, whether, or how many times to execute the forms they contain.

The simplest control structure is sequential execution: first form a, then form b, and so on. This is what happens when you write several forms in succession in the body of a function, or at top level in a file of Lisp code--the forms are executed in the order they are written. We call this textual order. For example, if a function body consists of two forms a and b, evaluation of the function evaluates first a and then b, and the function's value is the value of b.

Naturally, Emacs Lisp has many kinds of control structures, including other varieties of sequencing, function calls, conditionals, iteration, and (controlled) jumps. The built-in control structures are special forms since their subforms are not necessarily evaluated. You can use macros to define your own control structure constructs (see section Macros).

Sequencing

Evaluating forms in the order they are written is the most common control structure. Sometimes this happens automatically, such as in a function body. Elsewhere you must use a control structure construct to do this: `progn`, the simplest control construct of Lisp.

A `progn` special form looks like this:

```
(progn a b c ...)
```

and it says to execute the forms a, b, c and so on, in that order. These forms are called the body of the `progn` form. The value of the last form in the body becomes the value of the entire `progn`.

When Lisp was young, `progn` was the only way to execute two or more forms in succession and use the value of the last of them. But programmers found they often needed to use a `progn` in the body of a function, where (at that time) only one form was allowed. So the body of a function was made into an "implicit `progn`": several forms are allowed just as in the body of an actual `progn`. Many other control structures likewise contain an implicit `progn`. As a result, `progn` is not used as often as it used to be. It is needed now most often inside of an `unwind-protect`, `and`, or `or`.

Special Form: **progn** *forms...*

This special form evaluates all of the forms, in textual order, returning the result of the final form.

```
(progn (print "The first form")
       (print "The second form")
```

```
       (print "The third form"))
     -| "The first form"
     -| "The second form"
     -| "The third form"
=> "The third form"
```

Two other control constructs likewise evaluate a series of forms but return a different value:

Special Form: **prog1** *form1 forms...*

This special form evaluates form1 and all of the forms, in textual order, returning the result of form1.

```
(prog1 (print "The first form")
       (print "The second form")
       (print "The third form"))
     -| "The first form"
     -| "The second form"
     -| "The third form"
=> "The first form"
```

Here is a way to remove the first element from a list in the variable `x`, then return the value of that former element:

```
(prog1 (car x) (setq x (cdr x)))
```

Special Form: **prog2** *form1 form2 forms...*

This special form evaluates form1, form2, and all of the following forms, in textual order, returning the result of form2.

```
(prog2 (print "The first form")
       (print "The second form")
       (print "The third form"))
     -| "The first form"
     -| "The second form"
     -| "The third form"
=> "The second form"
```

Conditionals

Conditional control structures choose among alternatives. Emacs Lisp has two conditional forms: `if`, which is much the same as in other languages, and `cond`, which is a generalized case statement.

Special Form: **if** *condition then-form else-forms...*

`if` chooses between the then-form and the else-forms based on the value of condition. If the evaluated condition is non-`nil`, then-form is evaluated and the result returned. Otherwise, the else-forms are

evaluated in textual order, and the value of the last one is returned. (The else part of `if` is an exampl an implicit `progn`. See section Sequencing.)

If condition has the value `nil`, and no else-forms are given, `if` returns `nil`.

`if` is a special form because the branch which is not selected is never evaluated--it is ignored. Thus, in the example below, `true` is not printed because `print` is never called.

```
(if nil
    (print 'true)
  'very-false)
=> very-false
```

Special Form: **cond** *clause...*

`cond` chooses among an arbitrary number of alternatives. Each clause in the `cond` must be a list. The CAR of this list is the condition; the remaining elements, if any, the body-forms. Thus, a clause looks like this:

```
(condition body-forms...)
```

`cond` tries the clauses in textual order, by evaluating the condition of each clause. If the value of condition is non-`nil`, the body-forms are evaluated, and the value of the last of body-forms becomes the value of the `cond`. The remaining clauses are ignored.

If the value of condition is `nil`, the clause "fails", so the `cond` moves on to the following clause, trying its condition.

If every condition evaluates to `nil`, so that every clause fails, `cond` returns `nil`.

A clause may also look like this:

```
(condition)
```

Then, if condition is non-`nil` when tested, the value of condition becomes the value of the `cond` form.

The following example has four clauses, which test for the cases where the value of `x` is a number, string, buffer and symbol, respectively:

```
(cond ((numberp x) x)
      ((stringp x) x)
      ((bufferp x)
       (setq temporary-hack x) ; multiple body-forms
       (buffer-name x))        ; in one clause
      ((symbolp x) (symbol-value x)))
```

Often we want the last clause to be executed whenever none of the previous clauses was successful. To do this, we use `t` as the condition of the last clause, like this: `(t body-forms)`. The form `t` evaluates

to `t`, which is never `nil`, so this clause never fails, provided the `cond` gets to it at all.

For example,

```
(cond ((eq a 1) 'foo)
      (t "default"))
=> "default"
```

This expression is a `cond` which returns `foo` if the value of `a` is 1, and returns the string `"default"` otherwise.

Both `cond` and `if` can usually be written in terms of the other. Therefore, the choice between them is a matter of taste and style. For example:

```
(if a b c)
==
(cond (a b) (t c))
```

Constructs for Combining Conditions

This section describes three constructs that are often used together with `if` and `cond` to express complicated conditions. The constructs `and` and `or` can also be used individually as kinds of multiple conditional constructs.

Function: **not** *condition*

This function tests for the falsehood of condition. It returns `t` if condition is `nil`, and `nil` otherwise. The function `not` is identical to `null`, and we recommend using `null` if you are testing for an empty list.

Special Form: **and** *conditions...*

The `and` special form tests whether all the conditions are true. It works by evaluating the conditions one by one in the order written.

If any of the conditions evaluates to `nil`, then the result of the `and` must be `nil` regardless of the remaining conditions; so the remaining conditions are ignored and the `and` returns right away.

If all the conditions turn out non-`nil`, then the value of the last of them becomes the value of the `and` form.

Here is an example. The first condition returns the integer 1, which is not `nil`. Similarly, the second condition returns the integer 2, which is not `nil`. The third condition is `nil`, so the remaining condition is never evaluated.

```
(and (print 1) (print 2) nil (print 3))
     -| 1
     -| 2
```

```
=> nil
```

Here is a more realistic example of using `and`:

```
(if (and (consp foo) (eq (car foo) 'x))
    (message "foo is a list starting with x"))
```

Note that `(car foo)` is not executed if `(consp foo)` returns `nil`, thus avoiding an error.

`and` can be expressed in terms of either `if` or `cond`. For example:

```
(and arg1 arg2 arg3)
==
(if arg1 (if arg2 arg3))
==
(cond (arg1 (cond (arg2 arg3))))
```

Special Form: **or** *conditions...*

The `or` special form tests whether at least one of the conditions is true. It works by evaluating all the conditions one by one in the order written.

If any of the conditions evaluates to a non-`nil` value, then the result of the `or` must be non-`nil`; so the remaining conditions are ignored and the `or` returns right away. The value it returns is the non-`nil` value of the condition just evaluated.

If all the conditions turn out `nil`, then the `or` expression returns `nil`.

For example, this expression tests whether `x` is either 0 or `nil`:

```
(or (eq x nil) (= x 0))
```

Like the `and` construct, `or` can be written in terms of `cond`. For example:

```
(or arg1 arg2 arg3)
==
(cond (arg1)
      (arg2)
      (arg3))
```

You could almost write `or` in terms of `if`, but not quite:

```
(if arg1 arg1
  (if arg2 arg2
    arg3))
```

This is not completely equivalent because it can evaluate arg1 or arg2 twice. By contrast, `(or arg1 arg2 arg3)` never evaluates any argument more than once.

Iteration

Iteration means executing part of a program repetitively. For example, you might want to repeat some expressions once for each element of a list, or once for each integer from 0 to n. You can do this in Emacs Lisp with the special form `while`:

Special Form: **while** *condition forms...*

`while` first evaluates condition. If the result is non-`nil`, it evaluates forms in textual order. Then it reevaluates condition, and if the result is non-`nil`, it evaluates forms again. This process repeats until condition evaluates to `nil`.

There is no limit on the number of iterations that may occur. The loop will continue until either condition evaluates to `nil` or until an error or `throw` jumps out of it (see section Nonlocal Exits).

The value of a `while` form is always `nil`.

```
(setq num 0)
     => 0
(while (< num 4)
  (princ (format "Iteration %d." num))
  (setq num (1+ num)))
     -| Iteration 0.
     -| Iteration 1.
     -| Iteration 2.
     -| Iteration 3.
     => nil
```

If you would like to execute something on each iteration before the end-test, put it together with the end-test in a `progn` as the first argument of `while`, as shown here:

```
(while (progn
         (forward-line 1)
         (not (looking-at "^$"))))
```

This moves forward one line and continues moving by lines until an empty line is reached.

Nonlocal Exits

A nonlocal exit is a transfer of control from one point in a program to another remote point. Nonlocal exits can occur in Emacs Lisp as a result of errors; you can also use them under explicit control. Nonlocal exits unbind all variable bindings made by the constructs being exited.

Explicit Nonlocal Exits: `catch` and `throw`

Most control constructs affect only the flow of control within the construct itself. The function `throw` is the exception to this rule for of normal program execution: it performs a nonlocal exit on request. (There are other exceptions, but they are for error handling only.) `throw` is used inside a `catch`, and jumps back to that `catch`. For example:

```
(catch 'foo
  (progn
    ...
      (throw 'foo t)
    ...))
```

The `throw` transfers control straight back to the corresponding `catch`, which returns immediately. The code following the `throw` is not executed. The second argument of `throw` is used as the return value of the `catch`.

The `throw` and the `catch` are matched through the first argument: `throw` searches for a `catch` whose first argument is `eq` to the one specified. Thus, in the above example, the `throw` specifies `foo`, and the `catch` specifies the same symbol, so that `catch` is applicable. If there is more than one applicable `catch`, the innermost one takes precedence.

All Lisp constructs between the `catch` and the `throw`, including function calls, are exited automatically along with the `catch`. When binding constructs such as `let` or function calls are exited in this way, the bindings are unbound, just as they are when these constructs are exited normally (see section Local Variables). Likewise, the buffer and position saved by `save-excursion` (see section Excursions) are restored, and so is the narrowing status saved by `save-restriction` and the window selection saved by `save-window-excursion` (see section Window Configurations). Any cleanups established with the `unwind-protect` special form are executed if the `unwind-protect` is exited with a `throw`.

The `throw` need not appear lexically within the `catch` that it jumps to. It can equally well be called from another function called within the `catch`. As long as the `throw` takes place chronologically after entry to the `catch`, and chronologically before exit from it, it has access to that `catch`. This is why `throw` can be used in commands such as `exit-recursive-edit` which throw back to the editor command loop (see section Recursive Editing).

> **Common Lisp note:** most other versions of Lisp, including Common Lisp, have several ways of transferring control nonsequentially: `return`, `return-from`, and `go`, for example. Emacs Lisp has only `throw`.

Special Form: **catch** *tag body...*

`catch` establishes a return point for the `throw` function. The return point is distinguished from other such return points by tag, which may be any Lisp object. The argument tag is evaluated normally before the return point is established.

With the return point in effect, the forms of the body are evaluated in textual order. If the forms execute

normally, without error or nonlocal exit, the value of the last body form is returned from the `catch`.

If a `throw` is done within body specifying the same value tag, the `catch` exits immediately; the value it returns is whatever was specified as the second argument of `throw`.

Function: **throw** *tag value*

The purpose of `throw` is to return from a return point previously established with `catch`. The argument tag is used to choose among the various existing return points; it must be `eq` to the value specified in the `catch`. If multiple return points match tag, the innermost one is used.

The argument value is used as the value to return from that `catch`.

If no return point is in effect with tag tag, then a `no-catch` error is signaled with data `(tag value)`.

Examples of `catch` and `throw`

One way to use `catch` and `throw` is to exit from a doubly nested loop. (In most languages, this would be done with a "go to".) Here we compute `(foo i j)` for i and j varying from 0 to 9:

```
(defun search-foo ()
  (catch 'loop
    (let ((i 0))
      (while (< i 10)
        (let ((j 0))
          (while (< j 10)
            (if (foo i j)
                (throw 'loop (list i j)))
            (setq j (1+ j))))
        (setq i (1+ i))))))
```

If `foo` ever returns non-`nil`, we stop immediately and return a list of i and j. If `foo` always returns `nil`, the `catch` returns normally, and the value is `nil`, since that is the result of the `while`.

Here are two tricky examples, slightly different, showing two return points at once. First, two return points with the same tag, `hack`:

```
(defun catch2 (tag)
  (catch tag
    (throw 'hack 'yes)))
=> catch2

(catch 'hack
  (print (catch2 'hack))
  'no)
-| yes
=> no
```

Since both return points have tags that match the `throw`, it goes to the inner one, the one established in `catch2`. Therefore, `catch2` returns normally with value `yes`, and this value is printed. Finally the second body form in the outer `catch`, which is `'no`, is evaluated and returned from the outer `catch`.

Now let's change the argument given to `catch2`:

```
(defun catch2 (tag)
  (catch tag
    (throw 'hack 'yes)))
=> catch2

(catch 'hack
  (print (catch2 'quux))
  'no)
=> yes
```

We still have two return points, but this time only the outer one has the tag `hack`; the inner one has the tag `quux` instead. Therefore, the `throw` returns the value `yes` from the outer return point. The function `print` is never called, and the body-form `'no` is never evaluated.

Errors

When Emacs Lisp attempts to evaluate a form that, for some reason, cannot be evaluated, it signals an error.

When an error is signaled, Emacs's default reaction is to print an error message and terminate execution of the current command. This is the right thing to do in most cases, such as if you type C-f at the end of the buffer.

In complicated programs, simple termination may not be what you want. For example, the program may have made temporary changes in data structures, or created temporary buffers which should be deleted before the program is finished. In such cases, you would use `unwind-protect` to establish cleanup expressions to be evaluated in case of error. Occasionally, you may wish the program to continue execution despite an error in a subroutine. In these cases, you would use `condition-case` to establish error handlers to recover control in case of error.

Resist the temptation to use error handling to transfer control from one part of the program to another; use `catch` and `throw`. See section Explicit Nonlocal Exits: `catch` and `throw`.

How to Signal an Error

Most errors are signaled "automatically" within Lisp primitives which you call for other purposes, such as if you try to take the CAR of an integer or move forward a character at the end of the buffer; you can also signal errors explicitly with the functions `error` and `signal`.

Quitting, which happens when the user types C-g, is not considered an error, but it handled almost like an error. See section Quitting.

Function: **error** *format-string &rest args*

This function signals an error with an error message constructed by applying `format` (see section Conversion of Characters and Strings) to format-string and args.

Typical uses of `error` is shown in the following examples:

```
(error "You have committed an error.
        Try something else.")
     error--> You have committed an error.
        Try something else.

(error "You have committed %d errors." 10)
     error--> You have committed 10 errors.
```

`error` works by calling `signal` with two arguments: the error symbol `error`, and a list containing the string returned by `format`.

If you want to use a user-supplied string as an error message verbatim, don't just write `(error string)`. If string contains `%', it will be interpreted as a format specifier, with undesirable results. Instead, use `(error "%s" string)`.

Function: **signal** *error-symbol data*

This function signals an error named by error-symbol. The argument data is a list of additional Lisp objects relevant to the circumstances of the error.

The argument error-symbol must be an error symbol---a symbol bearing a property `error-conditions` whose value is a list of condition names. This is how different sorts of errors are classified.

The number and significance of the objects in data depends on error-symbol. For example, with a `wrong-type-arg` error, there are two objects in the list: a predicate which describes the type that was expected, and the object which failed to fit that type. See section Error Symbols and Condition Names, for a description of error symbols.

Both error-symbol and data are available to any error handlers which handle the error: a list `(error-symbol . data)` is constructed to become the value of the local variable bound in the `condition-case` form (see section Writing Code to Handle Errors). If the error is not handled, both of them are used in printing the error message.

The function `signal` never returns (though in older Emacs versions it could sometimes return).

```
(signal 'wrong-number-of-arguments '(x y))
     error--> Wrong number of arguments: x, y

(signal 'no-such-error '("My unknown error condition."))
     error--> peculiar error: "My unknown error condition."
```

Common Lisp note: Emacs Lisp has nothing like the Common Lisp concept of continuable errors.

How Emacs Processes Errors

When an error is signaled, Emacs searches for an active handler for the error. A handler is a specially marked place in the Lisp code of the current function or any of the functions by which it was called. If an applicable handler exists, its code is executed, and control resumes following the handler. The handler executes in the environment of the `condition-case` which established it; all functions called within that `condition-case` have already been exited, and the handler cannot return to them.

If no applicable handler is in effect in your program, the current command is terminated and control returns to the editor command loop, because the command loop has an implicit handler for all kinds of errors. The command loop's handler uses the error symbol and associated data to print an error message.

When an error is not handled explicitly, it may cause the Lisp debugger to be called. The debugger is enabled if the variable `debug-on-error` (see section Entering the Debugger on an Error) is non-`nil`. Unlike error handlers, the debugger runs in the environment of the error, so that you can examine values of variables precisely as they were at the time of the error.

Writing Code to Handle Errors

The usual effect of signaling an error is to terminate the command that is running and return immediately to the Emacs editor command loop. You can arrange to trap errors occurring in a part of your program by establishing an error handler with the special form `condition-case`. A simple example looks like this:

```
(condition-case nil
    (delete-file filename)
  (error nil))
```

This deletes the file named filename, catching any error and returning `nil` if an error occurs.

The second argument of `condition-case` is called the protected form. (In the example above, the protected form is a call to `delete-file`.) The error handlers go into effect when this form begins execution and are deactivated when this form returns. They remain in effect for all the intervening time. In particular, they are in effect during the execution of subroutines called by this form, and their subroutines, and so on. This is a good thing, since, strictly speaking, errors can be signaled only by Lisp primitives (including `signal` and `error`) called by the protected form, not by the protected form itself.

The arguments after the protected form are handlers. Each handler lists one or more condition names (which are symbols) to specify which errors it will handle. The error symbol specified when an error is signaled also defines a list of condition names. A handler applies to an error if they have any condition names in common. In the example above, there is one handler, and it specifies one condition name, `error`, which covers all errors.

The search for an applicable handler checks all the established handlers starting with the most recently established one. Thus, if two nested `condition-case` forms try to handle the same error, the inner of

the two will actually handle it.

When an error is handled, control returns to the handler. Before this happens, Emacs unbinds all variable bindings made by binding constructs that are being exited and executes the cleanups of all `unwind-protect` forms that are exited. Once control arrives at the handler, the body of the handler is executed.

After execution of the handler body, execution continues by returning from the `condition-case` form. Because the protected form is exited completely before execution of the handler, the handler cannot resume execution at the point of the error, nor can it examine variable bindings that were made within the protected form. All it can do is clean up and proceed.

`condition-case` is often used to trap errors that are predictable, such as failure to open a file in a call to `insert-file-contents`. It is also used to trap errors that are totally unpredictable, such as when the program evaluates an expression read from the user.

Error signaling and handling have some resemblance to `throw` and `catch`, but they are entirely separate facilities. An error cannot be caught by a `catch`, and a `throw` cannot be handled by an error handler (though using `throw` when there is no suitable `catch` signals an error which can be handled).

Special Form: **condition-case** *var protected-form handlers...*

This special form establishes the error handlers handlers around the execution of protected-form. If protected-form executes without error, the value it returns becomes the value of the `condition-case` form; in this case, the `condition-case` has no effect. The `condition-case` form makes a difference when an error occurs during protected-form.

Each of the handlers is a list of the form `(conditions body...)`. conditions is an error condition name to be handled, or a list of condition names; body is one or more Lisp expressions to be executed when this handler handles an error. Here are examples of handlers:

```
(error nil)

(arith-error (message "Division by zero"))

((arith-error file-error)
 (message
  "Either division by zero or failure to open a file"))
```

Each error that occurs has an error symbol which describes what kind of error it is. The `error-conditions` property of this symbol is a list of condition names (see section Error Symbols and Condition Names). Emacs searches all the active `condition-case` forms for a handler which specifies one or more of these names; the innermost matching `condition-case` handles the error. The handlers in this `condition-case` are tested in the order in which they appear.

The body of the handler is then executed, and the `condition-case` returns normally, using the value of the last form in the body as the overall value.

The argument var is a variable. `condition-case` does not bind this variable when executing the

protected-form, only when it handles an error. At that time, var is bound locally to a list of the form `(error-symbol . data)`, giving the particulars of the error. The handler can refer to this list to decide what to do. For example, if the error is for failure opening a file, the file name is the second element of data---the third element of var.

If var is `nil`, that means no variable is bound. Then the error symbol and associated data are not made available to the handler.

Here is an example of using `condition-case` to handle the error that results from dividing by zero. The handler prints out a warning message and returns a very large number.

```
(defun safe-divide (dividend divisor)
  (condition-case err
      ;; Protected form.
      (/ dividend divisor)
    ;; The handler.
    (arith-error                        ; Condition.
     (princ (format "Arithmetic error: %s" err))
     1000000)))
=> safe-divide

(safe-divide 5 0)
     -| Arithmetic error: (arith-error)
=> 1000000
```

The handler specifies condition name `arith-error` so that it will handle only division-by-zero errors. Other kinds of errors will not be handled, at least not by this `condition-case`. Thus,

```
(safe-divide nil 3)
     error--> Wrong type argument: integer-or-marker-p, nil
```

Here is a `condition-case` that catches all kinds of errors, including those signaled with `error`:

```
(setq baz 34)
     => 34

(condition-case err
    (if (eq baz 35)
        t
      ;; This is a call to the function error.
      (error "Rats!  The variable %s was %s, not 35." 'baz baz))
  ;; This is the handler; it is not a form.
  (error (princ (format "The error was: %s" err))
         2))
-| The error was: (error "Rats!  The variable baz was 34, not 35.")
=> 2
```

Error Symbols and Condition Names

When you signal an error, you specify an error symbol to specify the kind of error you have in mind. Each error has one and only one error symbol to categorize it. This is the finest classification of errors defined by the Lisp language.

These narrow classifications are grouped into a hierarchy of wider classes called error conditions, identified by condition names. The narrowest such classes belong to the error symbols themselves: each error symbol is also a condition name. There are also condition names for more extensive classes, up to the condition name `error` which takes in all kinds of errors. Thus, each error has one or more condition names: `error`, the error symbol if that is distinct from `error`, and perhaps some intermediate classifications.

In order for a symbol to be usable as an error symbol, it must have an `error-conditions` property which gives a list of condition names. This list defines the conditions which this kind of error belongs to. (The error symbol itself, and the symbol `error`, should always be members of this list.) Thus, the hierarchy of condition names is defined by the `error-conditions` properties of the error symbols.

In addition to the `error-conditions` list, the error symbol should have an `error-message` property whose value is a string to be printed when that error is signaled but not handled. If the `error-message` property exists, but is not a string, the error message `peculiar error' is used.

Here is how we define a new error symbol, `new-error`:

```
(put 'new-error
     'error-conditions
     '(error my-own-errors new-error))
     => (error my-own-errors new-error)
(put 'new-error 'error-message "A new error")
     => "A new error"
```

This error has three condition names: `new-error`, the narrowest classification; `my-own-errors`, which we imagine is a wider classification; and `error`, which is the widest of all. Naturally, Emacs will never signal a `new-error` on its own; only an explicit call to `signal` (see section Errors) in your code can do this:

```
(signal 'new-error '(x y))
     error--> A new error: x, y
```

This error can be handled through any of the three condition names. This example handles `new-error` and any other errors in the class `my-own-errors`:

```
(condition-case foo
    (bar nil t)
  (my-own-errors nil))
```

The significant way that errors are classified is by their condition names--the names used to match errors

with handlers. An error symbol serves only as a convenient way to specify the intended error messag and list of condition names. If `signal` were given a list of condition names rather than one error symbol, that would be cumbersome.

By contrast, using only error symbols without condition names would seriously decrease the power of `condition-case`. Condition names make it possible to categorize errors at various levels of generality when you write an error handler. Using error symbols alone would eliminate all but the narrowest level of classification.

See section Standard Errors, for a list of all the standard error symbols and their conditions.

Cleaning Up from Nonlocal Exits

The `unwind-protect` construct is essential whenever you temporarily put a data structure in an inconsistent state; it permits you to ensure the data are consistent in the event of an error or throw.

Special Form: **unwind-protect** *body cleanup-forms...*

`unwind-protect` executes the body with a guarantee that the cleanup-forms will be evaluated if control leaves body, no matter how that happens. The body may complete normally, or execute a `throw` out of the `unwind-protect`, or cause an error; in all cases, the cleanup-forms will be evaluated.

Only the body is actually protected by the `unwind-protect`. If any of the cleanup-forms themselves exit nonlocally (e.g., via a `throw` or an error), it is *not* guaranteed that the rest of them will be executed. If the failure of one of the cleanup-forms has the potential to cause trouble, then it should be protected by another `unwind-protect` around that form.

The number of currently active `unwind-protect` forms counts, together with the number of local variable bindings, against the limit `max-specpdl-size` (see section Local Variables).

For example, here we make an invisible buffer for temporary use, and make sure to kill it before finishing:

```
(save-excursion
  (let ((buffer (get-buffer-create " *temp*")))
    (set-buffer buffer)
    (unwind-protect
        body
      (kill-buffer buffer))))
```

You might think that we could just as well write `(kill-buffer (current-buffer))` and dispense with the variable `buffer`. However, the way shown above is safer, if body happens to get an error after switching to a different buffer! (Alternatively, you could write another `save-excursion` around the body, to ensure that the temporary buffer becomes current in time to kill it.)

Here is an actual example taken from the file `` `ftp.el' ``. It creates a process (see section Processes) to try to establish a connection to a remote machine. As the function `ftp-login` is highly susceptible to numerous problems which the writer of the function cannot anticipate, it is protected with a form that

guarantees deletion of the process in the event of failure. Otherwise, Emacs might fill up with useless subprocesses.

```
(let ((win nil))
  (unwind-protect
      (progn
        (setq process (ftp-setup-buffer host file))
        (if (setq win (ftp-login process host user password))
            (message "Logged in")
          (error "Ftp login failed")))
    (or win (and process (delete-process process)))))
```

This example actually has a small bug: if the user types C-g to quit, and the quit happens immediately after the function `ftp-setup-buffer` returns but before the variable `process` is set, the process will not be killed. There is no easy way to fix this bug, but at least it is very unlikely.

Go to the previous, next section.

Go to the previous, next section.

Variables

A variable is a name used in a program to stand for a value. Nearly all programming languages have variables of some sort. In the text for a Lisp program, variables are written using the syntax for symbols.

In Lisp, unlike most programming languages, programs are represented primarily as Lisp objects and only secondarily as text. The Lisp objects used for variables are symbols: the symbol name is the variable name, and the variable's value is stored in the value cell of the symbol. The use of a symbol as a variable is independent of whether the same symbol has a function definition. See section Symbol Components.

The textual form of a program is determined by its Lisp object representation; it is the read syntax for the Lisp object which constitutes the program. This is why a variable in a textual Lisp program is written as the read syntax for the symbol that represents the variable.

Global Variables

The simplest way to use a variable is globally. This means that the variable has just one value at a time, and this value is in effect (at least for the moment) throughout the Lisp system. The value remains in effect until you specify a new one. When a new value replaces the old one, no trace of the old value remains in the variable.

You specify a value for a symbol with `setq`. For example,

```
(setq x '(a b))
```

gives the variable `x` the value `(a b)`. Note that the first argument of `setq`, the name of the variable, is not evaluated, but the second argument, the desired value, is evaluated normally.

Once the variable has a value, you can refer to it by using the symbol by itself as an expression. Thus,

```
x
     => (a b)
```

assuming the `setq` form shown above has already been executed.

If you do another `setq`, the new value replaces the old one:

```
x
     => (a b)
(setq x 4)
     => 4
x
     => 4
```

Variables that Never Change

Emacs Lisp has two special symbols, `nil` and `t`, that always evaluate to themselves. These symbols cannot be rebound, nor can their value cells be changed. An attempt to change the value of `nil` or `t` signals a `setting-constant` error.

```
nil == 'nil
     => nil
(setq nil 500)
error--> Attempt to set constant symbol: nil
```

Local Variables

Global variables are given values that last until explicitly superseded with new values. Sometimes it is useful to create variable values that exist temporarily--only while within a certain part of the program. These values are called local, and the variables so used are called local variables.

For example, when a function is called, its argument variables receive new local values which last until the function exits. Similarly, the `let` special form explicitly establishes new local values for specified variables; these last until exit from the `let` form.

When a local value is established, the previous value (or lack of one) of the variable is saved away. When the life span of the local value is over, the previous value is restored. In the mean time, we say that the previous value is shadowed and not visible. Both global and local values may be shadowed (see section Scope).

If you set a variable (such as with `setq`) while it is local, this replaces the local value; it does not alter the global value, or previous local values that are shadowed. To model this behavior, we speak of a local binding of the variable as well as a local value.

The local binding is a conceptual place that holds a local value. Entry to a function, or a special form such as `let`, creates the local binding; exit from the function or from the `let` removes the local binding. As long as the local binding lasts, the variable's value is stored within it. Use of `setq` or `set` while there is a local binding stores a different value into the local binding; it does not create a new binding.

We also speak of the global binding, which is where (conceptually) the global value is kept.

A variable can have more than one local binding at a time (for example, if there are nested `let` forms that bind it). In such a case, the most recently created local binding that still exists is the current binding of the variable. (This is called dynamic scoping; see section Scoping Rules for Variable Bindings.) If there are no local bindings, the variable's global binding is its current binding. We also call the current binding the most-local existing binding, for emphasis. Ordinary evaluation of a symbol always returns the value of its current binding.

The special forms `let` and `let*` exist to create local bindings.

Special Form: **let** *(bindings...) forms...*

This function binds variables according to bindings and then evaluates all of the forms in textual order. The `let`-form returns the value of the last form in forms.

Each of the bindings is either (i) a symbol, in which case that symbol is bound to `nil`; or (ii) a list of the form `(symbol value-form)`, in which case symbol is bound to the result of evaluating value-form. If value-form is omitted, `nil` is used.

All of the value-forms in bindings are evaluated in the order they appear and *before* any of the symbols are bound. Here is an example of this: `Z` is bound to the old value of `Y`, which is 2, not the new value, 1.

```
(setq Y 2)
     => 2
(let ((Y 1)
      (Z Y))
  (list Y Z))
     => (1 2)
```

Special Form: **let*** *(bindings...) forms...*

This special form is like `let`, except that each symbol in bindings is bound as soon as its new value is computed, before the computation of the values of the following local bindings. Therefore, an expression in bindings may reasonably refer to the preceding symbols bound in this `let*` form. Compare the following example with the example above for `let`.

```
(setq Y 2)
     => 2
(let* ((Y 1)
       (Z Y))    ; Use the just-established value of Y.
  (list Y Z))
     => (1 1)
```

Here is a complete list of the other facilities which create local bindings:

- Function calls (see section Functions).
- Macro calls (see section Macros).
- `condition-case` (see section Errors).

Variable: **max-specpdl-size**

This variable defines the limit on the total number of local variable bindings and `unwind-protect` cleanups (see section Nonlocal Exits) that are allowed before signaling an error (with data `"Variable binding depth exceeds max-specpdl-size"`).

This limit, with the associated error when it is exceeded, is one way that Lisp avoids infinite recursion on an ill-defined function.

The default value is 600.

`max-lisp-eval-depth` provides another limit on depth of nesting. See section Eval.

When a Variable is "Void"

If you have never given a symbol any value as a global variable, we say that that symbol's global value is void. In other words, the symbol's value cell does not have any Lisp object in it. If you try to evaluate the symbol, you get a `void-variable` error rather than a value.

Note that a value of `nil` is not the same as void. The symbol `nil` is a Lisp object and can be the value of a variable just as any other object can be; but it is *a value*. A void variable does not have any value.

After you have given a variable a value, you can make it void once more using `makunbound`.

Function: **makunbound** *symbol*

This function makes the current binding of symbol void. This causes any future attempt to use this symbol as a variable to signal the error `void-variable`, unless or until you set it again.

`makunbound` returns symbol.

```
(makunbound 'x)      ; Make the global value
                     ;   of x void.
     => x
x
error--> Symbol's value as variable is void: x
```

If symbol is locally bound, `makunbound` affects the most local existing binding. This is the only way a symbol can have a void local binding, since all the constructs that create local bindings create them with values. In this case, the voidness lasts at most as long as the binding does; when the binding is removed due to exit from the construct that made it, the previous or global binding is reexposed as usual, and the variable is no longer void unless the newly reexposed binding was void all along.

```
(setq x 1)               ; Put a value in the global binding.
     => 1
(let ((x 2))             ; Locally bind it.
  (makunbound 'x)        ; Void the local binding.
  x)
error--> Symbol's value as variable is void: x
x                        ; The global binding is unchanged.
     => 1

(let ((x 2))             ; Locally bind it.
  (let ((x 3))           ; And again.
    (makunbound 'x)      ; Void the innermost-local binding.
    x))                  ; And refer: it's void.
```

```
error--> Symbol's value as variable is void: x

(let ((x 2))
  (let ((x 3))
    (makunbound 'x))     ; Void inner binding, then remove it.
  x)                     ; Now outer let binding is visible.
     => 2
```

A variable that has been made void with `makunbound` is indistinguishable from one that has never received a value and has always been void.

You can use the function `boundp` to test whether a variable is currently void.

Function: **boundp** *variable*

`boundp` returns `t` if variable (a symbol) is not void; more precisely, if its current binding is not void. It returns `nil` otherwise.

```
(boundp 'abracadabra)          ; Starts out void.
     => nil
(let ((abracadabra 5))         ; Locally bind it.
  (boundp 'abracadabra))
     => t
(boundp 'abracadabra)          ; Still globally void.
     => nil
(setq abracadabra 5)           ; Make it globally nonvoid.
     => 5
(boundp 'abracadabra)
     => t
```

Defining Global Variables

You may announce your intention to use a symbol as a global variable with a definition, using `defconst` or `defvar`.

In Emacs Lisp, definitions serve three purposes. First, they inform the user who reads the code that certain symbols are *intended* to be used as variables. Second, they inform the Lisp system of these things, supplying a value and documentation. Third, they provide information to utilities such as `etags` and `make-docfile`, which create data bases of the functions and variables in a program.

The difference between `defconst` and `defvar` is primarily a matter of intent, serving to inform human readers of whether programs will change the variable. Emacs Lisp does not restrict the ways in which a variable can be used based on `defconst` or `defvar` declarations. However, it also makes a difference for initialization: `defconst` unconditionally initializes the variable, while `defvar` initializes it only if it is void.

One would expect user option variables to be defined with `defconst`, since programs do not change

them. Unfortunately, this has bad results if the definition is in a library that is not preloaded: `defcu` would override any prior value when the library is loaded. Users would like to be able to set the opti their init files, and override the default value given in the definition. For this reason, user options must be defined with `defvar`.

Special Form: **defvar** *symbol [value [doc-string]]*

This special form informs a person reading your code that symbol will be used as a variable that the programs are likely to set or change. It is also used for all user option variables except in the preloaded parts of Emacs. Note that symbol is not evaluated; the symbol to be defined must appear explicitly in the `defvar`.

If symbol already has a value (i.e., it is not void), value is not even evaluated, and symbol's value remains unchanged. If symbol is void and value is specified, it is evaluated and symbol is set to the result. (If value is not specified, the value of symbol is not changed in any case.)

If symbol has a buffer-local binding in the current buffer, `defvar` sets the default value, not the local value.

If the doc-string argument appears, it specifies the documentation for the variable. (This opportunity to specify documentation is one of the main benefits of defining the variable.) The documentation is stored in the symbol's `variable-documentation` property. The Emacs help functions (see section Documentation) look for this property.

If the first character of doc-string is `*', it means that this variable is considered to be a user option. This affects commands such as `set-variable` and `edit-options`.

For example, this form defines `foo` but does not set its value:

```
(defvar foo)
     => foo
```

The following example sets the value of `bar` to `23`, and gives it a documentation string:

```
(defvar bar 23
  "The normal weight of a bar.")
     => bar
```

The following form changes the documentation string for `bar`, making it a user option, but does not change the value, since `bar` already has a value. (The addition `(1+ 23)` is not even performed.)

```
(defvar bar (1+ 23)
  "*The normal weight of a bar.")
     => bar
bar
     => 23
```

Here is an equivalent expression for the `defvar` special form:

```
(defvar symbol value doc-string)
==
(progn
  (if (not (boundp 'symbol))
      (setq symbol value))
  (put 'symbol 'variable-documentation 'doc-string)
  'symbol)
```

The `defvar` form returns symbol, but it is normally used at top level in a file where its value does not matter.

Special Form: **defconst** *symbol [value [doc-string]]*

This special form informs a person reading your code that symbol has a global value, established here, that will not normally be changed or locally bound by the execution of the program. The user, however, may be welcome to change it. Note that symbol is not evaluated; the symbol to be defined must appear explicitly in the `defconst`.

`defconst` always evaluates value and sets the global value of symbol to the result, provided value is given. If symbol has a buffer-local binding in the current buffer, `defconst` sets the default value, not the local value.

Please note: don't use `defconst` for user option variables in libraries that are not normally loaded. The user should be able to specify a value for such a variable in the `` `.emacs' `` file, so that it will be in effect if and when the library is loaded later.

Here, `pi` is a constant that presumably ought not to be changed by anyone (attempts by the Indiana State Legislature notwithstanding). As the second form illustrates, however, this is only advisory.

```
(defconst pi 3 "Pi to one place.")
     => pi
(setq pi 4)
     => pi
pi
     => 4
```

Function: **user-variable-p** *variable*

This function returns `t` if variable is a user option, intended to be set by the user for customization, `nil` otherwise. (Variables other than user options exist for the internal purposes of Lisp programs, and users need not know about them.)

User option variables are distinguished from other variables by the first character of the `variable-documentation` property. If the property exists and is a string, and its first character is `*', then the variable is a user option.

Note that if the `defconst` and `defvar` special forms are used while the variable has a local binding, the local binding's value is set, and the global binding is not changed. This would be confusing. But the

normal way to use these special forms is at top level in a file, where no local binding should be in eff

Accessing Variable Values

The usual way to reference a variable is to write the symbol which names it (see section Symbol Forms). This requires you to specify the variable name when you write the program. Usually that is exactly what you want to do. Occasionally you need to choose at run time which variable to reference; then you can use `symbol-value`.

Function: **symbol-value** *symbol*

This function returns the value of symbol. This is the value in the innermost local binding of the symbol, or its global value if it has no local bindings.

```
(setq abracadabra 5)
     => 5
(setq foo 9)
     => 9

;; Here the symbol abracadabra
;;   is the symbol whose value is examined.
(let ((abracadabra 'foo))
  (symbol-value 'abracadabra))
     => foo

;; Here the value of abracadabra,
;;   which is foo,
;;   is the symbol whose value is examined.
(let ((abracadabra 'foo))
  (symbol-value abracadabra))
     => 9

(symbol-value 'abracadabra)
     => 5
```

A `void-variable` error is signaled if symbol has neither a local binding nor a global value.

How to Alter a Variable Value

The usual way to change the value of a variable is with the special form `setq`. When you need to compute the choice of variable at run time, use the function `set`.

Special Form: **setq** *[symbol form]...*

This special form is the most common method of changing a variable's value. Each symbol is given a

new value, which is the result of evaluating the corresponding form. The most-local existing binding of the symbol is changed.

The value of the `setq` form is the value of the last form.

```
(setq x (1+ 2))
     => 3
x                    ; x now has a global value.
     => 3
(let ((x 5))
  (setq x 6)         ; The local binding of x is set.
  x)
     => 6
x                    ; The global value is unchanged.
     => 3
```

Note that the first form is evaluated, then the first symbol is set, then the second form is evaluated, then the second symbol is set, and so on:

```
(setq x 10           ; Notice that x is set before
      y (1+ x))      ;   the value of y is computed.
     => 11
```

Function: **set** *symbol value*

This function sets symbol's value to value, then returns value. Since `set` is a function, the expression written for symbol is evaluated to obtain the symbol to be set.

The most-local existing binding of the variable is the binding that is set; shadowed bindings are not affected. If symbol is not actually a symbol, a `wrong-type-argument` error is signaled.

```
(set one 1)
error--> Symbol's value as variable is void: one
(set 'one 1)
     => 1
(set 'two 'one)
     => one
(set two 2)          ; two evaluates to symbol one.
     => 2
one                  ; So it is one that was set.
     => 2
(let ((one 1))       ; This binding of one is set,
  (set 'one 3)       ;   not the global value.
  one)
     => 3
one
     => 2
```

Logically speaking, `set` is a more fundamental primitive that `setq`. Any use of `setq` can be trivially rewritten to use `set`; `setq` could even be defined as a macro, given the availability of `set`. However, `set` itself is rarely used; beginners hardly need to know about it. It is needed only when the choice of variable to be set is made at run time. For example, the command `set-variable`, which reads a variable name from the user and then sets the variable, needs to use `set`.

> **Common Lisp note:** in Common Lisp, `set` always changes the symbol's special value, ignoring any lexical bindings. In Emacs Lisp, all variables and all bindings are special, so `set` always affects the most local existing binding.

Scoping Rules for Variable Bindings

A given symbol `foo` may have several local variable bindings, established at different places in the Lisp program, as well as a global binding. The most recently established binding takes precedence over the others.

Local bindings in Emacs Lisp have indefinite scope and dynamic extent. Scope refers to *where* textually in the source code the binding can be accessed. Indefinite scope means that any part of the program can potentially access the variable binding. Extent refers to *when*, as the program is executing, the binding exists. Dynamic extent means that the binding lasts as long as the activation of the construct that established it.

The combination of dynamic extent and indefinite scope is called dynamic scoping. By contrast, most programming languages use lexical scoping, in which references to a local variable must be textually within the function or block that binds the variable.

> **Common Lisp note:** variables declared "special" in Common Lisp are dynamically scoped like variables in Emacs Lisp.

Scope

Emacs Lisp uses indefinite scope for local variable bindings. This means that any function anywhere in the program text might access a given binding of a variable. Consider the following function definitions:

```
(defun binder (x)   ; x is bound in binder.
  (foo 5))          ; foo is some other function.

(defun user ()      ; x is used in user.
  (list x))
```

In a lexically scoped language, the binding of `x` from `binder` would never be accessible in `user`, because `user` is not textually contained within the function `binder`. However, in dynamically scoped Emacs Lisp, `user` may or may not refer to the binding of `x` established in `binder`, depending on circumstances:

- If we call `user` directly without calling `binder` at all, then whatever binding of `x` is found, it cannot come from `binder`.

- If we define `foo` as follows and call `binder`, then the binding made in `binder` will be seen in `user`:

```
(defun foo (lose)
  (user))
```

- If we define `foo` as follows and call `binder`, then the binding made in `binder` *will not* be seen in `user`:

```
(defun foo (x)
  (user))
```

  Here, when `foo` is called by `binder`, it binds `x`. (The binding in `foo` is said to shadow the one made in `binder`.) Therefore, `user` will access the `x` bound by `foo` instead of the one bound by `binder`.

Extent

Extent refers to the time during program execution that a variable name is valid. In Emacs Lisp, a variable is valid only while the form that bound it is executing. This is called dynamic extent. "Local" or "automatic" variables in most languages, including C and Pascal, have dynamic extent.

One alternative to dynamic extent is indefinite extent. This means that a variable binding can live on past the exit from the form that made the binding. Common Lisp and Scheme, for example, support this, but Emacs Lisp does not.

To illustrate this, the function below, `make-add`, returns a function that purports to add n to its own argument m. This would work in Common Lisp, but it does not work as intended in Emacs Lisp, because after the call to `make-add` exits, the variable `n` is no longer bound to the actual argument 2.

```
(defun make-add (n)
    (function (lambda (m) (+ n m))))  ; Return a function.
     => make-add
(fset 'add2 (make-add 2))  ; Define function add2
                           ;   with (make-add 2).
     => (lambda (m) (+ n m))
(add2 4)                   ; Try to add 2 to 4.
error--> Symbol's value as variable is void: n
```

Implementation of Dynamic Scoping

A simple sample implementation (which is not how Emacs Lisp actually works) may help you understand dynamic binding. This technique is called deep binding and was used in early Lisp systems.

Suppose there is a stack of bindings: variable-value pairs. At entry to a function or to a `let` form, we can push bindings on the stack for the arguments or local variables created there. We can pop those bindings from the stack at exit from the binding construct.

We can find the value of a variable by searching the stack from top to bottom for a binding for that variable; the value from that binding is the value of the variable. To set the variable, we search for the current binding, then store the new value into that binding.

As you can see, a function's bindings remain in effect as long as it continues execution, even during its calls to other functions. That is why we say the extent of the binding is dynamic. And any other function can refer to the bindings, if it uses the same variables while the bindings are in effect. That is why we say the scope is indefinite.

The actual implementation of variable scoping in GNU Emacs Lisp uses a technique called shallow binding. Each variable has a standard place in which its current value is always found--the value cell of the symbol.

In shallow binding, setting the variable works by storing a value in the value cell. When a new local binding is created, the local value is stored in the value cell, and the old value (belonging to a previous binding) is pushed on a stack. When a binding is eliminated, the old value is popped off the stack and stored in the value cell.

We use shallow binding because it has the same results as deep binding, but runs faster, since there is never a need to search for a binding.

Proper Use of Dynamic Scoping

Binding a variable in one function and using it in another is a powerful technique, but if used without restraint, it can make programs hard to understand. There are two clean ways to use this technique:

- Use or bind the variable only in a few related functions, written close together in one file. Such a variable is used for communication within one program.

  You should write comments to inform other programmers that they can see all uses of the variable before them, and to advise them not to add uses elsewhere.
- Give the variable a well-defined, documented meaning, and make all appropriate functions refer to it (but not bind it or set it) wherever that meaning is relevant. For example, the variable `case-fold-search` is defined as "non-`nil` means ignore case when searching"; various search and replace functions refer to it directly or through their subroutines, but do not bind or set it.

  Then you can bind the variable in other programs, knowing reliably what the effect will be.

Buffer-Local Variables

Global and local variable bindings are found in most programming languages in one form or another. Emacs also supports another, unusual kind of variable binding: buffer-local bindings, which apply only to one buffer. Emacs Lisp is meant for programming editing commands, and having different values for a variable in different buffers is an important customization method.

Introduction to Buffer-Local Variables

A buffer-local variable has a buffer-local binding associated with a particular buffer. The binding is in effect when that buffer is current; otherwise, it is not in effect. If you set the variable while a buffer-local binding is in effect, the new value goes in that binding, so the global binding is unchanged; this means that the change is visible in that buffer alone.

A variable may have buffer-local bindings in some buffers but not in others. The global binding is shared by all the buffers that don't have their own bindings. Thus, if you set the variable in a buffer that does not have a buffer-local binding for it, the new value is visible in all buffers except those with buffer-local bindings. (Here we are assuming that there are no `let`-style local bindings to complicate the issue.)

The most common use of buffer-local bindings is for major modes to change variables that control the behavior of commands. For example, C mode and Lisp mode both set the variable `paragraph-start` to specify that only blank lines separate paragraphs. They do this by making the variable buffer-local in the buffer that is being put into C mode or Lisp mode, and then setting it to the new value for that mode.

The usual way to make a buffer-local binding is with `make-local-variable`, which is what major mode commands use. This affects just the current buffer; all other buffers (including those yet to be created) continue to share the global value.

A more powerful operation is to mark the variable as automatically buffer-local by calling `make-variable-buffer-local`. You can think of this as making the variable local in all buffers, even those yet to be created. More precisely, the effect is that setting the variable automatically makes the variable local to the current buffer if it is not already so. All buffers start out by sharing the global value of the variable as usual, but any `setq` creates a buffer-local binding for the current buffer. The new value is stored in the buffer-local binding, leaving the (default) global binding untouched. The global value can no longer be changed with `setq`; you need to use `setq-default` to do that.

Warning: when a variable has local values in one or more buffers, you can get Emacs very confused by binding the variable with `let`, changing to a different current buffer in which a different binding is in effect, and then exiting the `let`. To preserve your sanity, it is wise to avoid such situations. If you use `save-excursion` around each piece of code that changes to a different current buffer, you will not have this problem. Here is an example of incorrect code:

```
(setq foo 'b)
(set-buffer "a")
(make-local-variable 'foo)
(setq foo 'a)
(let ((foo 'temp))
  (set-buffer "b")
  ...)
foo => 'a       ; The old buffer-local value from buffer `a'
                ;   is now the default value.
(set-buffer "a")
foo => 'temp    ; The local value that should be gone
                ;   is now the buffer-local value in buffer `a'.
```

But `save-excursion` as shown here avoids the problem:

```
(let ((foo 'temp))
  (save-excursion
    (set-buffer "b")
    ...))
```

Local variables in a file you edit are also represented by buffer-local bindings for the buffer that holds the file within Emacs. See section How Emacs Chooses a Major Mode.

Creating and Destroying Buffer-local Bindings

Command: **make-local-variable** *variable*

This function creates a buffer-local binding in the current buffer for variable (a symbol). Other buffers are not affected. The value returned is variable.

The buffer-local value of variable starts out as the same value variable previously had. If variable was void, it remains void.

```
;; In buffer `b1':
(setq foo 5)                ; Affects all buffers.
     => 5
(make-local-variable 'foo)  ; Now it is local in `b1'.
     => foo
foo                         ; That did not change
     => 5                   ;   the value.
(setq foo 6)                ; Change the value
     => 6                   ;   in `b1'.
foo
     => 6

;; In buffer `b2', the value hasn't changed.
(save-excursion
  (set-buffer "b2")
  foo)
     => 5
```

Command: **make-variable-buffer-local** *variable*

This function marks variable (a symbol) automatically buffer-local, so that any attempt to set it will make it local to the current buffer at the time.

The value returned is variable.

Function: **buffer-local-variables** *&optional buffer*

This function tells you what the buffer-local variables are in buffer buffer. It returns an association li
(see section Association Lists) in which each association contains one buffer-local variable and its va
If buffer is omitted, the current buffer is used.

```
(setq lcl (buffer-local-variables))
=> ((fill-column . 75)
    (case-fold-search . t)
    ...
    (mark-ring #<marker at 5454 in buffers.texi>)
    (require-final-newline . t))
```

Note that storing new values into the CDRs of the elements in this list does *not* change the local values of the variables.

Command: **kill-local-variable** *variable*

This function deletes the buffer-local binding (if any) for variable (a symbol) in the current buffer. As a result, the global (default) binding of variable becomes visible in this buffer. Usually this results in a change in the value of variable, since the global value is usually different from the buffer-local value just eliminated.

It is possible to kill the local binding of a variable that automatically becomes local when set. This causes the variable to show its global value in the current buffer. However, if you set the variable again, this will once again create a local value.

`kill-local-variable` returns variable.

Function: **kill-all-local-variables**

This function eliminates all the buffer-local variable bindings of the current buffer except for variables marker as "permanent". As a result, the buffer will see the default values of most variables.

This function also resets certain other information pertaining to the buffer: its local keymap is set to `nil`, its syntax table is set to the value of `standard-syntax-table`, and its abbrev table is set to the value of `fundamental-mode-abbrev-table`.

Every major mode command begins by calling this function, which has the effect of switching to Fundamental mode and erasing most of the effects of the previous major mode. To ensure that this does its job, the variables that major modes set should not be marked permanent.

`kill-all-local-variables` returns `nil`.

A local variable is permanent if the variable name (a symbol) has a `permanent-local` property that is non-`nil`. Permanent locals are appropriate for data pertaining to where the file came from or how to save it, rather than with how to edit the contents.

The Default Value of a Buffer-Local Variable

The global value of a variable with buffer-local bindings is also called the default value, because it is the value that is in effect except when specifically overridden.

The functions `default-value` and `setq-default` allow you to access and change the default value regardless of whether the current buffer has a buffer-local binding. For example, you could use `setq-default` to change the default setting of `paragraph-start` for most buffers; and this would work even when you are in a C or Lisp mode buffer which has a buffer-local value for this variable.

The special forms `defvar` and `defconst` also set the default value (if they set the variable at all), rather than any local value.

Function: **default-value** *symbol*

This function returns symbol's default value. This is the value that is seen in buffers that do not have their own values for this variable. If symbol is not buffer-local, this is equivalent to `symbol-value` (see section Accessing Variable Values).

Function: **default-boundp** *variable*

The function `default-boundp` tells you whether variable's default value is nonvoid. If `(default-boundp 'foo)` returns `nil`, then `(default-value 'foo)` would get an error.

`default-boundp` is to `default-value` as `boundp` is to `symbol-value`.

Special Form: **setq-default** *symbol value*

This sets the default value of symbol to value. symbol is not evaluated, but value is. The value of the `setq-default` form is value.

If a symbol is not buffer-local for the current buffer, and is not marked automatically buffer-local, this has the same effect as `setq`. If symbol is buffer-local for the current buffer, then this changes the value that other buffers will see (as long as they don't have a buffer-local value), but not the value that the current buffer sees.

```
;; In buffer `foo':
(make-local-variable 'local)
     => local
(setq local 'value-in-foo)
     => value-in-foo
(setq-default local 'new-default)
     => new-default
local
     => value-in-foo
(default-value 'local)
     => new-default

;; In (the new) buffer `bar':
```

```
local
     => new-default
(default-value 'local)
     => new-default
(setq local 'another-default)
     => another-default
(default-value 'local)
     => another-default

;; Back in buffer `foo':
local
     => value-in-foo
(default-value 'local)
     => another-default
```

Function: **set-default** *symbol value*

This function is like `setq-default`, except that symbol is evaluated.

```
(set-default (car '(a b c)) 23)
     => 23
(default-value 'a)
     => 23
```

Functions

A Lisp program is composed mainly of Lisp functions. This chapter explains what functions are, how they accept arguments, and how to define them.

What Is a Function?

In a general sense, a function is a rule for carrying on a computation given several values called arguments. The result of the computation is called the value of the function. The computation can also have side effects: lasting changes in the values of variables or the contents of data structures.

Here are important terms for functions in Emacs Lisp and for other function-like objects.

function

In Emacs Lisp, a function is anything that can be applied to arguments in a Lisp program. In some cases, we use it more specifically to mean a function written in Lisp. Special forms and macros are not functions.

primitive

A primitive is a function callable from Lisp that is written in C, such as `car` or `append`. These functions are also called built-in functions or subrs. (Special forms are also considered primitives.)

Usually the reason that a function is a primitives is because it is fundamental, or provides a low-level interface to operating system services, or because it needs to run fast. Primitives can be modified or added only by changing the C sources and recompiling the editor. See section Writing Emacs Primitives.

lambda expression

A lambda expression is a function written in Lisp. These are described in the following section.

special form

A special form is a primitive that is like a function but does not evaluate all of its arguments in the usual way. It may evaluate only some of the arguments, or may evaluate them in an unusual order, or several times. Many special forms are described in section Control Structures.

macro

A macro is a construct defined in Lisp by the programmer. It differs from a function in that it translates a Lisp expression that you write into an equivalent expression to be evaluated instead of the original expression. See section Macros, for how to define and use macros.

command

A command is an object that `command-execute` can invoke; it is a possible definition for a key sequence. Some functions are commands; a function written in Lisp is a command if it contains an interactive declaration (see section Defining Commands). Such a function can be called from Lisp

expressions like other functions; in this case, the fact that the function is a command makes no difference.

Strings are commands also, even though they are not functions. A symbol is a command if its function definition is a command; such symbols can be invoked with M-x. The symbol is a function as well if the definition is a function. See section Command Loop Overview.

keystroke command

A keystroke command is a command that is bound to a key sequence (typically one to three keystrokes). The distinction is made here merely to avoid confusion with the meaning of "command" in non-Emacs editors; for programmers, the distinction is normally unimportant.

byte-code function

A byte-code function is a function that has been compiled by the byte compiler. See section Byte-Code Function Type.

Function: **subrp** *object*

This function returns `t` if object is a built-in function (i.e. a Lisp primitive).

```
(subrp 'message)            ; message is a symbol,
     => nil                 ;   not a subr object.
(subrp (symbol-function 'message))
     => t
```

Function: **byte-code-function-p** *object*

This function returns `t` if object is a byte-code function. For example:

```
(byte-code-function-p (symbol-function 'next-line))
     => t
```

Lambda Expressions

A function written in Lisp is a list that looks like this:

```
(lambda (arg-variables...)
  [documentation-string]
  [interactive-declaration]
  body-forms...)
```

(Such a list is called a lambda expression for historical reasons, even though it is not really an expression at all--it is not a form that can be evaluated meaningfully.)

Components of a Lambda Expression

The first element of a lambda expression is always the symbol `lambda`. This indicates that the list represents a function. The reason functions are defined to start with `lambda` is so that other lists, intended for other uses, will not accidentally be valid as functions.

The second element is a list of argument variable names (symbols). This is called the lambda list. When a Lisp function is called, the argument values are matched up against the variables in the lambda list, which are given local bindings with the values provided. See section Local Variables.

The documentation string is an actual string that serves to describe the function for the Emacs help facilities. See section Documentation Strings of Functions.

The interactive declaration is a list of the form `(interactive code-string)`. This declares how to provide arguments if the function is used interactively. Functions with this declaration are called commands; they can be called using M-x or bound to a key. Functions not intended to be called in this way should not have interactive declarations. See section Defining Commands, for how to write an interactive declaration.

The rest of the elements are the body of the function: the Lisp code to do the work of the function (or, as a Lisp programmer would say, "a list of Lisp forms to evaluate"). The value returned by the function is the value returned by the last element of the body.

A Simple Lambda-Expression Example

Consider for example the following function:

```
(lambda (a b c) (+ a b c))
```

We can call this function by writing it as the CAR of an expression, like this:

```
((lambda (a b c) (+ a b c))
 1 2 3)
```

The body of this lambda expression is evaluated with the variable `a` bound to 1, `b` bound to 2, and `c` bound to 3. Evaluation of the body adds these three numbers, producing the result 6; therefore, this call to the function returns the value 6.

Note that the arguments can be the results of other function calls, as in this example:

```
((lambda (a b c) (+ a b c))
 1 (* 2 3) (- 5 4))
```

Here all the arguments `1`, `(* 2 3)`, and `(- 5 4)` are evaluated, left to right. Then the lambda expression is applied to the argument values 1, 6 and 1 to produce the value 8.

It is not often useful to write a lambda expression as the CAR of a form in this way. You can get the

same result, of making local variables and giving them values, using the special form `let` (see sectio Local Variables). And `let` is clearer and easier to use. In practice, lambda expressions are either sto as the function definitions of symbols, to produce named functions, or passed as arguments to other functions (see section Anonymous Functions).

However, calls to explicit lambda expressions were very useful in the old days of Lisp, before the special form `let` was invented. At that time, they were the only way to bind and initialize local variables.

Advanced Features of Argument Lists

Our simple sample function, `(lambda (a b c) (+ a b c))`, specifies three argument variables, so it must be called with three arguments: if you try to call it with only two arguments or four arguments, you get a `wrong-number-of-arguments` error.

It is often convenient to write a function that allows certain arguments to be omitted. For example, the function `substring` accepts three arguments--a string, the start index and the end index--but the third argument defaults to the end of the string if you omit it. It is also convenient for certain functions to accept an indefinite number of arguments, as the functions `and` and `+` do.

To specify optional arguments that may be omitted when a function is called, simply include the keyword `&optional` before the optional arguments. To specify a list of zero or more extra arguments, include the keyword `&rest` before one final argument.

Thus, the complete syntax for an argument list is as follows:

```
(required-vars...
 [&optional optional-vars...]
 [&rest rest-var])
```

The square brackets indicate that the `&optional` and `&rest` clauses, and the variables that follow them, are optional.

A call to the function requires one actual argument for each of the required-vars. There may be actual arguments for zero or more of the optional-vars, and there cannot be any more actual arguments than these unless `&rest` exists. In that case, there may be any number of extra actual arguments.

If actual arguments for the optional and rest variables are omitted, then they always default to `nil`. However, the body of the function is free to consider `nil` an abbreviation for some other meaningful value. This is what `substring` does; `nil` as the third argument means to use the length of the string supplied. There is no way for the function to distinguish between an explicit argument of `nil` and an omitted argument.

> **Common Lisp note:** Common Lisp allows the function to specify what default value to use when an optional argument is omitted; GNU Emacs Lisp always uses `nil`.

For example, an argument list that looks like this:

```
(a b &optional c d &rest e)
```

binds `a` and `b` to the first two actual arguments, which are required. If one or two more arguments are provided, `c` and `d` are bound to them respectively; any arguments after the first four are collected into a list and `e` is bound to that list. If there are only two arguments, `c` is `nil`; if two or three arguments, `d` is `nil`; if four arguments or fewer, `e` is `nil`.

There is no way to have required arguments following optional ones--it would not make sense. To see why this must be so, suppose that `c` in the example were optional and `d` were required. If three actual arguments are given; then which variable would the third argument be for? Similarly, it makes no sense to have any more arguments (either required or optional) after a `&rest` argument.

Here are some examples of argument lists and proper calls:

```
((lambda (n) (1+ n))                    ; One required:
 1)                                     ; requires exactly one argument.
     => 2
((lambda (n &optional n1)               ; One required and one optional:
         (if n1 (+ n n1) (1+ n)))       ; 1 or 2 arguments.
 1 2)
     => 3
((lambda (n &rest ns)                   ; One required and one rest:
         (+ n (apply '+ ns)))           ; 1 or more arguments.
 1 2 3 4 5)
     => 15
```

Documentation Strings of Functions

A lambda expression may optionally have a documentation string just after the lambda list. This string does not affect execution of the function; it is a kind of comment, but a systematized comment which actually appears inside the Lisp world and can be used by the Emacs help facilities. See section Documentation, for how the documentation-string is accessed.

It is a good idea to provide documentation strings for all commands, and for all other functions in your program that users of your program should know about; internal functions might as well have only comments, since comments don't take up any room when your program is loaded.

The first line of the documentation string should stand on its own, because `apropos` displays just this first line. It should consist of one or two complete sentences that summarize the function's purpose.

The start of the documentation string is usually indented, but since these spaces come before the starting double-quote, they are not part of the string. Some people make a practice of indenting any additional lines of the string so that the text lines up. *This is a mistake.* The indentation of the following lines is inside the string; what looks nice in the source code will look ugly when displayed by the help commands.

You may wonder how the documentation string could be optional, since there are required components of the function that follow it (the body). Since evaluation of a string returns that string, without any side effects, it has no effect if it is not the last form in the body. Thus, in practice, there is no confusion

between the first form of the body and the documentation string; if the only body form is a string the serves both as the return value and as the documentation.

Naming a Function

In most computer languages, every function has a name; the idea of a function without a name is nonsensical. In Lisp, a function in the strictest sense has no name. It is simply a list whose first element is `lambda`, or a primitive subr-object.

However, a symbol can serve as the name of a function. This happens when you put the function in the symbol's function cell (see section Symbol Components). Then the symbol itself becomes a valid, callable function, equivalent to the list or subr-object that its function cell refers to. The contents of the function cell are also called the symbol's function definition. When the evaluator finds the function definition to use in place of the symbol, we call that symbol function indirection; see section Symbol Function Indirection.

In practice, nearly all functions are given names in this way and referred to through their names. For example, the symbol `car` works as a function and does what it does because the primitive subr-object `#<subr car>` is stored in its function cell.

We give functions names because it is more convenient to refer to them by their names in other functions. For primitive subr-objects such as `#<subr car>`, names are the only way you can refer to them: there is no read syntax for such objects. For functions written in Lisp, the name is more convenient to use in a call than an explicit lambda expression. Also, a function with a name can refer to itself--it can be recursive. Writing the function's name in its own definition is much more convenient than making the function definition point to itself (something that is not impossible but that has various disadvantages in practice).

Functions are often identified with the symbols used to name them. For example, we often speak of "the function `car`", not distinguishing between the symbol `car` and the primitive subr-object that is its function definition. For most purposes, there is no need to distinguish.

Even so, keep in mind that a function need not have a unique name. While a given function object *usually* appears in the function cell of only one symbol, this is just a matter of convenience. It is easy to store it in several symbols using `fset`; then each of the symbols is equally well a name for the same function.

A symbol used as a function name may also be used as a variable; these two uses of a symbol are independent and do not conflict.

Defining Named Functions

We usually give a name to a function when it is first created. This is called defining a function, and it is done with the `defun` special form.

Special Form: **defun** *name argument-list body-forms*

`defun` is the usual way to define new Lisp functions. It defines the symbol name as a function that l like this:

```
(lambda argument-list . body-forms)
```

This lambda expression is stored in the function cell of name. The value returned by evaluating the `defun` form is name, but usually we ignore this value.

As described previously (see section Lambda Expressions), argument-list is a list of argument names and may include the keywords `&optional` and `&rest`. Also, the first two forms in body-forms may be a documentation string and an interactive declaration.

Note that the same symbol name may also be used as a global variable, since the value cell is independent of the function cell.

Here are some examples:

```
(defun foo () 5)
     => foo
(foo)
     => 5

(defun bar (a &optional b &rest c)
    (list a b c))
     => bar
(bar 1 2 3 4 5)
     => (1 2 (3 4 5))
(bar 1)
     => (1 nil nil)
(bar)
error--> Wrong number of arguments.

(defun capitalize-backwards ()
  "Upcase the last letter of a word."
  (interactive)
  (backward-word 1)
  (forward-word 1)
  (backward-char 1)
  (capitalize-word 1))
     => capitalize-backwards
```

Be careful not to redefine existing functions unintentionally. `defun` redefines even primitive functions such as `car` without any hesitation or notification. Redefining a function already defined is often done deliberately, and there is no way to distinguish deliberate redefinition from unintentional redefinition.

Calling Functions

Defining functions is only half the battle. Functions don't do anything until you call them, i.e., tell them to run. This process is also known as invocation.

The most common way of invoking a function is by evaluating a list. For example, evaluating the list `(concat "a" "b")` calls the function `concat`. See section Evaluation, for a description of evaluation.

When you write a list as an expression in your program, the function name is part of the program. This means that the choice of which function to call is made when you write the program. Usually that's just what you want. Occasionally you need to decide at run time which function to call. Then you can use the functions `funcall` and `apply`.

Function: **funcall** *function &rest arguments*

`funcall` calls function with arguments, and returns whatever function returns.

Since `funcall` is a function, all of its arguments, including function, are evaluated before `funcall` is called. This means that you can use any expression to obtain the function to be called. It also means that `funcall` does not see the expressions you write for the arguments, only their values. These values are *not* evaluated a second time in the act of calling function; `funcall` enters the normal procedure for calling a function at the place where the arguments have already been evaluated.

The argument function must be either a Lisp function or a primitive function. Special forms and macros are not allowed, because they make sense only when given the "unevaluated" argument expressions. `funcall` cannot provide these because, as we saw above, it never knows them in the first place.

```
(setq f 'list)
     => list
(funcall f 'x 'y 'z)
     => (x y z)
(funcall f 'x 'y '(z))
     => (x y (z))
(funcall 'and t nil)
error--> Invalid function: #<subr and>
```

Compare this example with that of `apply`.

Function: **apply** *function &rest arguments*

`apply` calls function with arguments, just like `funcall` but with one difference: the last of arguments is a list of arguments to give to function, rather than a single argument. We also say that this list is appended to the other arguments.

`apply` returns the result of calling function. As with `funcall`, function must either be a Lisp function or a primitive function; special forms and macros do not make sense in `apply`.

```
(setq f 'list)
     => list
(apply f 'x 'y 'z)
error--> Wrong type argument: listp, z
(apply '+ 1 2 '(3 4))
     => 10
(apply '+ '(1 2 3 4))
     => 10

(apply 'append '((a b c) nil (x y z) nil))
     => (a b c x y z)
```

An interesting example of using `apply` is found in the description of `mapcar`; see the following section.

It is common for Lisp functions to accept functions as arguments or find them in data structures (especially in hook variables and property lists) and call them using `funcall` or `apply`. Functions that accept function arguments are often called functionals.

Sometimes, when you call such a function, it is useful to supply a no-op function as the argument. Here are two different kinds of no-op function:

Function: **identity** *arg*

This function returns arg and has no side effects.

Function: **ignore** *&rest args*

This function ignores any arguments and returns `nil`.

Mapping Functions

A mapping function applies a given function to each element of a list or other collection. Emacs Lisp has three such functions; `mapcar` and `mapconcat`, which scan a list, are described here. For the third mapping function, `mapatoms`, see section Creating and Interning Symbols.

Function: **mapcar** *function sequence*

`mapcar` applies function to each element of sequence in turn. The results are made into a `nil`-terminated list.

The argument sequence may be a list, a vector or a string. The result is always a list. The length of the result is the same as the length of sequence.

```
For example:

(mapcar 'car '((a b) (c d) (e f)))
     => (a c e)
```

```
(mapcar '1+ [1 2 3])
     => (2 3 4)
(mapcar 'char-to-string "abc")
     => ("a" "b" "c")

;; Call each function in my-hooks.
(mapcar 'funcall my-hooks)

(defun mapcar* (f &rest args)
  "Apply FUNCTION to successive cars of all ARGS, until one ends.
Return the list of results."
  ;; If no list is exhausted,
  (if (not (memq 'nil args))
      ;; Apply function to CARs.
      (cons (apply f (mapcar 'car args))
            (apply 'mapcar* f
                   ;; Recurse for rest of elements.
                   (mapcar 'cdr args)))))

(mapcar* 'cons '(a b c) '(1 2 3 4))
     => ((a . 1) (b . 2) (c . 3))
```

Function: **mapconcat** *function sequence separator*

`mapconcat` applies function to each element of sequence: the results, which must be strings, are concatenated. Between each pair of result strings, `mapconcat` inserts the string separator. Usually separator contains a space or comma or other suitable punctuation.

The argument function must be a function that can take one argument and returns a string.

```
(mapconcat 'symbol-name
           '(The cat in the hat)
           " ")
     => "The cat in the hat"

(mapconcat (function (lambda (x) (format "%c" (1+ x))))
           "HAL-8000"
           "")
     => "IBM.9111"
```

Anonymous Functions

In Lisp, a function is a list that starts with `lambda` (or alternatively a primitive subr-object); names are "extra". Although usually functions are defined with `defun` and given names at the same time, it is occasionally more concise to use an explicit lambda expression--an anonymous function. Such a list is valid wherever a function name is.

Any method of creating such a list makes a valid function. Even this:

```
(setq silly (append '(lambda (x)) (list (list '+ (* 3 4) 'x))))
     => (lambda (x) (+ 12 x))
```

This computes a list that looks like `(lambda (x) (+ 12 x))` and makes it the value (*not* the function definition!) of `silly`.

Here is how we might call this function:

```
(funcall silly 1)
     => 13
```

(It does *not* work to write `(silly 1)`, because this function is not the *function definition* of `silly`. We have not given `silly` any function definition, just a value as a variable.)

Most of the time, anonymous functions are constants that appear in your program. For example, you might want to pass one as an argument to the function `mapcar`, which applies any given function to each element of a list. Here we pass an anonymous function that multiplies a number by two:

```
(defun double-each (list)
  (mapcar '(lambda (x) (* 2 x)) list))
     => double-each
(double-each '(2 11))
     => (4 22)
```

In such cases, we usually use the special form `function` instead of simple quotation to quote the anonymous function.

Special Form: **function** *function-object*

This special form returns function-object without evaluating it. In this, it is equivalent to `quote`. However, it serves as a note to the Emacs Lisp compiler that function-object is intended to be used only as a function, and therefore can safely be compiled. See section Quoting, for comparison.

Using `function` instead of `quote` makes a difference inside a function or macro that you are going to compile. For example:

```
(defun double-each (list)
  (mapcar (function (lambda (x) (* 2 x))) list))
     => double-each
(double-each '(2 11))
     => (4 22)
```

If this definition of `double-each` is compiled, the anonymous function is compiled as well. By contrast, in the previous definition where ordinary `quote` is used, the argument passed to `mapcar` is the precise list shown:

```
(lambda (arg) (+ arg 5))
```

The Lisp compiler cannot assume this list is a function, even though it looks like one, since it does not know what `mapcar` does with the list. Perhaps `mapcar` will check that the CAR of the third element is the symbol `+`! The advantage of `function` is that it tells the compiler to go ahead and compile the constant function.

We sometimes write `function` instead of `quote` when quoting the name of a function, but this usage is just a sort of comment.

```
(function symbol) == (quote symbol) == 'symbol
```

See `documentation` in section Access to Documentation Strings, for a realistic example using `function` and an anonymous function.

Accessing Function Cell Contents

The function definition of a symbol is the object stored in the function cell of the symbol. The functions described here access, test, and set the function cell of symbols.

Function: **symbol-function** *symbol*

This returns the object in the function cell of symbol. If the symbol's function cell is void, a `void-function` error is signaled.

This function does not check that the returned object is a legitimate function.

```
(defun bar (n) (+ n 2))
     => bar
(symbol-function 'bar)
     => (lambda (n) (+ n 2))
(fset 'baz 'bar)
     => bar
(symbol-function 'baz)
     => bar
```

If you have never given a symbol any function definition, we say that that symbol's function cell is void. In other words, the function cell does not have any Lisp object in it. If you try to call such a symbol as a function, it signals a `void-function` error.

Note that void is not the same as `nil` or the symbol `void`. The symbols `nil` and `void` are Lisp objects, and can be stored into a function cell just as any other object can be (and they can be valid functions if you define them in turn with `defun`); but `nil` or `void` is *an object*. A void function cell contains no object whatsoever.

You can test the voidness of a symbol's function definition with `fboundp`. After you have given a

symbol a function definition, you can make it void once more using `fmakunbound`.

Function: **fboundp** *symbol*

Returns `t` if the symbol has an object in its function cell, `nil` otherwise. It does not check that the object is a legitimate function.

Function: **fmakunbound** *symbol*

This function makes symbol's function cell void, so that a subsequent attempt to access this cell will cause a `void-function` error. (See also `makunbound`, in section Local Variables.)

```
(defun foo (x) x)
     => x
(fmakunbound 'foo)
     => x
(foo 1)
error--> Symbol's function definition is void: foo
```

Function: **fset** *symbol object*

This function stores object in the function cell of symbol. The result is object. Normally object should be a function or the name of a function, but this is not checked.

There are three normal uses of this function:

- Copying one symbol's function definition to another. (In other words, making an alternate name for a function.)
- Giving a symbol a function definition that is not a list and therefore cannot be made with `defun`. See section Classification of List Forms, for an example of this usage.
- In constructs for defining or altering functions. If `defun` were not a primitive, it could be written in Lisp (as a macro) using `fset`.

Here are examples of the first two uses:

```
;; Give first the same definition car has.
(fset 'first (symbol-function 'car))
     => #<subr car>
(first '(1 2 3))
     => 1

;; Make the symbol car the function definition of xfirst.
(fset 'xfirst 'car)
     => car
(xfirst '(1 2 3))
     => 1
(symbol-function 'xfirst)
     => car
```

```
(symbol-function (symbol-function 'xfirst))
     => #<subr car>

;; Define a named keyboard macro.
(fset 'kill-two-lines "\^u2\^k")
     => "\^u2\^k"
```

When writing a function that extends a previously defined function, the following idiom is often used:

```
(fset 'old-foo (symbol-function 'foo))

(defun foo ()
  "Just like old-foo, except more so."
  (old-foo)
  (more-so))
```

This does not work properly if `foo` has been defined to autoload. In such a case, when `foo` calls `old-foo`, Lisp attempts to define `old-foo` by loading a file. Since this presumably defines `foo` rather than `old-foo`, it does not produce the proper results. The only way to avoid this problem is to make sure the file is loaded before moving aside the old definition of `foo`.

See also the function `indirect-function` in section Symbol Function Indirection.

Inline Functions

You can define an inline function by using `defsubst` instead of `defun`. An inline function works just like an ordinary function except for one thing: when you compile a call to the function, the function's definition is open-coded into the caller.

Making a function inline makes explicit calls run faster. But it also has disadvantages. For one thing, it reduces flexibility; if you change the definition of the function, calls already inlined still use the old definition until you recompile them.

Another disadvantage is that making a large function inline can increase the size of compiled code both in files and in memory. Since the advantages of inline functions are greatest for small functions, you generally should not make large functions inline.

It's possible to define a macro to expand into the same code that an inline function would execute. But the macro would have a limitation: you can use it only explicitly--a macro cannot be called with `apply`, `mapcar` and so on. Also, it takes some work to convert an ordinary function into a macro. (See section Macros.) To convert it into an inline function is very easy; simply replace `defun` with `defsubst`.

Inline functions can be used and open coded later on in the same file, following the definition, just like macros.

Emacs versions prior to 19 did not have inline functions.

Other Topics Related to Functions

Here is a table of several functions that do things related to function calling and function definitions. They are documented elsewhere, but we provide cross references here.

`apply`
: See section Calling Functions.

`autoload`
: See section Autoload.

`call-interactively`
: See section Interactive Call.

`commandp`
: See section Interactive Call.

`documentation`
: See section Access to Documentation Strings.

`eval`
: See section Eval.

`funcall`
: See section Calling Functions.

`ignore`
: See section Calling Functions.

`indirect-function`
: See section Symbol Function Indirection.

`interactive`
: See section Using `interactive`.

`interactive-p`
: See section Interactive Call.

`mapatoms`
: See section Creating and Interning Symbols.

`mapcar`
: See section Mapping Functions.

`mapconcat`
: See section Mapping Functions.

`undefined`
: See section Key Lookup.

Macros

Macros enable you to define new control constructs and other language features. A macro is defined much like a function, but instead of telling how to compute a value, it tells how to compute another Lisp expression which will in turn compute the value. We call this expression the expansion of the macro.

Macros can do this because they operate on the unevaluated expressions for the arguments, not on the argument values as functions do. They can therefore construct an expansion containing these argument expressions or parts of them.

If you are using a macro to do something an ordinary function could do, just for the sake of speed, consider using an inline function instead. See section Inline Functions.

A Simple Example of a Macro

Suppose we would like to define a Lisp construct to increment a variable value, much like the `++` operator in C. We would like to write `(inc x)` and have the effect of `(setq x (1+ x))`. Here's a macro definition that does the job:

```
(defmacro inc (var)
   (list 'setq var (list '1+ var)))
```

When this is called with `(inc x)`, the argument `var` has the value `x`---*not* the *value* of `x`. The body of the macro uses this to construct the expansion, which is `(setq x (1+ x))`. Once the macro definition returns this expansion, Lisp proceeds to evaluate it, thus incrementing `x`.

Expansion of a Macro Call

A macro call looks just like a function call in that it is a list which starts with the name of the macro. The rest of the elements of the list are the arguments of the macro.

Evaluation of the macro call begins like evaluation of a function call except for one crucial difference: the macro arguments are the actual expressions appearing in the macro call. They are not evaluated before they are given to the macro definition. By contrast, the arguments of a function are results of evaluating the elements of the function call list.

Having obtained the arguments, Lisp invokes the macro definition just as a function is invoked. The argument variables of the macro are bound to the argument values from the macro call, or to a list of them in the case of a `&rest` argument. And the macro body executes and returns its value just as a function body does.

The second crucial difference between macros and functions is that the value returned by the macro body

is not the value of the macro call. Instead, it is an alternate expression for computing that value, also known as the expansion of the macro. The Lisp interpreter proceeds to evaluate the expansion as soon it comes back from the macro.

Since the expansion is evaluated in the normal manner, it may contain calls to other macros. It may even be a call to the same macro, though this is unusual.

You can see the expansion of a given macro call by calling `macroexpand`.

Function: **macroexpand** *form &optional environment*

This function expands form, if it is a macro call. If the result is another macro call, it is expanded in turn, until something which is not a macro call results. That is the value returned by `macroexpand`. If form is not a macro call to begin with, it is returned as given.

Note that `macroexpand` does not look at the subexpressions of form (although some macro definitions may do so). Even if they are macro calls themselves, `macroexpand` does not expand them.

The function `macroexpand` does not expand calls to inline functions. Normally there is no need for that, since a call to an inline function is no harder to understand than a call to an ordinary function.

If environment is provided, it specifies an alist of macro definitions that shadow the currently defined macros. This is used by byte compilation.

```
(defmacro inc (var)
    (list 'setq var (list '1+ var)))
     => inc

(macroexpand '(inc r))
     => (setq r (1+ r))

(defmacro inc2 (var1 var2)
    (list 'progn (list 'inc var1) (list 'inc var2)))
     => inc2

(macroexpand '(inc2 r s))
     => (progn (inc r) (inc s))  ; inc not expanded here.
```

Macros and Byte Compilation

You might ask why we take the trouble to compute an expansion for a macro and then evaluate the expansion. Why not have the macro body produce the desired results directly? The reason has to do with compilation.

When a macro call appears in a Lisp program being compiled, the Lisp compiler calls the macro definition just as the interpreter would, and receives an expansion. But instead of evaluating this expansion, it compiles the expansion as if it had appeared directly in the program. As a result, the

compiled code produces the value and side effects intended for the macro, but executes at full compi speed. This would not work if the macro body computed the value and side effects itself--they woul computed at compile time, which is not useful.

In order for compilation of macro calls to work, the macros must be defined in Lisp when the calls to them are compiled. The compiler has a special feature to help you do this: if a file being compiled contains a `defmacro` form, the macro is defined temporarily for the rest of the compilation of that file. To use this feature, you must define the macro in the same file where it is used and before its first use.

While byte-compiling a file, any `require` calls at top-level are executed. One way to ensure that necessary macro definitions are available during compilation is to require the file that defines them. See section Features.

Defining Macros

A Lisp macro is a list whose CAR is `macro`. Its CDR should be a function; expansion of the macro works by applying the function (with `apply`) to the list of unevaluated argument-expressions from the macro call.

It is possible to use an anonymous Lisp macro just like an anonymous function, but this is never done, because it does not make sense to pass an anonymous macro to mapping functions such as `mapcar`. In practice, all Lisp macros have names, and they are usually defined with the special form `defmacro`.

Special Form: **defmacro** *name argument-list body-forms...*

`defmacro` defines the symbol name as a macro that looks like this:

```
(macro lambda argument-list . body-forms)
```

This macro object is stored in the function cell of name. The value returned by evaluating the `defmacro` form is name, but usually we ignore this value.

The shape and meaning of argument-list is the same as in a function, and the keywords `&rest` and `&optional` may be used (see section Advanced Features of Argument Lists). Macros may have a documentation string, but any `interactive` declaration is ignored since macros cannot be called interactively.

Backquote

It could prove rather awkward to write macros of significant size, simply due to the number of times the function `list` needs to be called. To make writing these forms easier, a macro ``' (often called backquote) exists.

Backquote allows you to quote a list, but selectively evaluate elements of that list. In the simplest case, it is identical to the special form `quote` (see section Quoting). For example, these two forms yield identical results:

```
(` (a list of (+ 2 3) elements))
     => (a list of (+ 2 3) elements)
(quote (a list of (+ 2 3) elements))
     => (a list of (+ 2 3) elements)
```

By inserting a special marker, `,', inside of the argument to backquote, it is possible to evaluate desired portions of the argument:

```
(list 'a 'list 'of (+ 2 3) 'elements)
     => (a list of 5 elements)
(` (a list of (, (+ 2 3)) elements))
     => (a list of 5 elements)
```

It is also possible to have an evaluated list spliced into the resulting list by using the special marker `,@'. The elements of the spliced list become elements at the same level as the other elements of the resulting list. The equivalent code without using ` is often unreadable. Here are some examples:

```
(setq some-list '(2 3))
     => (2 3)
(cons 1 (append some-list '(4) some-list))
     => (1 2 3 4 2 3)
(` (1 (,@ some-list) 4 (,@ some-list)))
     => (1 2 3 4 2 3)

(setq list '(hack foo bar))
     => (hack foo bar)
(cons 'use
  (cons 'the
    (cons 'words (append (cdr list) '(as elements)))))
     => (use the words foo bar as elements)
(` (use the words (,@ (cdr list)) as elements (,@ nil)))
     => (use the words foo bar as elements)
```

The reason for `(,@ nil)` is to avoid a bug in Emacs version 18. The bug occurs when a call to `,@` is followed only by constant elements. Thus,

```
(` (use the words (,@ (cdr list)) as elements))
```

would not work, though it really ought to. `(,@ nil)` avoids the problem by being a nonconstant element that does not affect the result.

Macro: ` *list*

This macro returns list as `quote` would, except that the list is copied each time this expression is evaluated, and any sublist of the form `(, subexp)` is replaced by the value of subexp. Any sublist of the form `(,@ listexp)` is replaced by evaluating listexp and splicing its elements into the containing

list in place of this sublist. (A single sublist can in this way be replaced by any number of new elements in the containing list.)

There are certain contexts in which `,' would not be recognized and should not be used:

```
;; Use of a `,' expression as the CDR of a list.
(` (a . (, 1)))                               ; Not (a . 1)
     => (a \, 1)

;; Use of `,' in a vector.
(` [a (, 1) c])                               ; Not [a 1 c]
     error--> Wrong type argument

;; Use of a `,' as the entire argument of ``'.
(` (, 2))                                     ; Not 2
     => (\, 2)
```

Common Lisp note: in Common Lisp, `,' and `,@' are implemented as reader macros, so they do not require parentheses. Emacs Lisp implements them as functions because reader macros are not supported (to save space).

Common Problems Using Macros

The basic facts of macro expansion have all been described above, but there consequences are often counterintuitive. This section describes some important consequences that can lead to trouble, and rules to follow to avoid trouble.

Evaluating Macro Arguments Too Many Times

When defining a macro you must pay attention to the number of times the arguments will be evaluated when the expansion is executed. The following macro (used to facilitate iteration) illustrates the problem. This macro allows us to write a simple "for" loop such as one might find in Pascal.

```
(defmacro for (var from init to final do &rest body)
  "Execute a simple \"for\" loop, e.g.,
    (for i from 1 to 10 do (print i))."
  (list 'let (list (list var init))
        (cons 'while (cons (list '<= var final)
                           (append body (list (list 'inc var)))))))
=> for

(for i from 1 to 3 do
   (setq square (* i i))
   (princ (format "\n%d %d" i square)))
==>
```

```
(let ((i 1))
  (while (<= i 3)
    (setq square (* i i))
    (princ (format "%d      %d" i square))
    (inc i)))

     -|1       1
     -|2       4
     -|3       9
=> nil
```

(The arguments `from`, `to`, and `do` in this macro are "syntactic sugar"; they are entirely ignored. The idea is that you will write noise words (such as `from`, `to`, and `do`) in those positions in the macro call.)

This macro suffers from the defect that final is evaluated on every iteration. If final is a constant, this is not a problem. If it is a more complex form, say `(long-complex-calculation x)`, this can slow down the execution significantly. If final has side effects, executing it more than once is probably incorrect.

A well-designed macro definition takes steps to avoid this problem by producing an expansion that evaluates the argument expressions exactly once unless repeated evaluation is part of the intended purpose of the macro. Here is a correct expansion for the `for` macro:

```
(let ((i 1)
      (max 3))
  (while (<= i max)
    (setq square (* i i))
    (princ (format "%d      %d" i square))
    (inc i)))
```

Here is a macro definition that creates this expansion:

```
(defmacro for (var from init to final do &rest body)
  "Execute a simple for loop: (for i from 1 to 10 do (print i))."
  (` (let ((, var) (, init))
           (max (, final)))
       (while (<= (, var) max)
         (,@ body)
         (inc (, var))))))
```

Unfortunately, this introduces another problem.

Local Variables in Macro Expansions

The new definition of `for` has a new problem: it introduces a local variable named `max` which the user does not expect. This causes trouble in examples such as the following:

```
(let ((max 0))
  (for x from 0 to 10 do
    (let ((this (frob x)))
      (if (< max this)
          (setq max this)))))
```

The references to `max` inside the body of the `for`, which are supposed to refer to the user's binding of `max`, really access the binding made by `for`.

The way to correct this is to use an uninterned symbol instead of `max` (see section Creating and Interning Symbols). The uninterned symbol can be bound and referred to just like any other symbol, but since it is created by `for`, we know that it cannot appear in the user's program. Since it is not interned, there is no way the user can put it into the program later. It will never appear anywhere except where put by `for`. Here is a definition of `for` which works this way:

```
(defmacro for (var from init to final do &rest body)
  "Execute a simple for loop: (for i from 1 to 10 do (print i))."
  (let ((tempvar (make-symbol "max")))
    (` (let (((, var) (, init))
             ((, tempvar) (, final)))
         (while (<= (, var) (, tempvar))
                (,@ body)
                (inc (, var)))))))
```

This creates an uninterned symbol named `max` and puts it in the expansion instead of the usual interned symbol `max` that appears in expressions ordinarily.

Evaluating Macro Arguments in Expansion

Another problem can happen if you evaluate any of the macro argument expressions during the computation of the expansion, such as by calling `eval` (see section Eval). If the argument is supposed to refer to the user's variables, you may have trouble if the user happens to use a variable with the same name as one of the macro arguments. Inside the macro body, the macro argument binding is the most local binding of this variable, so any references inside the form being evaluated do refer to it. Here is an example:

```
(defmacro foo (a)
  (list 'setq (eval a) t))
     => foo
(setq x 'b)
(foo x) ==> (setq b t)
     => t                  ; and b has been set.
;; but
(setq a 'b)
(foo a) ==> (setq 'b t)     ; invalid!
```

```
error--> Symbol's value is void: b
```

It makes a difference whether the user types `a` or `x`, because `a` conflicts with the macro argument variable `a`.

In general it is best to avoid calling `eval` in a macro definition at all.

How Many Times is the Macro Expanded?

Occasionally problems result from the fact that a macro call is expanded each time it is evaluated in an interpreted function, but is expanded only once (during compilation) for a compiled function. If the macro definition has side effects, they will work differently depending on how many times the macro is expanded.

In particular, constructing objects is a kind of side effect. If the macro is called once, then the objects are constructed only once. In other words, the same structure of objects is used each time the macro call is executed. In interpreted operation, the macro is reexpanded each time, producing a fresh collection of objects each time. Usually this does not matter--the objects have the same contents whether they are shared or not. But if the surrounding program does side effects on the objects, it makes a difference whether they are shared. Here is an example:

```
(defmacro new-object ()
  (list 'quote (cons nil nil)))

(defun initialize (condition)
  (let ((object (new-object)))
    (if condition
        (setcar object condition))
    object))
```

If `initialize` is interpreted, a new list `(nil)` is constructed each time `initialize` is called. Thus, no side effect survives between calls. If `initialize` is compiled, then the macro `new-object` is expanded during compilation, producing a single "constant" `(nil)` that is reused and altered each time `initialize` is called.

Go to the previous, next section.

Go to the previous, next section.

Loading

Loading a file of Lisp code means bringing its contents into the Lisp environment in the form of Lisp objects. Emacs finds and opens the file, reads the text, evaluates each form, and then closes the file.

The load functions evaluate all the expressions in a file just as the `eval-current-buffer` function evaluates all the expressions in a buffer. The difference is that the load functions read and evaluate the text in the file as found on disk, not the text in an Emacs buffer.

The loaded file must contain Lisp expressions, either as source code or, optionally, as byte-compiled code. Each form in the file is called a top-level form. There is no special format for the forms in a loadable file; any form in a file may equally well be typed directly into a buffer and evaluated there. (Indeed, most code is tested this way.) Most often, the forms are function definitions and variable definitions.

A file containing Lisp code is often called a library. Thus, the "Rmail library" is a file containing code for Rmail mode. Similarly, a "Lisp library directory" is a directory of files containing Lisp code.

How Programs Do Loading

There are several interface functions for loading. For example, the `autoload` function creates a Lisp object that loads a file when it is evaluated (see section Autoload). `require` also causes files to be loaded (see section Features). Ultimately, all these facilities call the `load` function to do the work.

Function: **load** *filename &optional missing-ok nomessage nosuffix*

This function finds and opens a file of Lisp code, evaluates all the forms in it, and closes the file.

To find the file, `load` first looks for a file named `` `filename.elc' ``, that is, for a file whose name has `.elc' appended. If such a file exists, it is loaded. But if there is no file by that name, then `load` looks for a file whose name has `.el' appended. If that file exists, it is loaded. Finally, if there is no file by either name, `load` looks for a file named filename with nothing appended, and loads it if it exists. (The `load` function is not clever about looking at filename. In the perverse case of a file named `` `foo.el.el' ``, evaluation of `(load "foo.el")` will indeed find it.)

If the optional argument nosuffix is non-`nil`, then the suffixes `.elc' and `.el' are not tried. In this case, you must specify the precise file name you want.

If filename is a relative file name, such as `` `foo' `` or `` `baz/foo.bar' ``, `load` searches for the file using the variable `load-path`. It appends filename to each of the directories listed in `load-path`, and loads the first file it finds whose name matches. The current default directory is tried only if it is specified in `load-path`, where it is represented as `nil`. All three possible suffixes are tried in the first directory in `load-path`, then all three in the second directory in `load-path`, etc.

If you get a warning that `foo.elc' is older than `foo.el', it means you should consider recompiling `foo.el'. See section Byte Compilation.

Messages like `Loading foo...' and `Loading foo...done' appear in the echo area during loading unless nomessage is non-nil.

Any errors that are encountered while loading a file cause load to abort. If the load was done for the sake of autoload, certain kinds of top-level forms, those which define functions, are undone.

The error file-error is signaled (with `Cannot open load file filename') if no file is found. No error is signaled if missing-ok is non-nil---then load just returns nil.

load returns t if the file loads successfully.

User Option: **load-path**

The value of this variable is a list of directories to search when loading files with load. Each element is a string (which must be a directory name) or nil (which stands for the current working directory). The value of load-path is initialized from the environment variable EMACSLOADPATH, if it exists; otherwise it is set to the default specified in `emacs/src/paths.h' when Emacs is built.

The syntax of EMACSLOADPATH is the same as that of PATH; fields are separated by `:', and `.' is used for the current default directory. Here is an example of how to set your EMACSLOADPATH variable from a csh `.login' file:

```
setenv EMACSLOADPATH .:/user/bil/emacs:/usr/local/lib/emacs/lisp
```

Here is how to set it using sh:

```
export EMACSLOADPATH
EMACSLOADPATH=.:/user/bil/emacs:/usr/local/lib/emacs/lisp
```

Here is an example of code you can place in a `.emacs' file to add several directories to the front of your default load-path:

```
(setq load-path
      (append
       (list nil
             "/user/bil/emacs"
             "/usr/local/lisplib")
       load-path))
```

In this example, the path searches the current working directory first, followed then by the `/user/bil/emacs' directory and then by the `/usr/local/lisplib' directory, which are then followed by the standard directories for Lisp code.

When Emacs version 18 processes command options `-l' or `-load' which specify Lisp libraries to be loaded, it temporarily adds the current directory to the front of load-path so that files in the current directory can be specified easily. Newer Emacs versions also find such files in the current directory, but

without altering `load-path`.

Variable: **load-in-progress**

This variable is non-`nil` if Emacs is in the process of loading a file, and it is `nil` otherwise. This is how `defun` and `provide` determine whether a load is in progress, so that their effect can be undone if the load fails.

To learn how `load` is used to build Emacs, see section Building Emacs.

Autoload

The autoload facility allows you to make a function or macro available but put off loading its actual definition. An attempt to call a symbol whose definition is an autoload object automatically reads the file to install the real definition and its other associated code, and then calls the real definition.

To prepare a function or macro for autoloading, you must call `autoload`, specifying the function name and the name of the file to be loaded. A file such as `` `emacs/lisp/loaddefs.el' `` usually does this when Emacs is first built.

The following example shows how `doctor` is prepared for autoloading in `` `loaddefs.el' ``:

```
(autoload 'doctor "doctor"
  "\
Switch to *doctor* buffer and start giving psychotherapy."
  t)
```

The backslash and newline immediately following the double-quote are a convention used only in the preloaded Lisp files such as `` `loaddefs.el' ``; they cause the documentation string to be put in the `` `etc/DOC' `` file. (See section Building Emacs.) In any other source file, you would write just this:

```
(autoload 'doctor "doctor"
  "Switch to *doctor* buffer and start giving psychotherapy."
  t)
```

Calling `autoload` creates an autoload object containing the name of the file and some other information, and makes this the function definition of the specified symbol. When you later try to call that symbol as a function or macro, the file is loaded; the loading should redefine that symbol with its proper definition. After the file completes loading, the function or macro is called as if it had been there originally.

If, at the end of loading the file, the desired Lisp function or macro has not been defined, then the error `error` is signaled (with data `"Autoloading failed to define function function-name"`).

The autoloaded file may, of course, contain other definitions and may require or provide one or more features. If the file is not completely loaded (due to an error in the evaluation of the contents) any

function definitions or `provide` calls that occurred during the load are undone. This is to ensure that next attempt to call any function autoloading from this file will try again to load the file. If not for this then some of the functions in the file might appear defined, but they may fail to work properly for the lack of certain subroutines defined later in the file and not loaded successfully.

Emacs as distributed comes with many autoloaded functions. The calls to `autoload` are in the file `` `loaddefs.el' ``. There is a convenient way of updating them automatically.

Write `;;;###autoload' on a line by itself before a function definition before the real definition of the function, in its autoloadable source file; then the command M-x update-file-autoloads automatically puts the `autoload` call into `` `loaddefs.el' ``. M-x update-directory-autoloads is more powerful; it updates autoloads for all files in the current directory.

You can also put other kinds of forms into `` `loaddefs.el' ``, by writing `;;;###autoload' followed on the same line by the form. M-x update-file-autoloads copies the form from that line.

The commands for updating autoloads work by visiting and editing the file `` `loaddefs.el' ``. To make the result take effect, you must save that file's buffer.

Function: **autoload** *symbol filename &optional docstring interactive type*

This function defines the function (or macro) named symbol so as to load automatically from filename. The string filename is a file name which will be passed to `load` when the function is called.

The argument docstring is the documentation string for the function. Normally, this is the same string that is in the function definition itself. This makes it possible to look at the documentation without loading the real definition.

If interactive is non-`nil`, then the function can be called interactively. This lets completion in M-x work without loading the function's real definition. The complete interactive specification need not be given here. If type is `macro`, then the function is really a macro. If type is `keymap`, then the function is really a keymap.

If symbol already has a non-`nil` function definition that is not an autoload object, `autoload` does nothing and returns `nil`. If the function cell of symbol is void, or is already an autoload object, then it is set to an autoload object that looks like this:

```
(autoload filename docstring interactive type)
```

For example,

```
(symbol-function 'run-prolog)
     => (autoload "prolog" 169681 t nil)
```

In this case, `"prolog"` is the name of the file to load, 169681 refers to the documentation string in the `` `emacs/etc/DOC' `` file (see section Documentation Basics), `t` means the function is interactive, and `nil` that it is not a macro.

Repeated Loading

You may load a file more than once in an Emacs session. For example, after you have rewritten and reinstalled a function definition by editing it in a buffer, you may wish to return to the original version; you can do this by reloading the file in which it is located.

When you load or reload files, bear in mind that the `load` and `load-library` functions automatically load a byte-compiled file rather than a non-compiled file of similar name. If you rewrite a file that you intend to save and reinstall, remember to byte-compile it if necessary; otherwise you may find yourself inadvertently reloading the older, byte-compiled file instead of your newer, non-compiled file!

When writing the forms in a library, keep in mind that the library might be loaded more than once. For example, the choice of `defvar` vs. `defconst` for defining a variable depends on whether it is desirable to reinitialize the variable if the library is reloaded: `defconst` does so, and `defvar` does not. (See section Defining Global Variables.)

The simplest way to add an element to an alist is like this:

```
(setq minor-mode-alist
      (cons '(leif-mode " Leif") minor-mode-alist))
```

But this would add multiple elements if the library is reloaded. To avoid the problem, write this:

```
(or (assq 'leif-mode minor-mode-alist)
    (setq minor-mode-alist
          (cons '(leif-mode " Leif") minor-mode-alist)))
```

Occasionally you will want to test explicitly whether a library has already been loaded; you can do so as follows:

```
(if (not (boundp 'foo-was-loaded))
    execute-first-time-only)

(setq foo-was-loaded t)
```

Features

`provide` and `require` are an alternative to `autoload` for loading files automatically. They work in terms of named features. Autoloading is triggered by calling a specific function, but a feature is loaded the first time another program asks for it by name.

The use of named features simplifies the task of determining whether required definitions have been defined. A feature name is a symbol that stands for a collection of functions, variables, etc. A program that needs the collection may ensure that they are defined by requiring the feature. If the file that contains the feature has not yet been loaded, then it will be loaded (or an error will be signaled if it cannot be

loaded). The file thus loaded must provide the required feature or an error will be signaled.

To require the presence of a feature, call `require` with the feature name as argument. `require` looks in the global variable `features` to see whether the desired feature has been provided already. If not, it loads the feature from the appropriate file. This file should call `provide` at the top-level to add the feature to `features`.

Features are normally named after the files they are provided in so that `require` need not be given the file name.

For example, in `` `emacs/lisp/prolog.el' ``, the definition for `run-prolog` includes the following code:

```
(defun run-prolog ()
  "Run an inferior Prolog process,\
 input and output via buffer *prolog*."
  (interactive)
  (require 'comint)
  (switch-to-buffer (make-comint "prolog" prolog-program-name))
  (inferior-prolog-mode))
```

The expression `(require 'shell)` loads the file `` `shell.el' `` if it has not yet been loaded. This ensures that `make-shell` is defined.

The `` `shell.el' `` file contains the following top-level expression:

```
(provide 'shell)
```

This adds `shell` to the global `features` list when the `` `shell' `` file is loaded, so that `(require 'shell)` will henceforth know that nothing needs to be done.

When `require` is used at top-level in a file, it takes effect if you byte-compile that file (see section Byte Compilation). This is in case the required package contains macros that the byte compiler must know about.

Although top-level calls to `require` are evaluated during byte compilation, `provide` calls are not. Therefore, you can ensure that a file of definitions is loaded before it is byte-compiled by including a `provide` followed by a `require` for the same feature, as in the following example.

```
(provide 'my-feature)  ; Ignored by byte compiler,
                       ;   evaluated by load.
(require 'my-feature)  ; Evaluated by byte compiler.
```

Function: **provide** *feature*

This function announces that feature is now loaded, or being loaded, into the current Emacs session. This means that the facilities associated with feature are or will be available for other Lisp programs.

The direct effect of calling `provide` is to add feature to the front of the list `features` if it is not

already in the list. The argument feature must be a symbol. `provide` returns feature.

```
features
     => (bar bish)

(provide 'foo)
     => foo
features
     => (foo bar bish)
```

During autoloading, if the file is not completely loaded (due to an error in the evaluation of the contents) any function definitions or `provide` calls that occurred during the load are undone. See section Autoload.

Function: **require** *feature &optional filename*

This function checks whether feature is present in the current Emacs session (using `(featurep feature)`; see below). If it is not, then `require` loads filename with `load`. If filename is not supplied, then the name of the symbol feature is used as the file name to load.

If feature is not provided after the file has been loaded, Emacs will signal the error `error` (with data `Required feature feature was not provided').

Function: **featurep** *feature*

This function returns `t` if feature has been provided in the current Emacs session (i.e., feature is a member of `features`.)

Variable: **features**

The value of this variable is a list of symbols that are the features loaded in the current Emacs session. Each symbol was put in this list with a call to `provide`. The order of the elements in the `features` list is not significant.

Unloading

You can discard the functions and variables loaded by a library to reclaim memory for other Lisp objects. To do this, use the function `unload-feature`:

Command: **unload-feature** *feature*

This command unloads the library that provided feature feature. It undefines all functions and variables defined with `defvar`, `defmacro`, `defconst`, `defsubst` and `defalias` by the library which provided feature feature. It then restores any autoloads associated with those symbols.

The `unload-feature` function is written in Lisp; its actions are based on the variable `load-history`.

Variable: **load-history** *feature association list*

This variable's value is an alist connecting library names with the names of functions and variables th define, the features they provide, and the features they require.

Each element is a list and describes one library. The CAR of the list is the name of the library, as a string. The rest of the list is composed of these kinds of objects:

- Symbols, which were defined as functions or variables.
- Lists of the form `(require . feature)` indicating the features that are required.
- Lists of the form `(provide . feature)` indicating the features that are provided.

The value of `load-history` may have one element whose CAR is `nil`. This element describes definitions made with `eval-buffer` on a buffer that is not visiting a file.

The command `eval-region` updates `load-history`, but does so by adding the symbols defined to the element for the file being visited, rather than replacing that element.

Hooks for Loading

You can ask for code to be executed if and when a particular library is loaded, by calling `eval-after-load`.

Function: **eval-after-load** *library form*

This function arranges to evaluate form at the end of loading the library library, if and when library is loaded.

The library name library must exactly match the argument of `load`. To get the proper results when an installed library is found by searching `load-path`, you should not include any directory names in library.

An error in form does not undo the load, but does prevent execution of the rest of form.

Variable: **after-load-alist**

An alist of expressions to evaluate if and when particular libraries are loaded. Each element looks like this:

```
(filename forms...)
```

The function `load` checks `after-load-alist` in order to implement `eval-after-load`.

Go to the previous, next section.

Go to the previous, next section.

Byte Compilation

GNU Emacs Lisp has a compiler that translates functions written in Lisp into a special representation called byte-code that can be executed more efficiently. The compiler replaces Lisp function definitions with byte-code. When a byte-code function is called, its definition is evaluated by the byte-code interpreter.

Because the byte-compiled code is evaluated by the byte-code interpreter, instead of being executed directly by the machine's hardware (as true compiled code is), byte-code is completely transportable from machine to machine without recompilation. It is not, however, as fast as true compiled code.

In general, any version of Emacs can run byte-compiled code produced by recent earlier versions of Emacs, but the reverse is not true. In particular, if you compile a program with Emacs 18, you can run the compiled code in Emacs 19, but not vice versa.

See section Debugging Problems in Compilation, for how to investigate errors occurring in byte compilation.

The Compilation Functions

You can byte-compile an individual function or macro definition with the `byte-compile` function. You can compile a whole file with `byte-compile-file`, or several files with `byte-recompile-directory` or `batch-byte-compile`.

When you run the byte compiler, you may get warnings in a buffer called `*Compile-Log*'. These report usage in your program that suggest a problem, but are not necessarily erroneous.

Be careful when byte-compiling code that uses macros. Macro calls are expanded when they are compiled, so the macros must already be defined for proper compilation. For more details, see section Macros and Byte Compilation.

While byte-compiling a file, any `require` calls at top-level are executed. One way to ensure that necessary macro definitions are available during compilation is to require the file that defines them. See section Features.

A byte-compiled function is not as efficient as a primitive function written in C, but runs much faster than the version written in Lisp. For a rough comparison, consider the example below:

```
(defun silly-loop (n)
  "Return time before and after N iterations of a loop."
  (let ((t1 (current-time-string)))
    (while (> (setq n (1- n))
              0))
```

```
    (list t1 (current-time-string))))
=> silly-loop

(silly-loop 100000)
=> ("Thu Jan 12 20:18:38 1989"
    "Thu Jan 12 20:19:29 1989")  ; 51 seconds

(byte-compile 'silly-loop)
=> [Compiled code not shown]

(silly-loop 100000)
=> ("Thu Jan 12 20:21:04 1989"
    "Thu Jan 12 20:21:17 1989")  ; 13 seconds
```

In this example, the interpreted code required 51 seconds to run, whereas the byte-compiled code required 13 seconds. These results are representative, but actual results will vary greatly.

Function: **byte-compile** *symbol*

This function byte-compiles the function definition of symbol, replacing the previous definition with the compiled one. The function definition of symbol must be the actual code for the function; i.e., the compiler does not follow indirection to another symbol. `byte-compile` does not compile macros. `byte-compile` returns the new, compiled definition of symbol.

```
(defun factorial (integer)
  "Compute factorial of INTEGER."
  (if (= 1 integer) 1
    (* integer (factorial (1- integer)))))
     => factorial

(byte-compile 'factorial)
     =>
#[(integer)
  "^H\301U\203^H^@\301\207\302^H\303^HS!\"\207"
  [integer 1 * factorial]
  4 "Compute factorial of INTEGER."]
```

The result is a compiled function object. The string it contains is the actual byte-code; each character in it is an instruction. The vector contains all the constants, variable names and function names used by the function, except for certain primitives that are coded as special instructions.

Command: **compile-defun**

This command reads the defun containing point, compiles it, and evaluates the result. If you use this on a defun that is actually a function definition, the effect is to install a compiled version of that function.

Command: **byte-compile-file** *filename*

This function compiles a file of Lisp code named filename into a file of byte-code. The output file's n is made by appending `c' to the end of filename.

Compilation works by reading the input file one form at a time. If it is a definition of a function or macro, the compiled function or macro definition is written out. Other forms are batched together, then each batch is compiled, and written so that its compiled code will be executed when the file is read. All comments are discarded when the input file is read.

This command returns `t`. When called interactively, it prompts for the file name.

```
% ls -l push*
-rw-r--r--  1 lewis     791 Oct  5 20:31 push.el

(byte-compile-file "~/emacs/push.el")
     => t

% ls -l push*
-rw-r--r--  1 lewis     791 Oct  5 20:31 push.el
-rw-rw-rw-  1 lewis     638 Oct  8 20:25 push.elc
```

Command: **byte-recompile-directory** *directory flag*

This function recompiles every `.el' file in directory that needs recompilation. A file needs recompilation if a `.elc' file exists but is older than the `.el' file.

If a `.el' file exists, but there is no corresponding `.elc' file, then flag is examined. If it is `nil`, the file is ignored. If it is non-`nil`, the user is asked whether the file should be compiled.

The returned value of this command is unpredictable.

Function: **batch-byte-compile**

This function runs `byte-compile-file` on the files remaining on the command line. This function must be used only in a batch execution of Emacs, as it kills Emacs on completion. An error in one file does not prevent processing of subsequent files. (The file which gets the error will not, of course, produce any compiled code.)

```
% emacs -batch -f batch-byte-compile *.el
```

Function: **byte-code** *code-string data-vector max-stack*

This function actually interprets byte-code. A byte-compiled function is actually defined with a body that calls `byte-code`. Don't call this function yourself. Only the byte compiler knows how to generate valid calls to this function.

In newer Emacs versions (19 and up), byte-code is usually executed as part of a compiled function object, and only rarely as part of a call to `byte-code`.

Evaluation During Compilation

These features permit you to write code to be evaluated during compilation of a program.

Special Form: **eval-and-compile** *body*

This form marks body to be evaluated both when you compile the containing code and when you run it (whether compiled or not).

You can get a similar result by putting body in a separate file and referring to that file with `require`. Using `require` is preferable if there is a substantial amount of code to be executed in this way.

Special Form: **eval-when-compile** *body*

This form marks body to be evaluated at compile time *only*. The result of evaluation by the compiler becomes a constant which appears in the compiled program. When the program is interpreted, not compiled at all, body is evaluated normally.

At top-level, this is analogous to the Common Lisp idiom `(eval-when (compile) ...)`. Elsewhere, the Common Lisp `#.' reader macro (but not when interpreting) is closer to what `eval-when-compile` does.

Byte-Code Objects

Byte-compiled functions have a special data type: they are byte-code function objects.

Internally, a byte-code function object is much like a vector; however, the evaluator handles this data type specially when it appears as a function to be called. The printed representation for a byte-code function object is like that for a vector, with an additional `#' before the opening `['.

In Emacs version 18, there was no byte-code function object data type; compiled functions used the function `byte-code` to run the byte code.

A byte-code function object must have at least four elements; there is no maximum number, but only the first six elements are actually used. They are:

arglist
: The list of argument symbols.

byte-code
: The string containing the byte-code instructions.

constants
: The vector of constants referenced by the byte code.

stacksize
: The maximum stack size this function needs.

docstring
: The documentation string (if any); otherwise, `nil`. For functions preloaded before Emacs is

dumped, this is usually an integer which is an index into the `DOC' file; use `documentati` to convert this into a string (see section Access to Documentation Strings).

interactive

The interactive spec (if any). This can be a string or a Lisp expression. It is `nil` for a function that isn't interactive.

Here's an example of a byte-code function object, in printed representation. It is the definition of the command `backward-sexp`.

```
#[(&optional arg)
  "^H\204^F^@\301^P\302^H[!\207"
  [arg 1 forward-sexp]
  2
  254435
  "p"]
```

The primitive way to create a byte-code object is with `make-byte-code`:

Function: **make-byte-code** *&rest elements*

This function constructs and returns a byte-code function object with elements as its elements.

You should not try to come up with the elements for a byte-code function yourself, because if they are inconsistent, Emacs may crash when you call the function. Always leave it to the byte-compiler to create these objects; it, we hope, always makes the elements consistent.

You can access the elements of a byte-code object using `aref`; you can also use `vconcat` to create a vector with the same elements.

Disassembled Byte-Code

People do not write byte-code; that job is left to the byte compiler. But we provide a disassembler to satisfy a cat-like curiosity. The disassembler converts the byte-compiled code into humanly readable form.

The byte-code interpreter is implemented as a simple stack machine. Values get stored by being pushed onto the stack, and are popped off and manipulated, the results being pushed back onto the stack. When a function returns, the top of the stack is popped and returned as the value of the function.

In addition to the stack, values used during byte-code execution can be stored in ordinary Lisp variables. Variable values can be pushed onto the stack, and variables can be set by popping the stack.

Command: **disassemble** *object &optional stream*

This function prints the disassembled code for object. If stream is supplied, then output goes there. Otherwise, the disassembled code is printed to the stream `standard-output`. The argument object can be a function name or a lambda expression.

As a special exception, if this function is used interactively, it outputs to a buffer named `*Disassembl

Here are two examples of using the `disassemble` function. We have added explanatory comments to help you relate the byte-code to the Lisp source; these do not appear in the output of `disassemble`. These examples show unoptimized byte-code. Nowadays byte-code is usually optimized, but we did not want to rewrite these examples, since they still serve their purpose.

```
(defun factorial (integer)
  "Compute factorial of an integer."
  (if (= 1 integer) 1
    (* integer (factorial (1- integer)))))
     => factorial

(factorial 4)
     => 24

(disassemble 'factorial)
     -| byte-code for factorial:
 doc: Compute factorial of an integer.
 args: (integer)

0   constant 1              ; Push 1 onto stack.

1   varref   integer        ; Get value of integer
                            ;   from the environment
                            ;   and push the value
                            ;   onto the stack.

2   eqlsign                 ; Pop top two values off stack,
                            ;   compare them,
                            ;   and push result onto stack.

3   goto-if-nil 10          ; Pop and test top of stack;
                            ;   if nil, go to 10,
                            ;   else continue.

6   constant 1              ; Push 1 onto top of stack.

7   goto     17             ; Go to 17 (in this case, 1 will be
                            ;   returned by the function).

10  constant *              ; Push symbol * onto stack.

11  varref   integer        ; Push value of integer onto stack.

12  constant factorial      ; Push factorial onto stack.
```

```
13  varref   integer        ; Push value of integer onto stack.

14  sub1                    ; Pop integer, decrement value,
                            ;   push new value onto stack.

                            ; Stack now contains:
                            ;   - decremented value of integer
                            ;   - factorial
                            ;   - value of integer
                            ;   - *

15  call     1              ; Call function factorial using
                            ;   the first (i.e., the top) element
                            ;   of the stack as the argument;
                            ;   push returned value onto stack.

                            ; Stack now contains:
                            ;   - result of result of recursive
                            ;       call to factorial
                            ;   - value of integer
                            ;   - *

16  call     2              ; Using the first two
                            ;   (i.e., the top two)
                            ;   elements of the stack
                            ;   as arguments,
                            ;   call the function *,
                            ;   pushing the result onto the stack.

17  return                  ; Return the top element
                            ;   of the stack.
     => nil
```

The `silly-loop` function is somewhat more complex:

```
(defun silly-loop (n)
  "Return time before and after N iterations of a loop."
  (let ((t1 (current-time-string)))
    (while (> (setq n (1- n))
              0))
    (list t1 (current-time-string))))
     => silly-loop

(disassemble 'silly-loop)
     -| byte-code for silly-loop:
```

```
 doc: Return time before and after N iterations of a loop.
 args: (n)

0   constant current-time-string  ; Push
                                  ;   current-time-string
                                  ;   onto top of stack.

1   call     0                    ; Call current-time-string
                                  ;    with no argument,
                                  ;    pushing result onto stack.

2   varbind  t1                   ; Pop stack and bind t1
                                  ;   to popped value.

Debugging Lisp Programs

There are three ways to investigate a problem in an Emacs Lisp program, depending on what you are doing with the program when the problem appears.

- If the problem occurs when you run the program, you can use the Lisp debugger to investigate what is happening during execution.
- If the problem is syntactic, so that Lisp cannot even read the program, you can use the Emacs facilities for editing Lisp to localize it.
- If the problem occurs when trying to compile the program with the byte compiler, you need to know how to examine the compiler's input buffer.

Another useful debugging tool is a dribble file. When a dribble file is open, Emacs copies all keyboard input characters to that file. Afterward, you can examine the file to find out what input was used. See section Terminal Input.

For debugging problems in terminal descriptions, the `open-termscript` function can be useful. See section Terminal Output.

The Lisp Debugger

The Lisp debugger provides you with the ability to suspend evaluation of a form. While evaluation is suspended (a state that is commonly known as a break), you may examine the run time stack, examine the values of local or global variables, or change those values. Since a break is a recursive edit, all the usual editing facilities of Emacs are available; you can even run programs that will enter the debugger recursively. See section Recursive Editing.

Entering the Debugger on an Error

The most important time to enter the debugger is when a Lisp error happens. This allows you to investigate the immediate causes of the error.

However, entry to the debugger is not a normal consequence of an error. Many commands frequently get Lisp errors when invoked in inappropriate contexts (such as C-f at the end of the buffer) and during ordinary editing it would be very unpleasant to enter the debugger each time this happens. If you want errors to enter the debugger, set the variable `debug-on-error` to non-`nil`.

User Option: **debug-on-error**

This variable determines whether the debugger is called when a error is signaled and not handled. If `debug-on-error` is `t`, all errors call the debugger. If it is `nil`, none call the debugger.

The value can also be a list of error conditions that should call the debugger. For example, if you set it to

the list `(void-variable)`, then only errors about a variable that has no value invoke the debugge

Debugging Infinite Loops

When a program loops infinitely and fails to return, your first problem is to stop the loop. On most operating systems, you can do this with C-g, which causes quit.

Ordinary quitting gives no information about why the program was looping. To get more information, you can set the variable `debug-on-quit` to non-`nil`. Quitting with C-g is not considered an error, and `debug-on-error` has no effect on the handling of C-g. Contrariwise, `debug-on-quit` has no effect on errors.

Once you have the debugger running in the middle of the infinite loop, you can proceed from the debugger using the stepping commands. If you step through the entire loop, you will probably get enough information to solve the problem.

User Option: **debug-on-quit**

This variable determines whether the debugger is called when `quit` is signaled and not handled. If `debug-on-quit` is non-`nil`, then the debugger is called whenever you quit (that is, type C-g). If `debug-on-quit` is `nil`, then the debugger is not called when you quit. See section Quitting.

Entering the Debugger on a Function Call

To investigate a problem that happens in the middle of a program, one useful technique is to cause the debugger to be entered when a certain function is called. You can do this to the function in which the problem occurs, and then step through the function, or you can do this to a function called shortly before the problem, step quickly over the call to that function, and then step through its caller.

Command: **debug-on-entry** *function-name*

This function requests function-name to invoke the debugger each time it is called. It works by inserting the form `(debug 'debug)` into the function definition as the first form.

Any function defined as Lisp code may be set to break on entry, regardless of whether it is interpreted code or compiled code. Even functions that are commands may be debugged--they will enter the debugger when called inside a function, or when called interactively (after the reading of the arguments). Primitive functions (i.e., those written in C) may not be debugged.

When `debug-on-entry` is called interactively, it prompts for function-name in the minibuffer.

Caveat: if `debug-on-entry` is called more than once on the same function, the second call does nothing. If you redefine a function after using `debug-on-entry` on it, the code to enter the debugger is lost.

`debug-on-entry` returns function-name.

```
(defun fact (n)
  (if (zerop n) 1
```

```
      (* n (fact (1- n)))))
     => fact
(debug-on-entry 'fact)
     => fact
(fact 3)
     => 6

------ Buffer: *Backtrace* ------
Entering:
* fact(3)
  eval-region(4870 4878 t)
  byte-code("...")
  eval-last-sexp(nil)
  (let ...)
  eval-insert-last-sexp(nil)
* call-interactively(eval-insert-last-sexp)
------ Buffer: *Backtrace* ------

(symbol-function 'fact)
     => (lambda (n)
          (debug (quote debug))
          (if (zerop n) 1 (* n (fact (1- n)))))
```

Command: **cancel-debug-on-entry** *function-name*

This function undoes the effect of `debug-on-entry` on function-name. When called interactively, it prompts for function-name in the minibuffer.

If `cancel-debug-on-entry` is called more than once on the same function, the second call does nothing. `cancel-debug-on-entry` returns function-name.

Explicit Entry to the Debugger

You can cause the debugger to be called at a certain point in your program by writing the expression `(debug)` at that point. To do this, visit the source file, insert the text `(debug)' at the proper place, and type C-M-x. Be sure to undo this insertion before you save the file!

The place where you insert `(debug)' must be a place where an additional form can be evaluated and its value ignored. (If the value isn't ignored, it will alter the execution of the program!) Usually this means inside a `progn` or an implicit `progn` (see section Sequencing).

Using the Debugger

When the debugger is entered, it displays the previously selected buffer in one window and a buffer named `*Backtrace*' in another window. The backtrace buffer contains one line for each level of Lisp function execution currently going on. At the beginning of this buffer is a message describing the reason that the debugger was invoked (such as the error message and associated data, if it was invoked due to an

error).

The backtrace buffer is read-only and uses a special major mode, Debugger mode, in which letters are defined as debugger commands. The usual Emacs editing commands are available; thus, you can switch windows to examine the buffer that was being edited at the time of the error, switch buffers, visit files, or do any other sort of editing. However, the debugger is a recursive editing level (see section Recursive Editing) and it is wise to go back to the backtrace buffer and exit the debugger (with the q command) when you are finished with it. Exiting the debugger gets out of the recursive edit and kills the backtrace buffer.

The contents of the backtrace buffer show you the functions that are executing and the arguments that were given to them. It also allows you to specify a stack frame by moving point to the line describing that frame. (A stack frame is the place where the Lisp interpreter records information about a particular invocation of a function. The frame whose line point is on is considered the current frame.) Some of the debugger commands operate on the current frame.

The debugger itself should always be run byte-compiled, since it makes assumptions about how many stack frames are used for the debugger itself. These assumptions are false if the debugger is running interpreted.

Debugger Commands

Inside the debugger (in Debugger mode), these special commands are available in addition to the usual cursor motion commands. (Keep in mind that all the usual facilities of Emacs, such as switching windows or buffers, are still available.)

The most important use of debugger commands is for stepping through code, so that you can see how control flows. The debugger can step through the control structures of an interpreted function, but cannot do so in a byte-compiled function. If you would like to step through a byte-compiled function, replace it with an interpreted definition of the same function. (To do this, visit the source file for the function and type C-M-x on its definition.)

c

Exit the debugger and continue execution. When continuing is possible, it resumes execution of the program as if the debugger had never been entered (aside from the effect of any variables or data structures you may have changed while inside the debugger).

Continuing is possible after entry to the debugger due to function entry or exit, explicit invocation, quitting or certain errors. Most errors cannot be continued; trying to continue an unsuitable error causes the same error to occur again.

d

Continue execution, but enter the debugger the next time any Lisp function is called. This allows you to step through the subexpressions of an expression, seeing what values the subexpressions compute, and what else they do.

The stack frame made for the function call which enters the debugger in this way will be flagged automatically so that the debugger will be called again when the frame is exited. You can use the u

command to cancel this flag.

b

Flag the current frame so that the debugger will be entered when the frame is exited. Frames flagged in this way are marked with stars in the backtrace buffer.

u

Don't enter the debugger when the current frame is exited. This cancels a b command on that frame.

e

Read a Lisp expression in the minibuffer, evaluate it, and print the value in the echo area. This is the same as the command M-ESC, except that e is not normally disabled like M-ESC.

q

Terminate the program being debugged; return to top-level Emacs command execution.

If the debugger was entered due to a C-g but you really want to quit, and not debug, use the q command.

r

Return a value from the debugger. The value is computed by reading an expression with the minibuffer and evaluating it.

The r command makes a difference when the debugger was invoked due to exit from a Lisp call frame (as requested with b); then the value specified in the r command is used as the value of that frame.

You can't use r when the debugger was entered due to an error.

Invoking the Debugger

Here we describe fully the function used to invoke the debugger.

Function: **debug** *&rest debugger-args*

This function enters the debugger. It switches buffers to a buffer named `*Backtrace*' (or `*Backtrace*<2>' if it is the second recursive entry to the debugger, etc.), and fills it with information about the stack of Lisp function calls. It then enters a recursive edit, leaving that buffer in Debugger mode and displayed in the selected window.

Debugger mode provides a c command which operates by exiting the recursive edit, switching back to the previous buffer, and returning to whatever called `debug`. The r command also returns from `debug`. These are the only ways the function `debug` can return to its caller.

If the first of the debugger-args passed to `debug` is `nil` (or if it is not one of the following special values), then the rest of the arguments to `debug` are printed at the top of the `*Backtrace*' buffer. This mechanism is used to display a message to the user.

However, if the first argument passed to `debug` is one of the following special values, then it has special significance. Normally, these values are passed to `debug` only by the internals of Emacs and the

debugger, and not by programmers calling `debug`.

The special values are:

`lambda`

When the first argument is `lambda`, the debugger displays `Entering:' as a line of text at the top of the buffer. This means that a function is being entered when `debug-on-next-call` is non-`nil`.

`debug`

When the first argument is `debug`, the debugger displays `Entering:' just as in the `lambda` case. However, `debug` as the argument indicates that the reason for entering the debugger is that a function set to debug on entry is being entered.

In addition, `debug` as the first argument directs the debugger to mark the function that called `debug` so that it will invoke the debugger when exited. (When `lambda` is the first argument, the debugger does not do this, because it has already been done by the interpreter.)

`t`

When the first argument is `t`, the debugger displays the following as the top line in the buffer:

```
Beginning evaluation of function call form:
```

This indicates that it was entered due to the evaluation of a list form at a time when `debug-on-next-call` is non-`nil`.

`exit`

When the first argument is `exit`, it indicates the exit of a stack frame previously marked to invoke the debugger on exit. The second argument given to `debug` in this case is the value being returned from the frame. The debugger displays `Return value:' on the top line of the buffer, followed by the value being returned.

`error`

When the first argument is `error`, the debugger indicates that it is being entered because an error or `quit` was signaled and not handled, by displaying `Signaling:' followed by the error signaled and any arguments to `signal`. For example,

```
(let ((debug-on-error t))
     (/ 1 0))

------ Buffer: *Backtrace* ------
Signaling: (arith-error)
  /(1 0)
...
------ Buffer: *Backtrace* ------
```

If an error was signaled, presumably the variable `debug-on-error` is non-`nil`. If `quit` was signaled, then presumably the variable `debug-on-quit` is non-`nil`.

`nil`

Use `nil` as the first of the debugger-args when you want to enter the debugger explicitly. The rest of the debugger-args are printed on the top line of the buffer. You can use this feature to display messages--for example, to remind yourself of the conditions under which `debug` is called.

Internals of the Debugger

This section describes functions and variables used internally by the debugger.

Variable: **debugger**

The value of this variable is the function to call to invoke the debugger. Its value must be a function of any number of arguments (or, more typically, the name of a function). Presumably this function will enter some kind of debugger. The default value of the variable is `debug`.

The first argument that Lisp hands to the function indicates why it was called. The convention for arguments is detailed in the description of `debug`.

Command: **backtrace**

This function prints a trace of Lisp function calls currently active. This is the function used by `debug` to fill up the `*Backtrace*' buffer. It is written in C, since it must have access to the stack to determine which function calls are active. The return value is always `nil`.

In the following example, `backtrace` is called explicitly in a Lisp expression. When the expression is evaluated, the backtrace is printed to the stream `standard-output`: in this case, to the buffer `backtrace-output'. Each line of the backtrace represents one function call. If the arguments of the function call are all known, they are displayed; if they are being computed, that fact is stated. The arguments of special forms are elided.

```
(with-output-to-temp-buffer "backtrace-output"
  (let ((var 1))
    (save-excursion
      (setq var (eval '(progn
                         (1+ var)
                         (list 'testing (backtrace)))))))

     => nil

---------- Buffer: backtrace-output ------------
  backtrace()
  (list ...computing arguments...)
  (progn ...)
  eval((progn (1+ var) (list (quote testing) (backtrace))))
  (setq ...)
  (save-excursion ...)
  (let ...)
  (with-output-to-temp-buffer ...)
```

```
  eval-region(1973 2142 #<buffer *scratch*>)
  byte-code("...  for eval-print-last-sexp ...")
  eval-print-last-sexp(nil)
* call-interactively(eval-print-last-sexp)
---------- Buffer: backtrace-output ------------
```

The character `*' indicates a frame whose debug-on-exit flag is set.

Variable: **debug-on-next-call**

This variable determines whether the debugger is called before the next `eval`, `apply` or `funcall`. It is automatically reset to `nil` when the debugger is entered.

The d command in the debugger works by setting this variable.

Function: **backtrace-debug** *level flag*

This function sets the debug-on-exit flag of the eval frame level levels down to flag. If flag is non-`nil`, this will cause the debugger to be entered when that frame exits. Even a nonlocal exit through that frame will enter the debugger.

The debug-on-exit flag is an entry in the stack frame of a function call. This flag is examined on every exit from a function.

Normally, this function is only called by the debugger.

Variable: **command-debug-status**

This variable records the debugging status of current interactive command. Each time a command is called interactively, this variable is bound to `nil`. The debugger can set this variable to leave information for future debugger invocations during the same command.

The advantage of using this variable rather that defining another global variable is that the data will never carry over to a later other command invocation.

Function: **backtrace-frame** *frame-number*

The function `backtrace-frame` is intended for use in Lisp debuggers. It returns information about what computation is happening in the eval frame level levels down.

If that frame has not evaluated the arguments yet (or is a special form), the value is `(nil function arg-forms...)`.

If that frame has evaluated its arguments and called its function already, the value is `(t function arg-values...)`.

In the return value, function is whatever was supplied as CAR of evaluated list, or a `lambda` expression in the case of a macro call. If the function has a `&rest` argument, that is represented as the tail of the list arg-values.

If the argument is out of range, `backtrace-frame` returns `nil`.

Debugging Invalid Lisp Syntax

The Lisp reader reports invalid syntax, but cannot say where the real problem is. For example, the error "End of file during parsing" in evaluating an expression indicates an excess of open parentheses (or square brackets). The reader detects this imbalance at the end of the file, but it cannot figure out where the close parenthesis should have been. Likewise, "Invalid read syntax: ")"" indicates an excess close parenthesis or missing open parenthesis, but not where the missing parenthesis belongs. How, then, to find what to change?

If the problem is not simply an imbalance of parentheses, a useful technique is to try C-M-e at the beginning of each defun, and see if it goes to the place where that defun appears to end. If it does not, there is a problem in that defun.

However, unmatched parentheses are the most common syntax errors in Lisp, and we can give further advice for those cases.

Excess Open Parentheses

The first step is to find the defun that is unbalanced. If there is an excess open parenthesis, the way to do this is to insert a close parenthesis at the end of the file and type C-M-b (`backward-sexp`). This will move you to the beginning of the defun that is unbalanced. (Then type C-SPC C-_ C-u C-SPC to set the mark there, undo the insertion of the close parenthesis, and finally return to the mark.)

The next step is to determine precisely what is wrong. There is no way to be sure of this except to study the program, but often the existing indentation is a clue to where the parentheses should have been. The easiest way to use this clue is to reindent with C-M-q and see what moves.

Before you do this, make sure the defun has enough close parentheses. Otherwise, C-M-q will get an error, or will reindent all the rest of the file until the end. So move to the end of the defun and insert a close parenthesis there. Don't use C-M-e to move there, since that too will fail to work until the defun is balanced.

Then go to the beginning of the defun and type C-M-q. Usually all the lines from a certain point to the end of the function will shift to the right. There is probably a missing close parenthesis, or a superfluous open parenthesis, near that point. (However, don't assume this is true; study the code to make sure.) Once you have found the discrepancy, undo the C-M-q, since the old indentation is probably appropriate to the intended parentheses.

After you think you have fixed the problem, use C-M-q again. It should not change anything, if the problem is really fixed.

Excess Close Parentheses

To deal with an excess close parenthesis, first insert an open parenthesis at the beginning of the file and type C-M-f to find the end of the unbalanced defun. (Then type C-SPC C-_ C-u C-SPC to set the mark there, undo the insertion of the open parenthesis, and finally return to the mark.)

Then find the actual matching close parenthesis by typing C-M-f at the beginning of the defun. This will leave you somewhere short of the place where the defun ought to end. It is possible that you will find a spurious close parenthesis in that vicinity.

If you don't see a problem at that point, the next thing to do is to type C-M-q at the beginning of the defun. A range of lines will probably shift left; if so, the missing open parenthesis or spurious close parenthesis is probably near the first of those lines. (However, don't assume this is true; study the code to make sure.) Once you have found the discrepancy, undo the C-M-q, since the old indentation is probably appropriate to the intended parentheses.

Debugging Problems in Compilation

When an error happens during byte compilation, it is normally due to invalid syntax in the program you are compiling. The compiler prints a suitable error message in the `*Compile-Log*' buffer, and then stops. The message may state a function name in which the error was found, or it may not. Regardless, here is how to find out where in the file the error occurred.

What you should do is switch to the buffer ` *Compiler Input*'. (Note that the buffer name starts with a space, so it does not show up in M-x list-buffers.) This buffer contains the program being compiled, and point shows how far the byte compiler was able to read.

If the error was due to invalid Lisp syntax, point shows exactly where the invalid syntax was *detected*. The cause of the error is not necessarily near by! Use the techniques in the previous section to find the error.

If the error was detected while compiling a form that had been read successfully, then point is located at the end of the form. In this case, it can't localize the error precisely, but can still show you which function to check.

Edebug

Edebug is a source-level debugger for Emacs Lisp programs that provides the following features:

- Step through evaluation, stopping before and after each expression.
- Set conditional or unconditional breakpoints.
- Trace slow or fast stopping briefly at each stop point, or each breakpoint.
- Evaluate expressions as if outside of Edebug.
- Automatically reevaluate a list of expressions and display their results each time Edebug updates the display.
- Output trace info on function enter and exit.

The first three sections of this chapter should tell you enough about Edebug to enable you to use it.

Using Edebug

To debug a Lisp program with Edebug, you must first prepare the Lisp functions that you want to debug. See section Preparing Functions for Edebug.

Once a function is prepared, any call to the function activates Edebug. This involves entering a recursive edit which is a level of Edebug activation.

Activating Edebug may stop execution and let you step through the function, or it may continue execution while checking for debugging commands, depending on the selected Edebug execution mode. See section Edebug Modes.

Within Edebug, you normally view an Emacs buffer showing the source of the Lisp function you are debugging. We call this the Edebug buffer---but note that it is not always the same buffer, and it is not reserved for Edebug use.

An arrow at the left margin indicates the line where the function is executing. Point initially shows where within the line the function is executing, but this ceases to be true if you move point yourself.

If you prepare the definition of `fac` (shown below) for Edebug and then execute `(fac 3)`, here is what you normally see. Point is at the open-parenthesis before `if`.

```
(defun fac (n)
=>-!-(if (< 0 n)
       (* n (fac (1- n)))
    1))
```

The places within a function where Edebug can stop execution are called stop points. These occur both before and after each subexpression that is a list, and also after each variable reference. Stop points before variables are optional, under the control of the value of `edebug-stop-before-symbols`. Here we show with periods the stop points normally found in the function `fac`:

```
(defun fac (n)
  .(if .(< 0 n.).
       .(* n. .(fac (1- n.).).).
    1).)
```

While a buffer is the Edebug buffer, the special commands of Edebug are available in it, instead of many usual editing commands. Type ? to display a list of Edebug commands. In particular, you can exit the innermost Edebug activation level with C-], and you can return all the way to top level with q.

For example, you can type the Edebug command SPC to execute until the next stop point. If you type SPC once after entry to `fac`, here is the state that you get:

```
(defun fac (n)
=>(if -!-(< 0 n)
       (* n (fac (1- n)))
```

```
    1))
```

When Edebug stops execution after an expression, it displays the expression's value in the echo area. Use the r command to display the value again later.

While Edebug is active, it catches all errors (if `debug-on-error` is non-`nil`) and quits (if `debug-on-quit` is non-`nil`) instead of the standard debugger. When this happens, Edebug displays the last stop point that it knows about. This may be the location of a call to a function which was not prepared for Edebug debugging, within which the error actually occurred.

Preparing Functions for Edebug

In order to use Edebug to debug a function, you must first prepare the function. Preparing a function inserts additional code into it which invokes Edebug at the proper places.

Any call to an Edebug-prepared function activates Edebug. This may or may not stop execution, depending on the Edebug execution mode in use. Some Edebug modes only update the display to indicate the progress of the evaluation without stopping execution. The default initial Edebug mode is `step` which does stop execution. See section Edebug Modes.

Once you have loaded Edebug, the command C-M-x is redefined so that when used on a function or macro definition, it prepares the function or macro if given a prefix argument. If the variable `edebug-all-defuns` is non-`nil`, that inverts the meaning of the prefix argument: then C-M-x prepares the function or macro *unless* it has a prefix argument. The default value of `edebug-all-defuns` is `nil`. The command M-x edebug-all-defuns toggles the value of the variable `edebug-all-defuns`.

If `edebug-all-defuns` is non-`nil`, then the commands `eval-region` and `eval-current-buffer` also prepare any functions and macros whose definitions they evaluate.

Loading a file does not prepare functions and macros for Edebug.

See section Evaluation for discussion of other evaluation functions available inside of Edebug.

Edebug Modes

Edebug supports several execution modes for running the program you are debugging. We call these alternatives Edebug modes; do not confuse them with major modes or minor modes. The current Edebug mode determines how Edebug displays the progress of the evaluation, whether it stops at each stop point, or continues to the next breakpoint, for example.

Normally, you specify the Edebug mode for execution by typing a command to continue the program in a certain mode. Here is a table of these commands. All except for S resume execution of the program, at least for a certain distance.

S

Stop: don't execute any more of the program for now, just wait for more Edebug commands.

SPC

Step: stop at the next stop point encountered.

t

Trace: pause one second at each Edebug stop point.

T

Rapid trace: mention each stop point, but don't actually pause.

g

Go: run until the next breakpoint. See section Breakpoints.

c

Continue: pause for one second at each breakpoint, but don't stop.

C

Continue: mention each breakpoint, but don't actually pause.

G

Non-stop: ignore breakpoints. You can still stop the program by typing S.

In general, the execution modes earlier in the above list run the program more slowly or stop sooner.

When you enter a new Edebug level, the mode comes from the value of the variable `edebug-initial-mode`. By default, this specifies step mode. If the mode thus specified is not stop mode, then the Edebug level executes the program (or part of it).

While executing or tracing, you can interrupt the execution by typing any Edebug command. Edebug stops the program at the next stop point and then executes the command that you typed. For example, typing t during execution switches to trace mode at the next stop point.

You can use the S command to stop execution without doing anything else.

If your function happens to read input, a character you hit intending to interrupt execution may be read by the function instead. You can avoid such unintended results by paying attention to when your program wants input.

Keyboard macros containing the commands in this section do not completely work: exiting from Edebug, to resume the program, loses track of the keyboard macro. This is not easy to fix.

Stepping

f

Run the program forward over one expression. More precisely, set a temporary breakpoint at the position that C-M-f would reach, then execute in go mode so that the program will stop at breakpoints. See section Breakpoints for the details on breakpoints.

With a prefix argument n, the temporary breakpoint is placed n sexps beyond point. If the containing list ends before n more elements, then the place to stop is after the containing expression.

Be careful that the position C-M-f finds is a place that the program will really get to; this may not

be true in a `condition-case`, for example.

This command does `forward-sexp` starting at point rather than the stop point, thus providing more flexibility. If you want to execute one expression from the current stop point, type w first, to move point there.

o

Run the program until the end of the containing sexp. If the containing sexp is the top level defun, run until just before the function returns. If that is where you are now, return from the function and then stop.

This command does not exit the currently executing function unless you are positioned after the last sexp of the function.

If the program does a non-local exit, it may fail to reach the temporary breakpoint that this command sets.

i

Step into the function about to be called. Use this command before any of the arguments of the function call are evaluated, since otherwise it is too late.

One undesirable side effect of using `edebug-step-in` is that the next time the stepped-into function is called, Edebug will be called there as well.

h

Proceed to the stop point near where point is. This uses a temporary breakpoint.

The f command runs the program forward over one expression. More precisely, set a temporary breakpoint at the position that C-M-f would reach, then execute in go mode so that the program will stop at breakpoints. See section Breakpoints for the details on breakpoints.

With a prefix argument n, the temporary breakpoint is placed n sexps beyond point. If the containing list ends before n more elements, then the place to stop is after the containing expression.

Be careful that the position C-M-f finds is a place that the program will really get to; this may not be true in a `condition-case`, for example.

The f command uses the existing value of point as the basis for setting the breakpoint, because that is more flexible. To execute one expression *from the current stop point*, type w and then f.

The o command continues "out of" an expression. It places a temporary breakpoints at the end of the containing sexp. If the containing sexp is the top level defun, it continues until just before the function returns. If that is where you are now, it returns from the function and then stops.

This command does not exit the currently executing function unless you are positioned after the last sexp of the function.

The i command steps into the function about to be called. Use this command before any of the arguments of the function call are evaluated, since otherwise it is too late.

One undesirable side effect of using i is that the next time the stepped-into function is called, Edebug will

be called there as well.

The h command proceeds to the stop point near where point is, using a temporary breakpoint.

All the commands in this section may fail to work as expected in case of nonlocal exit, because a nonlocal exit can bypass the temporary breakpoint where you expected the program to stop.

Miscellaneous

Some miscellaneous commands are described here.

C-]

Abort one level of Edebug activity.

q

Return to the top level editor command loop. This exits all recursive editing levels, including all levels of Edebug activity.

r

Redisplay the result of the previous expression in the echo area.

d

Display a backtrace, excluding Edebug's own functions for clarity.

You cannot use debugger commands in the backtrace buffer in Edebug as you would in the standard debugger.

The backtrace buffer is killed automatically when you continue execution.

Breakpoints

While using Edebug, you can specify breakpoints in the program you are testing: points where execution should stop. You can set a breakpoint at any stop point, as defined in section Using Edebug---even before a symbol. For setting and unsetting breakpoints, the stop point that is affected is the first one at or after point in the Edebug buffer. Here are the Edebug commands for breakpoints:

b

Set a breakpoint at the stop point at or after point. If you use a prefix argument, the breakpoint is temporary (it turns off the first time it stops the program).

u

Unset the breakpoint (if any) at the stop point at or after the current point.

x cond RET

Set a conditional breakpoint which stops the program only if cond evaluates to a non-`nil` value. If you use a prefix argument, the breakpoint is temporary (it turns off the first time it stops the program).

B

Move point to the next breakpoint in the current function definition.

While in Edebug, you can set a breakpoint with b (`edebug-set-breakpoint`) and unset one wi (`edebug-unset-breakpoint`). First you must move point to a position at or before the desired Edebug stop point, then hit the key to change the breakpoint. Unsetting a breakpoint that has not been set does nothing.

Reevaluating the function with `edebug-defun` clears all breakpoints in the function.

A conditional breakpoint tests a condition each time the program gets there, to decide whether to stop. To set a conditional breakpoint, use x, and specify the condition expression in the minibuffer.

You can make both conditional and unconditional breakpoints temporary by using a prefix arg to the command to set the breakpoint. After breaking at a temporary breakpoint, it is automatically cleared.

Edebug always stops or pauses at a breakpoint except when the Edebug mode is Go-nonstop. In that mode, it ignores breakpoints entirely.

To find out where your breakpoints are, use the B (`edebug-next-breakpoint`) command, which moves point to the next breakpoint in the function following point, or to the first breakpoint if there are no following breakpoints. This command does not continue execution--it just moves point in the buffer.

Views

These Edebug commands let you view aspects of the buffer and window status that obtained before entry to Edebug.

v
: View the outside window configuration.

p
: Temporarily display the outside current buffer with point at its outside position.

w
: Switch back to the buffer showing the currently executing function, and move point back to the current stop point.

W
: Forget the saved outside window configuration--so that the current window configuration will remain unchanged when you next exit Edebug (by continuing the program). Also toggle the `edebug-save-windows` variable.

Evaluation

While within Edebug, you can evaluate expressions "as if" Edebug were not running. Edebug tries to be invisible to the expression's evaluation.

e exp RET
: Evaluate expression exp in the context outside of Edebug. That is, Edebug tries to avoid altering the effect of exp.

M-ESC exp RET

Evaluate expression exp in the context of Edebug itself.

C-x C-e

Evaluate the expression in the buffer before point, in the context outside of Edebug.

Evaluation List Buffer

You can use the evaluation list buffer, called `*edebug*', to evaluate expressions interactively. You can also set up the evaluation list of expressions to be evaluated automatically each time Edebug is reentered.

E

Switch to the evaluation list buffer `*edebug*'.

In the `*edebug*' buffer you can use the commands of Lisp Interaction as well as these special commands:

LFD

Evaluate the expression before point, in the context outside of Edebug, and insert the value in the buffer.

C-x C-e

Evaluate the expression before point, in the context outside of Edebug.

C-c C-u

Build a new evaluation list from the first expression of each group, reevaluate and redisplay. Groups are separated by a line starting with a comment.

C-c C-d

Delete the evaluation list group that point is in.

C-c C-w

Switch back to the Edebug buffer at the current stop point.

You can evaluate expressions in the evaluation list window with LFD or C-x C-e, just as you would in `*scratch*'; but they are evaluated in the context outside of Edebug.

The expressions you enter interactively (and their results) are lost when you continue execution of your function unless you add them to the evaluation list with C-c C-u (`edebug-update-eval-list`). This command builds a new list from the first expression of each evaluation list group. Groups are separated by a line starting with a comment.

When the evaluation list is redisplayed, each expression is displayed followed by the result of evaluating it, and a comment line. If an error occurs during an evaluation, the error message is displayed in a string as if it were the result. Therefore expressions that use variables not currently valid do not interrupt your debugging.

Here is an example of what the evaluation list window looks like after several expressions have been added to it:

```
(current-buffer)
```

```
#<buffer *scratch*>
;-----------------------------------------------------------------
(point-min)
1
;-----------------------------------------------------------------
(point-max)
2
;-----------------------------------------------------------------
edebug-outside-point-max
"Symbol's value as variable is void: edebug-outside-point-max"
;-----------------------------------------------------------------
(recursion-depth)
0
;-----------------------------------------------------------------
this-command
eval-last-sexp
;-----------------------------------------------------------------
```

To delete a group, move point into it and type C-c C-d (`edebug-delete-eval-item`), or simply delete the text for it and update the evaluation list with C-c C-u. When you add a new group, be sure to add a comment at the beginning.

After selecting `*edebug*', you can return to the source code buffer (the Edebug buffer) with C-c C-w. The `*edebug*` buffer is killed when you continue execution of your function, and recreated next time it is needed.

Printing

If the results of your expressions contain circular references to other parts of the same structure, you can print them more usefully with the `` `custom-print' ``.

To load the package and activate custom printing only for Edebug, simply use the command `edebug-install-custom-print-funcs`. Then set the variable `print-circle` to enable special handling of circular structure. To restore the standard print functions, use `edebug-reset-print-funcs`.

The Outside Context

Edebug tries to be transparent to the program you are debugging, but it does not succeed completely. In addition, most evaluations you do within Edebug (see section Evaluation) occur in the same outside context which is temporarily restored for the evaluation. This section explains precisely how use Edebug fails to be completely transparent.

Just Checking

Whenever Edebug is entered just to think about whether to take some action, it needs to save and restore

certain data.

- `max-lisp-eval-depth` and `max-specpdl-size` are both incremented for each `edebug-enter` call so that your code should not be impacted by Edebug frames on the stack.
- The state of keyboard macro execution is saved and cleared out.

Outside Window Configuration

When Edebug needs to display something (e.g., in trace mode), it saves the current window configuration from "outside" Edebug (see section Window Configurations). When you exit Edebug (by continuing the program), it restores the previous window configuration.

Emacs redisplays only when it pauses. Usually, when you continue Edebug, the program comes back into Edebug at a breakpoint or after stepping, without pausing or reading input in between. In such cases, Emacs never gets a chance to redisplay the "outside" configuration. What you see is the window configuration for within Edebug, with no interruption.

The window configuration proper does not include which buffer is current or where point and mark are in the current buffer, but Edebug saves and restores these also.

Entry to Edebug for displaying something also saves and restores the following data. (Some of these variables are deliberately not restored if an error or quit signal occurs.)

- The position of point in the Edebug buffer is saved and restored if the outside current buffer is the same as the Edebug buffer.
- The outside window configuration, as described above, is saved and restored if `edebug-save-windows` is non-`nil`.
- The current buffer, and point and mark in the current buffer are normally saved and restored even if the current buffer is the same as the Edebug buffer.
- The value of point in each displayed buffers is saved and restored if `edebug-save-displayed-buffer-points` is non-`nil`.
- The variables `overlay-arrow-position` and `overlay-arrow-string` are saved and restored. This permits recursive use of Edebug, and use of Edebug while using GUD.
- `cursor-in-echo-area` is locally bound to `nil` so that the cursor shows up in the window.

Recursive Edit

When Edebug is entered and actually reads commands from the user, it saves (and later restores) these additional data:

- The current match data, for whichever buffer was current.
- `last-command`, `this-command`, `last-command-char`, and `last-input-char`. Commands used within Edebug do not affect these variables outside of Edebug.

  But note that it is not possible to preserve the status reported by `(this-command-keys)` and the variable `unread-command-char`.
- `standard-output` and `standard-input`.

Side Effects

Edebug operation unavoidably alters some data in Emacs, and this can interfere with debugging certain programs.

- Lisp stack usage is increased, but the limits, `max-lisp-eval-depth` and `max-specpdl-size`, are also increased proportionally.
- The key sequence returned by `this-command-keys` is changed by executing commands within Edebug and there appears to be no way to reset the key sequence from Lisp.
- Edebug cannot save and restore the value of `unread-command-char` or `unread-command-events`. Entering Edebug while these variables have nontrivial values can interfere with execution of the program you are debugging.
- Complex commands executed while in Edebug are added to the variable `command-history`. In rare cases this can alter execution.
- Within Edebug, the recursion depth appears one deeper than the recursion depth outside Edebug.
- Horizontal scrolling of the Edebug buffer is not recovered.

Macro Calls

When Edebug prepares for stepping through an expression that uses a Lisp macro, it needs additional advice to do the job properly. This is because there is no way to tell which parts of the macro call are forms to be evaluated. You must explain the format of calls to each macro to enable Edebug to handle it. To do this, use `def-edebug-form-spec` to define the format of calls to a given macro.

Macro: **def-edebug-form-spec** *macro argpattern*

Specify which parts of a call to macro macro are subexpressions to be evaluated. The second argument, argpattern, details what the argument list looks like.

Here is a table of the possibilities for argpattern and its subexpressions:

`t`
: A list of any number of evaluated arguments.

`0`
: A list of unevaluated arguments.

`sexp`
: A single unevaluated object.

`form`
: A single evaluated expression.

`symbolp`
: An unevaluated symbol.

`integerp`
: An unevaluated number.

`stringp`

An unevaluated string.

`vectorp`
: An unevaluated vector.

`atom`
: An unevaluated object that is not a cons cell.

`function`
: A function argument: a quoted symbol, a quoted lambda expression, or a form (that should evaluate to a function or lambda expression). Edebug treats the body of a lambda expression treated as evaluated.

`function`
: A function serves as a predicate--it designates the set of possible arguments for which it would return non-`nil`.

`'object`
: The precise object object, treated as unevaluated.

`(patterns)`
: A list whose elements are described by patterns. A sublist of the same format as the top level, processed recursively.

`[patterns]`
: A sequence of arguments that are described by patterns.

`&optional`
: This symbol serves as a flag saying that all following elements in the specification list at this level are optional. They may or may not match arguments; as soon as one does not match, processing of the specification list at this level terminates. To make just one item optional, use `[&optional pattern]`.

`&rest`
: This symbol serves as a flag saying that the following elements in the specification list at this level may be repeated, in order, zero or more times. Only one `&rest` may appear at the same level of a specification list, and `&rest` must not be followed by `&optional`.

  To specify repetition of certain types of arguments, followed by dissimilar arguments, use `[&rest patterns...]`.

`&or`
: This symbol serves as an operator saying that the following elements in the specification list at this level are alternatives. To group two or more list elements as one alternative, bracket them in `[...]`. Only one `&or` may appear in a list, and it may not be followed by `&optional` or `&rest`. One of the alternatives must match, unless the `&or` is preceded by `&optional` or `&rest`.

If the actual arguments of a macro call fail to match the specification, taking account of alternatives, optional arguments and repeated arguments, Edebug reports a syntax error in use of the macro.

The combination of backtracking, `&optional`, `&rest`, `&or`, and `[...]` for grouping provides the equivalent of regular expressions. The `(...)` lists require balanced parentheses, which is the only context free (finite state with stack) construct supported.

Here are some examples of using `def-edebug-form-spec`. First, for the `let` special form:

```
(def-edebug-form-spec let
  '((&rest
    &or symbolp (symbolp &optional form))
   &rest form))
```

Here's the spec for the `for` loop macro (see section Common Problems Using Macros) and for the `case` and `do` macros in `` `cl.el' ``:

```
(def-edebug-form-spec for
  '(symbolp 'from form 'to form 'do &rest form))

(def-edebug-form-spec case
  '(form &rest (sexp form)))

(def-edebug-form-spec do
  '((&rest &or symbolp (symbolp &optional form form))
    (form &rest form)
    &rest body))
```

Finally, the functions `mapcar`, `mapconcat`, `mapatoms`, `apply`, and `funcall` all take function arguments, and Edebug defines specifications for them. Here's one example:

```
(def-edebug-form-spec apply '(function &rest form))
```

The backquote (`) macro results in an expression that is not necessarily evaluated. Edebug cannot step through code generated by use of backquote.

Edebug Options

These options affect the behavior of Edebug:

User Option: **edebug-all-defuns**

If non-`nil`, normal evaluation of `defun` and `defmacro` forms prepares the functions and macros for stepping with Edebug. This applies to `eval-defun`, `eval-region` and `eval-current-buffer`.

The default value is `nil`.

User Option: **edebug-stop-before-symbols**

If non-`nil`, Edebug places stop points before symbols as well as after.

This option takes effect for a function when you prepare it for stepping with Edebug. Changing the option's value during execution of Edebug has no effect on the functions already set up for Edebug execution.

User Option: **edebug-save-windows**

If non-`nil`, save and restore window configuration on Edebug calls. It takes some time to save and restore, so if your program does not care what happens to the window configurations, it is better to set this variable to `nil`.

The default value is `t`.

User Option: **edebug-save-point**

If non-`nil`, Edebug saves and restores point and the mark in source code buffers. The default value is `t`.

User Option: **edebug-save-displayed-buffer-points**

If non-`nil`, save and restore point in all buffers when entering Edebug mode.

Saving and restoring point in other buffers is necessary if you are debugging code that changes the point of a buffer which is displayed in a non-selected window. If Edebug or the user then selects the window, the buffer's point will be changed to the window's point.

Saving and restoring is an expensive operation since it visits each window and each displayed buffer twice for each Edebug call, so it is best to avoid it if you can.

The default value is `nil`.

User Option: **edebug-initial-mode**

If this variable is non-`nil`, it specifies an Edebug mode to start in each time the program enters a new Edebug recursive-edit level. Possible values are `step`, `go`, `Go-nonstop`, `trace`, `Trace-fast`, `continue`, and `Continue-fast`.

The default value is `step`.

User Option: **edebug-trace**

Non-`nil` means display a trace of function entry and exit. Tracing output is displayed in a buffer named `*edebug-trace*', one function entry or exit per line, indented by the recursion level. You can customize this display by replacing the functions `edebug-print-trace-entry` and `edebug-print-trace-exit`.

The default value is `nil`.

Reading and Printing Lisp Objects

Printing and reading are the operations of converting Lisp objects to textual form and vice versa. They use the printed representations and read syntax described in section Lisp Data Types.

This chapter describes the Lisp functions for reading and printing. It also describes streams, which specify where to get the text (if reading) or where to put it (if printing).

Introduction to Reading and Printing

Reading a Lisp object means parsing a Lisp expression in textual form and producing a corresponding Lisp object. This is how Lisp programs get into Lisp from files of Lisp code. We call the text the read syntax of the object. For example, reading the text `(a . 5)' returns a cons cell whose CAR is `a` and whose CDR is the number 5.

Printing a Lisp object means producing text that represents that object--converting the object to its printed representation. Printing the cons cell described above produces the text `(a . 5)'.

Reading and printing are more or less inverse operations: printing the object that results from reading a given piece of text often produces the same text, and reading the text that results from printing an object usually produces a similar-looking object. For example, printing the symbol `foo` produces the text `foo', and reading that text returns the symbol `foo`. Printing a list whose elements are `a` and `b` produces the text `(a b)', and reading that text produces a list (but not the same list) with elements are `a` and `b`.

However, these two operations are not precisely inverses. There are two kinds of exceptions:

- Printing can produce text that cannot be read. For example, buffers, windows, subprocesses and markers print into text that starts with `#'; if you try to read this text, you get an error. There is no way to read those data types.
- One object can have multiple textual representations. For example, `1' and `01' represent the same integer, and `(a b)' and `(a . (b))' represent the same list. Reading will accept any of the alternatives, but printing must choose one of them.

Input Streams

Most of the Lisp functions for reading text take an input stream as an argument. The input stream specifies where or how to get the characters of the text to be read. Here are the possible types of input stream:

buffer

> The input characters are read from buffer, starting with the character directly after point. Point advances as characters are read.

marker

The input characters are read from the buffer that marker is in, starting with the character direc after the marker. The marker position advances as characters are read. The value of point in the buffer has no effect when the stream is a marker.

string

The input characters are taken from string, starting at the first character in the string and using as many characters as required.

function

The input characters are generated by function, one character per call. Normally function is called with no arguments, and should return a character.

Occasionally function is called with one argument (always a character). When that happens, function should save the argument and arrange to return it on the next call. This is called unreading the character; it happens when the Lisp reader reads one character too many and want to "put it back where it came from".

`t`

`t` used as a stream means that the input is read from the minibuffer. In fact, the minibuffer is invoked once and the text given by the user is made into a string that is then used as the input stream.

`nil`

`nil` used as a stream means that the value of `standard-input` should be used instead; that value is the default input stream, and must be a non-`nil` input stream.

symbol

A symbol as output stream is equivalent to the symbol's function definition (if any).

Here is an example of reading from a stream which is a buffer, showing where point is located before and after:

```
---------- Buffer: foo ----------
This-!- is the contents of foo.
---------- Buffer: foo ----------

(read (get-buffer "foo"))
     => is
(read (get-buffer "foo"))
     => the

---------- Buffer: foo ----------
This is the-!- contents of foo.
---------- Buffer: foo ----------
```

Note that the first read skips a space at the beginning of the buffer. Reading skips any amount of whitespace preceding the significant text.

In Emacs 18, reading a symbol discarded the delimiter terminating the symbol. Thus, point would end up

at the beginning of `contents' rather than after `the'. The Emacs 19 behavior is superior because it correctly handles input such as `bar(foo)' where the delimiter that ends one object is needed as the beginning of another object.

Here is an example of reading from a stream that is a marker, initialized to point at the beginning of the buffer shown. The value read is the symbol `This`.

```
---------- Buffer: foo ----------
This is the contents of foo.
---------- Buffer: foo ----------

(setq m (set-marker (make-marker) 1 (get-buffer "foo")))
     => #<marker at 1 in foo>
(read m)
     => This
m
     => #<marker at 6 in foo>   ;; After the first space.
```

Here we read from the contents of a string:

```
(read "(When in) the course")
     => (When in)
```

The following example reads from the minibuffer. The prompt is: `Lisp expression: '. (That is always the prompt used when you read from the stream `t`.) The user's input is shown following the prompt.

```
(read t)
     => 23
---------- Buffer: Minibuffer ----------
Lisp expression: 23 RET
---------- Buffer: Minibuffer ----------
```

Finally, here is an example of a stream that is a function, named `useless-stream`. Before we use the stream, we initialize the variable `useless-list` to a list of characters. Then each call to the function `useless-stream` obtains the next characters in the list or unreads a character by adding it to the front of the list.

```
(setq useless-list (append "XY()" nil))
     => (88 89 40 41)

(defun useless-stream (&optional unread)
  (if unread
      (setq useless-list (cons unread useless-list))
    (prog1 (car useless-list)
           (setq useless-list (cdr useless-list)))))
```

```
     => useless-stream
```

Now we read using the stream thus constructed:

```
(read 'useless-stream)
     => XY

useless-list
     => (41)
```

Note that the close parenthesis remains in the list. The reader has read it, discovered that it ended the input, and unread it. Another attempt to read from the stream at this point would get an error due to the unmatched close parenthesis.

Function: **get-file-char**

This function is used internally as an input stream to read from the input file opened by the function `load`. Don't use this function yourself.

Input Functions

This section describes the Lisp functions and variables that pertain to reading.

In the functions below, stream stands for an input stream (see the previous section). If stream is `nil` or omitted, it defaults to the value of `standard-input`.

An `end-of-file` error results if an unterminated list or vector is found.

Function: **read** *&optional stream*

This function reads one textual Lisp expression from stream, returning it as a Lisp object. This is the basic Lisp input function.

Function: **read-from-string** *string &optional start end*

This function reads the first textual Lisp expression from the text in string. It returns a cons cell whose CAR is that expression, and whose CDR is an integer giving the position of the next remaining character in the string (i.e., the first one not read).

If start is supplied, then reading begins at index start in the string (where the first character is at index 0). If end is also supplied, then reading stops at that index as if the rest of the string were not there.

For example:

```
(read-from-string "(setq x 55) (setq y 5)")
     => ((setq x 55) . 11)
(read-from-string "\"A short string\"")
     => ("A short string" . 16)
```

```
;; Read starting at the first character.
(read-from-string "(list 112)" 0)
     => ((list 112) . 10)
;; Read starting at the second character.
(read-from-string "(list 112)" 1)
     => (list . 6)
;; Read starting at the seventh character,
;;   and stopping at the ninth.
(read-from-string "(list 112)" 6 8)
     => (11 . 8)
```

Variable: **standard-input**

This variable holds the default input stream: the stream that `read` uses when the stream argument is `nil`.

Output Streams

An output stream specifies what to do with the characters produced by printing. Most print functions accept an output stream as an optional argument. Here are the possible types of output stream:

buffer

The output characters are inserted into buffer at point. Point advances as characters are inserted.

marker

The output characters are inserted into the buffer that marker is in at the marker position. The position advances as characters are inserted. The value of point in the buffer has no effect when the stream is a marker.

function

The output characters are passed to function, which is responsible for storing them away. It is called with a single character as argument, as many times as there are characters to be output, and is free to do anything at all with the characters it receives.

`t`

The output characters are displayed in the echo area.

`nil`

`nil` specified as an output stream means that the value of `standard-output` should be used as the output stream; that value is the default output stream, and must be a non-`nil` output stream.

symbol

A symbol as output stream is equivalent to the symbol's function definition (if any).

Here is an example of a buffer used as an output stream. Point is initially located as shown immediately before the `h' in `the'. At the end, point is located directly before that same `h'.

```
---------- Buffer: foo ----------
This is t-!-he contents of foo.
```

```
---------- Buffer: foo ----------

(print "This is the output" (get-buffer "foo"))
     => "This is the output"

---------- Buffer: foo ----------
This is t
"This is the output"
-!-he contents of foo.
---------- Buffer: foo ----------
```

Now we show a use of a marker as an output stream. Initially, the marker points in buffer `foo`, between the `t' and the `h' in the word `the'. At the end, the marker has been advanced over the inserted text so that it still points before the same `h'. Note that the location of point, shown in the usual fashion, has no effect.

```
---------- Buffer: foo ----------
"This is the -!-output"
---------- Buffer: foo ----------

m
     => #<marker at 11 in foo>

(print "More output for foo." m)
     => "More output for foo."

---------- Buffer: foo ----------
"This is t
"More output for foo."
he -!-output"
---------- Buffer: foo ----------

m
     => #<marker at 35 in foo>
```

The following example shows output to the echo area:

```
(print "Echo Area output" t)
     => "Echo Area output"
---------- Echo Area ----------
"Echo Area output"
---------- Echo Area ----------
```

Finally, we show an output stream which is a function. The function `eat-output` takes each character that it is given and conses it onto the front of the list `last-output` (see section Building Cons Cells and Lists). At the end, the list contains all the characters output, but in reverse order.

```
(setq last-output nil)
     => nil

(defun eat-output (c)
  (setq last-output (cons c last-output)))
     => eat-output

(print "This is the output" 'eat-output)
     => "This is the output"

last-output
     => (10 34 116 117 112 116 117 111 32 101 104
    116 32 115 105 32 115 105 104 84 34 10)
```

Now we can put the output in the proper order by reversing the list:

```
(concat (nreverse last-output))
     => "
\"This is the output\"
"
```

Output Functions

This section describes the Lisp functions for printing Lisp objects.

Some of the Emacs printing functions add quoting characters to the output when necessary so that it can be read properly. The quoting characters used are `\' and `"'; they are used to distinguish strings from symbols, and to prevent punctuation characters in strings and symbols from being taken as delimiters. See section Printed Representation and Read Syntax, for full details. You specify quoting or no quoting by the choice of printing function.

If the text is to be read back into Lisp, then it is best to print with quoting characters to avoid ambiguity. Likewise, if the purpose is to describe a Lisp object clearly for a Lisp programmer. However, if the purpose of the output is to look nice for humans, then it is better to print without quoting.

Printing a self-referent Lisp object requires an infinite amount of text. In certain cases, trying to produce this text leads to a stack overflow. Emacs detects such recursion and prints `#level' instead of recursively printing an object already being printed. For example, here `#0' indicates a recursive reference to the object at level 0 of the current print operation:

```
(setq foo (list nil))
     => (nil)
(setcar foo foo)
     => (#0)
```

In the functions below, stream stands for an output stream. (See the previous section for a description of output streams.) If stream is `nil` or omitted, it defaults to the value of `standard-output`.

Function: **print** *object &optional stream*

The `print` is a convenient way of printing. It outputs the printed representation of object to stream, printing in addition one newline before object and another after it. Quoting characters are used. `print` returns object. For example:

```
(progn (print 'The\ cat\ in)
       (print "the hat")
       (print " came back"))
     -|
     -| The\ cat\ in
     -|
     -| "the hat"
     -|
     -| " came back"
     -|
     => " came back"
```

Function: **prin1** *object &optional stream*

This function outputs the printed representation of object to stream. It does not print any spaces or newlines to separate output as `print` does, but it does use quoting characters just like `print`. It returns object.

```
(progn (prin1 'The\ cat\ in)
       (prin1 "the hat")
       (prin1 " came back"))
     -| The\ cat\ in"the hat"" came back"
     => " came back"
```

Function: **princ** *object &optional stream*

This function outputs the printed representation of object to stream. It returns object.

This function is intended to produce output that is readable by people, not by `read`, so quoting characters are not used and double-quotes are not printed around the contents of strings. It does not add any spacing between calls.

```
(progn
  (princ 'The\ cat)
  (princ " in the \"hat\""))
     -| The cat in the "hat"
     => " in the \"hat\""
```

Function: **terpri** *&optional stream*

This function outputs a newline to stream. The name stands for "terminate print".

Function: **write-char** *character &optional stream*

This function outputs character to stream. It returns character.

Function: **prin1-to-string** *object &optional noescape*

This function returns a string containing the text that `prin1` would have printed for the same argument.

```
(prin1-to-string 'foo)
     => "foo"
(prin1-to-string (mark-marker))
     => "#<marker at 2773 in strings.texi>"
```

If noescape is non-`nil`, that inhibits use of quoting characters in the output. (This argument is supported in Emacs versions 19 and later.)

```
(prin1-to-string "foo")
     => "\"foo\""
(prin1-to-string "foo" t)
     => "foo"
```

See `format`, in section Conversion of Characters and Strings, for other ways to obtain the printed representation of a Lisp object as a string.

Variables Affecting Output

Variable: **standard-output**

The value of this variable is the default output stream, used when the stream argument is omitted or `nil`.

Variable: **print-escape-newlines**

If this variable is non-`nil`, then newline characters in strings are printed as `\n'. Normally they are printed as actual newlines.

This variable affects the print functions `prin1` and `print`, as well as everything that uses them. It does not affect `princ`. Here is an example using `prin1`:

```
(prin1 "a\nb")
     -| "a
     -| b"
     => "a
     => b"

(let ((print-escape-newlines t))
```

```
(prin1 "a\nb"))
   -| "a\nb"
   => "a
   => b"
```

In the second expression, the local binding of `print-escape-newlines` is in effect during the call to `prin1`, but not during the printing of the result.

Variable: **print-length**

The value of this variable is the maximum number of elements of a list that will be printed. If the list being printed has more than this many elements, then it is abbreviated with an ellipsis.

If the value is `nil` (the default), then there is no limit.

```
(setq print-length 2)
     => 2
(print '(1 2 3 4 5))
     -| (1 2 ...)
     => (1 2 ...)
```

Variable: **print-level**

The value of this variable is the maximum depth of nesting of parentheses that will be printed. Any list or vector at a depth exceeding this limit is abbreviated with an ellipsis. A value of `nil` (which is the default) means no limit.

This variable exists in version 19 and later versions.

Go to the previous, next section.

Go to the previous, next section.

Minibuffers

A minibuffer is a special buffer that Emacs commands use to read arguments more complicated than the single numeric prefix argument. These arguments include file names, buffer names, and command names (as in M-x). The minibuffer is displayed on the bottom line of the screen, in the same place as the echo area, but only while it is in use for reading an argument.

Introduction to Minibuffers

In most ways, a minibuffer is a normal Emacs buffer. Most operations *within* a buffer, such as editing commands, work normally in a minibuffer. However, many operations for managing buffers do not apply to minibuffers. The name of a minibuffer always has the form ` *Minibuf-number', and it cannot be changed. Minibuffers are displayed only in special windows used only for minibuffers; these windows always appear at the bottom of a frame. (Sometime frames have no minibuffer window, and sometimes a special kind of frame contains nothing but a minibuffer window; see section Minibuffers and Frames.)

The minibuffers window is normally a single line; you can resize it temporarily with the window sizing commands, but reverts to its normal size when the minibuffer is exited.

A recursive minibuffer may be created when there is an active minibuffer and a command is invoked that requires input from a minibuffer. The first minibuffer is named ` *Minibuf-0*'. Recursive minibuffers are named by incrementing the number at the end of the name. (The names begin with a space so that they won't show up in normal buffer lists.) Of several recursive minibuffers, the innermost (or most recently entered) is the active minibuffer. We usually call this "the" minibuffer. You can permit or forbid recursive minibuffers by setting the variable `enable-recursive-minibuffers` or by putting properties of that name on command symbols (see section Minibuffer Miscellany).

Like other buffers, a minibuffer may use any of several local keymaps (see section Keymaps); these contain various exit commands and in some cases completion commands. See section Completion.

- `minibuffer-local-map` is for ordinary input (no completion).
- `minibuffer-local-ns-map` is similar, except that SPC exits just like RET. This is used mainly for Mocklisp compatibility.
- `minibuffer-local-completion-map` is for permissive completion.
- `minibuffer-local-must-match-map` is for strict completion and for cautious completion.

Reading Text Strings with the Minibuffer

The minibuffer is usually used to read text which is returned as a string, but can also be used to read a Lisp object in textual form. The most basic primitive for minibuffer input is `read-from-minibuffer`.

Function: **read-from-minibuffer** *prompt-string &optional initial keymap read hist*

This function is the most general way to get input through the minibuffer. By default, it accepts arbitrary text and returns it as a string; however, if read is non-`nil`, then it uses `read` to convert the text into a Lisp object (see section Input Functions).

The first thing this function does is to activate a minibuffer and display it with prompt-string as the prompt. This value must be a string.

Then, if initial is a string; its contents are inserted into the minibuffer as initial contents. The text thus inserted is treated as if the user had inserted it; the user can alter it with Emacs editing commands.

The value of initial may also be a cons cell of the form `(string . position)`. This means to insert string in the minibuffer but put the cursor position characters from the beginning, rather than at the end.

If keymap is non-`nil`, that keymap is the local keymap to use while reading. If keymap is omitted or `nil`, the value of `minibuffer-local-map` is used as the keymap. Specifying a keymap is the most important way to customize minibuffer input for various applications including completion.

The argument hist specifies which history list variable to use for saving the input and for history commands used in the minibuffer. It defaults to `minibuffer-history`. See section Minibuffer History.

When the user types a command to exit the minibuffer, the current minibuffer contents are usually made into a string which becomes the value of `read-from-minibuffer`. However, if read is non-`nil`, `read-from-minibuffer` converts the result to a Lisp object, and returns that object, unevaluated.

Suppose, for example, you are writing a search command and want to record the last search string and provide it as a default for the next search. Suppose that the previous search string is stored in the variable `last-search-string`. Here is how you can read a search string while providing the previous string as initial input to be edited:

```
(read-from-minibuffer "Find string: " last-search-string)
```

Assuming the value of `last-search-string` is `No', and the user wants to search for `Nope', the interaction looks like this:

```
(setq last-search-string "No")

(read-from-minibuffer "Find string: " last-search-string)
---------- Buffer: Minibuffer ----------
Find string: No-!-
---------- Buffer: Minibuffer ----------
;; The user now types pe RET:
     => "Nope"
```

This technique is no longer preferred for most applications; it is usually better to use a history list.

Function: **read-string** *prompt &optional initial*

This function reads a string from the minibuffer and returns it. The arguments prompt and initial are as in `read-from-minibuffer`.

This is a simplified interface to the `read-from-minibuffer` function:

```
(read-string prompt initial)
==
(read-from-minibuffer prompt initial nil nil)
```

Variable: **minibuffer-local-map**

This is the default local keymap for reading from the minibuffer. It is the keymap used by the minibuffer for local bindings in the function `read-string`. By default, it makes the following bindings:

LFD
: `exit-minibuffer`

RET
: `exit-minibuffer`

C-g
: `abort-recursive-edit`

M-n and M-p
: `next-history-element` and `previous-history-element`

M-r
: `next-matching-history-element`

M-s
: `previous-matching-history-element`

Function: **read-no-blanks-input** *prompt &optional initial*

This function reads a string from the minibuffer, but does not allow whitespace characters as part of the input: instead, those characters terminate the input. The arguments prompt and initial are used as in `read-from-minibuffer`.

This is a simplified interface to the `read-from-minibuffer` function, and passes the value of the `minibuffer-local-ns-map` keymap as the keymap argument for that function. Since the keymap `minibuffer-local-ns-map` does not rebind C-q, it *is* possible to put a space into the string, by quoting it.

```
(read-no-blanks-input prompt initial)
==
(read-from-minibuffer prompt initial minibuffer-local-ns-map)
```

Variable: **minibuffer-local-ns-map**

This built-in variable is the keymap used as the minibuffer local keymap in the function

`read-no-blanks-input`. By default, it makes the following bindings:

LFD
: `exit-minibuffer`

SPC
: `exit-minibuffer`

TAB
: `exit-minibuffer`

RET
: `exit-minibuffer`

C-g
: `abort-recursive-edit`

?
: `self-insert-and-exit`

M-n and M-p
: `next-history-element` and `previous-history-element`

M-r
: `next-matching-history-element`

M-s
: `previous-matching-history-element`

Reading Lisp Objects with the Minibuffer

This section describes functions for reading Lisp objects with the minibuffer.

Function: **read-minibuffer** *prompt &optional initial*

This function reads a Lisp object in the minibuffer and returns it, without evaluating it. The arguments prompt and initial are used as in `read-from-minibuffer`; in particular, initial must be a string or `nil`.

This is a simplified interface to the `read-from-minibuffer` function:

```
(read-minibuffer prompt initial)
==
(read-from-minibuffer prompt initial nil t)
```

Here is an example in which we supply the string `"(testing)"` as initial input:

```
(read-minibuffer
 "Enter an expression: " (format "%s" '(testing)))
```

```
;; Here is how the minibuffer is displayed:

---------- Buffer: Minibuffer ----------
Enter an expression: (testing)-!-
---------- Buffer: Minibuffer ----------
```

The user can type RET immediately to use the initial input as a default, or can edit the input.

Function: **eval-minibuffer** *prompt &optional initial*

This function reads a Lisp expression in the minibuffer, evaluates it, then returns the result. The arguments prompt and initial are used as in `read-from-minibuffer`.

This function simply evaluates the result of a call to `read-minibuffer`:

```
(eval-minibuffer prompt initial)
==
(eval (read-minibuffer prompt initial))
```

Function: **edit-and-eval-command** *prompt form*

This function reads a Lisp expression in the minibuffer, and then evaluates it. The difference between this command and `eval-minibuffer` is that here the initial form is not optional and it is treated as a Lisp object to be converted to printed representation rather than as a string of text. It is printed with `prin1`, so if it is a string, double-quote characters (`"') appear in the initial text. See section Output Functions.

The first thing `edit-and-eval-command` does is to activate the minibuffer with prompt as the prompt. Then it inserts the printed representation of form in the minibuffer, and lets the user edit. When the user exits the minibuffer, the edited text is read with `read` and then evaluated. The resulting value becomes the value of `edit-and-eval-command`.

In the following example, we offer the user an expression with initial text which is a valid form already:

```
(edit-and-eval-command "Please edit: " '(forward-word 1))

;; After evaluating the preceding expression,
;;   the following appears in the minibuffer:

---------- Buffer: Minibuffer ----------
Please edit: (forward-word 1)-!-
---------- Buffer: Minibuffer ----------
```

Typing RET right away would exit the minibuffer and evaluate the expression, thus moving point forward one word. `edit-and-eval-command` returns `nil` in this example.

Minibuffer History

A minibuffer history list records previous minibuffer inputs so the user can reuse them conveniently. There are many separate history lists which contain different kinds of inputs. The Lisp programmer's job is to specify the right history list for each use of the minibuffer.

The basic minibuffer input functions `read-from-minibuffer` and `completing-read` both accept an optional argument named hist which is how you specify the history list. Here are the possible values:

variable

If you specify a variable (a symbol), that variable is the history list.

(variable . startpos)

If you specify a cons cell of this form, then variable is the history list variable, and startpos specifies the initial history position (an integer, counting from zero which specifies the most recent element of the history).

If you specify startpos, then you should also specify that element of the history as initial, for consistency.

If you don't specify hist, then the default history list `minibuffer-history` is used. For other standard history lists, see below. You can also create your own history list variable; just initialize it to `nil` before the first use. The value of the history list variable is a list of strings, most recent first.

Both `read-from-minibuffer` and `completing-read` add new elements to the history list automatically, and provide commands to allow the user to reuse items on the list. The only thing your program needs to do to use a history list is to initialize it and to pass its name to the input functions when you wish. But it is safe to modify the list by hand when the minibuffer input functions are not using it.

Variable: **minibuffer-history**

The default history list for minibuffer history input.

Variable: **query-replace-history**

A history list for arguments to `query-replace` (and similar arguments to other commands).

Variable: **file-name-history**

A history list for file name arguments.

Completion

Completion is a feature that fills in the rest of a name starting from an abbreviation for it. Completion works by comparing the user's input against a list of valid names and determining how much of the name is determined uniquely by what the user has typed.

For example, when you type C-x b (`switch-to-buffer`) and then type the first few letters of the

name of the buffer to which you wish to switch, and then type TAB (`minibuffer-complete`), Emacs extends the name as far as it can. Standard Emacs commands offer completion for names of symbols, files, buffers, and processes; with the functions in this section, you can implement completion for other kinds of names.

The `try-completion` function is the basic primitive for completion: it returns the longest determined completion of a given initial string, with a given set of strings to match against.

The function `completing-read` provides a higher-level interface for completion. A call to `completing-read` specifies how to determine the list of valid names. The function then activates the minibuffer with a local keymap that binds a few keys to commands useful for completion. Other functions provide convenient simple interfaces for reading certain kinds of names with completion.

Basic Completion Functions

Function: **try-completion** *string collection &optional predicate*

This function returns the longest common substring of all possible completions of string in collection. The value of collection must be an alist, an obarray, or a function which implements a virtual set of strings.

If collection is an alist (see section Association Lists), completion compares the CAR of each cons cell in it against string; if the beginning of the CAR equals string, the cons cell matches. If no cons cells match, `try-completion` returns `nil`. If only one cons cell matches, and the match is exact, then `try-completion` returns `t`. Otherwise, the value is the longest initial sequence common to all the matching strings in the alist.

If collection is an obarray (see section Creating and Interning Symbols), the names of all symbols in the obarray form the space of possible completions. They are tested and used just like the CARs of the elements of an association list. (The global variable `obarray` holds an obarray containing the names of all interned Lisp symbols.)

Note that the only valid way to make a new obarray is to create it empty and then add symbols to it one by one using `intern`. Also, you cannot intern a given symbol in more than one obarray.

If the argument predicate is non-`nil`, then it must be a function of one argument. It is used to test each possible match, and the match is accepted only if predicate returns non-`nil`. The argument given to predicate is either a cons cell from the alist (the CAR of which is a string) or else it is a symbol (*not* a symbol name) from the obarray.

It is also possible to use a function symbol as collection. Then the function is solely responsible for performing completion; `try-completion` returns whatever this function returns. The function is called with three arguments: string, predicate and `nil`. (The reason for the third argument is so that the same function can be used in `all-completions` and do the appropriate thing in either case.) See section Programmed Completion.

In the first of the following examples, the string `foo' is matched by three of the alist CARs. All of the matches begin with the characters `fooba', so that is the result. In the second example, there is only one

possible match, and it is exact, so the value is `t`.

```
(try-completion
 "foo"
 '(("foobar1" 1) ("barfoo" 2) ("foobaz" 3) ("foobar2" 4)))
     => "fooba"

(try-completion "foo" '(("barfoo" 2) ("foo" 3)))
     => t
```

In the following example, numerous symbols begin with the characters `forw', and all of them begin with the word `forward'. In most of the symbols, this is followed with a `-', but not in all, so no more than `forward' can be completed.

```
(try-completion "forw" obarray)
     => "forward"
```

Finally, in the following example, only two of the three possible matches pass the predicate `test` (the string `foobaz' is too short). Both of those begin with the string `foobar'.

```
(defun test (s)
  (> (length (car s)) 6))
     => test
(try-completion
 "foo"
 '(("foobar1" 1) ("barfoo" 2) ("foobaz" 3) ("foobar2" 4))
     'test)
     => "foobar"
```

Function: **all-completions** *string collection &optional predicate*

This function returns a list of all possible completions, instead of the longest substring they share. The parameters to this function are the same as to `try-completion`.

If collection is a function, it is called with three arguments: string, predicate and `t`, and `all-completions` returns whatever the function returns. See section Programmed Completion.

Here is an example, using the function `test` shown in the example for `try-completion`:

```
(defun test (s)
  (> (length (car s)) 6))
     => test

(all-completions
 "foo"
 '(("foobar1" 1) ("barfoo" 2) ("foobaz" 3) ("foobar2" 4))
 (function test))
```

```
=> ("foobar1" "foobar2")
```

Variable: **completion-ignore-case**

If the value of this variable is non-`nil`, Emacs does not consider case significant in completion.

The two functions `try-completion` and `all-completions` have nothing in themselves to do with minibuffers. However, completion is most often used there, which is why it is described in this chapter.

Programmed Completion

Sometimes it is not possible to create an alist or an obarray containing all the intended possible completions. In such a case, you can supply your own function to compute the completion of a given string. This is called programmed completion.

To use this feature, pass a symbol with a function definition as the collection argument to `completing-read`. This command arranges to pass the function along to `try-completion` and `all-completions`, which will then let your function do all the work.

The completion function should accept three arguments:

- The string to be completed.
- The predicate function to filter possible matches, or `nil` if none. Your function should call the predicate for each possible match and ignore the possible match if the predicate returns `nil`.
- A flag specifying the type of operation.

There are three flag values for three operations:

- `nil` specifies `try-completion`. The completion function should return the completion of the specified string, or `t` if the string is an exact match already, or `nil` if the string matches no possibility.
- `t` specifies `all-completions`. The completion function should return a list of all possible completions of the specified string.
- `lambda` specifies a test for an exact match. The completion function should return `t` if the specified string is an exact match for some possibility; `nil` otherwise.

It would be consistent and clean for completion functions to allow lambda expressions (lists which are functions) as well as function symbols as collection, but this is impossible. Lists as completion tables are already assigned another meaning--as alists. It would be unreliable to fail to handle an alist normally because it is also a possible function. So you must arrange for any function you wish to use for completion to be encapsulated in a symbol.

Emacs uses programmed completion when completing file names. See section File Name Completion.

Completion and the Minibuffer

This section describes the basic interface for reading from the minibuffer with completion.

Function: **completing-read** *prompt collection &optional predicate require-match initial hist*

This function reads a string in the minibuffer, assisting the user by providing completion. It activates the minibuffer with prompt prompt, which must be a string. If initial is non-`nil`, `completing-read` inserts it into the minibuffer as part of the input. Then it allows the user to edit the input, providing several commands to attempt completion.

The actual completion is done by passing collection and predicate to the function `try-completion`. This happens in certain commands bound in the local keymaps used for completion.

If require-match is `t`, the user is not allowed to exit unless the input completes to an element of collection. If require-match is neither `nil` nor `t`, then `completing-read` does not exit unless the input typed is itself an element of collection. To accomplish this, `completing-read` calls `read-minibuffer`. It uses the value of `minibuffer-local-completion-map` as the keymap if require-match is `nil`, and uses `minibuffer-local-must-match-map` if require-match is non-`nil`.

The argument hist specifies which history list variable to use for saving the input and for minibuffer history commands. It defaults to `minibuffer-history`. See section Minibuffer History.

Case is ignored when comparing the input against the possible matches if the built-in variable `completion-ignore-case` is non-`nil`. See section Basic Completion Functions.

For example:

```
(completing-read
 "Complete a foo: "
 '(("foobar1" 1) ("barfoo" 2) ("foobaz" 3) ("foobar2" 4))
 nil t "fo")

;; After evaluating the preceding expression,
;;   the following appears in the minibuffer:

---------- Buffer: Minibuffer ----------
Complete a foo: fo-!-
---------- Buffer: Minibuffer ----------
```

If the user then types DEL DEL b RET, `completing-read` returns `barfoo`.

The `completing-read` function binds three variables to pass information to the commands which actually do completion. Here they are:

`minibuffer-completion-table`

This variable is bound to the collection argument. It is passed to the `try-completion` function.

`minibuffer-completion-predicate`

This variable is bound to the predicate argument. It is passed to the `try-completion` function.

`minibuffer-completion-confirm`

This variable is bound to the require-match argument. It is used in the `minibuffer-complete-and-exit` function.

Minibuffer Commands That Do Completion

This section describes the keymaps, commands and user options used in the minibuffer to do completion.

Variable: **minibuffer-local-completion-map**

`completing-read` uses this value as the local keymap when an exact match of one of the completions is not required. By default, this keymap makes the following bindings:

?

`minibuffer-completion-help`

SPC

`minibuffer-complete-word`

TAB

`minibuffer-complete`

with other characters bound as in `minibuffer-local-map`.

Variable: **minibuffer-local-must-match-map**

`completing-read` uses this value as the local keymap when an exact match of one of the completions is required. Therefore, no keys are bound to `exit-minibuffer`, the command which exits the minibuffer unconditionally. By default, this keymap makes the following bindings:

?

`minibuffer-completion-help`

SPC

`minibuffer-complete-word`

TAB

`minibuffer-complete`

LFD

`minibuffer-complete-and-exit`

RET

`minibuffer-complete-and-exit`

with other characters bound as in `minibuffer-local-map`.

Variable: **minibuffer-completion-table**

The value of this variable is the alist or obarray used for completion in the minibuffer. This is the global

variable that contains what `completing-read` passes to `try-completion`. It is used by all the minibuffer completion functions, such as `minibuffer-complete-word`.

Variable: **minibuffer-completion-predicate**

This variable's value is the predicate that `completing-read` passes to `try-completion`. The variable is also used by the other minibuffer completion functions.

Command: **minibuffer-complete-word**

This function completes the minibuffer contents by at most a single word. Even if the minibuffer contents have only one completion, `minibuffer-complete-word` does not add any characters beyond the first character that is not a word constituent. See section Syntax Tables.

Command: **minibuffer-complete**

This function completes the minibuffer contents as far as possible.

Command: **minibuffer-complete-and-exit**

This function completes the minibuffer contents, and exits if confirmation is not required, i.e., if `minibuffer-completion-confirm` is non-`nil`. If confirmation *is* required, it is given by repeating this command immediately.

Variable: **minibuffer-completion-confirm**

When the value of this variable is non-`nil`, Emacs asks for confirmation of a completion before exiting the minibuffer. The function `minibuffer-complete-and-exit` checks the value of this variable before it exits.

Command: **minibuffer-completion-help**

This function creates a list of the possible completions of the current minibuffer contents. It works by calling `all-completions` using the value of the variable `minibuffer-completion-table` as the collection argument, and the value of `minibuffer-completion-predicate` as the predicate argument. The list of completions is displayed as text in a buffer named `*Completions*'.

Function: **display-completion-list** *completions*

This function displays completions to the stream in `standard-output`, usually a buffer. (See section Reading and Printing Lisp Objects, for more information about streams.) The argument completions is normally a list of completions just returned by `all-completions`, but it does not have to be. Each element may be a symbol or a string, either of which is simply printed, or a list of two strings, which is printed as if the strings were concatenated.

This function is called by `minibuffer-completion-help`. The most common way to use it is together with `with-output-to-temp-buffer`, like this:

```
(with-output-to-temp-buffer " *Completions*"
  (display-completion-list
    (all-completions (buffer-string) my-alist)))
```

User Option: **completion-auto-help**

If this variable is non-`nil`, the completion commands automatically display a list of possible completions whenever nothing can be completed because the next character is not uniquely determined.

High-Level Completion Functions

This section describes the higher-level convenient functions for reading certain sorts of names with completion.

Function: **read-buffer** *prompt &optional default existing*

This function reads the name of a buffer and returns it as a string. The argument default is the default name to use, the value to return if the user exits with an empty minibuffer. If non-`nil`, it should be a string. It is mentioned in the prompt, but is not inserted in the minibuffer as initial input.

If existing is non-`nil`, then the name specified must be that of an existing buffer. The usual commands to exit the minibuffer do not exit if the text is not valid, and RET does completion to attempt to find a valid name. (However, default is not checked for this; it is returned, whatever it is, if the user exits with the minibuffer empty.)

In the following example, the user enters `minibuffer.t', and then types RET. The argument existing is `t`, and the only buffer name starting with the given input is `minibuffer.texi', so that name is the value.

```
(read-buffer "Buffer name? " "foo" t)

;; After evaluating the preceding expression,
;;   the following prompt appears,
;;   with an empty minibuffer:

---------- Buffer: Minibuffer ----------
Buffer name? (default foo) -!-
---------- Buffer: Minibuffer ----------

;; The user types minibuffer.t RET.

     => "minibuffer.texi"
```

Function: **read-command** *prompt*

This function reads the name of a command and returns it as a Lisp symbol. The argument prompt is used as in `read-from-minibuffer`. Recall that a command is anything for which `commandp` returns `t`, and a command name is a symbol for which `commandp` returns `t`. See section Interactive Call.

```
(read-command "Command name? ")
```

```
;; After evaluating the preceding expression,
;;   the following appears in the minibuffer:

---------- Buffer: Minibuffer ----------
Command name?
---------- Buffer: Minibuffer ----------
```

If the user types forward-c RET, then this function returns `forward-char`.

The `read-command` function is a simplified interface to the `completing-read` function. It uses the `commandp` predicate to allow only commands to be entered, and it uses the variable `obarray` so as to be able to complete all extant Lisp symbols:

```
(read-command prompt)
==
(intern (completing-read prompt obarray 'commandp t nil))
```

Function: **read-variable** *prompt*

This function reads the name of a user variable and returns it as a symbol.

```
(read-variable "Variable name? ")

;; After evaluating the preceding expression,
;;   the following prompt appears,
;;   with an empty minibuffer:

---------- Buffer: Minibuffer ----------
Variable name? -!-
---------- Buffer: Minibuffer ----------
```

If the user then types fill-p RET, `read-variable` will return `fill-prefix`.

This function is similar to `read-command`, but uses the predicate `user-variable-p` instead of `commandp`:

```
(read-variable prompt)
==
(intern
 (completing-read prompt obarray 'user-variable-p t nil))
```

Reading File Names

Here is another high-level completion function, designed for reading a file name. It provides special features including automatic insertion of the default directory.

Function: **read-file-name** *prompt &optional directory default existing initial*

This function reads a file name in the minibuffer, prompting with prompt and providing completion. If default is non-`nil`, then the function returns default if the user just types RET.

If existing is non-`nil`, then the name must refer to an existing file; then RET performs completion to make the name valid if possible, and then refuses to exit if it is not valid. If the value of existing is neither `nil` nor `t`, then RET also requires confirmation after completion.

The argument directory specifies the directory to use for completion of relative file names. Usually it is inserted in the minibuffer as initial input as well. It defaults to the current buffer's default directory.

If you specify initial, that is an initial file name to insert in the buffer along with directory. In this case, point goes after directory, before initial. The default for initial is `nil`---don't insert any file name. To see what initial does, try the command C-x C-v.

Here is an example:

```
(read-file-name "The file is ")

;; After evaluating the preceding expression,
;;   the following appears in the minibuffer:

---------- Buffer: Minibuffer ----------
The file is /gp/gnu/elisp/-!-
---------- Buffer: Minibuffer ----------
```

Typing manual TAB results in the following:

```
---------- Buffer: Minibuffer ----------
The file is /gp/gnu/elisp/manual.texi-!-
---------- Buffer: Minibuffer ----------
```

If the user types RET, `read-file-name` returns `"/gp/gnu/elisp/manual.texi"`.

User Option: **insert-default-directory**

This variable is used by `read-file-name`. Its value controls whether `read-file-name` starts by placing the name of the default directory in the minibuffer, plus the initial file name if any. If the value of this variable is `nil`, then `read-file-name` does not place any initial input in the minibuffer. In that case, the default directory is still used for completion of relative file names, but is not displayed.

For example:

```
;; Here the minibuffer starts out containing the default directory.

(let ((insert-default-directory t))
  (read-file-name "The file is "))

---------- Buffer: Minibuffer ----------
```

```
The file is ~lewis/manual/-!-
---------- Buffer: Minibuffer ----------

;; Here the minibuffer is empty and only the prompt
;;   appears on its line.

(let ((insert-default-directory nil))
  (read-file-name "The file is "))

---------- Buffer: Minibuffer ----------
The file is -!-
---------- Buffer: Minibuffer ----------
```

Lisp Symbol Completion

If you type a part of a symbol, and then type M-TAB (`lisp-complete-symbol`), this command attempts to fill in as much more of the symbol name as it can. Not only does this save typing, but it can help you with the name of a symbol that you have partially forgotten.

Command: **lisp-complete-symbol**

This function performs completion on the symbol name preceding point. The name is completed against the symbols in the global variable `obarray`, and characters from the completion are inserted into the buffer, making the name longer. If there is more than one completion, a list of all possible completions is placed in the `*Help*' buffer. The bell rings if there is no possible completion in `obarray`.

If an open parenthesis immediately precedes the name, only symbols with function definitions are considered. (By reducing the number of alternatives, this may succeed in completing more characters.) Otherwise, symbols with either a function definition, a value, or at least one property are considered.

`lisp-complete-symbol` returns `t` if the symbol had an exact, and unique, match; otherwise, it returns `nil`.

In the following example, the user has already inserted `(forwa' into the buffer `` `foo.el' ``. The command `lisp-complete-symbol` then completes the name to `(forward-'.

```
---------- Buffer: foo.el ----------
(forwa-!-
---------- Buffer: foo.el ----------

(lisp-complete-symbol)
     => nil

---------- Buffer: foo.el ----------
(forward--!-
---------- Buffer: foo.el ----------
```

Yes-or-No Queries

This section describes functions used to ask the user a yes-or-no question. The function `y-or-n-p` can be answered with a single character; it is useful for questions where an inadvertent wrong answer will not have serious consequences. `yes-or-no-p` is suitable for more momentous questions, since it requires three or four characters to answer.

Strictly speaking, `yes-or-no-p` uses the minibuffer and `y-or-n-p` does not; but it seems best to describe them together.

Function: **y-or-n-p** *prompt*

This function asks the user a question, expecting input in the echo area. It returns `t` if the user types y, `nil` if the user types n. This function also accepts SPC to mean yes and DEL to mean no. It accepts C-] to mean "quit", like C-g, because the question might look like a minibuffer and for that reason the user might try to use C-] to get out. The answer is a single character, with no RET needed to terminate it. Upper and lower case are equivalent.

"Asking the question" means printing prompt in the echo area, followed by the string `(y or n) '. If the input is not one of the expected answers (y, n, SPC, DEL, or something that quits), the function responds `Please answer y or n.', and repeats the request.

This function does not actually use the minibuffer, since it does not allow editing of the answer. It actually uses the echo area (see section The Echo Area), which uses the same screen space as the minibuffer. The cursor moves to the echo area while the question is being asked.

The meanings of answers, even `y' and `n', are not hardwired. They are controlled by the keymap `query-replace-map`. See section Replacement.

In the following example, the user first types q, which is invalid. At the next prompt the user types n.

```
(y-or-n-p "Do you need a lift? ")

;; After evaluating the preceding expression,
;;   the following prompt appears in the echo area:

---------- Echo area ----------
Do you need a lift? (y or n)
---------- Echo area ----------

;; If the user then types q, the following appears:

---------- Echo area ----------
Please answer y or n.  Do you need a lift? (y or n)
---------- Echo area ----------

;; When the user types a valid answer,
```

```
;;   it is displayed after the question:

---------- Echo area ----------
Do you need a lift? (y or n) y
---------- Echo area ----------
```

Note that we show successive lines of echo area messages here. Only one actually appears on the screen at a time.

Function: **yes-or-no-p** *prompt*

This function asks the user a question, expecting input in minibuffer. It returns `t` if the user enters `yes', `nil` if the user types `no'. The user must type RET to finalize the response. Upper and lower case are equivalent.

`yes-or-no-p` starts by displaying prompt in the echo area, followed by `(yes or no) '. The user must type one of the expected responses; otherwise, the function responds `Please answer yes or no.', waits about two seconds and repeats the request.

`yes-or-no-p` requires more work from the user than `y-or-n-p` and is appropriate for more crucial decisions.

Here is an example:

```
(yes-or-no-p "Do you really want to remove everything? ")

;; After evaluating the preceding expression,
;;   the following prompt appears,
;;   with an empty minibuffer:

---------- Buffer: minibuffer ----------
Do you really want to remove everything? (yes or no)
---------- Buffer: minibuffer ----------
```

If the user first types y RET, which is invalid because this function demands the entire word `yes', it responds by displaying these prompts, with a brief pause between them:

```
---------- Buffer: minibuffer ----------
Please answer yes or no.
Do you really want to remove everything? (yes or no)
---------- Buffer: minibuffer ----------
```

Asking Multiple Y-or-N Queries

Function: **map-y-or-n-p** *prompter actor list &optional help action-alist*

This function, new in Emacs 19, asks the user a series of questions, reading a single-character answer in

the echo area for each one.

The value of list specifies what varies from question to question within the series. It should be either a list of objects or a generator function. If it is a function, it should expect no arguments, and should return either the next object or `nil` meaning there are no more questions.

The argument prompter specifies how to ask each question. If prompter is a string, the question text is computed like this:

```
(format prompter object)
```

where object is the next object to ask about (as obtained from list).

If not a string, prompter should be a function of one argument (the next object to ask about) and should return the question text.

The argument actor says how to act on the answers that the user gives. It should be a function of one argument, and it is called with each object that the user says yes for. Its argument is always an object obtained from list.

If the argument help is given, it should be a list of this form:

```
(singular plural action)
```

where singular is a string containing a singular noun that describes the objects conceptually being acted on, plural is the corresponding plural noun, and action is a transitive verb describing what actor does.

If you don't specify help, the default is `("object" "objects" "act on")`.

Each time a question is asked, the user may enter y, Y, or SPC to act on that object; n, N, or DEL to skip that object; ! to act on all following objects; ESC or q to exit (skip all following objects); . (period) to act on the current object and then exit; or C-h to get help. These are the same answers that `query-replace` accepts. The keymap `query-replace-map` defines their meaning for `map-y-or-n-p` as well as for `query-replace`; see section Replacement.

You can use action-alist to specify additional possible answers and what they mean. It is an alist of elements of the form `(char function help)`, each of which defines one additional answer. In this element, char is a character (the answer); function is a function of one argument (an object from list); help is a string.

When the user responds with char, `map-y-or-n-p` calls function. If it returns non-`nil`, the object is considered "acted upon", and `map-y-or-n-p` advances to the next object in list. If it returns `nil`, the prompt is repeated for the same object.

The return value of `map-y-or-n-p` is the number of objects acted on.

Minibuffer Miscellany

This section describes some basic functions and variables related to minibuffers.

Command: **exit-minibuffer**

This command exits the active minibuffer. It is normally bound to keys in minibuffer local keymaps.

Command: **self-insert-and-exit**

This command exits the active minibuffer after inserting the last character typed on the keyboard (found in `last-command-char`; see section Information from the Command Loop).

Command: **previous-history-element** *n*

This command replaces the minibuffer contents with the value of the nth previous (older) history element.

Command: **next-history-element** *n*

This command replaces the minibuffer contents with the value of the nth more recent history element.

Command: **previous-matching-history-element** *pattern*

This command replaces the minibuffer contents with the value of the previous (older) history element that matches pattern. At the time of printing, we have not made a final decision about how to get the pattern interactively or how to match it against history elements.

Command: **next-matching-history-element** *pattern*

This command replaces the minibuffer contents with the value of the next (newer) history element that matches pattern.

Variable: **minibuffer-help-form**

The current value of this variable is used to rebind `help-form` locally inside the minibuffer (see section Help Functions).

Function: **minibuffer-window** *&optional frame*

This function returns the window that is used for the minibuffer. In Emacs 18, there is one and only one minibuffer window; this window always exists and cannot be deleted. In Emacs 19, each frame can have its own minibuffer, and this function returns the minibuffer window used for frame frame (which defaults to the currently selected frame).

Function: **window-minibuffer-p** *window*

This function returns non-`nil` if window is a minibuffer window.

It is not correct to determine whether a given window is a minibuffer by comparing it with the result of `(minibuffer-window)`, because there can be more than one minibuffer window there is more than one frame.

Variable: **minibuffer-scroll-window**

If the value of this variable is non-`nil`, it should be a window object. When the function `scroll-other-window` is called in the minibuffer, it scrolls this window.

Finally, some functions and variables deal with recursive minibuffers (see section Recursive Editing):

Function: **minibuffer-depth**

This function returns the current depth of activations of the minibuffer, a nonnegative integer. If no minibuffers are active, it returns zero.

User Option: **enable-recursive-minibuffers**

If this variable is non-`nil`, you can invoke commands (such as `find-file`) which use minibuffers even while in the minibuffer window. Such invocation produces a recursive editing level for a new minibuffer. The outer-level minibuffer is invisible while you are editing the inner one.

This variable only affects invoking the minibuffer while the minibuffer window is selected. If you switch windows while in the minibuffer, you can always invoke minibuffer commands while some other window is selected.

If a command name has a property `enable-recursive-minibuffers` which is non-`nil`, then the command can use the minibuffer to read arguments even if it is invoked from the minibuffer. The minibuffer command `next-matching-history-element` (normally bound to M-s in the minibuffer) uses this feature.

Go to the previous, next section.

Go to the previous, next section.

Command Loop

When you run Emacs, it enters the editor command loop almost immediately. This loop reads key sequences, executes their definitions, and displays the results. In this chapter, we describe how these things are done, and the subroutines that allow Lisp programs to do them.

Command Loop Overview

The first thing the command loop must do is read a key sequence, which is a sequence of events that translates into a command. It does this by calling the function `read-key-sequence`. Your Lisp code can also call this function (see section Key Sequence Input). Lisp programs can also do input at a lower level with `read-event` (see section Reading One Event) or discard pending input with `discard-input` (see section Peeking and Discarding).

The key sequence is translated into a command through the currently active keymaps. See section Key Lookup, for information on how this is done. The result should be a keyboard macro or an interactively callable function. If the key is M-x, then it reads the name of another command, which is used instead. This is done by the command `execute-extended-command` (see section Interactive Call).

Once the command is chosen, it must be executed, which includes reading arguments to be given to it. This is done by calling `command-execute` (see section Interactive Call). For commands written in Lisp, the `interactive` specification says how to read the arguments. This may use the prefix argument (see section Prefix Command Arguments) or may read with prompting in the minibuffer (see section Minibuffers). For example, the command `find-file` has an `interactive` specification which says to read a file name using the minibuffer. The command's function body does not use the minibuffer; if you call this command from Lisp code as a function, you must supply the file name string as an ordinary Lisp function argument.

If the command is a string or vector (i.e., a keyboard macro) then `execute-kbd-macro` is used to execute it. You can call this function yourself (see section Keyboard Macros).

If a command runs away, typing C-g terminates its execution immediately. This is called quitting (see section Quitting).

Variable: **pre-command-hook**

The editor command loop runs this normal hook before each command.

Variable: **post-command-hook**

The editor command loop runs this normal hook after each command.

Defining Commands

A Lisp function becomes a command when its body contains, at top level, a form which calls the special form `interactive`. This form does nothing when actually executed, but its presence serves as a flag to indicate that interactive calling is permitted. Its argument controls the reading of arguments for an interactive call.

Using `interactive`

This section describes how to write the `interactive` form that makes a Lisp function an interactively-callable command.

Special Form: **interactive** *arg-descriptor*

This special form declares that the function in which it appears is a command, and that it may therefore be called interactively (via M-x or by entering a key sequence bound to it). The argument arg-descriptor declares the way the arguments to the command are to be computed when the command is called interactively.

A command may be called from Lisp programs like any other function, but then the arguments are supplied by the caller and arg-descriptor has no effect.

The `interactive` form has its effect because the command loop (actually, its subroutine `call-interactively`) scans through the function definition looking for it, before calling the function. Once the function is called, all its body forms including the `interactive` form are executed, but at this time `interactive` simply returns `nil` without even evaluating its argument.

There are three possibilities for the argument arg-descriptor:

- It may be omitted or `nil`; then the command is called with no arguments. This leads quickly to an error if the command requires one or more arguments.
- It may be a Lisp expression that is not a string; then it should be a form that is evaluated to get a list of arguments to pass to the command.
- It may be a string; then its contents should consist of a code character followed by a prompt (which some code characters use and some ignore). The prompt ends either with the end of the string or with a newline. Here is a simple example:

  ```
  (interactive "bFrobnicate buffer: ")
  ```

  The code letter `b' says to read the name of an existing buffer, with completion. The buffer name is the sole argument passed to the command. The rest of the string is a prompt.

  If there is a newline character in the string, it terminates the prompt. If the string does not end there, then the rest of the string should contain another code character and prompt, specifying another argument. You can specify any number of arguments in this way.

  The prompt string can use `%' to include previous argument values in the prompt. This is done

using `format` (see section Formatting Strings). For example, here is how you could read the name of an existing buffer followed by a new name to give to that buffer:

```
(interactive "bBuffer to rename: \nsRename buffer %s to: ")
```

If the first character in the string is `*', then an error is signaled if the buffer is read-only.

If the first character in the string is `@', and if the key sequence used to invoke the command includes any mouse events, then the window associated with the first of those events is selected before the command is run.

You can use `*' and `@' together; the order does not matter. Actual reading of arguments is controlled by the rest of the prompt string (starting with the first character that is not `*' or `@').

Code Characters for `interactive`

The code character descriptions below contain a number of key words, defined here as follows:

Completion

Provide completion. TAB, SPC, and RET perform name completion because the argument is read using `completing-read` (see section Completion). ? displays a list of possible completions.

Existing

Require the name of an existing object. An invalid name is not accepted; the commands to exit the minibuffer do not exit if the current input is not valid.

Default

A default value of some sort is used if the user enters no text in the minibuffer. The default depends on the code character.

No I/O

This code letter computes an argument without reading any input. Therefore, it does not use a prompt string, and any prompt string you supply is ignored.

Prompt

A prompt immediately follows the code character. The prompt ends either with the end of the string or with a newline.

Special

This code character is meaningful only at the beginning of the interactive string, and it does not look for a prompt or a newline. It is a single, isolated character.

Here are the code character descriptions for use with `interactive`:

`*'

Signal an error if the current buffer is read-only. Special.

`@'

Select the window mentioned in the first mouse event in the key sequence that invoked this command. Special.

`a'

A function name (i.e., a symbol which is `fboundp`). Existing, Completion, Prompt.

`b'

The name of an existing buffer. By default, uses the name of the current buffer (see section Buffers). Existing, Completion, Default, Prompt.

`B'

A buffer name. The buffer need not exist. By default, uses the name of a recently used buffer other than the current buffer. Completion, Prompt.

`c'

A character. The cursor does not move into the echo area. Prompt.

`C'

A command name (i.e., a symbol satisfying `commandp`). Existing, Completion, Prompt.

`d'

The position of point as a number (see section Point). No I/O.

`D'

A directory name. The default is the current default directory of the current buffer, `default-directory` (see section Operating System Environment). Existing, Completion, Default, Prompt.

`e'

The first or next mouse event in the key sequence that invoked the command. More precisely, `e' gets events which are lists, so you can look at the data in the lists. See section Input Events. No I/O.

You can use `e' more than once in a single command's interactive specification. If the key sequence which invoked the command has n events with parameters, the nth `e' provides the nth list event. Events which are not lists, such as function keys and ASCII characters, do not count where `e' is concerned.

Even though `e' does not use a prompt string, you must follow it with a newline if it is not the last code character.

`f'

A file name of an existing file (see section File Names). The default directory is `default-directory`. Existing, Completion, Default, Prompt.

`F'

A file name. The file need not exist. Completion, Default, Prompt.

`k'

A key sequence (see section Keymap Terminology). This keeps reading events until a command (or undefined command) is found in the current key maps. The key sequence argument is represented as a string or vector. The cursor does not move into the echo area. Prompt.

This kind of input is used by commands such as `describe-key` and `global-set-key`.

`m'

The position of the mark as a number. No I/O.

`n'

A number read with the minibuffer. If the input is not a number, the user is asked to try again. The prefix argument, if any, is not used. Prompt.

`N'

The raw prefix argument. If the prefix argument is `nil`, then a number is read as with n. Requires a number. Prompt.

`p'

The numeric prefix argument. (Note that this `p' is lower case.) No I/O.

`P'

The raw prefix argument. (Note that this `P' is upper case.) See section Prefix Command Arguments. No I/O.

`r'

Point and the mark, as two numeric arguments, smallest first. This is the only code letter that specifies two successive arguments rather than one. No I/O.

`s'

Arbitrary text, read in the minibuffer and returned as a string (see section Reading Text Strings with the Minibuffer). Terminate the input with either LFD or RET. (C-q may be used to include either of these characters in the input.) Prompt.

`S'

An interned symbol whose name is read in the minibuffer. Any whitespace character terminates the input. (Use C-q to include whitespace in the string.) Other characters that normally terminate a symbol (e.g., parentheses and brackets) do not do so here. Prompt.

`v'

A variable declared to be a user option (i.e., satisfying the predicate `user-variable-p`). See section High-Level Completion Functions. Existing, Completion, Prompt.

`x'

A Lisp object specified in printed representation, terminated with a LFD or RET. The object is not evaluated. See section Reading Lisp Objects with the Minibuffer. Prompt.

`X'

A Lisp form is read as with x, but then evaluated so that its value becomes the argument for the command. Prompt.

Examples of Using `interactive`

Here are some examples of `interactive`:

```
(defun foo1 ()                  ; foo1 takes no arguments,
```

```
    (interactive)           ;   just moves forward two words.
    (forward-word 2))
     => foo1

(defun foo2 (n)             ; foo2 takes one argument,
    (interactive "p")       ;   which is the numeric prefix.
    (forward-word (* 2 n)))
     => foo2

(defun foo3 (n)             ; foo3 takes one argument,
    (interactive "nCount:") ;   which is read with the Minibuffer.
    (forward-word (* 2 n)))
     => foo3

(defun three-b (b1 b2 b3)
  "Select three existing buffers.
Put them into three windows, selecting the last one."
    (interactive "bBuffer1:\nbBuffer2:\nbBuffer3:")
    (delete-other-windows)
    (split-window (selected-window) 8)
    (switch-to-buffer b1)
    (other-window 1)
    (split-window (selected-window) 8)
    (switch-to-buffer b2)
    (other-window 1)
    (switch-to-buffer b3))
     => three-b
(three-b "*scratch*" "declarations.texi" "*mail*")
     => nil
```

Interactive Call

After the command loop has translated a key sequence into a definition, it invokes that definition using the function `command-execute`. If the definition is a function that is a command, `command-execute` calls `call-interactively`, which reads the arguments and calls the command. You can also call these functions yourself.

Function: **commandp** *object*

Returns `t` if object is suitable for calling interactively; that is, if object is a command. Otherwise, returns `nil`.

The interactively callable objects include strings and vectors (treated as keyboard macros), lambda expressions that contain a top-level call to `interactive`, byte-code function objects, autoload objects that are declared as interactive (non-`nil` fourth argument to `autoload`), and some of the primitive functions.

A symbol is `commandp` if its function definition is `commandp`.

Keys and keymaps are not commands. Rather, they are used to look up commands (see section Keymaps).

See `documentation` in section Access to Documentation Strings, for a realistic example of using `commandp`.

Function: **call-interactively** *command &optional record-flag*

This function calls the interactively callable function command, reading arguments according to its interactive calling specifications. An error is signaled if command cannot be called interactively (i.e., it is not a command). Note that keyboard macros (strings and vectors) are not accepted, even though they are considered commands.

If record-flag is non-`nil`, then this command and its arguments are unconditionally added to the list `command-history`. Otherwise, the command is added only if it uses the minibuffer to read an argument. See section Command History.

Function: **command-execute** *command &optional record-flag*

This function executes command as an editing command. The argument command must satisfy the `commandp` predicate; i.e., it must be an interactively callable function or a string.

A string or vector as command is executed with `execute-kbd-macro`. A function is passed to `call-interactively`, along with the optional record-flag.

A symbol is handled by using its function definition in its place. A symbol with an `autoload` definition counts as a command if it was declared to stand for an interactively callable function. Such a definition is handled by loading the specified library and then rechecking the definition of the symbol.

Command: **execute-extended-command** *prefix-argument*

This function reads a command name from the minibuffer using `completing-read` (see section Completion). Then it uses `command-execute` to call the specified command. Whatever that command returns becomes the value of `execute-extended-command`.

If the command asks for a prefix argument, the value prefix-argument is supplied. If `execute-extended-command` is called interactively, the current raw prefix argument is used for prefix-argument, and thus passed on to whatever command is run.

`execute-extended-command` is the normal definition of M-x, so it uses the string `M-x ' as a prompt. (It would be better to take the prompt from the events used to invoke `execute-extended-command`, but that is painful to implement.) A description of the value of the prefix argument, if any, also becomes part of the prompt.

```
(execute-extended-command 1)
---------- Buffer: Minibuffer ----------
M-x forward-word RET
```

```
---------- Buffer: Minibuffer ----------
     => t
```

Function: **interactive-p**

This function returns `t` if the containing function (the one that called `interactive-p`) was called interactively, with the function `call-interactively`. (It makes no difference whether `call-interactively` was called from Lisp or directly from the editor command loop.) Note that if the containing function was called by Lisp evaluation (or with `apply` or `funcall`), then it was not called interactively.

The usual application of `interactive-p` is for deciding whether to print an informative message. As a special exception, `interactive-p` returns `nil` whenever a keyboard macro is being run. This is to suppress the informative messages and speed execution of the macro.

For example:

```
(defun foo ()
  (interactive)
  (and (interactive-p)
       (message "foo")))
     => foo

(defun bar ()
  (interactive)
  (setq foobar (list (foo) (interactive-p))))
     => bar

;; Type M-x foo.
     -| foo

;; Type M-x bar.
;; This does not print anything.

foobar
     => (nil t)
```

Information from the Command Loop

The editor command loop sets several Lisp variables to keep status records for itself and for commands that are run.

Variable: **last-command**

This variable records the name of the previous command executed by the command loop (the one before the current command). Normally the value is a symbol with a function definition, but this is not guaranteed.

The value is set by copying the value of `this-command` when a command returns to the command loop, except when the command specifies a prefix argument for the following command.

Variable: **this-command**

This variable records the name of the command now being executed by the editor command loop. Like `last-command`, it is normally a symbol with a function definition.

This variable is set by the command loop just before the command is run, and its value is copied into `last-command` when the command finishes (unless the command specifies a prefix argument for the following command).

Some commands change the value of this variable during their execution, simply as a flag for whatever command runs next. In particular, the functions that kill text set `this-command` to `kill-region` so that any kill commands immediately following will know to append the killed text to the previous kill.

Function: **this-command-keys**

This function returns a string or vector containing the key sequence that invoked the present command, plus any previous commands that generated the prefix argument for this command. The value is a string if all those events were characters. See section Input Events.

```
(this-command-keys)
;; Now type C-u C-x C-e.
     => "^U^X^E"
```

Variable: **last-nonmenu-event**

This variable holds the last input event read as part of a key sequence, aside from events resulting from mouse menus.

One use of this variable is to figure out a good default location to pop up another menu.

Variable: **last-command-event**

Variable: **last-command-char**

This variable is set to the last input event that was read by the command loop as part of a command. The principal use of this variable is in `self-insert-command`, which uses it to decide which character to insert.

```
last-command-char
;; Now type C-u C-x C-e.
     => 5
```

The value is 5 because that is the ASCII code for C-e.

The alias `last-command-char` exists for compatibility with Emacs version 18.

Variable: **last-event-frame**

This variable records which frame the last input event was directed to. Usually this is the frame that was selected when the event was generated, but if that frame has redirected input focus to another frame, the value is the frame to which the event was redirected. See section Input Focus.

Variable: **echo-keystrokes**

This variable determines how much time should elapse before command characters echo. Its value must be an integer, which specifies the number of seconds to wait before echoing. If the user types a prefix key (say C-x) and then delays this many seconds before continuing, the key C-x is echoed in the echo area. Any subsequent characters in the same command will be echoed as well.

If the value is zero, then command input is not echoed.

Input Events

The Emacs command loop reads a sequence of input events that represent keyboard or mouse activity. The events for keyboard activity are characters or symbols; mouse events are always lists. This section describes the representation and meaning of input events in detail.

A command invoked using events that are lists can get the full values of these events using the `e' interactive code. See section Code Characters for `interactive`.

A key sequence that starts with a mouse event is read using the keymaps of the buffer in the window that the mouse was in, not the current buffer. This does not imply that clicking in a window selects that window or its buffer--that is entirely under the control of the command binding of the key sequence.

Function: **eventp** *object*

This function returns non-`nil` if event is an input event.

Keyboard Events

There are two kinds of input you can get from the keyboard: ordinary keys, and function keys. Ordinary keys correspond to characters; the events they generate are represented in Lisp as characters. In Emacs versions 18 and earlier, characters were the only events.

An input character event consists of a basic code between 0 and 255, plus any or all of these modifier bits:

meta

The 2**23 bit in the character code indicates a character typed with the meta key held down.

control

The 2**22 bit in the character code indicates a non-ASCII control character.

ASCII control characters such as C-a have special basic codes of their own, so Emacs needs no special bit to indicate them. Thus, the code for C-a is just 1.

But if you type a control combination not in ASCII, such as % with the control key, the numeric

value you get is the code for % plus 2**22 (assuming the terminal supports non-ASCII control characters).

shift

The 2**21 bit in the character code indicates an ASCII control character typed with the shift key held down.

For letters, the basic code indicates upper versus lower case; for digits and punctuation, the shift key selects an entirely different character with a different basic code. In order to keep within the ASCII character set whenever possible, Emacs avoids using the 2**21 bit for those characters.

However, ASCII provides no way to distinguish C-A from C-A, so Emacs uses the 2**21 bit in C-A and not in C-a.

hyper

The 2**20 bit in the character code indicates a character typed with the hyper key held down.

super

The 2**19 bit in the character code indicates a character typed with the super key held down.

alt

The 2**18 bit in the character code indicates a character typed with the alt key held down. (On some terminals, the key labeled ALT is actually the meta key.)

In the future, Emacs may support a larger range of basic codes. We may also move the modifier bits to larger bit numbers. Therefore, you should avoid mentioning specific bit numbers in your program. Instead, the way to test the modifier bits of a character is with the function `event-modifiers` (see section Classifying Events).

Function Keys

Most keyboards also have function keys---keys which have names or symbols that are not characters. Function keys are represented in Lisp as symbols; the symbol's name is the function key's label. For example, pressing a key labeled F1 places the symbol `f1` in the input stream.

For all keyboard events, the event type (which classifies the event for key lookup purposes) is identical to the event--it is the character or the symbol. See section Classifying Events.

Here are a few special cases in the symbol naming convention for function keys:

`backspace`, `tab`, `newline`, `return`, `delete`

These keys correspond to common ASCII control characters that have special keys on most keyboards.

In ASCII, C-i and TAB are the same character. Emacs lets you distinguish them if you wish, by returning the former as the integer 9, and the latter as the symbol `tab`.

Most of the time, it's not useful to distinguish the two. So normally `function-key-map` is set up to map `tab` into 9. Thus, a key binding for character code 9 also applies to `tab`. Likewise for the other symbols in this group. The function `read-char` also converts these events into

characters.

In ASCII, BS is really C-h. But `backspace` converts into the character code 127 (DEL), not into code 8 (BS). This is what most users prefer.

`kp-add`, `kp-decimal`, `kp-divide`, ...

Keypad keys (to the right of the regular keyboard).

`kp-0`, `kp-1`, ...

Keypad keys with digits.

`kp-f1`, `kp-f2`, `kp-f3`, `kp-f4`

Keypad PF keys.

`left`, `up`, `right`, `down`

Cursor arrow keys

You can use the modifier keys CTRL, META, HYPER, SUPER, ALT and SHIFT with function keys. The way to represent them is with prefixes in the symbol name:

`A-'

The alt modifier.

`C-'

The control modifier.

`H-'

The hyper modifier.

`M-'

The meta modifier.

`S-'

The shift modifier.

`s-'

The super modifier.

Thus, the symbol for the key F3 with META held down is M-F3. When you use more than one prefix, we recommend you write them in alphabetical order (though the order does not matter in arguments to the key-binding lookup and modification functions).

Click Events

When the user presses a mouse button and releases it at the same location, that generates a click event. Mouse click events have this form:

```
(event-type
 (window buffer-pos
  (column . row) timestamp))
```

Here is what the elements normally mean:

event-type

This is a symbol that indicates which mouse button was used. It is one of the symbols `mouse-1`, `mouse-2`, ..., where the buttons are numbered numbered left to right.

You can also use prefixes `A-', `C-', `H-', `M-', `S-' and `s-' for modifiers alt, control, hyper, meta, shift and super, just as you would with function keys.

This symbol also serves as the event type of the event. Key bindings describe events by their types; thus, if there is a key binding for `mouse-1`, that binding would apply to all events whose event-type is `mouse-1`.

window

This is the window in which the click occurred.

column

row

These are the column and row of the click, relative to the top left corner of window, which is `(0 . 0)`.

buffer-pos

This is the buffer position of the character clicked on.

timestamp

This is the time at which the event occurred, in milliseconds. (Since this value wraps around the entire range of Emacs Lisp integers in about five hours, it is useful only for relating the times of nearby events.)

The meanings of buffer-pos, row and column are somewhat different when the event location is in a special part of the screen, such as the mode line or a scroll bar.

If the location is in a scroll bar, then buffer-pos is the symbol `vertical-scroll-bar` or `horizontal-scroll-bar`, and the pair `(column . row)` is replaced with a pair `(portion . whole)`, where portion is the distance of the click from the top or left end of the scroll bar, and whole is the length of the entire scroll bar.

If the position is on a mode line or the vertical line separating window from its neighbor to the right, then buffer-pos is the symbol `mode-line` or `vertical-line`. For the mode line, row does not have meaningful data. For the vertical line, column does not have meaningful data.

Drag Events

With Emacs, you can have a drag event without even changing your clothes. A drag event happens every time the user presses a mouse button and then moves the mouse to a different character position before releasing the button. Like all mouse events, drag events are represented in Lisp as lists. The lists record both the starting mouse position and the final position, like this:

```
(event-type
 (window1 buffer-pos1
```

```
 (column1 . row1) timestamp1)
(window2 buffer-pos2
 (column2 . row2) timestamp2))
```

For a drag event, the name of the symbol event-type contains the prefix `drag-'. The second and third elements of the event give the starting and ending position of the drag. Aside from that, the data have the same meanings as in a click event (see section Click Events). You can access the second element of any mouse event in the same way, with no need to distinguish drag events from others.

The `drag-' prefix follows the modifier key prefixes such as `C-' and `M-'.

If `read-key-sequence` receives a drag event which has no key binding, and the corresponding click event does have a binding, it changes the drag event into a click event at the drag's starting position. This means that you don't have to distinguish between click and drag events unless you want to.

Button-Down Events

Click and drag events happen when the user releases a mouse button. They cannot happen earlier, because there is no way to distinguish a click from a drag until the button is released.

If you want to take action as soon as a button is pressed, you need to handle button-down events.(2). These occur as soon as a button is pressed. They are represented by lists which look exactly like click events (see section Click Events), except that the name of event-type contains the prefix `down-'. The `down-' prefix follows the modifier key prefixes such as `C-' and `M-'.

The function `read-key-sequence`, and the Emacs command loop, ignore any button-down events that don't have command bindings. This means that you need not worry about defining button-down events unless you want them to do something. The usual reason to define a button-down event is so that you can track mouse motion (by reading motion events) until the button is released.

Motion Events

Emacs sometimes generates mouse motion events to describe motion of the mouse without any button activity. Mouse motion events are represented by lists that look like this:

```
(mouse-movement
 (window buffer-pos
  (column . row) timestamp))
```

The second element of the list describes the current position of the mouse, just as in a click event (see section Click Events).

The special form `track-mouse` enables generation of motion events within its body. Outside of `track-mouse` forms, Emacs does not generate events for mere motion of the mouse, and these events do not appear.

Special Form: **track-mouse** *body...*

This special form executes body, with generation of mouse motion events enabled. Typically body would use `read-event` to read the motion events and modify the display accordingly.

When the user releases the button, that generates a click event. Normally body should return when it sees the click event, and discard the event.

Focus Events

Window systems provide general ways for the user to control which window gets keyboard input. This choice of window is called the focus. When the user does something to switch between Emacs frames, that generates a focus event. The normal definition of a focus event, in the global keymap, is to select a new frame within Emacs, as the user would expect. See section Input Focus.

Focus events are represented in Lisp as lists that look like this:

```
(switch-frame new-frame)
```

where new-frame is the frame switched to.

In X windows, most window managers are set up so that just moving the mouse into a window is enough to set the focus there. Emacs appears to do this, because it changes the cursor to solid in the new frame. However, there is no need for the Lisp program to know about the focus change until some other kind of input arrives. So Emacs generates the focus event only when the user actually types a keyboard key or presses a mouse button in the new frame; just moving the mouse between frames does not generate a focus event.

A focus event in the middle of a key sequence would garble the sequence. So Emacs never generates a focus event in the middle of a key sequence. If the user changes focus in the middle of a key sequence--that is, after a prefix key--then Emacs reorders the events so that the focus event comes either before or after the multi-event key sequence, and not within it.

Event Examples

If the user presses and releases the left mouse button over the same location, that generates a sequence of events like this:

```
(down-mouse-1 (#<window 18 on NEWS> 2613 (0 . 38) -864320))
(mouse-1      (#<window 18 on NEWS> 2613 (0 . 38) -864180))
```

Or, while holding the control key down, the user might hold down the second mouse button, and drag the mouse from one line to the next. That produces two events, as shown here:

```
(C-down-mouse-2 (#<window 18 on NEWS> 3440 (0 . 27) -731219))
(C-drag-mouse-2 (#<window 18 on NEWS> 3440 (0 . 27) -731219)
                (#<window 18 on NEWS> 3510 (0 . 28) -729648))
```

Or, while holding down the meta and shift keys, the user might press the second mouse button on the

window's mode line, and then drag the mouse into another window. That produces the following pair of events:

```
(M-S-down-mouse-2 (#<window 18 on NEWS> mode-line (33 . 31) -457844))
(M-S-drag-mouse-2 (#<window 18 on NEWS> mode-line (33 . 31) -457844)
                  (#<window 20 on carlton-sanskrit.tex> 161 (33 . 3)
                   -453816))
```

Classifying Events

Every event has an event type which classifies the event for key binding purposes. For a keyboard event, the event type equals the event value; thus, the event type for a character is the character, and the event type for a function key symbol is the symbol itself. For events which are lists, the event type is the symbol in the CAR of the list. Thus, the event type is always a symbol or a character.

Two events of the same type are equivalent where key bindings are concerned; thus, they always run the same command. That does not necessarily mean they do the same things, however, as some commands look at the whole event to decide what to do. For example, some commands use the location of a mouse event to decide what text to act on.

Sometimes broader classifications of events are useful. For example, you might want to ask whether an event involved the META key, regardless of which other key or mouse button was used.

To get such information conveniently, call the functions `event-modifiers` and `event-basic-type`.

Function: **event-modifiers** *event*

This function returns a list of the modifiers that event has. The modifiers are symbols; they include `shift`, `control`, `meta`, `alt`, `hyper` and `super`. In addition, the property of a mouse event symbol always has one of `click`, `drag`, and `down` among the modifiers. For example:

```
(event-modifiers ?a)
     => nil
(event-modifiers ?\C-a)
     => (control)
(event-modifiers ?\C-%)
     => (control)
(event-modifiers ?\C-\S-a)
     => (control shift)
(event-modifiers 'f5)
     => nil
(event-modifiers 's-f5)
     => (super)
(event-modifiers 'M-S-f5)
     => (meta shift)
(event-modifiers 'mouse-1)
```

```
     => (click)
(event-modifiers 'down-mouse-1)
     => (down)
```

The modifiers list for a click event explicitly contains `click`, but the event symbol name itself does not contain `click'.

Function: **event-basic-type** *event*

This function returns the key or mouse button that event describes, with all modifiers removed. For example:

```
(event-basic-type ?a)
     => 97
(event-basic-type ?A)
     => 97
(event-basic-type ?\C-a)
     => 97
(event-basic-type ?\C-\S-a)
     => 97
(event-basic-type 'f5)
     => f5
(event-basic-type 's-f5)
     => f5
(event-basic-type 'M-S-f5)
     => f5
(event-basic-type 'down-mouse-1)
     => mouse-1
```

Function: **mouse-movement-p** *object*

This function returns non-`nil` if object is a mouse movement event.

Accessing Events

This section describes convenient functions for accessing the data in an event which is a list.

The following functions return the starting or ending position of a mouse-button event. The position is a list of this form:

```
(window buffer-position (col . row) timestamp)
```

Function: **event-start** *event*

This returns the starting position of event.

If event is a click or button-down event, this returns the location of the event. If event is a drag event, this returns the drag's starting position.

Function: **event-end** *event*

This returns the ending position of event.

If event is a drag event, this returns the position where the user released the mouse button. If event is a click or button-down event, the value is actually the starting position, which is the only position such events have.

These four functions take a position-list as described above, and return various parts of it.

Function: **posn-window** *position*

Return the window that position is in.

Function: **posn-point** *position*

Return the buffer location in position.

Function: **posn-col-row** *position*

Return the row and column in position, as a list `(col . row)`.

Function: **posn-timestamp** *position*

Return the timestamp of position.

Function: **scroll-bar-scale** *ratio total*

This function multiples (in effect) ratio by total, rounding the result to an integer. ratio is not a number, but rather a pair `(num . denom)`.

This is handy for scaling a position on a scroll bar into a buffer position. Here's how to do that:

```
(scroll-bar-scale (posn-col-row (event-start event))
                  (buffer-size))
```

Putting Keyboard Events in Strings

In most of the places where strings are used, we conceptualize the string as containing text characters--the same kind of characters found in buffers or files. Occasionally Lisp programs use strings which conceptually contain keyboard characters; for example, they may be key sequences or keyboard macro definitions. There are special rules for how to put keyboard characters into a string, because they are not limited to the range of 0 to 255 as text characters are.

A keyboard character typed using the META key is called a meta character. The numeric code for such an event includes the 2**23 bit; it does not even come close to fitting in a string. However, earlier Emacs versions used a different representation for these characters, which gave them codes in the range of 128 to 255. That did fit in a string, and many Lisp programs contain string constants that use `\M-' to express meta characters, especially as the argument to `define-key` and similar functions.

We provide backward compatibility to run those programs with special rules for how to put a keyboard

character event in a string. Here are the rules:

- If the keyboard event value is in the range of 0 to 127, it can go in the string unchanged.
- The meta variants of those events, with codes in the range of 2**23 to 2**23+127, can also go in the string, but you must change their numeric values. You must set the 2**7 bit instead of the 2**23 bit, resulting in a value between 128 and 255.
- Other keyboard character events cannot fit in a string. This includes keyboard events in the range of 128 to 255.

Functions such as `read-key-sequence` that can construct strings containing events follow these rules.

When you use the read syntax `\M-' in a string, it produces a code in the range of 128 to 255--the same code that you get if you modify the corresponding keyboard event to put it in the string. Thus, meta events in strings work consistently regardless of how they get into the strings.

New programs can avoid dealing with these rules by using vectors instead of strings for key sequences when there is any possibility that these issues might arise.

The reason we changed the representation of meta characters as keyboard events is to make room for basic character codes beyond 127, and support meta variants of such larger character codes.

Reading Input

The editor command loop reads keyboard input using the function `read-key-sequence`, which uses `read-event`. These and other functions for keyboard input are also available for use in Lisp programs. See also `momentary-string-display` in section Temporary Displays, and `sit-for` in section Waiting for Elapsed Time or Input. See section Terminal Input, for functions and variables for controlling terminal input modes and debugging terminal input.

For higher-level input facilities, see section Minibuffers.

Key Sequence Input

The command loop reads input a key sequence at a time, by calling `read-key-sequence`. Lisp programs can also call this function; for example, `describe-key` uses it to read the key to describe.

Function: **read-key-sequence** *prompt*

This function reads a key sequence and returns it as a string or vector. It keeps reading events until it has accumulated a full key sequence; that is, enough to specify a non-prefix command using the currently active keymaps.

If the events are all characters and all can fit in a string, then `read-key-sequence` returns a string (see section Putting Keyboard Events in Strings). Otherwise, it returns a vector, since a vector can hold all kinds of events--characters, symbols, and lists. The elements of the string or vector are the events in the key sequence.

Quitting is suppressed inside `read-key-sequence`. In other words, a C-g typed while reading with this function is treated like any other character, and does not set `quit-flag`. See section Quitting.

The argument prompt is either a string to be displayed in the echo area as a prompt, or `nil`, meaning not to display a prompt.

In the example below, the prompt `?' is displayed in the echo area, and the user types C-x C-f.

```
(read-key-sequence "?")

---------- Echo Area ----------
?C-x C-f
---------- Echo Area ----------

     => "^X^F"
```

Variable: **num-input-keys**

This variable's value is the number of key sequences processed so far in this Emacs session. This includes key sequences read from the terminal and key sequences read from keyboard macros being executed.

If an input character is an upper case letter and has no key binding, but the lower case equivalent has one, then `read-key-sequence` converts the character to lower case. Note that `lookup-key` does not perform case conversion in this way.

The function `read-key-sequence` also transforms some mouse events. It converts unbound drag events into click events, and discards unbound button-down events entirely. It also reshuffles focus events so that they never appear in a key sequence with any other events.

When mouse events occur in special parts of a window, such as a mode line or a scroll bar, the event itself shows nothing special--only the symbol that would normally represent that mouse button and modifier keys. The information about the screen region is kept elsewhere in the event--in the coordinates. But `read-key-sequence` translates this information into imaginary prefix keys, all of which are symbols: `mode-line`, `vertical-line`, `horizontal-scroll-bar` and `vertical-scroll-bar`.

For example, if you call `read-key-sequence` and then click the mouse on the window's mode line, this is what happens:

```
(read-key-sequence "Click on the mode line: ")
     => [mode-line
         (mouse-1
          (#<window 6 on NEWS> mode-line
           (40 . 63) 5959987))]
```

You can define meanings for mouse clicks in special window regions by defining key sequences using these imaginary prefix keys.

Reading One Event

The lowest level functions for command input are those which read a single event.

Function: **read-event**

This function reads and returns the next event of command input, waiting if necessary until an event is available. Events can come directly from the user or from a keyboard macro.

The function `read-event` does not display any message to indicate it is waiting for input; use `message` first, if you wish to display one. If you have not displayed a message, `read-event` does prompting: it displays descriptions of the events that led to or were read by the current command. See section The Echo Area.

If `cursor-in-echo-area` is non-`nil`, then `read-event` moves the cursor temporarily to the echo area, to the end of any message displayed there. Otherwise `read-event` does not move the cursor.

Here is what happens if you call `read-event` and then press the right-arrow function key:

```
(read-event)
     => right
```

Function: **read-char**

This function reads and returns a character of command input. It discards any events that are not characters until it gets a character.

In the first example, the user types 1 (which is ASCII code 49). The second example shows a keyboard macro definition that calls `read-char` from the minibuffer. `read-char` reads the keyboard macro's very next character, which is 1. The value of this function is displayed in the echo area by the command `eval-expression`.

```
(read-char)
     => 49

(symbol-function 'foo)
     => "^[^[(read-char)^M1"
(execute-kbd-macro foo)
     -| 49
     => nil
```

Quoted Character Input

You can use the function `read-quoted-char` when you want the user to specify a character, and allow the user to specify a control or meta character conveniently with quoting or as an octal character code. The command `quoted-insert` calls this function.

Function: **read-quoted-char** *&optional prompt*

This function is like `read-char`, except that if the first character read is an octal digit (0-7), it reads to two more octal digits (but stopping if a non-octal digit is found) and returns the character represented by those digits as an octal number.

Quitting is suppressed when the first character is read, so that the user can enter a C-g. See section Quitting.

If prompt is supplied, it specifies a string for prompting the user. The prompt string is always printed in the echo area and followed by a single `-'.

In the following example, the user types in the octal number 177 (which is 127 in decimal).

```
(read-quoted-char "What character")

---------- Echo Area ----------
What character-177
---------- Echo Area ----------

     => 127
```

Peeking and Discarding

Variable: **unread-command-events**

This variable holds a list of events waiting to be read as command input. The events are used in the order they appear in the list.

The variable is used because in some cases a function reads a event and then decides not to use it. Storing the event in this variable causes it to be processed normally by the command loop or when the functions to read command input are called.

For example, the function that implements numeric prefix arguments reads any number of digits. When it finds a non-digit event, it must unread the event so that it can be read normally by the command loop. Likewise, incremental search uses this feature to unread events it does not recognize.

Variable: **unread-command-char**

This variable holds a character to be read as command input. A value of -1 means "empty".

This variable is pretty much obsolete now that you can use `unread-command-events` instead; it exists only to support programs written for Emacs versions 18 and earlier.

Function: **listify-key-sequence** *key*

This function converts the string or vector key to a list of events which you can put in `unread-command-events`. Converting a vector is simple, but converting a string is tricky because of the special representation used for meta characters in a string (see section Putting Keyboard Events in Strings).

Function: **input-pending-p**

This function determines whether any command input is currently available to be read. It returns immediately, with value `t` if there is input, `nil` otherwise. On rare occasions it may return `t` when no input is available.

Variable: **last-input-event**

Variable: **last-input-char**

This variable records the last terminal input event read, whether as part of a command or explicitly by a Lisp program.

In the example below, a character is read (the character 1, ASCII code 49). It becomes the value of `last-input-char`, while C-e (from the C-x C-e command used to evaluate this expression) remains the value of `last-command-char`.

```
(progn (print (read-char))
       (print last-command-char)
       last-input-char)
     -| 49
     -| 5
     => 49
```

The alias `last-input-char` exists for compatibility with Emacs version 18.

Function: **discard-input**

This function discards the contents of the terminal input buffer and cancels any keyboard macro that might be in the process of definition. It returns `nil`.

In the following example, the user may type a number of characters right after starting the evaluation of the form. After the `sleep-for` finishes sleeping, any characters that have been typed are discarded.

```
(progn (sleep-for 2)
  (discard-input))
     => nil
```

Waiting for Elapsed Time or Input

The waiting commands are designed to make Emacs wait for a certain amount of time to pass or until there is input. For example, you may wish to pause in the middle of a computation to allow the user time to view the display. `sit-for` pauses and updates the screen, and returns immediately if input comes in, while `sleep-for` pauses without updating the screen.

Function: **sit-for** *seconds &optional millisec nodisp*

This function performs redisplay (provided there is no pending input from the user), then waits seconds

seconds, or until input is available. The result is `t` if `sit-for` waited the full time with no input arriving (see `input-pending-p` in section Peeking and Discarding). Otherwise, the value is `nil`.

The optional argument millisec specifies an additional waiting period measured in milliseconds. This adds to the period specified by seconds. Not all operating systems support waiting periods other than multiples of a second; on those that do not, you get an error if you specify nonzero millisec.

Redisplay is always preempted if input arrives, and does not happen at all if input is available before it starts. Thus, there is no way to force screen updating if there is pending input; however, if there is no input pending, you can force an update with no delay by using `(sit-for 0)`.

If nodisp is non-`nil`, then `sit-for` does not redisplay, but it still returns as soon as input is available (or when the timeout elapses).

The usual purpose of `sit-for` is to give the user time to read text that you display.

Function: **sleep-for** *seconds &optional millisec*

This function simply pauses for seconds seconds without updating the display. It pays no attention to available input. It returns `nil`.

The optional argument millisec specifies an additional waiting period measured in milliseconds. This adds to the period specified by seconds. Not all operating systems support waiting periods other than multiples of a second; on those that do not, you get an error if you specify nonzero millisec.

Use `sleep-for` when you wish to guarantee a delay.

See section Time of Day, for functions to get the current time.

Quitting

Typing C-g while the command loop has run a Lisp function causes Emacs to quit whatever it is doing. This means that control returns to the innermost active command loop.

Typing C-g while the command loop is waiting for keyboard input does not cause a quit; it acts as an ordinary input character. In the simplest case, you cannot tell the difference, because C-g normally runs the command `keyboard-quit`, whose effect is to quit. However, when C-g follows a prefix key, the result is an undefined key. The effect is to cancel the prefix key as well as any prefix argument.

In the minibuffer, C-g has a different definition: it aborts out of the minibuffer. This means, in effect, that it exits the minibuffer and then quits. (Simply quitting would return to the command loop *within* the minibuffer.) The reason why C-g does not quit directly when the command reader is reading input is so that its meaning can be redefined in the minibuffer in this way. C-g following a prefix key is not redefined in the minibuffer, and it has its normal effect of canceling the prefix key and prefix argument. This too would not be possible if C-g quit directly.

C-g causes a quit by setting the variable `quit-flag` to a non-`nil` value. Emacs checks this variable at appropriate times and quits if it is not `nil`. Setting `quit-flag` non-`nil` in any way thus causes a quit.

At the level of C code, quits cannot happen just anywhere; only at the special places which check `quit-flag`. The reason for this is that quitting at other places might leave an inconsistency in Ema internal state. Because quitting is delayed until a safe place, quitting cannot make Emacs crash.

Certain functions such as `read-key-sequence` or `read-quoted-char` prevent quitting entirely even though they wait for input. Instead of quitting, C-g serves as the requested input. In the case of `read-key-sequence`, this serves to bring about the special behavior of C-g in the command loop. In the case of `read-quoted-char`, this is so that C-q can be used to quote a C-g.

You can prevent quitting for a portion of a Lisp function by binding the variable `inhibit-quit` to a non-`nil` value. Then, although C-g still sets `quit-flag` to `t` as usual, the usual result of this--a quit--is prevented. Eventually, `inhibit-quit` will become `nil` again, such as when its binding is unwound at the end of a `let` form. At that time, if `quit-flag` is still non-`nil`, the requested quit happens immediately. This behavior is ideal for a "critical section", where you wish to make sure that quitting does not happen within that part of the program.

In some functions (such as `read-quoted-char`), C-g is handled in a special way which does not involve quitting. This is done by reading the input with `inhibit-quit` bound to `t` and setting `quit-flag` to `nil` before `inhibit-quit` becomes `nil` again. This excerpt from the definition of `read-quoted-char` shows how this is done; it also shows that normal quitting is permitted after the first character of input.

```
(defun read-quoted-char (&optional prompt)
  "...documentation..."
  (let ((count 0) (code 0) char)
    (while (< count 3)
      (let ((inhibit-quit (zerop count))
            (help-form nil))
        (and prompt (message "%s-" prompt))
        (setq char (read-char))
        (if inhibit-quit (setq quit-flag nil)))
      ...)
    (logand 255 code)))
```

Variable: **quit-flag**

If this variable is non-`nil`, then Emacs quits immediately, unless `inhibit-quit` is non-`nil`. Typing C-g sets `quit-flag` non-`nil`, regardless of `inhibit-quit`.

Variable: **inhibit-quit**

This variable determines whether Emacs should quit when `quit-flag` is set to a value other than `nil`. If `inhibit-quit` is non-`nil`, then `quit-flag` has no special effect.

Command: **keyboard-quit**

This function signals the `quit` condition with `(signal 'quit nil)`. This is the same thing that quitting does. (See `signal` in section Errors.)

You can specify a character other than C-g to use for quitting. See the function `set-input-mode` section Terminal Input.

Prefix Command Arguments

Most Emacs commands can use a prefix argument, a number specified before the command itself. (Don't confuse prefix arguments with prefix keys.) The prefix argument is represented by a value that is always available (though it may be `nil`, meaning there is no prefix argument). Each command may use the prefix argument or ignore it.

There are two representations of the prefix argument: raw and numeric. The editor command loop uses the raw representation internally, and so do the Lisp variables that store the information, but commands can request either representation.

Here are the possible values of a raw prefix argument:

- `nil`, meaning there is no prefix argument. Its numeric value is 1, but numerous commands make a distinction between `nil` and the integer 1.
- An integer, which stands for itself.
- A list of one element, which is an integer. This form of prefix argument results from one or a succession of C-u's with no digits. The numeric value is the integer in the list, but some commands make a distinction between such a list and an integer alone.
- The symbol `-`. This indicates that M-- or C-u - was typed, without following digits. The equivalent numeric value is -1, but some commands make a distinction between the integer -1 and the symbol `-`.

The various possibilities may be illustrated by calling the following function with various prefixes:

```
(defun display-prefix (arg)
  "Display the value of the raw prefix arg."
  (interactive "P")
  (message "%s" arg))
```

Here are the results of calling `print-prefix` with various raw prefix arguments:

```
        M-x print-prefix  -| nil

C-u     M-x print-prefix  -| (4)

C-u C-u M-x print-prefix  -| (16)

C-u 3   M-x print-prefix  -| 3

M-3     M-x print-prefix  -| 3      ; (Same as C-u 3.)

C-u -   M-x print-prefix  -| -
```

```
M- -    M-x print-prefix  -| -      ; (Same as C-u -.)

C-u -7  M-x print-prefix  -| -7

M- -7   M-x print-prefix  -| -7     ; (Same as C-u -7.)
```

Emacs uses two variables to store the prefix argument: `prefix-arg` and `current-prefix-arg`. Commands such as `universal-argument` that set up prefix arguments for other commands store them in `prefix-arg`. In contrast, `current-prefix-arg` conveys the prefix argument to the current command, so setting it has no effect on the prefix arguments for future commands.

Normally, commands specify which representation to use for the prefix argument, either numeric or raw, in the `interactive` declaration. (See section Interactive Call.) Alternatively, functions may look at the value of the prefix argument directly in the variable `current-prefix-arg`, but this is less clean.

Do not call the functions `universal-argument`, `digit-argument`, or `negative-argument` unless you intend to let the user enter the prefix argument for the *next* command.

Command: **universal-argument**

This command reads input and specifies a prefix argument for the following command. Don't call this command yourself unless you know what you are doing.

Command: **digit-argument** *arg*

This command adds to the prefix argument for the following command. The argument arg is the raw prefix argument as it was before this command; it is used to compute the updated prefix argument. Don't call this command yourself unless you know what you are doing.

Command: **negative-argument** *arg*

This command adds to the numeric argument for the next command. The argument arg is the raw prefix argument as it was before this command; its value is negated to form the new prefix argument. Don't call this command yourself unless you know what you are doing.

Function: **prefix-numeric-value** *arg*

This function returns the numeric meaning of a valid raw prefix argument value, arg. The argument may be a symbol, a number, or a list. If it is `nil`, the value 1 is returned; if it is any other symbol, the value -1 is returned. If it is a number, that number is returned; if it is a list, the CAR of that list (which should be a number) is returned.

Variable: **current-prefix-arg**

This variable is the value of the raw prefix argument for the *current* command. Commands may examine it directly, but the usual way to access it is with `(interactive "P")`.

Variable: **prefix-arg**

The value of this variable is the raw prefix argument for the *next* editing command. Commands that

specify prefix arguments for the following command work by setting this variable.

Recursive Editing

The Emacs command loop is entered automatically when Emacs starts up. This top-level invocation of the command loop is never exited until the Emacs is killed. Lisp programs can also invoke the command loop. Since this makes more than one activation of the command loop, we call it recursive editing. A recursive editing level has the effect of suspending whatever command invoked it and permitting the user to do arbitrary editing before resuming that command.

The commands available during recursive editing are the same ones available in the top-level editing loop and defined in the keymaps. Only a few special commands exit the recursive editing level; the others return to the recursive editing level when finished. (The special commands for exiting are always available, but do nothing when recursive editing is not in progress.)

All command loops, including recursive ones, set up all-purpose error handlers so that an error in a command run from the command loop will not exit the loop.

Minibuffer input is a special kind of recursive editing. It has a few special wrinkles, such as enabling display of the minibuffer and the minibuffer window, but fewer than you might suppose. Certain keys behave differently in the minibuffer, but that is only because of the minibuffer's local map; if you switch windows, you get the usual Emacs commands.

To invoke a recursive editing level, call the function `recursive-edit`. This function contains the command loop; it also contains a call to `catch` with tag `exit`, which makes it possible to exit the recursive editing level by throwing to `exit` (see section Explicit Nonlocal Exits: `catch` and `throw`). If you throw a value other than `t`, then `recursive-edit` returns normally to the function that called it. The command C-M-c (`exit-recursive-edit`) does this. Throwing a `t` value causes `recursive-edit` to quit, so that control returns to the command loop one level up. This is called aborting, and is done by C-] (`abort-recursive-edit`).

Most applications should not use recursive editing, except as part of using the minibuffer. Usually it is more convenient for the user if you change the major mode of the current buffer temporarily to a special major mode, which has a command to go back to the previous mode. (This technique is used by the w command in Rmail.) Or, if you wish to give the user different text to edit "recursively", create and select a new buffer in a special mode. In this mode, define a command to complete the processing and go back to the previous buffer. (The m command in Rmail does this.)

Recursive edits are useful in debugging. You can insert a call to `debug` into a function definition as a sort of breakpoint, so that you can look around when the function gets there. `debug` invokes a recursive edit but also provides the other features of the debugger.

Recursive editing levels are also used when you type C-r in `query-replace` or use C-x q (`kbd-macro-query`).

Function: **recursive-edit**

This function invokes the editor command loop. It is called automatically by the initialization of Emacs,

to let the user begin editing. When called from a Lisp program, it enters a recursive editing level.

In the following example, the function `simple-rec` first advances point one word, then enters a recursive edit, printing out a message in the echo area. The user can then do any editing desired, and then type C-M-c to exit and continue executing `simple-rec`.

```
(defun simple-rec ()
  (forward-word 1)
  (message "Recursive edit in progress.")
  (recursive-edit)
  (forward-word 1))
     => simple-rec
(simple-rec)
     => nil
```

Command: **exit-recursive-edit**

This function exits from the innermost recursive edit (including minibuffer input). Its definition is effectively `(throw 'exit nil)`.

Command: **abort-recursive-edit**

This function aborts the command that requested the innermost recursive edit (including minibuffer input), by signaling `quit` after exiting the recursive edit. Its definition is effectively `(throw 'exit t)`. See section Quitting.

Command: **top-level**

This function exits all recursive editing levels; it does not return a value, as it jumps completely out of any computation directly back to the main command loop.

Function: **recursion-depth**

This function returns the current depth of recursive edits. When no recursive edit is active, it returns 0.

Disabling Commands

Disabling a command marks the command as requiring user confirmation before it can be executed. Disabling is used for commands which might be confusing to beginning users, to prevent them from using the commands by accident.

The low-level mechanism for disabling a command is to put a non-`nil` `disabled` property on the Lisp symbol for the command. These properties are normally set up by the user's `` `.emacs' `` file with Lisp expressions such as this:

```
(put 'upcase-region 'disabled t)
```

For a few commands, these properties are present by default and may be removed by the `` `.emacs' ``

file.

If the value of the `disabled` property is a string, that string is included in the message printed when the command is used:

```
(put 'delete-region 'disabled
     "Text deleted this way cannot be yanked back!\n")
```

See section 'Disabling' in The GNU Emacs Manual, for the details on what happens when a disabled command is invoked interactively. Disabling a command has no effect on calling it as a function from Lisp programs.

Command: **enable-command** *command*

Allow command to be executed without special confirmation from now on. The user's `` `.emacs' `` file is optionally altered so that this will apply to future sessions.

Command: **disable-command** *command*

Require special confirmation to execute command from now on. The user's `` `.emacs' `` file is optionally altered so that this will apply to future sessions.

Variable: **disabled-command-hook**

This variable is a normal hook that is run instead of a disabled command, when the user runs the disabled command interactively. The hook functions can use `this-command-keys` to determine what the user typed to run the command, and thus find the command itself.

By default, `disabled-command-hook` contains a function that asks the user whether to proceed.

Command History

The command loop keeps a history of the complex commands that have been executed, to make it convenient to repeat these commands. A complex command is one for which the interactive argument reading uses the minibuffer. This includes any M-x command, any M-ESC command, and any command whose `interactive` specification reads an argument from the minibuffer. Explicit use of the minibuffer during the execution of the command itself does not cause the command to be considered complex.

Variable: **command-history**

This variable's value is a list of recent complex commands, each represented as a form to evaluate. It continues to accumulate all complex commands for the duration of the editing session, but all but the first (most recent) thirty elements are deleted when a garbage collection takes place (see section Garbage Collection).

```
command-history
=> ((switch-to-buffer "chistory.texi")
```

```
(describe-key "^X^[")
(visit-tags-table "~/emacs/src/")
(find-tag "repeat-complex-command"))
```

This history list is actually a special case of minibuffer history (see section Minibuffer History), with one special twist: the elements are expressions rather than strings.

There are a number of commands devoted to the editing and recall of previous commands. The commands `repeat-complex-command`, and `list-command-history` are described in the user manual (see section 'Repetition' in The GNU Emacs Manual). Within the minibuffer, the history commands used are the same ones available in any minibuffer.

Keyboard Macros

A keyboard macro is a canned sequence of input events that can be considered a command and made the definition of a key. Don't confuse keyboard macros with Lisp macros (see section Macros).

Function: **execute-kbd-macro** *macro &optional count*

This function executes macro as a sequence of events. If macro is a string or vector, then the events in it are executed exactly as if they had been input by the user. The sequence is *not* expected to be a single key sequence; normally a keyboard macro definition consists of several key sequences concatenated.

If macro is a symbol, then its function definition is used in place of macro. If that is another symbol, this process repeats. Eventually the result should be a string or vector. If the result is not a symbol, string, or vector, an error is signaled.

The argument count is a repeat count; macro is executed that many times. If count is omitted or `nil`, macro is executed once. If it is 0, macro is executed over and over until it encounters an error or a failing search.

Variable: **last-kbd-macro**

This variable is the definition of the most recently defined keyboard macro. Its value is a string or vector, or `nil`.

Variable: **executing-macro**

This variable contains the string or vector that defines the keyboard macro that is currently executing. It is `nil` if no macro is currently executing.

Variable: **defining-kbd-macro**

This variable indicates whether a keyboard macro is being defined. It is set to `t` by `start-kbd-macro`, and `nil` by `end-kbd-macro`. You can use this variable to make a command behave differently when run from a keyboard macro (perhaps indirectly by calling `interactive-p`). However, do not set this variable yourself.

The commands are described in the user's manual (see section 'Keyboard Macros' in The GNU Emacs

TOC

Manual).

Go to the previous, next section.

Go to the previous, next section.

Keymaps

The bindings between input events and commands are recorded in data structures called keymaps. Each binding in a keymap associates (or binds) an individual event type either with another keymap or with a command. When an event is bound to a keymap, that keymap is used to look up the next character typed; this continues until a command is found. The whole process is called key lookup.

Keymap Terminology

A keymap is a table mapping event types to definitions (which can be any Lisp objects, though only certain types are meaningful for execution by the command loop). Given an event (or an event type) and a keymap, Emacs can get the event's definition. Events include ordinary ASCII characters, function keys, and mouse actions (see section Input Events).

A sequence of input events that form a unit is called a key sequence, or key for short. A sequence of one event is always a key sequence, and so are some multi-event sequences.

A keymap determines a binding or definition for any key sequence. If the key sequence is a single event, its binding is the definition of the event in the keymap. The binding of a key sequence of more than one event is found by an iterative process: the binding of the first event is found, and must be a keymap; then the second event's binding is found in that keymap, and so on until all the events in the key sequence are used up.

If the binding of a key sequence is a keymap, we call the key sequence a prefix key. Otherwise, we call it a complete key (because no more characters can be added to it). If the binding is `nil`, we call the key undefined. Examples of prefix keys are C-c, C-x, and C-x 4. Examples of defined complete keys are X, RET, and C-x 4 C-f. Examples of undefined complete keys are C-x C-g, and C-c 3. See section Prefix Keys, for more details.

The rule for finding the binding of a key sequence assumes that the intermediate bindings (found for the events before the last) are all keymaps; if this is not so, the sequence of events does not form a unit--it is not really a key sequence. In other words, removing one or more events from the end of any valid key must always yield a prefix key. For example, C-f C-f is not a key; C-f is not a prefix key, so a longer sequence starting with C-f cannot be a key.

Note that the set of possible multi-event key sequences depends on the bindings for prefix keys; therefore, it can be different for different keymaps, and can change when bindings are changed. However, a one-event sequence is always a key sequence, because it does not depend on any prefix keys for its well-formedness.

At any time, several primary keymaps are active---that is, in use for finding key bindings. These are the global map, which is shared by all buffers; the local keymap, which is usually associated with a specific major mode; and zero or more minor mode keymaps which belong to currently enabled minor modes.

(Not all minor modes have keymaps.) The local keymap bindings shadow (i.e., take precedence over) corresponding global bindings. The minor mode keymaps shadow both local and global keymaps. See section Active Keymaps, for details.

Format of Keymaps

A keymap is a list whose CAR is the symbol `keymap`. The remaining elements of the list define the key bindings of the keymap. Use the function `keymapp` (see below) to test whether an object is a keymap.

An ordinary element is a cons cell of the form `(type . binding)`. This specifies one binding which applies to events of type type. Each ordinary binding applies to events of a particular event type, which is always a character or a symbol. See section Classifying Events.

A cons cell whose CAR is `t` is a default key binding; any event not bound by other elements of the keymap is given binding as its binding. Default bindings allow a keymap to bind all possible event types without having to enumerate all of them. A keymap that has a default binding completely masks any lower-precedence keymap.

If an element of a keymap is a vector, the vector counts as bindings for all the ASCII characters; vector element n is the binding for the character with code n. This is a more compact way to record lots of bindings. A keymap with such a vector is called a full keymap. Other keymaps are called sparse keymaps.

When a keymap contains a vector, it always defines a binding for every ASCII character even if the vector element is `nil`. Such a binding of `nil` overrides any default binding in the keymap. However, default bindings are still meaningful for events that are not ASCII characters. A binding of `nil` does *not* override lower-precedence keymaps; thus, if the local map gives a binding of `nil`, Emacs uses the binding from the global map.

Aside from bindings, a keymap can also have a string as an element. This is called the overall prompt string and makes it possible to use the keymap as a menu. See section Menu Keymaps.

Keymaps do not directly record bindings for the meta characters, whose codes are from 128 to 255. Instead, meta characters are regarded for purposes of key lookup as sequences of two characters, the first of which is ESC (or whatever is currently the value of `meta-prefix-char`). Thus, the key M-a is really represented as ESC a, and its global binding is found at the slot for a in `esc-map`.

Here as an example is the local keymap for Lisp mode, a sparse keymap. It defines bindings for DEL and TAB, plus C-c C-l, M-C-q, and M-C-x.

```
lisp-mode-map
=>
(keymap
 ;; TAB
 (9 . lisp-indent-line)
 ;; DEL
 (127 . backward-delete-char-untabify)
```

```
(3 keymap
   ;; C-c C-l
   (12 . run-lisp))
(27 keymap
    ;; M-C-q, treated as ESC C-q
    (17 . indent-sexp)
    ;; M-C-x, treated as ESC C-x
    (24 . lisp-send-defun)))
```

Function: **keymapp** *object*

This function returns `t` if object is a keymap, `nil` otherwise. Practically speaking, this function tests for a list whose CAR is `keymap`.

```
(keymapp '(keymap))
    => t
(keymapp (current-global-map))
    => t
```

Creating Keymaps

Here we describe the functions for creating keymaps.

Function: **make-keymap** *&optional prompt*

This function creates and returns a new full keymap (i.e., one which contains a vector of length 128 for defining all the ASCII characters). The new keymap initially binds all ASCII characters to `nil`, and does not bind any other kind of event.

```
(make-keymap)
    => (keymap [nil nil nil ... nil nil])
```

If you specify prompt, that becomes the overall prompt string for the keymap. The prompt string is useful for menu keymaps (see section Menu Keymaps).

Function: **make-sparse-keymap** *&optional prompt*

This function creates and returns a new sparse keymap with no entries. The new keymap does not bind any events. The argument prompt specifies a prompt string, as in `make-keymap`.

```
(make-sparse-keymap)
    => (keymap)
```

Function: **copy-keymap** *keymap*

This function returns a copy of keymap. Any keymaps which appear directly as bindings in keymap are also copied recursively, and so on to any number of levels. However, recursive copying does not take

place when the definition of a character is a symbol whose function definition is a keymap; the same symbol appears in the new copy.

```
(setq map (copy-keymap (current-local-map)))
=> (keymap
     ;; (This implements meta characters.)
     (27 keymap
         (83 . center-paragraph)
         (115 . center-line))
     (9 . tab-to-tab-stop))

(eq map (current-local-map))
    => nil
(equal map (current-local-map))
    => t
```

Inheritance and Keymaps

A keymap can inherit the bindings of another keymap. Do do this, make a keymap whose "tail" is another existing keymap to inherit from. Such a keymap looks like this:

```
(keymap bindings... . other-keymap)
```

The effect is that this keymap inherits all the bindings of other-keymap, whatever they may be at the time a key is looked up, but can add to them or override them with bindings.

If you change the bindings in other-keymap using `define-key` or other key-binding functions, these changes are visible in the inheriting keymap unless shadowed by bindings. The converse is not true: if you use `define-key` to change the inheriting keymap, that affects bindings, but has no effect on other-keymap.

Here is an example showing how to make a keymap that inherits from `text-mode-map`:

```
(setq my-mode-map (cons 'keymap text-mode-map))
```

Prefix Keys

A prefix key has an associated keymap which defines what to do with key sequences that start with the prefix key. For example, C-x is a prefix key, and it uses a keymap which is also stored in the variable `ctl-x-map`. Here is a list of the standard prefix keys of Emacs and their keymaps:

- `esc-map` is used for events that follow ESC. Thus, the global definitions of all meta characters are actually found here. This map is also the function definition of `ESC-prefix`.
- `help-map` is used for events that follow C-h.
- `mode-specific-map` is for events that follow C-c. This map is not actually mode specific; its

name was chosen to be informative for the user in C-h b (`display-bindings`), where it describes the main use of the C-c prefix key.

- `ctl-x-map` is the variable name for the map used for events that follow C-x. This map is also the function definition of `Control-X-prefix`.
- `ctl-x-4-map` is used for events that follow C-x 4.
- `ctl-x-5-map` used is for events that follow C-x 5.
- A nameless keymap is used for events that follow C-x n. Others are used for events following C-x r and C-x a.

The binding of a prefix key is the keymap to use for looking up the events that follow the prefix key. (It may instead be a symbol whose function definition is a keymap. The effect is the same, but the symbol serves as a name for the prefix key.) Thus, the binding of C-x is the symbol `Control-X-prefix`, whose function definition is the keymap for C-x commands. (The same keymap is also the value of `ctl-x-map`.)

Prefix key definitions of this sort can appear in any active keymap. The definitions of C-c, C-x, C-h and ESC as prefix keys appear in the global map, so these prefix keys are always available. Major and minor modes can redefine a key as a prefix by putting a prefix key definition for it in the local map or the minor mode's map. See section Active Keymaps.

If a key is defined as a prefix in more than one active map, then the various definitions are in effect merged: the commands defined in the minor mode keymaps come first, followed by those in the local map's prefix definition, and then by those from the global map.

In the following example, we make C-p a prefix key in the local keymap, in such a way that C-p is identical to C-x. Then the binding for C-p C-f is the function `find-file`, just like C-x C-f. The key sequence C-p 6 is not found in any active keymap.

```
(use-local-map (make-sparse-keymap))
    => nil
(local-set-key "\C-p" ctl-x-map)
    => nil
(key-binding "\C-p\C-f")
    => find-file

(key-binding "\C-p6")
    => nil
```

Function: **define-prefix-command** *symbol*

This function defines symbol as a prefix command: it creates a full keymap and stores it as symbol's function definition. Storing the symbol as the binding of a key makes the key a prefix key which has a name. It also sets symbol as a variable, to have the keymap as its value. The function returns symbol.

In Emacs version 18, only the function definition of symbol was set, not the value as a variable.

Menu Keymaps

A keymap can define a menu as well as ordinary keys and mouse button meanings. Menus are normally actuated with the mouse, but they can work with the keyboard also.

Defining Menus

A keymap is suitable for menu use if it has an overall prompt string, which is a string that appears as an element of the keymap. (See section Format of Keymaps.) The string should describe the purpose of the menu. The easiest way to construct a keymap with a prompt string is to specify the string as an argument when you call `make-keymap` or `make-sparse-keymap` (see section Creating Keymaps).

The individual bindings in the menu keymap should also have prompt strings; these strings become the items displayed in the menu. A binding with a prompt string looks like this:

```
(string . real-binding)
```

As far as `define-key` and `lookup-key` are concerned, the string is part of the event's binding. However, only real-binding is used for executing the key.

You can also supply a second string, called the help string, as follows:

```
(string help-string . real-binding)
```

Currently Emacs does not actually use help-string; it knows only how to ignore help-string in order to extract real-binding. In the future we hope to make help-string serve as extended documentation for the menu item, available on request.

The prompt string for a binding should be short--one or two words. It should describe the action of the command it corresponds to.

If real-binding is `nil`, then string appears in the menu but cannot be selected.

If real-binding is a symbol, and has a non-`nil` `menu-enable` property, that property is an expression which controls whether the menu item is enabled. Every time the keymap is used to display a menu, Emacs evaluates the expression, and it enables the menu item only if the expression's value is non-`nil`. When a menu item is disabled, it is displayed in a "fuzzy" fashion, and cannot be selected with the mouse.

The order of items in the menu is the same as the order of bindings in the keymap. Since `define-key` puts new bindings at the front, you should define the menu items starting at the bottom of the menu and moving to the top, if you care about the order.

Menus and the Mouse

The way to make a menu keymap produce a menu is to make it the definition of a prefix key.

When the prefix key ends with a mouse event, Emacs handles the menu keymap by popping up a visible menu, so that the user can select a choice with the mouse. When the user clicks on a menu item, the event generated is whatever character or symbol has the binding which brought about that menu item.

It's often best to use a button-down event to trigger the menu. Then the user can select a menu item by releasing the button.

A single keymap can appear as multiple menu panes, if you explicitly arrange for this. The way to do this is to make a keymap for each pane, then create a binding for each of those maps in the main keymap of the menu. Give each of these bindings a prompt string that starts with `@'. The rest of the prompt string becomes the name of the pane. See the file `lisp/mouse.el' for an example of this. Any ordinary bindings with `@'-less prompt strings are grouped into one pane, which appears along with the other panes explicitly created for the submaps.

You can also get multiple panes from separate keymaps. The full definition of a prefix key always comes from merging the definitions supplied by the various active keymaps (minor mode, local, and global). When more than one of these keymaps is a menu, each of them makes a separate pane or panes. See section Active Keymaps.

A Lisp program can explicitly pop up a menu and receive the user's choice. You can use keymaps for this also. See section Pop-Up Menus.

Menus and the Keyboard

When a prefix key ending with a keyboard event (a character or function key) has a definition that is a menu keymap, the user can use the keyboard to choose a menu item.

Emacs displays the menu alternatives (the prompt strings of the bindings) in the echo area. If they don't all fit at once, the user can type SPC to see the next line of alternatives. Successive uses of SPC eventually get to the end of the menu and then cycle around to the beginning.

When the user has found the desired alternative from the menu, he or she should type the corresponding character--the one whose binding is that alternative.

In a menu intended for keyboard use, each menu item must clearly indicate what character to type. The best convention to use is to make the character the first letter of the menu item prompt string. That is something users will understand without being told.

This way of using menus in an Emacs-like editor was inspired by the Hierarkey system.

Variable: **menu-prompt-more-char**

This variable specifies the character to use to ask to see the next line of a menu. Its initial value is 32, the code for SPC.

Menu Example

Here is a simple example of how to set up a menu for mouse use.

```
(defvar my-menu-map
  (make-sparse-keymap "Key Commands <==> Functions"))
(fset 'help-for-keys my-menu-map)

(define-key my-menu-map [bindings]
  '("List all keystroke commands" . describe-bindings))
(define-key my-menu-map [key]
  '("Describe key briefly" . describe-key-briefly))
(define-key my-menu-map [key-verbose]
  '("Describe key verbose" . describe-key))
(define-key my-menu-map [function]
  '("Describe Lisp function" . describe-function))
(define-key my-menu-map [where-is]
  '("Where is this command" . where-is))

(define-key global-map [C-S-down-mouse-1] 'help-for-keys)
```

The symbols used in the key sequences bound in the menu are fictitious "function keys"; they don't appear on the keyboard, but that doesn't stop you from using them in the menu. Their names were chosen to be mnemonic, because they show up in the output of `where-is` and `apropos` to identify the corresponding menu items.

However, if you want the menu to be usable from the keyboard as well, you must use real ASCII characters instead of fictitious function keys.

The Menu Bar

Under X Windows, each frame can have a menu bar---a permanently displayed menu stretching horizontally across the top of the frame. The items of the menu bar are the subcommands of the fake "function key" `menu-bar`, as defined by all the active keymaps.

To add an item to the menu bar, invent a fake "function key" of your own (let's call it key), and make a binding for the key sequence `[menu-bar key]`. Most often, the binding is a menu keymap, so that pressing a button on the menu bar item leads to another menu.

When more than one active keymap defines the same fake function key for the menu bar, the item appears just once. If the user clicks on that menu bar item, it brings up a single, combined submenu containing all the subcommands of that item--the global subcommands, the local subcommands, and the minor mode subcommands, all together.

In order for a frame to display a menu bar, its `menu-bar-lines` property must be greater than zero. Emacs uses just one line for the menu bar itself; if you specify more than one line, the other lines serve to separate the menu bar from the windows in the frame. We recommend you try one or two as the value of

`menu-bar-lines`. See section X Window Frame Parameters.

Here's an example of setting up a menu bar item:

```
(modify-frame-parameters (selected-frame) '((menu-bar-lines . 2)))

;; Make a menu keymap (with a prompt string)
;; to be the menu bar item's definition.
(define-key global-map [menu-bar words]
  (cons "Words" (make-sparse-keymap "Words")))

;; Make specific subcommands in the item's submenu.
(define-key global-map
  [menu-bar words forward]
  '("Forward word" . forward-word))
(define-key global-map
  [menu-bar words backward]
  '("Backward word" . backward-word))
```

Active Keymaps

Emacs normally contains many keymaps; at any given time, just a few of them are active in that they participate in the interpretation of user input. These are the global keymap, the current buffer's local keymap, and the keymaps of any enabled minor modes.

The global keymap holds the bindings of keys that are defined regardless of the current buffer, such as C-f. The variable `global-map` holds this keymap, which is always active.

Each buffer may have another keymap, its local keymap, which may contain new or overriding definitions for keys. At all times, the current buffer's local keymap is active. Text properties can specify an alternative local map for certain parts of the buffer; see section Special Properties.

Each minor mode may have a keymap; if it does, the keymap is active whenever the minor mode is enabled.

All the active keymaps are used together to determine what command to execute when a key is entered. The key lookup proceeds as described earlier (see section Key Lookup), but Emacs *first* searches for the key in the minor mode maps (one map at a time); if they do not supply a binding for the key, Emacs searches the local map; if that too has no binding, Emacs then searches the global map.

Since every buffer that uses the same major mode normally uses the very same local keymap, it may appear as if the keymap is local to the mode. A change to the local keymap of a buffer (using `local-set-key`, for example) will be seen also in the other buffers that share that keymap.

The local keymaps that are used for Lisp mode, C mode, and several other major modes exist even if they have not yet been used. These local maps are the values of the variables `lisp-mode-map`, `c-mode-map`, and so on. For most other modes, which are less frequently used, the local keymap is

constructed only when the mode is used for the first time in a session.

The minibuffer has local keymaps, too; they contain various completion and exit commands. See section Minibuffers.

See section Standard Keymaps, for a list of standard keymaps.

Variable: **global-map**

This variable contains the default global keymap that maps Emacs keyboard input to commands. Normally this keymap is the global keymap. The default global keymap is a full keymap that binds `self-insert-command` to all of the printing characters.

Function: **current-global-map**

This function returns the current global keymap. This is always the same as the value of `global-map` unless you change one or the other.

```
(current-global-map)
=> (keymap [set-mark-command beginning-of-line ...
            delete-backward-char])
```

Function: **current-local-map**

This function returns the current buffer's local keymap, or `nil` if it has none. In the following example, the keymap for the `*scratch*' buffer (using Lisp Interaction mode) is a sparse keymap in which the entry for ESC, ASCII code 27, is another sparse keymap.

```
(current-local-map)
=> (keymap
    (10 . eval-print-last-sexp)
    (9 . lisp-indent-line)
    (127 . backward-delete-char-untabify)
    (27 keymap
        (24 . eval-defun)
        (17 . indent-sexp)))
```

Function: **current-minor-mode-maps**

This function returns a list of the keymaps of currently enabled minor modes.

Function: **use-global-map** *keymap*

This function makes keymap the new current global keymap. It returns `nil`.

It is very unusual to change the global keymap.

Function: **use-local-map** *keymap*

This function makes keymap the new current local keymap of the current buffer. If keymap is `nil`, then

there will be no local keymap. It returns `nil`. Most major modes use this function.

Variable: **minor-mode-map-alist**

This variable is an alist describing keymaps that may or may not be active according to the values of certain variables. Its elements look like this:

```
(variable . keymap)
```

The keymap keymap is active whenever variable has a non-`nil` value. Typically variable is the variable which enables or disables a minor mode. See section Keymaps and Minor Modes.

When more than one minor mode keymap is active, their order of priority is the order of `minor-mode-map-alist`.

See also `minor-mode-key-binding` in section Functions for Key Lookup.

Key Lookup

Key lookup is the process of finding the binding of a key sequence from a given keymap. Actual execution of the binding is not part of key lookup.

Key lookup uses just the event types of each event in the key sequence; the rest of the event is ignored. In fact, a key sequence used for key lookup may designate mouse events with just their types (symbols) instead of with entire mouse events (lists). See section Input Events. Such a pseudo-key-sequence is insufficient for `command-execute`, but it is sufficient for looking up or rebinding a key.

When the key sequence consists of multiple events, key lookup processes the events sequentially: the binding of the first event is found, and must be a keymap; then the second event's binding is found in that keymap, and so on until all the events in the key sequence are used up. (The binding thus found for the last event may or may not be a keymap.) Thus, the process of key lookup is defined in terms of a simpler process for looking up a single event in a keymap. How that is done depends on the type of object associated with the event in that keymap.

Let's use the term keymap entry to describe the value directly associated with an event type in a keymap. While any Lisp object may be stored as a keymap entry, not all make sense for key lookup. Here is a list of the meaningful kinds of keymap entries:

`nil`
: `nil` means that the events used so far in the lookup form an undefined key. When a keymap fails to mention an event type at all, that is equivalent to an entry of `nil` for that type.

keymap
: The events used so far in the lookup form a prefix key. The next event of the key sequence is looked up in keymap.

command
: The events used so far in the lookup form a complete key, and command is its binding.

string

vector

The events used so far in the lookup form a complete key, whose binding is a keyboard macro. See section Keyboard Macros, for more information.

list

The meaning of a list depends on the types of the elements of the list.

If the CAR of list is the symbol `keymap`, then the list is a keymap, and is treated as a keymap (see above).

If the CAR of list is `lambda`, then the list is a lambda expression. This is presumed to be a command, and is treated as such (see above).

If the CAR of list is a keymap and the CDR is an event type, then this is an indirect entry:

```
(othermap . othertype)
```

When key lookup encounters an indirect entry, it looks up instead the binding of othertype in othermap and uses that.

This feature permits you to define one key as an alias for another key. For example, an entry whose CAR is the keymap called `esc-map` and whose CDR is 32 (the code for space) means, "Use the global binding of Meta-SPC, whatever that may be."

If the CAR of list is a string, it serves as a menu item name if the keymap is used as a menu. For executing the key, the string is discarded and the CDR of list is used instead. (Any number of strings can be discarded from the front of the list in this way.) See section Menu Keymaps.

symbol

The function definition of symbol is used in place of symbol. If that too is a symbol, then this process is repeated, any number of times. Ultimately this should lead to an object which is a keymap, a command or a keyboard macro. A list is allowed if it is a keymap or a command, but indirect entries are not understood when found via symbols.

Note that keymaps and keyboard macros (strings and vectors) are not valid functions, so a symbol with a keymap, string or vector as its function definition is also invalid as a function. It is, however, valid as a key binding. If the definition is a keyboard macro, then the symbol is also valid as an argument to `command-execute` (see section Interactive Call).

The symbol `undefined` is worth special mention: it means to treat the key as undefined. Strictly speaking, the key is defined, and its binding is the command `undefined`; but that command does the same thing that is done automatically for an undefined key: it rings the bell (by calling `ding`) but does not signal an error.

`undefined` is used in local keymaps to override a global key binding and make the key "undefined" locally. A local binding of `nil` would fail to do this because it would not override the global binding.

anything else

If any other type of object is found, the events used so far in the lookup form a complete key, and the object is its binding, but the binding is not executable as a command.

In short, a keymap entry may be a keymap, a command, a keyboard macro, a symbol which leads to one of them, or an indirection or `nil`. Here is an example of a sparse keymap with two characters bound to commands and one bound to another keymap. This map is the normal value of `emacs-lisp-mode-map`. Note that 9 is the code for TAB, 127 for DEL, 27 for ESC, 17 for C-q and 24 for C-x.

```
(keymap (9 . lisp-indent-line)
        (127 . backward-delete-char-untabify)
        (27 keymap (17 . indent-sexp) (24 . eval-defun)))
```

Functions for Key Lookup

Here are the functions and variables pertaining to key lookup.

Function: **lookup-key** *keymap key &optional accept-defaults*

This function returns the definition of key in keymap. If the string or vector key is not a valid key sequence according to the prefix keys specified in keymap (which means it is "too long" and has extra events at the end), then the value is a number, the number of events at the front of key that compose a complete key.

If accept-defaults is non-`nil`, then `lookup-key` considers default bindings as well as bindings for the specific events in key. Otherwise, `lookup-key` reports only bindings for the specific sequence key, ignoring default bindings except when an element of key is `t`.

All the other functions described in this chapter that look up keys use `lookup-key`.

```
(lookup-key (current-global-map) "\C-x\C-f")
    => find-file
(lookup-key (current-global-map) "\C-x\C-f12345")
    => 2
```

If key contains a meta character, that character is implicitly replaced by a two-character sequence: the value of `meta-prefix-char`, followed by the corresponding non-meta character. Thus, the first example below is handled by conversion into the second example.

```
(lookup-key (current-global-map) "\M-f")
    => forward-word
(lookup-key (current-global-map) "\ef")
    => forward-word
```

This function does not modify the specified events in ways that discard information as

`read-key-sequence` does (see section Key Sequence Input). In particular, it does not convert le to lower case and it does not change drag events to clicks.

Command: **undefined**

Used in keymaps to undefine keys. It calls `ding`, but does not cause an error.

Function: **key-binding** *key &optional accept-defaults*

This function returns the binding for key in the current keymaps, trying all the active keymaps. The result is `nil` if key is undefined in the keymaps.

The argument accept-defaults controls checking for default bindings, as in `lookup-key`.

An error is signaled if key is not a string or a vector.

```
(key-binding "\C-x\C-f")
    => find-file
```

Function: **local-key-binding** *key &optional accept-defaults*

This function returns the binding for key in the current local keymap, or `nil` if it is undefined there.

The argument accept-defaults controls checking for default bindings, as in `lookup-key` (above).

Function: **global-key-binding** *key &optional accept-defaults*

This function returns the binding for command key in the current global keymap, or `nil` if it is undefined there.

The argument accept-defaults controls checking for default bindings, as in `lookup-key` (above).

Function: **minor-mode-key-binding** *key &optional accept-defaults*

This function returns a list of all the active minor mode bindings of key. More precisely, it returns an alist of pairs `(modename . binding)`, where modename is the the variable which enables the minor mode, and binding is key's binding in that mode. If key has no minor-mode bindings, the value is `nil`.

If the first binding is a non-prefix, all subsequent bindings from other minor modes are omitted, since they would be completely shadowed. Similarly, the list omits non-prefix bindings that follow prefix bindings.

The argument accept-defaults controls checking for default bindings, as in `lookup-key` (above).

Variable: **meta-prefix-char**

This variable is the meta-prefix character code. It is used when translating a meta character to a two-character sequence so it can be looked up in a keymap. For useful results, the value should be a prefix event (see section Prefix Keys). The default value is 27, which is the ASCII code for ESC.

As long as the value of `meta-prefix-char` remains 27, key lookup translates M-b into ESC b, which is normally defined as the `backward-word` command. However, if you set `meta-prefix-char` to

24, the code for C-x, then Emacs will translate M-b into C-x b, whose standard binding is the `switch-to-buffer` command.

```
meta-prefix-char                        ; The default value.
     => 27
(key-binding "\M-b")
     => backward-word
?\C-x                                   ; The print representation
     => 24                              ;   of a character.
(setq meta-prefix-char 24)
     => 24
(key-binding "\M-b")
     => switch-to-buffer                ; Now, typing M-b is
                                        ;   like typing C-x b.

(setq meta-prefix-char 27)              ; Avoid confusion!
     => 27                              ; Restore the default value!
```

Changing Key Bindings

The way to rebind a key is to change its entry in a keymap. You can change the global keymap, so that the change is effective in all buffers (except those that override the global binding with a local one). Or you can change the current buffer's local map, which usually affects all buffers using the same major mode. The `global-set-key` and `local-set-key` functions are convenient interfaces for these operations. Or you can use `define-key` and specify explicitly which map to change.

People often use `global-set-key` in their `.emacs' file for simple customization. For example,

```
(global-set-key "\C-x\C-\\" 'next-line)
```

or

```
(global-set-key [?\C-x ?\C-\\] 'next-line)
```

redefines C-x C-\ to move down a line.

```
(global-set-key [M-mouse-1] 'mouse-set-point)
```

redefines the first (leftmost) mouse button, typed with the Meta key, to set point where you click.

In writing the key sequence to rebind, it is useful to use the special escape sequences for control and meta characters (see section String Type). The syntax `\C-' means that the following character is a control character and `\M-' means that the following character is a meta character. Thus, the string `"\M-x"` is read as containing a single M-x, `"\C-f"` is read as containing a single C-f, and `"\M-\C-x"` and `"\C-\M-x"` are both read as containing a single C-M-x.

For the functions below, an error is signaled if keymap is not a keymap or if key is not a string or ve representing a key sequence. However, you can use event types (symbols) as shorthand for events th are lists.

Function: **define-key** *keymap key binding*

This function sets the binding for key in keymap. (If key is more than one event long, the change is actually made in another keymap reached from keymap.) The argument binding can be any Lisp object, but only certain types are meaningful. (For a list of meaningful types, see section Key Lookup.) The value returned by `define-key` is binding.

Every prefix of key must be a prefix key (i.e., bound to a keymap) or undefined; otherwise an error is signaled.

If some prefix of key is undefined, then `define-key` defines it as a prefix key so that the rest of key may be defined as specified.

The following example creates a sparse keymap and makes a number of bindings:

```
(setq map (make-sparse-keymap))
    => (keymap)
(define-key map "\C-f" 'forward-char)
    => forward-char
map
    => (keymap (6 . forward-char))

;; Build sparse submap for C-x and bind f in that.
(define-key map "\C-xf" 'forward-word)
    => forward-word
map
=> (keymap
    (24 keymap                ; C-x
        (102 . forward-word)) ;      f
    (6 . forward-char))       ; C-f

;; Bind C-p to the ctl-x-map.
(define-key map "\C-p" ctl-x-map)
;; ctl-x-map
=> [nil ... find-file ... backward-kill-sentence]

;; Bind C-f to foo in the ctl-x-map.
(define-key map "\C-p\C-f" 'foo)
=> 'foo
map
=> (keymap     ; Note foo in ctl-x-map.
    (16 keymap [nil ... foo ... backward-kill-sentence])
    (24 keymap
```

```
        (102 . forward-word))
    (6 . forward-char))
```

Note that storing a new binding for C-p C-f actually works by changing an entry in `ctl-x-map`, and this has the effect of changing the bindings of both C-p C-f and C-x C-f in the default global map.

Function: **substitute-key-definition** *olddef newdef keymap &optional oldmap*

This function replaces olddef with newdef for any keys in keymap that were bound to olddef. In other words, olddef is replaced with newdef wherever it appears. The function returns `nil`.

For example, this redefines C-x C-f, if you do it in an Emacs with standard bindings:

```
(substitute-key-definition
 'find-file 'find-file-read-only (current-global-map))
```

If oldmap is non-`nil`, then its bindings determine which keys to rebind. The rebindings still happen in newmap, not in oldmap. Thus, you can change one map under the control of the bindings in another. For example,

```
(substitute-key-definition
  'delete-backward-char 'my-funny-delete
  my-map global-map)
```

puts the special deletion command in `my-map` for whichever keys are globally bound to the standard deletion command.

Here is an example showing a keymap before and after substitution:

```
(setq map '(keymap
            (?1 . olddef-1)
            (?2 . olddef-2)
            (?3 . olddef-1)))
=> (keymap (49 . olddef-1) (50 . olddef-2) (51 . olddef-1))

(substitute-key-definition 'olddef-1 'newdef map)
=> nil
map
=> (keymap (49 . newdef) (50 . olddef-2) (51 . newdef))
```

Function: **suppress-keymap** *keymap &optional nodigits*

This function changes the contents of the full keymap keymap by replacing the self-insertion commands for numbers with the `digit-argument` function, unless nodigits is non-`nil`, and by replacing the functions for the rest of the printing characters with `undefined`. This means that ordinary insertion of text is impossible in a buffer with a local keymap on which `suppress-keymap` has been called.

`suppress-keymap` returns `nil`.

The `suppress-keymap` function does not make it impossible to modify a buffer, as it does not suppress commands such as `yank` and `quoted-insert`. To prevent any modification of a buffer, make it read-only (see section Read-Only Buffers).

Since this function modifies keymap, you would normally use it on a newly created keymap. Operating on an existing keymap that is used for some other purpose is likely to cause trouble; for example, suppressing `global-map` would make it impossible to use most of Emacs.

Most often, `suppress-keymap` is used to initialize local keymaps of modes such as Rmail and Dired where insertion of text is not desirable and the buffer is read-only. Here is an example taken from the file `` `emacs/lisp/dired.el' ``, showing how the local keymap for Dired mode is set up:

```
...
(setq dired-mode-map (make-keymap))
(suppress-keymap dired-mode-map)
(define-key dired-mode-map "r" 'dired-rename-file)
(define-key dired-mode-map "\C-d" 'dired-flag-file-deleted)
(define-key dired-mode-map "d" 'dired-flag-file-deleted)
(define-key dired-mode-map "v" 'dired-view-file)
(define-key dired-mode-map "e" 'dired-find-file)
(define-key dired-mode-map "f" 'dired-find-file)
...
```

Commands for Binding Keys

This section describes some convenient interactive interfaces for changing key bindings. They work by calling `define-key`.

Command: **global-set-key** *key definition*

This function sets the binding of key in the current global map to definition.

```
(global-set-key key definition)
==
(define-key (current-global-map) key definition)
```

Command: **global-unset-key** *key*

This function removes the binding of key from the current global map.

One use of this function is in preparation for defining a longer key which uses it implicitly as a prefix--which would not be allowed if key has a non-prefix binding. For example:

```
(global-unset-key "\C-l")
    => nil
(global-set-key "\C-l\C-l" 'redraw-display)
```

```
    => nil
```

This function is implemented simply using `define-key`:

```
(global-unset-key key)
==
(define-key (current-global-map) key nil)
```

Command: **local-set-key** *key definition*

This function sets the binding of key in the current local keymap to definition.

```
(local-set-key key definition)
==
(define-key (current-local-map) key definition)
```

Command: **local-unset-key** *key*

This function removes the binding of key from the current local map.

```
(local-unset-key key)
==
(define-key (current-local-map) key nil)
```

Scanning Keymaps

This section describes functions used to scan all the current keymaps for the sake of printing help information.

Function: **accessible-keymaps** *keymap*

This function returns a list of all the keymaps that can be accessed (via prefix keys) from keymap. The value is an association list with elements of the form `(key . map)`, where key is a prefix key whose definition in keymap is map.

The elements of the alist are ordered so that the key increases in length. The first element is always `("" . keymap)`, because the specified keymap is accessible from itself with a prefix of no events.

In the example below, the returned alist indicates that the key ESC, which is displayed as `^[', is a prefix key whose definition is the sparse keymap `(keymap (83 . center-paragraph) (115 . foo))`.

```
(accessible-keymaps (current-local-map))
=>(("" keymap
      (27 keymap   ; Note this keymap for ESC is repeated below.
          (83 . center-paragraph)
          (115 . center-line))
```

```
     (9 . tab-to-tab-stop))

   ("^[" keymap
    (83 . center-paragraph)
    (115 . foo)))
```

In the following example, C-h is a prefix key that uses a sparse keymap starting `(keymap (118 . describe-variable)...)`. Another prefix, C-x 4, uses a keymap which happens to be `ctl-x-4-map`. The event `mode-line` is one of several dummy events used as prefixes for mouse actions in special parts of a window.

```
(accessible-keymaps (current-global-map))
=> (("" keymap [set-mark-command beginning-of-line ...
                delete-backward-char])
    ("^H" keymap (118 . describe-variable) ...
     (8 . help-for-help))
    ("^X" keymap [x-flush-mouse-queue ... backward-kill-sentence])
    ("^[" keymap [mark-sexp backward-sexp ... backward-kill-word])
    ("^X4" keymap (15 . display-buffer) ...)
    ([mode-line] keymap
     (S-mouse-2 . mouse-split-window-horizontally) ...))
```

These are not all the keymaps you would see in an actual case.

Function: **where-is-internal** *command &optional keymap firstonly*

This function returns a list of key sequences (of any length) that are bound to command in keymap and the global keymap. The argument command can be any object; it is compared with all keymap entries using `eq`. If keymap is not supplied, then the global map alone is used.

If firstonly is non-`nil`, then the value is a single string representing the first key sequence found, rather than a list of all possible key sequences.

This function is used by `where-is` (see section 'Help' in The GNU Emacs Manual).

```
(where-is-internal 'describe-function)
    => ("\^hf" "\^hd")
```

Command: **describe-bindings**

This function creates a listing of all defined keys, and their definitions. The listing is put in a buffer named `*Help*', which is then displayed in a window.

A meta character is shown as ESC followed by the corresponding non-meta character. Control characters are indicated with C-.

When several characters with consecutive ASCII codes have the same definition, they are shown together, as `firstchar..lastchar'. In this instance, you need to know the ASCII codes to understand which characters this means. For example, in the default global map, the characters `SPC .. ~' are described by a

single line. SPC is ASCII 32, ~ is ASCII 126, and the characters between them include all the normal printing characters, (e.g., letters, digits, punctuation, etc.); all these characters are bound to `self-insert-command`.

Go to the previous, next section.

Go to the previous, next section.

Major and Minor Modes

A mode is a set of definitions that customize Emacs and can be turned on and off while you edit. There are two varieties of modes: major modes, which are mutually exclusive and used for editing particular kinds of text, and minor modes, which provide features that may be enabled individually.

This chapter covers both major and minor modes, the way they are indicated in the mode line, and how they run hooks supplied by the user. Related topics such as keymaps and syntax tables are covered in separate chapters. (See section Keymaps, and section Syntax Tables.)

Major Modes

Major modes specialize Emacs for editing particular kinds of text. Each buffer has only one major mode at a time.

The least specialized major mode is called Fundamental mode. This mode has no mode-specific definitions or variable settings, so each Emacs command behaves in its default manner, and each option is in its default state. All other major modes redefine various keys and options. For example, Lisp Interaction mode provides special key bindings for LFD (`eval-print-last-sexp`), TAB (`lisp-indent-line`), and other keys.

When you need to write several editing commands to help you perform a specialized editing task, creating a new major mode is usually a good idea. In practice, writing a major mode is easy (in contrast to writing a minor mode, which is often difficult).

If the new mode is similar to an old one, it is often unwise to modify the old one to serve two purposes, since it may become harder to use and maintain. Instead, copy and rename an existing major mode definition and alter it for its new function. For example, Rmail Edit mode, which is in `` `emacs/lisp/rmailedit.el' ``, is a major mode that is very similar to Text mode except that it provides three additional commands. Its definition is distinct from that of Text mode, but was derived from it.

Rmail Edit mode is an example of a case where one piece of text is put temporarily into a different major mode so it can be edited in a different way (with ordinary Emacs commands rather than Rmail). In such cases, the temporary major mode usually has a command to switch back to the buffer's usual mode (Rmail mode, in this case). You might be tempted to present the temporary redefinitions inside a recursive edit and restore the usual ones when the user exits; but this is a bad idea because it constrains the user's options when it is done in more than one buffer: recursive edits must be exited most-recently-entered first. Using alternative major modes avoids this limitation. See section Recursive Editing.

The standard GNU Emacs Lisp library directory contains the code for several major modes, in files including `` `text-mode.el' ``, `` `texinfo.el' ``, `` `lisp-mode.el' ``, `` `c-mode.el' ``, and `` `rmail.el' ``. You can look at these libraries to see how modes are written. Text mode is perhaps the simplest major mode aside from Fundamental mode. Rmail mode is a rather complicated, full-featured mode.

Major Mode Conventions

The code for existing major modes follows various coding conventions, including conventions for local keymap and syntax table initialization, global names, and hooks. Please keep these conventions in mind when you create a new major mode:

- Define a command whose name ends in `-mode', with no arguments, that switches to the new mode in the current buffer. This command should set up the keymap, syntax table, and local variables in an existing buffer without changing the buffer's text.
- Write a documentation string for this command which describes the special commands available in this mode. C-h m (`describe-mode`) will print this.

  The documentation string may include the special documentation substrings, `\[command]', `\{keymap}', and `\<keymap>', that enable the documentation to adapt automatically to the user's own key bindings. See section Substituting Key Bindings in Documentation. The `describe-mode` function replaces these special documentation substrings with their current meanings. See section Access to Documentation Strings.
- The major mode command should set the variable `major-mode` to the major mode command symbol. This is how `describe-mode` discovers which documentation to print.
- The major mode command should set the variable `mode-name` to the "pretty" name of the mode, as a string. This appears in the mode line.
- Since all global names are in the same name space, all the global variables, constants, and functions that are part of the mode should have names that start with the major mode name (or with an abbreviation of it if the name is long). See section Writing Clean Lisp Programs.
- The major mode should usually have its own keymap, which is used as the local keymap in all buffers in that mode. The major mode function should call `use-local-map` to install this local map. See section Active Keymaps, for more information.

  This keymap should be kept in a global variable named `modename-mode-map`. Normally the library that defines the mode sets this variable. Use `defvar` to set the variable, so that it is not reinitialized if it already has a value. (Such reinitialization could discard customizations made by the user.)
- The mode may have its own syntax table or may share one with other related modes. If it has its own syntax table, it should store this in a variable named `modename-mode-syntax-table`. The reasons for this are the same as for using a keymap variable. See section Syntax Tables.
- The mode may have its own abbrev table or may share one with other related modes. If it has its own abbrev table, it should store this in a variable named `modename-mode-abbrev-table`. See section Abbrev Tables.
- To give a variable a buffer-local binding, use `make-local-variable` in the major mode command, not `make-variable-buffer-local`. The latter function would make the variable local to every buffer in which it is subsequently set, which would affect buffers that do not use this mode. It is undesirable for a mode to have such global effects. See section Buffer-Local Variables.
- If hooks are appropriate for the mode, the major mode command should run the hooks after completing all other initialization so the user may further customize any of the settings. See section Hooks.
- If this mode is appropriate only for specially-prepared text, then the major mode command symbol should have a property named `mode-class` with value `special`, put on as follows:

```
(put 'funny-mode 'mode-class 'special)
```

This tells Emacs that new buffers created while the current buffer has Funny mode should not inherit Funny mode. Modes such as Dired, Rmail, and Buffer List use this feature.

- If it is desirable that Emacs use the new mode by default after visiting files with certain recognizable names, add an element to `auto-mode-alist` to select the mode for those file names. If you define the mode command to autoload, you should add this element in the same file that calls `autoload`. Otherwise, it is sufficient to add the element in the file that contains the mode definition. See section How Emacs Chooses a Major Mode.
- In the documentation, you should provide a sample `autoload` form and an example of how to add to `auto-mode-alist`, that users can include in their `.emacs' files.
- The top level forms in the file defining the mode should be written so that they may be evaluated more than once without adverse consequences. Even if you never load the file more than once, someone else will.

Major Mode Examples

Text mode is perhaps the simplest mode besides Fundamental mode. Here are excerpts from `text-mode.el' that illustrate many of the conventions listed above:

```
;; Create mode-specific tables.
(defvar text-mode-syntax-table nil
  "Syntax table used while in text mode.")

(if text-mode-syntax-table
    ()              ; Do not change the table if it is already set up.
  (setq text-mode-syntax-table (make-syntax-table))
  (modify-syntax-entry ?\" ".   " text-mode-syntax-table)
  (modify-syntax-entry ?\\ ".   " text-mode-syntax-table)
  (modify-syntax-entry ?' "w   " text-mode-syntax-table))

(defvar text-mode-abbrev-table nil
  "Abbrev table used while in text mode.")
(define-abbrev-table 'text-mode-abbrev-table ())

(defvar text-mode-map nil)   ; Create a mode-specific keymap.

(if text-mode-map
    ()              ; Do not change the keymap if it is already set up.
  (setq text-mode-map (make-sparse-keymap))
  (define-key text-mode-map "\t" 'tab-to-tab-stop)
  (define-key text-mode-map "\es" 'center-line)
  (define-key text-mode-map "\eS" 'center-paragraph))
```

Here is the complete major mode function definition for Text mode:

```
(defun text-mode ()
  "Major mode for editing text intended for humans to read.
 Special commands: \\{text-mode-map}
Turning on text-mode runs the hook `text-mode-hook'."
  (interactive)
  (kill-all-local-variables)
  (use-local-map text-mode-map)     ; This provides the local keymap.
  (setq mode-name "Text")           ; This name goes into the mode line.
  (setq major-mode 'text-mode)      ; This is how describe-mode
                                    ;   finds the doc string to print.
  (setq local-abbrev-table text-mode-abbrev-table)
  (set-syntax-table text-mode-syntax-table)
  (run-hooks 'text-mode-hook))      ; Finally, this permits the user to
                                    ;   customize the mode with a hook.
```

The three Lisp modes (Lisp mode, Emacs Lisp mode, and Lisp Interaction mode) have more features than Text mode and the code is correspondingly more complicated. Here are excerpts from `lisp-mode.el' that illustrate how these modes are written.

```
;; Create mode-specific table variables.
(defvar lisp-mode-syntax-table nil "")
(defvar emacs-lisp-mode-syntax-table nil "")
(defvar lisp-mode-abbrev-table nil "")

(if (not emacs-lisp-mode-syntax-table) ; Do not change the table
                                       ;   if it is already set.
    (let ((i 0))
      (setq emacs-lisp-mode-syntax-table (make-syntax-table))

      ;; Set syntax of chars up to 0 to class of chars that are
      ;;   part of symbol names but not words.
      ;;   (The number 0 is 48 in the ASCII character set.)
      (while (< i ?0)
        (modify-syntax-entry i "_   " emacs-lisp-mode-syntax-table)
        (setq i (1+ i)))
      ...
      ;; Set the syntax for other characters.
      (modify-syntax-entry ?  "    " emacs-lisp-mode-syntax-table)
      (modify-syntax-entry ?\t "    " emacs-lisp-mode-syntax-table)
      ...
      (modify-syntax-entry ?\( "()  " emacs-lisp-mode-syntax-table)
      (modify-syntax-entry ?\) ")(  " emacs-lisp-mode-syntax-table)
      ...))
;; Create an abbrev table for lisp-mode.
(define-abbrev-table 'lisp-mode-abbrev-table ())
```

Much code is shared among the three Lisp modes. The following function sets various variables; it is called by each of the major Lisp mode functions:

```
(defun lisp-mode-variables (lisp-syntax)
  ;; The lisp-syntax argument is nil in Emacs Lisp mode,
  ;;   and t in the other two Lisp modes.
  (cond (lisp-syntax
         (if (not lisp-mode-syntax-table)
             ;; The Emacs Lisp mode syntax table always exists, but
             ;;   the Lisp Mode syntax table is created the first time a
             ;;   mode that needs it is called.  This is to save space.
             (progn (setq lisp-mode-syntax-table
                          (copy-syntax-table emacs-lisp-mode-syntax-table))
                    ;; Change some entries for Lisp mode.
                    (modify-syntax-entry ?\| "\"   "
                                         lisp-mode-syntax-table)
                    (modify-syntax-entry ?\[ "_   "
                                         lisp-mode-syntax-table)
                    (modify-syntax-entry ?\] "_   "
                                         lisp-mode-syntax-table)))
          (set-syntax-table lisp-mode-syntax-table)))
  (setq local-abbrev-table lisp-mode-abbrev-table)
  ...)
```

Functions such as `forward-paragraph` use the value of the `paragraph-start` variable. Since Lisp code is different from ordinary text, the `paragraph-start` variable needs to be set specially to handle Lisp. Also, comments are indented in a special fashion in Lisp and the Lisp modes need their own mode-specific `comment-indent-function`. The code to set these variables is the rest of `lisp-mode-variables`.

```
  (make-local-variable 'paragraph-start)
  (setq paragraph-start (concat "^$\\|" page-delimiter))
  ...
  (make-local-variable 'comment-indent-function)
  (setq comment-indent-function 'lisp-comment-indent))
```

Each of the different Lisp modes has a slightly different keymap. For example, Lisp mode binds C-c C-l to `run-lisp`, but the other Lisp modes do not. However, all Lisp modes have some commands in common. The following function adds these common commands to a given keymap.

```
(defun lisp-mode-commands (map)
  (define-key map "\e\C-q" 'indent-sexp)
  (define-key map "\177" 'backward-delete-char-untabify)
  (define-key map "\t" 'lisp-indent-line))
```

Here is an example of using `lisp-mode-commands` to initialize a keymap, as part of the code for Emacs Lisp mode. First we declare a variable with `defvar` to hold the mode-specific keymap. When this `defvar` executes, it sets the variable to `nil` if it was void. Then we set up the keymap if the variable is `nil`.

This code avoids changing the keymap or the variable if it is already set up. This lets the user customize the keymap if he or she so wishes.

```
(defvar emacs-lisp-mode-map () "")

(if emacs-lisp-mode-map
    ()
  (setq emacs-lisp-mode-map (make-sparse-keymap))
  (define-key emacs-lisp-mode-map "\e\C-x" 'eval-defun)
  (lisp-mode-commands emacs-lisp-mode-map))
```

Finally, here is the complete major mode function definition for Emacs Lisp mode.

```
(defun emacs-lisp-mode ()
  "Major mode for editing Lisp code to run in Emacs.
Commands:
Delete converts tabs to spaces as it moves back.
Blank lines separate paragraphs.  Semicolons start comments.
\\{emacs-lisp-mode-map}
Entry to this mode runs the hook `emacs-lisp-mode-hook'."
  (interactive)
  (kill-all-local-variables)
  (use-local-map emacs-lisp-mode-map)    ; This provides the local keymap.
  (set-syntax-table emacs-lisp-mode-syntax-table)
  (setq major-mode 'emacs-lisp-mode)     ; This is how describe-mode
                                         ;   finds out what to describe.
  (setq mode-name "Emacs-Lisp")          ; This goes into the mode line.
  (lisp-mode-variables nil)              ; This define various variables.
  (run-hooks 'emacs-lisp-mode-hook))     ; This permits the user to use a
                                         ;   hook to customize the mode.
```

How Emacs Chooses a Major Mode

Based on information in the file name or in the file itself, Emacs automatically selects a major mode for the new buffer when a file is visited.

Command: **fundamental-mode**

Fundamental mode is a major mode that is not specialized for anything in particular. Other major modes are defined in effect by comparison with this one--their definitions say what to change, starting from Fundamental mode. The `fundamental-mode` function does *not* run any hooks, so it is not readily customizable.

Command: **normal-mode** *&optional find-file*

This function establishes the proper major mode and local variable bindings for the current buffer. First it calls `set-auto-mode`, then it runs `hack-local-variables` to parse, and bind or evaluate as appropriate, any local variables.

If the find-file argument to `normal-mode` is non-`nil`, `normal-mode` assumes that the `find-file` function is calling it. In this case, it may process a local variables list at the end of the file. The variable `enable-local-variables` controls whether to do so.

If you run `normal-mode` yourself, the argument find-file is normally `nil`. In this case, `normal-mode` unconditionally processes any local variables list. See section 'Local Variables in Files' in The GNU Emacs Manual, for the syntax of the local variables section of a file.

`normal-mode` uses `condition-case` around the call to the major mode function, so errors are caught and reported as a `File mode specification error', followed by the original error message.

User Option: **enable-local-variables**

This variable controls processing of local variables lists in files being visited. A value of `t` means process the local variables lists unconditionally; `nil` means ignore them; anything else means ask the user what to do for each file. The default value is `t`.

User Option: **enable-local-eval**

This variable controls processing of `Eval:' in local variables lists in files being visited. A value of `t` means process them unconditionally; `nil` means ignore them; anything else means ask the user what to do for each file. The default value is `maybe`.

Function: **set-auto-mode**

This function selects the major mode that is appropriate for the current buffer. It may base its decision on the value of the `-*-' line, on the visited file name (using `auto-mode-alist`), or on the value of a local variable). However, this function does not look for the `mode:' local variable near the end of a file; the `hack-local-variables` function does that. See section 'How Major Modes are Chosen' in The GNU Emacs Manual.

User Option: **default-major-mode**

This variable holds the default major mode for new buffers. The standard value is `fundamental-mode`.

If the value of `default-major-mode` is `nil`, Emacs uses the (previously) current buffer's major mode for the major mode of a new buffer. However, if the major mode symbol has a `mode-class` property with value `special`, then it is not used for new buffers; Fundamental mode is used instead. The modes that have this property are those such as Dired and Rmail that are useful only with text that has been specially prepared.

Variable: **initial-major-mode**

The value of this variable determines the major mode of the initial `*scratch*' buffer. The value should be a symbol that is a major mode command name. The default value is `lisp-interaction-mode`.

Variable: **auto-mode-alist**

This variable contains an association list of file name patterns (regular expressions; see section Regular Expressions) and corresponding major mode functions. Usually, the file name patterns test for suffixes, such as `.el' and `.c', but this need not be the case. Each element of the alist looks like `(regexp . mode-function)`.

For example,

```
(("^/tmp/fol/" . text-mode)
 ("\\.texinfo$" . texinfo-mode)
 ("\\.texi$" . texinfo-mode)
```

```
("\\.el$" . emacs-lisp-mode)
("\\.c$" . c-mode)
("\\.h$" . c-mode)
...)
```

When you visit a file whose *expanded* file name (see section Functions that Expand Filenames) matches a regexp, `set-auto-mode` calls the corresponding mode-function. This feature enables Emacs to select the proper major mode for most files.

Here is an example of how to prepend several pattern pairs to `auto-mode-alist`. (You might use this sort of expression in your `.emacs' file.)

```
(setq auto-mode-alist
  (append
   ;; Filename starts with a dot.
   '(("/\\.[^/]*$" . fundamental-mode)
     ;; Filename has no dot.
     ("[^\\./]*$" . fundamental-mode)
     ("\\.C$" . c++-mode))
   auto-mode-alist))
```

Function: **hack-local-variables** *&optional force*

This function parses, and binds or evaluates as appropriate, any local variables for the current buffer.

The handling of `enable-local-variables` documented for `normal-mode` actually takes place here. The argument force reflects the argument find-file given to `normal-mode`.

Getting Help about a Major Mode

The `describe-mode` function is used to provide information about major modes. It is normally called with C-h m. The `describe-mode` function uses the value of `major-mode`, which is why every major mode function needs to set the `major-mode` variable.

Command: **describe-mode**

This function displays the documentation of the current major mode.

The `describe-mode` function calls the `documentation` function using the value of `major-mode` as an argument. Thus, it displays the documentation string of the major mode function. (See section Access to Documentation Strings.)

Variable: **major-mode**

This variable holds the symbol for the current buffer's major mode. This symbol should be the name of the function that is called to initialize the mode. The `describe-mode` function uses the documentation string of this symbol as the documentation of the major mode.

Minor Modes

A minor mode provides features that users may enable or disable independently of the choice of major mode. Minor modes can be enabled individually or in combination. Minor modes would be better named "Generally available, optional feature modes" except that such a name is unwieldy.

A minor mode is not usually a modification of single major mode. For example, Auto Fill mode may be used in any major mode that permits text insertion. To be general, a minor mode must be effectively independent of the things major modes do.

A minor mode is often much more difficult to implement than a major mode. One reason is that you should be able to deactivate a minor mode and restore the environment of the major mode to the state it was in before the minor mode was activated.

Often the biggest problem in implementing a minor mode is finding a way to insert the necessary hook into the rest of Emacs. Minor mode keymaps make this easier.

Conventions for Writing Minor Modes

There are conventions for writing minor modes just as there are for major modes. Several of the major mode conventions apply to minor modes as well: those regarding the name of the mode initialization function, the names of global symbols, and the use of keymaps and other tables.

In addition, there are several conventions that are specific to minor modes.

- Make a variable whose name ends in `-mode' to represent the minor mode. Its value should enable or disable the mode (`nil` to disable; anything else to enable.) We call this the mode variable.

  This variable is used in conjunction with the `minor-mode-alist` to display the minor mode name in the mode line. It can also enable or disable a minor mode keymap. Individual commands or hooks can also check the variable's value.

  If you want the minor mode to be enabled separately in each buffer, make the variable buffer-local.

- Define a command whose name is the same as the mode variable. Its job is to enable and disable the mode by setting the variable.

  The command should accept one optional argument. If the argument is `nil`, it should toggle the mode (turn it on if it is off, and off if it is on). Otherwise, it should turn the mode on if the argument is a positive integer, a symbol other than `nil` or `-`, or a list whose CAR is such an integer or symbol; it should turn the mode off otherwise.

  Here is an example taken from the definition of `overwrite-mode`. It shows the use of `overwrite-mode` as a variable which enables or disables the mode's behavior.

```
(setq overwrite-mode
      (if (null arg) (not overwrite-mode)
        (> (prefix-numeric-value arg) 0)))
```

- Add an element to `minor-mode-alist` for each minor mode (see section Variables Used in the Mode Line). This element should be a list of the following form:

```
(mode-variable string)
```

Here mode-variable is the variable that controls enablement of the minor mode, and string is a short string, starting with a space, to represent the mode in the mode line. These strings must be short so that there is room for several of them at once.

When you add an element to `minor-mode-alist`, use `assq` to check for an existing element, to avoid duplication. For example:

```
(or (assq 'leif-mode minor-mode-alist)
    (setq minor-mode-alist
          (cons '(leif-mode " Leif") minor-mode-alist)))
```

Keymaps and Minor Modes

As of Emacs version 19, each minor mode can have its own keymap which is active when the mode is enabled. See section Active Keymaps. To set up a keymap for a minor mode, add an element to the alist `minor-mode-map-alist`.

One use of minor mode keymaps is to modify the behavior of certain self-inserting characters so that they do something else as well as self-insert. This is the only way to accomplish this in general, since there is no way to customize what `self-insert-command` does except in certain special cases (designed for abbrevs and Auto Fill mode). (Do not try substituting your own definition of `self-insert-command` for the standard one. The editor command loop handles this function specially.)

Variable: **minor-mode-map-alist**

This variable is an alist of elements element that look like this:

```
(variable . keymap)
```

where variable is the variable which indicates whether the minor mode is enabled, and keymap is the keymap. The keymap keymap is active whenever variable has a non-`nil` value.

Note that elements of `minor-mode-map-alist` do not have the same structure as elements of `minor-mode-alist`. The map must be the CDR of the element; a list with the map as the second element will not do.

What's more, the keymap itself must appear in the CDR. It does not work to store a variable in the CDR and make the map the value of that variable.

When more than one minor mode keymap is active, their order of priority is the order of `minor-mode-map-alist`. But you should design minor modes so that they don't interfere with each other. If you do this properly, the order will not matter.

Mode Line Format

Each Emacs window (aside from minibuffer windows) includes a mode line which displays status information about the buffer displayed in the window. The mode line contains information about the buffer such as its name, associated file, depth of recursive editing, and the major and minor modes of the buffer.

This section describes how the contents of the mode line are controlled. It is in the chapter on modes because much of the information displayed in the mode line relates to the enabled major and minor modes.

`mode-line-format` is a buffer-local variable that holds a template used to display the mode line of the current buffer. All windows for the same buffer use the same `mode-line-format` and the mode lines will appear the same (except perhaps for the percentage of the file scrolled off the top).

The mode line of a window is normally updated whenever a different buffer is shown in the window, or when the buffer's modified-status changes from `nil` to `t` or vice-versa. If you modify any of the variables referenced by `mode-line-format`, you may want to force an update of the mode line so as to display the new information.

Function: **force-mode-line-update**

Force redisplay of the current buffer's mode line.

The mode line is usually displayed in inverse video; see `mode-line-inverse-video` in section Inverse Video.

The Data Structure of the Mode Line

The mode line contents are controlled by a data structure of lists, strings, symbols and numbers kept in the buffer-local variable `mode-line-format`. The data structure is called a mode line construct, and it is built in recursive fashion out of simpler mode line constructs.

Variable: **mode-line-format**

The value of this variable is a mode line construct with overall responsibility for the mode line format. The value of this variable controls which other variables are used to form the mode line text, and where they appear.

A mode line construct may be as simple as a fixed string of text, but it usually specifies how to use other variables to construct the text. Many of these variables are themselves defined to have mode line constructs as their values.

The default value of `mode-line-format` incorporates the values of variables such as `mode-name` and `minor-mode-alist`. Because of this, very few modes need to alter `mode-line-format`. For most purposes, it is sufficient to alter the variables referenced by `mode-line-format`.

A mode line construct may be a list, cons cell, symbol, or string. If the value is a list, each element may be a list, a cons cell, a symbol, or a string.

`string`

A string as a mode line construct is displayed verbatim in the mode line except for %-constructs. Decimal digits after the % specify the field width for space filling on the right (i.e., the data is left

justified). See section %-Constructs in the Mode Line.

`symbol`

A symbol as a mode line construct stands for its value. The value of symbol is used in place of symbol unless symbol is `t` or `nil`, or is void, in which case symbol is ignored.

There is one exception: if the value of symbol is a string, it is processed verbatim in that the %-constructs are not recognized.

`(string rest...) or (list rest...)`

A list whose first element is a string or list, means to concatenate all the elements. This is the most common form of mode line construct.

`(symbol then else)`

A list whose first element is a symbol is a conditional. Its meaning depends on the value of symbol. If the value is non-`nil`, the second element of the list (then) is processed recursively as a mode line element. But if the value of symbol is `nil`, the third element of the list (if there is one) is processed recursively.

`(width rest...)`

A list whose first element is an integer specifies truncation or padding of the results of rest. The remaining elements rest are processed recursively as mode line constructs and concatenated together. Then the result is space filled (if width is positive) or truncated (to -width columns, if width is negative) on the right.

For example, the usual way to show what percentage of a buffer is above the top of the window is to use a list like this: `(-3 . "%p")`.

If you do alter `mode-line-format` itself, the new value should use all the same variables that are used by the default value, rather than duplicating their contents or displaying the information in another fashion. This permits customizations made by the user, by libraries (such as `display-time`) or by major modes via changes to those variables remain effective.

Here is an example of a `mode-line-format` that might be useful for `shell-mode` since it contains the hostname and default directory.

```
(setq mode-line-format
  (list ""
   'mode-line-modified
   "%b--"
   (getenv "HOST")      ; One element is not constant.
   ":"
   'default-directory
   "   "
   'global-mode-string
   "   %[(" 'mode-name
   'minor-mode-alist
   "%n"
   'mode-line-process
   ")%]----"
   '(-3 . "%p")
```

```
  "-%-"))
```

Variables Used in the Mode Line

This section describes variables incorporated by the standard value of `mode-line-format` into the text of the mode line. There is nothing inherently special about these variables; any other variables could have the same effects on the mode line if `mode-line-format` were changed to use them.

Variable: **mode-line-modified**

This variable holds the value of the mode-line construct that displays whether the current buffer is modified.

The default value of `mode-line-modified` is `("--%1*%1*-")`. This means that the mode line displays `--**-' if the buffer is modified, `-----' if the buffer is not modified, and `--%%-' if the buffer is read only.

Changing this variable does not force an update of the mode line.

Variable: **mode-line-buffer-identification**

This variable identifies the buffer being displayed in the window. Its default value is `Emacs: %17b', which means that it displays `Emacs:' followed by the buffer name. You may want to change this in modes such as Rmail that do not behave like a "normal" Emacs.

Variable: **global-mode-string**

This variable holds a string that is displayed in the mode line. The command `display-time` puts the time and load in this variable. The `%M' construct substitutes the value of `global-mode-string`, but this is obsolete, since the variable is included directly in the mode line.

Variable: **mode-name**

This buffer-local variable holds the "pretty" name of the current buffer's major mode. Each major mode should set this variable so that the mode name will appear in the mode line.

Variable: **minor-mode-alist**

This variable holds an association list whose elements specify how the mode line should indicate that a minor mode is active. Each element of the `minor-mode-alist` should be a two-element list:

```
(minor-mode-variable mode-line-string)
```

The string mode-line-string is included in the mode line when the value of minor-mode-variable is non-`nil` and not otherwise. These strings should begin with spaces so that they don't run together. Conventionally, the minor-mode-variable for a specific mode is set to a non-`nil` value when that minor mode is activated.

The default value of `minor-mode-alist` is:

```
minor-mode-alist
=> ((abbrev-mode " Abbrev")
    (overwrite-mode " Ovwrt")
    (auto-fill-function " Fill")
    (defining-kbd-macro " Def"))
```

(In earlier Emacs versions, `auto-fill-function` was called `auto-fill-hook`.)

`minor-mode-alist` is not buffer-local. The variables mentioned in the alist should be buffer-local if the minor mode can be enabled separately in each buffer.

Variable: **mode-line-process**

This buffer-local variable contains the mode line information on process status in modes used for communicating with subprocesses. It is displayed immediately following the major mode name, with no intervening space. For example, its value in the `*shell*' buffer is `(": %s")`, which allows the shell to display its status along with the major mode as: `(Shell: run)'. Normally this variable is `nil`.

Variable: **default-mode-line-format**

This variable holds the default `mode-line-format` for buffers that do not override it. This is the same as `(default-value 'mode-line-format)`.

The default value of `default-mode-line-format` is:

```
("" 
 mode-line-modified
 mode-line-buffer-identification
 "   "
 global-mode-string
 "   %[("
 mode-name
 minor-mode-alist
 "%n"
 mode-line-process
 ")%]----"
 (-3 . "%p")
 "-%-")
```

%-Constructs in the Mode Line

The following table lists the recognized %-constructs and what they mean.

%b
: the current buffer name, using the `buffer-name` function.

%f
: the visited file name, using the `buffer-file-name` function.

%*
: `%' if the buffer is read only (see `buffer-read-only`);
`*' if the buffer is modified (see `buffer-modified-p`);
`-' otherwise.

%s
: the status of the subprocess belonging to the current buffer, using `process-status`.

%p

the percent of the buffer above the top of window, or `Top', `Bottom' or `All'.

`%n`

`Narrow' when narrowing is in effect; nothing otherwise (see `narrow-to-region` in section Narrowing).

`%[`

an indication of the depth of recursive editing levels (not counting minibuffer levels): one `[' for each editing level.

`%]`

one `]' for each recursive editing level (not counting minibuffer levels).

`%%`

the character `%'---this is how to include a literal `%' in a string in which %-constructs are allowed.

`%-`

dashes sufficient to fill the remainder of the mode line.

The following two %-constructs are still supported but are obsolete since use of the `mode-name` and `global-mode-string` variables will produce the same results.

`%m`

the value of `mode-name`.

`%M`

the value of `global-mode-string`. Currently, only `display-time` modifies the value of `global-mode-string`.

Hooks

A hook is a variable where you can store a function or functions to be called on a particular occasion by an existing program. Emacs provides lots of hooks for the sake of customization. Most often, hooks are set up in the `.emacs' file, but Lisp programs can set them also. See section Standard Hooks, for a list of standard hook variables.

Most of the hooks in Emacs are normal hooks. These variables contain lists of functions to be called with no arguments. The reason most hooks are normal hooks is so that you can use them in a uniform way. You can always tell when a hook is a normal hook, because its name ends in `-hook'.

The recommended way to add a hook function to a normal hook is by calling `add-hook` (see below). The hook functions may be any of the valid kinds of functions that `funcall` accepts (see section What Is a Function?). Most normal hook variables are initially void; `add-hook` knows how to deal with this.

As for abnormal hooks, those whose names end in `-function' have a value which is a single function. Those whose names end in `-hooks' have a value which is a list of functions. Any hook which is abnormal is abnormal because a normal hook won't do the job; either the functions are called with arguments, or their values are meaningful. The name shows you that the hook is abnormal and you need to look up how to use it properly.

Most major modes run hooks as the last step of initialization. This makes it easy for a user to customize the behavior of the mode, by overriding the local variable assignments already made by the mode. But hooks may

also be used in other contexts. For example, the hook `suspend-hook` runs just before Emacs suspends (see section Suspending Emacs).

For example, you can put the following expression in your `.emacs' file if you want to turn on Auto Fill mode when in Lisp Interaction mode:

```
(add-hook 'lisp-interaction-mode-hook 'turn-on-auto-fill)
```

The next example shows how to use a hook to customize the way Emacs formats C code. (People often have strong personal preferences for one format compared to another.) Here the hook function is an anonymous lambda expression.

```
(add-hook 'c-mode-hook
  (function (lambda ()
              (setq c-indent-level 4
                    c-argdecl-indent 0
                    c-label-offset -4
                    c-continued-statement-indent 0
                    c-brace-offset 0
                    comment-column 40))))

(setq c++-mode-hook c-mode-hook)
```

Finally, here is an example of how to use the Text mode hook to provide a customized mode line for buffers in Text mode, displaying the default directory in addition to the standard components of the mode line. (This may cause the mode line to run out of space if you have very long file names or display the time and load.)

```
(add-hook 'text-mode-hook
  (function (lambda ()
              (setq mode-line-format
                    '(mode-line-modified
                      "Emacs: %14b"
                      "  "
                      default-directory
                      " "
                      global-mode-string
                      "%[("
                      mode-name
                      minor-mode-alist
                      "%n"
                      mode-line-process
                      ") %]---"
                      (-3 . "%p")
                      "-%-"))))))
```

At the appropriate time, Emacs uses the `run-hooks` function to run particular hooks. This function calls the hook functions you have added with `add-hooks`.

Function: **run-hooks** *&rest hookvar*

This function takes one or more hook names as arguments and runs each one in turn. Each hookvar argument should be a symbol that is a hook variable. These arguments are processed in the order specified.

If a hook variable has a non-`nil` value, that value may be a function or a list of functions. If the value is a function (either a lambda expression or a symbol with a function definition), it is called. If it is a list, the elements are called, in order. The hook functions are called with no arguments.

For example:

```
(run-hooks 'emacs-lisp-mode-hook)
```

Major mode functions use this function to call any hooks defined by the user.

Function: **add-hook** *hook function &optional append*

This function is the handy way to add function function to hook variable hook. For example,

```
(add-hook 'text-mode-hook 'my-text-hook-function)
```

adds `my-text-hook-function` to the hook called `text-mode-hook`.

It is best to design your hook functions so that the order in which they are executed does not matter. Any dependence on the order is "asking for trouble." However, the order is predictable: normally, function goes at the front of the hook list, so it will be executed first (barring another `add-hook` call).

If the optional argument append is non-`nil`, the new hook function goes at the end of the hook list and will be executed last.

Go to the previous, next section.

Go to the previous, next section.

Documentation

GNU Emacs Lisp has convenient on-line help facilities, most of which derive their information from the documentation strings associated with functions and variables. This chapter describes how to write good documentation strings for your Lisp programs, as well as how to write programs to access documentation.

Note that the documentation strings for Emacs are not the same thing as the Emacs manual. Manuals have their own source files, written in the Texinfo language; documentation strings are specified in the definitions of the functions and variables they apply to. A collection of documentation strings is not sufficient as a manual because a good manual is not organized in that fashion; it is organized in terms of topics of discussion.

Documentation Basics

A documentation string is written using the Lisp syntax for strings, with double-quote characters surrounding the text of the string. This is because it really is a Lisp string object. The string serves as documentation when it is written in the proper place in the definition of a function or variable. In a function definition, the documentation string follows the argument list. In a variable definition, the documentation string follows the initial value of the variable.

When you write a documentation string, make the first line a complete sentence (or two complete sentences) since some commands, such as `apropos`, print only the first line of a multi-line documentation string. Also, you should not indent the second line of a documentation string, if you have one, because that looks odd when you use C-h f (`describe-function`) or C-h v (`describe-variable`).

Documentation strings may contain several special substrings, which stand for key bindings to be looked up in the current keymaps when the documentation is displayed. This allows documentation strings to refer to the keys for related commands and be accurate even when a user rearranges the key bindings. (See section Access to Documentation Strings.)

Within the Lisp world, a documentation string is kept with the function or variable that it describes:

- The documentation for a function is stored in the function definition itself (see section Lambda Expressions). The function `documentation` knows how to extract it.
- The documentation for a variable is stored on the variable's property list under the property name `variable-documentation`. The function `documentation-property` knows how to extract it.

However, to save space, the documentation for preloaded functions and variables (including primitive functions and autoloaded functions) are stored in the `` `emacs/etc/DOC-version' `` file. Both the `documentation` and the `documentation-property` functions know how to access `` `emacs/etc/DOC-version' ``, and the process is transparent to the user. In this case, the documentation string is replaced with an integer offset into the `` `emacs/etc/DOC-version' `` file. Keeping the documentation strings out of the Emacs core image saves a significant amount of space. See section Building Emacs.

For information on the uses of documentation strings, see section 'Help' in The GNU Emacs Manual.

The `emacs/etc' directory contains two utilities that you can use to print nice-looking hardcopy for th file `emacs/etc/DOC-version'. These are `sorted-doc.c' and `digest-doc.c'.

Access to Documentation Strings

Function: **documentation-property** *symbol property &optional verbatim*

This function returns the documentation string that is recorded symbol's property list under property property. This uses the function `get`, but does more than that: it also retrieves the string from the file `emacs/etc/DOC-version' if necessary, and runs `substitute-command-keys` to substitute the actual (current) key bindings.

If verbatim is non-`nil`, that inhibits running `substitute-command-keys`. (The verbatim argument exists only as of Emacs 19.)

```
(documentation-property 'command-line-processed
   'variable-documentation)
     => "t once command line has been processed"
(symbol-plist 'command-line-processed)
     => (variable-documentation 188902)
```

Function: **documentation** *function &optional verbatim*

This function returns the documentation string of function. If the documentation string is stored in the `emacs/etc/DOC-version' file, this function will access it there.

In addition, `documentation` runs `substitute-command-keys` on the resulting string, so the value contains the actual (current) key bindings. (This is not done if verbatim is non-`nil`; the verbatim argument exists only as of Emacs 19.)

The function `documentation` signals a `void-function` error unless function has a function definition. However, function does not need to have a documentation string. If there is no documentation string, `documentation` returns `nil`.

Here is an example of using the two functions, `documentation` and `documentation-property`, to display the documentation strings for several symbols in a `*Help*' buffer.

```
(defun describe-symbols (pattern)
  "Describe the Emacs Lisp symbols matching PATTERN.
All symbols that have PATTERN in their name are described
in the `*Help*' buffer."
  (interactive "sDescribe symbols matching: ")
  (let ((describe-func
         (function
          (lambda (s)
            ;; Print description of symbol.
            (if (fboundp s)             ; It is a function.
                (princ
```

```
                (format "%s\t%s\n%s\n\n" s
                  (if (commandp s)
                      (let ((keys (where-is-internal s)))
                        (if keys
                            (concat
                             "Keys: "
                             (mapconcat 'key-description
                                        keys " "))
                          "Keys: none"))
                    "Function")
                  (or (documentation s)
                      "not documented"))))

          (if (boundp s)             ; It is a variable.
              (princ
               (format "%s\t%s\n%s\n\n" s
                 (if (user-variable-p s)
                     "Option " "Variable")
                 (or (documentation-property
                       s 'variable-documentation)
                     "not documented")))))))
      sym-list)

    ;; Build a list of symbols that match pattern.
    (mapatoms (function
               (lambda (sym)
                 (if (string-match pattern (symbol-name sym))
                     (setq sym-list (cons sym sym-list))))))

    ;; Display the data.
    (with-output-to-temp-buffer "*Help*"
      (mapcar describe-func (sort sym-list 'string<))
      (print-help-return-message))))
```

The `describe-symbols` function works like `apropos`, but provides more information.

```
(describe-symbols "goal")

---------- Buffer: *Help* ----------
goal-column     Option
*Semipermanent goal column for vertical motion, as set by C-x C-n, or nil.

set-goal-column Command: C-x C-n
Set the current horizontal position as a goal for C-n and C-p.
Those commands will move to this position in the line moved to
rather than trying to keep the same horizontal position.
With a non-nil argument, clears out the goal column
so that C-n and C-p resume vertical motion.
```

```
The goal column is stored in the variable `goal-column'.

temporary-goal-column   Variable
Current goal column for vertical motion.
It is the column where point was
at the start of current run of vertical motion commands.
When the `track-eol' feature is doing its job, the value is 9999.
---------- Buffer: *Help* ----------
```

Function: **Snarf-documentation** *filename*

This function is used only during Emacs initialization, just before the runnable Emacs is dumped. It finds the file offsets of the documentation strings stored in the file filename, and records them in the in-core function definitions and variable property lists in place of the actual strings. See section Building Emacs.

Emacs finds the file filename in the `emacs/etc' directory. When the dumped Emacs is later executed, the same file is found in the directory `data-directory`. Usually filename is `"DOC-version"`.

Variable: **data-directory**

This variable holds the name of the directory in which Emacs finds certain data files that come with Emacs or are built as part of building Emacs. (In older Emacs versions, this directory was the same as `exec-directory`.)

Substituting Key Bindings in Documentation

This function makes it possible for you to write a documentation string that enables a user to display information about the current, actual key bindings. if you call `documentation` with non-`nil` verbatim, you might later call this function to do the substitution that you prevented `documentation` from doing.

Function: **substitute-command-keys** *string*

This function returns string with certain special substrings replaced by the actual (current) key bindings. This permits the documentation to be displayed with accurate information about key bindings. (The key bindings may be changed by the user between the time Emacs is built and the time that the documentation is asked for.)

This table lists the forms of the special substrings and what they are replaced with:

`\[command]`
: is replaced either by a keystroke sequence that will invoke command, or by `M-x command' if command is not bound to any key sequence.

`\{mapvar}`
: is replaced by a summary of the value of mapvar, taken as a keymap. (The summary is made by `describe-bindings`.)

`\<mapvar>`
: makes this call to `substitute-command-keys` use the value of mapvar as the keymap for future `\[command]' substrings. This special string does not produce any replacement text itself; it only affects the replacements done later.

Please note: each `\' must be doubled when written in a string in Emacs Lisp.

Here are examples of the special substrings:

```
(substitute-command-keys
   "To abort recursive edit, type: \\[abort-recursive-edit]")

=> "To abort recursive edit, type: C-]"

(substitute-command-keys
   "The keys that are defined for the minibuffer here are:
  \\{minibuffer-local-must-match-map}")

=> "The keys that are defined for the minibuffer here are:

?               minibuffer-completion-help
SPC             minibuffer-complete-word
TAB             minibuffer-complete
LFD             minibuffer-complete-and-exit
RET             minibuffer-complete-and-exit
C-g             abort-recursive-edit
"

(substitute-command-keys
   "To abort a recursive edit from the minibuffer, type\
\\<minibuffer-local-must-match-map>\\[abort-recursive-edit].")
=> "To abort a recursive edit from the minibuffer, type C-g."
```

Describing Characters for Help Messages

These functions convert events, key sequences or characters to textual descriptions. These descriptions are useful for including arbitrary text characters or key sequences in messages, because they convert non-printing characters to sequences of printing characters. The description of a printing character is the character itself.

Function: **key-description** *sequence*

This function returns a string containing the Emacs standard notation for the input events in sequence. The argument sequence may be a string, vector or list. See section Input Events, for more information about valid events. See also the examples for `single-key-description`, below.

Function: **single-key-description** *event*

This function returns a string describing event in the standard Emacs notation for keyboard input. A normal printing character is represented by itself, but a control character turns into a string starting with `C-', a meta character turns into a string starting with `M-', and space, linefeed, etc. are transformed to `SPC', `LFD', etc. A function key is represented by its name. An event which is a list is represented by the name of the symbol in the CAR of the list.

```
(single-key-description ?\C-x)
```

```
     => "C-x"
(key-description "\C-x \M-y \n \t \r \f123")
     => "C-x SPC M-y SPC LFD SPC TAB SPC RET SPC C-l 1 2 3"
(single-key-description 'C-mouse-1)
     => "C-mouse-1"
```

Function: **text-char-description** *character*

This function returns a string describing character in the standard Emacs notation for characters that appear in text--like `single-key-description`, except that control characters are represented with a leading caret (which is how control characters in Emacs buffers are usually displayed).

```
(text-char-description ?\C-c)
     => "^C"
(text-char-description ?\M-m)
     => "M-m"
(text-char-description ?\C-\M-m)
     => "M-^M"
```

Help Functions

Emacs provides a variety of on-line help functions, all accessible to the user as subcommands of the prefix C-h. For more information about them, see section 'Help' in The GNU Emacs Manual. Here we describe some program-level interfaces to the same information.

Command: **apropos** *regexp &optional do-all predicate*

This function finds all symbols whose names contain a match for the regular expression regexp, and returns a list of them. It also displays the symbols in a buffer named `*Help*', each with a one-line description.

If do-all is non-`nil`, then `apropos` also shows key bindings for the functions that are found.

If predicate is non-`nil`, it should be a function to be called on each symbol that has matched regexp. Only symbols for which predicate returns a non-`nil` value are listed or displayed.

In the first of the following examples, `apropos` finds all the symbols with names containing `exec'. In the second example, it finds and returns only those symbols that are also commands. (We don't show the output that results in the `*Help*' buffer.)

```
(apropos "exec")
     => (Buffer-menu-execute command-execute exec-directory
    exec-path execute-extended-command execute-kbd-macro
    executing-kbd-macro executing-macro)

(apropos "exec" nil 'commandp)
     => (Buffer-menu-execute execute-extended-command)
```

The command C-h a (`command-apropos`) calls `apropos`, but specifies a predicate to restrict the output to symbols that are commands. The call to `apropos` looks like this:

```
(apropos string t 'commandp)
```

Command: **super-apropos** *regexp &optional do-all*

This function differs from `apropos` in that it searches documentation strings as well as symbol names for matches for regexp. By default, it searches only the documentation strings, and only those of functions and variables that are included in Emacs when it is dumped. If do-all is non-`nil`, it scans the names and documentation strings of all functions and variables.

Command: **help-command**

This command is not a function, but rather a symbol which is equivalent to the keymap called `help-map`. It is defined in `` `help.el' `` as follows:

```
(define-key global-map "\C-h" 'help-command)
(fset 'help-command help-map)
```

Variable: **help-map**

The value of this variable is a local keymap for characters following the Help key, C-h.

Function: **print-help-return-message** *&optional function*

This function builds a string which is a message explaining how to restore the previous state of the windows after a help command. After building the message, it applies function to it if function is non-`nil`. Otherwise it calls `message` to display it in the echo area.

This function expects to be called inside a `with-output-to-temp-buffer` special form, and expects `standard-output` to have the value bound by that special form. For an example of its use, see the example in the section describing the `documentation` function (see section Access to Documentation Strings).

The constructed message will have one of the forms shown below.

```
---------- Echo Area ----------
Type C-x 1 to remove help window.
---------- Echo Area ----------

---------- Echo Area ----------
Type C-x 4 b RET to restore old contents of help window.
---------- Echo Area ----------
```

Variable: **help-char**

The value of this variable is the character that Emacs recognizes as meaning Help. When Emacs reads this character (which is usually 8, the value of C-h), Emacs evaluates `(eval help-form)`, and displays the result if it is a string. If `help-form`'s value is `nil`, this character is read normally.

Variable: **help-form**

The value of this variable is a form to execute when the character `help-char` is read. If the form returns a

string, that string is displayed. If `help-form` is `nil`, then the help character is not recognized.

Entry to the minibuffer binds this variable to the value of `minibuffer-help-form`.

The following two functions are found in the library `` `helper' ``. They are for modes that want to provide help without relinquishing control, such as the "electric" modes. You must load that library with `(require 'helper)` in order to use them. Their names begin with `Helper' to distinguish them from the ordinary help functions.

Command: **Helper-describe-bindings**

This command pops up a window displaying a help buffer containing a listing of all of the key bindings from both the local and global keymaps. It works by calling `describe-bindings`.

Command: **Helper-help**

This command provides help for the current mode. It prompts the user in the minibuffer with the message `Help (Type ? for further options)', and then provides assistance in finding out what the key bindings are, and what the mode is intended for. It returns `nil`.

This can be customized by changing the map `Helper-help-map`.

Go to the previous, next section.

Go to the previous, next section.

Files

In Emacs, you can find, create, view, save, and otherwise work with files and file directories. This chapter describes most of the file-related functions of Emacs Lisp, but a few others are described in section Buffers, and those related to backups and auto-saving are described in section Backups and Auto-Saving.

Visiting Files

Visiting a file means reading a file into a buffer. Once this is done, we say that the buffer is visiting that file, and call the file "the visited file" of the buffer.

A file and a buffer are two different things. A file is information recorded permanently in the computer (unless you delete it). A buffer, on the other hand, is information inside of Emacs that will vanish at the end of the editing session (or when you kill the buffer). Usually, a buffer contains information that you have copied from a file; then we say the buffer is visiting that file. The copy in the buffer is what you modify with editing commands. Such changes to the buffer do not change the file; therefore, to make the changes permanent, you must save the buffer, which means copying the altered buffer contents back into the file.

In spite of the distinction between files and buffers, people often refer to a file when they mean a buffer and vice-versa. Indeed, we say, "I am editing a file," rather than, "I am editing a buffer which I will soon save as a file of the same name." Humans do not usually need to make the distinction explicit. When dealing with a computer program, however, it is good to keep the distinction in mind.

Functions for Visiting Files

This section describes the functions normally used to visit files. For historical reasons, these functions have names starting with `find-' rather than `visit-'. See section Buffer File Name, for functions and variables that access the visited file name of a buffer or that find an existing buffer by its visited file name.

Command: **find-file** *filename*

This function reads the file filename into a buffer and displays that buffer in the selected window so that the user can edit it.

The body of the `find-file` function is very simple and looks like this:

```
(switch-to-buffer (find-file-noselect filename))
```

(See `switch-to-buffer` in section Displaying Buffers in Windows.)

When `find-file` is called interactively, it prompts for filename in the minibuffer.

Function: **find-file-noselect** *filename*

This function is the guts of all the file-visiting functions. It reads a file into a buffer and returns the buffer. You may then make the buffer current or display it in a window if you wish, but this function does not do so.

If no buffer is currently visiting filename, then one is created and the file is visited. If filename does not exist, the buffer is left empty, and `find-file-noselect` displays the message `New file' in the echo area.

If a buffer is already visiting filename, then the `find-file-noselect` function uses that buffer rather than creating a new one. However, it does verify that the file has not changed since it was last visited or saved in that buffer. If the file has changed, then this function asks the user whether to reread the changed file. If the user says `yes', any changes previously made in the buffer are lost.

The `find-file-noselect` function calls `after-find-file` after the file is read in (see section Subroutines of Visiting). The `after-find-file` function sets the buffer major mode, parses local variables, warns the user if there exists an auto-save file more recent than the file just visited, and finishes by running the functions in `find-file-hooks`.

The `find-file-noselect` function returns the buffer that is visiting the file filename.

```
(find-file-noselect "/etc/fstab")
     => #<buffer fstab>
```

Command: **find-alternate-file** *filename*

This function reads the file filename into a buffer and selects it, killing the buffer current at the time the command is run. It is useful if you have visited the wrong file by mistake, so that you can get rid of the buffer that you did not want to create, at the same time as you visit the file you intended.

When this function is called interactively, it prompts for filename.

Command: **find-file-other-window** *filename*

This function visits the file filename and displays its buffer in a window other than the selected window. It may use another existing window or split a window; see section Displaying Buffers in Windows.

When this function is called interactively, it prompts for filename.

Command: **find-file-read-only** *filename*

This function visits the file named filename and selects its buffer, just like `find-file`, but it marks the buffer as read-only. See section Read-Only Buffers, for related functions and variables.

When this function is called interactively, it prompts for filename.

Command: **view-file** *filename*

This function views filename in View mode, returning to the previous buffer when done. View mode is a mode that allows you to skim rapidly through the file but does not let you modify it.

After loading the file, `view-file` runs the normal hook `view-hook` using `run-hooks`. See section Hooks.

When this function is called interactively, it prompts for filename.

Variable: **find-file-hooks**

The value of this variable is a list of functions to be called after a file is visited. The file's local-variables specification (if any) will have been processed before the hooks are run. The buffer visiting the file is current when the hook functions are run.

This variable could be a normal hook, but we think that renaming it would not be advisable.

Variable: **find-file-not-found-hooks**

The value of this variable is a list of functions to be called when `find-file` or `find-file-noselect` is passed a nonexistent filename. These functions are called as soon as the error is detected. `buffer-file-name` is already set up. The functions are called in the order given, until one of them returns non-`nil`.

This is not a normal hook because the values of the functions are used and they may not all be run.

Subroutines of Visiting

The `find-file-noselect` function uses the `create-file-buffer` and `after-find-file` functions as subroutines. Sometimes it is useful to call them directly.

Function: **create-file-buffer** *filename*

This function creates a suitably named buffer for visiting filename, and returns it. The string filename (sans directory) is used unchanged if that name is free; otherwise, a string such as `<2>' is appended to get an unused name. See also section Creating Buffers.

Please note: `create-file-buffer` does *not* associate the new buffer with a file and does not make it the current buffer.

```
(create-file-buffer "foo")
     => #<buffer foo>
(create-file-buffer "foo")
     => #<buffer foo<2>>
(create-file-buffer "foo")
     => #<buffer foo<3>>
```

This function is used by `find-file-noselect`. It uses `generate-new-buffer` (see section Creating Buffers).

Function: **after-find-file** *&optional error warn*

This function is called by `find-file-noselect` and by the default revert function (see section Reverting). It sets the buffer major mode, and parses local variables (see section How Emacs Chooses a Major Mode).

If there was an error in opening the file, the calling function should pass error a non-`nil` value. In that case, `after-find-file` issues a warning: `(New File)'. Note that, for serious errors, you would not even call `after-find-file`. Only "file not found" errors get here with a non-`nil` error.

If warn is non-`nil`, then this function issues a warning if an auto-save file exists and is more recent than the visited file.

The last thing `after-find-file` does is call all the functions in `find-file-hooks`.

Saving Buffers

When you edit a file in Emacs, you are actually working on a buffer that is visiting that file--that is, the contents of the file are copied into the buffer and the copy is what you edit. Changes to the buffer do not change the file until you save the buffer, which means copying the contents of the buffer into the file.

Command: **save-buffer** *&optional backup-option*

This function saves the contents of the current buffer in its visited file if the buffer has been modified since it was last visited or saved. Otherwise it does nothing.

`save-buffer` is responsible for making backup files. Normally, backup-option is `nil`, and `save-buffer` makes a backup file only if this is the first save or if the buffer was previously modified. Other values for backup-option request the making of backup files in other circumstances:

- With an argument of 4 or 64, reflecting 1 or 3 C-u's, the `save-buffer` function marks this version of the file to be backed up when the buffer is next saved.
- With an argument of 16 or 64, reflecting 2 or 3 C-u's, the `save-buffer` function unconditionally backs up the previous version of the file before saving it.

Command: **save-some-buffers** *&optional save-silently-p exiting*

This command saves some modified file-visiting buffers. Normally it asks the user about each buffer. But if save-silently-p is non-`nil`, it saves all the file-visiting buffers without querying the user.

The optional exiting argument, if non-`nil`, requests this function to offer also to save certain other buffers that are not visiting files. These are buffers that have a non-`nil` local value of `buffer-offer-save`. (A user who says yes to saving one of these is asked to specify a file name to use.) The `save-buffers-kill-emacs` function passes a non-`nil` value for this argument.

Variable: **buffer-offer-save**

When this variable is non-`nil` in a buffer, Emacs offers to save the buffer on exit even if the buffer is not visiting a file. The variable is automatically local in all buffers. Normally, Mail mode (used for editing outgoing mail) sets this to `t`.

Command: **write-file** *filename*

This function writes the current buffer into file filename, makes the buffer visit that file, and marks it not modified. The buffer is renamed to correspond to filename unless that name is already in use.

Variable: **write-file-hooks**

The value of this variable is a list of functions to be called before writing out a buffer to its visited file. If one of them returns non-`nil`, the file is considered already written and the rest of the functions are not called, nor is the usual code for writing the file executed.

If a function in `write-file-hooks` returns non-`nil`, it is responsible for making a backup file (if that is appropriate). To do so, execute the following code:

```
(or buffer-backed-up (backup-buffer))
```

You might wish to save the file modes value returned by `backup-buffer` and use that to set the mode bits of the file that you write. This is what `basic-save-buffer` does when it writes a file in the usual way.

Here is an example showing how to add an element to `write-file-hooks` but avoid adding it twice:

```
(or (memq 'my-write-file-hook write-file-hooks)
    (setq write-file-hooks
          (cons
          'my-write-file-hook write-file-hooks)))
```

Variable: **local-write-file-hooks**

This works just like `write-file-hooks`, but it is intended to be made local to particular buffers. It's not a good idea to make `write-file-hooks` local to a buffer--use this variable instead.

The variable is marked as a permanent local, so that changing the major mode does not alter a buffer-local value. This is convenient for packages that read "file" contents in special ways, and set up hooks to save the data in a corresponding way.

Variable: **write-contents-hooks**

This works just like `write-file-hooks`, but it is intended to be used for hooks that pertain to the contents of the file, as opposed to hooks that pertain to where the file came from.

Variable: **after-save-hook**

This normal hook runs after a buffer has been saved in its visited file.

Variable: **file-precious-flag**

If this variable is non-`nil`, then `save-buffer` protects against I/O errors while saving by writing the new file to a temporary name instead of the name it is supposed to have, and then renaming it to the intended name after it is clear there are no errors. This procedure prevents problems such as a lack of disk space from resulting in an invalid file.

(This feature worked differently in older Emacs versions.)

Some modes set this non-`nil` locally in particular buffers.

User Option: **require-final-newline**

This variable determines whether files may be written out that do *not* end with a newline. If the value of the variable is `t`, then Emacs silently puts a newline at the end of the file whenever the buffer being saved does not already end in one. If the value of the variable is non-`nil`, but not `t`, then Emacs asks the user whether to add a newline each time the case arises.

If the value of the variable is `nil`, then Emacs doesn't add newlines at all. `nil` is the default value, but a few major modes set it to `t` in particular buffers.

Reading from Files

You can copy a file from the disk and insert it into a buffer using the `insert-file-contents` function. Don't use the user-level command `insert-file` in a Lisp program, as that sets the mark.

Function: **insert-file-contents** *filename &optional visit*

This function inserts the contents of file filename into the current buffer after point. It returns a list of the absolute file name and the length of the data inserted. An error is signaled if filename is not the name of a file that can be read.

If visit is non-`nil`, it also marks the buffer as unmodified and sets up various fields in the buffer so that it is visiting the file filename: these include the buffer's visited file name and its last save file modtime. This feature is used by `find-file-noselect` and you should probably not use it yourself.

If you want to pass a file name to another process so that another program can read the file, see the function `file-local-copy` in section Making Certain File Names "Magic".

Writing to Files

You can write the contents of a buffer, or part of a buffer, directly to a file on disk using the `append-to-file` and `write-region` functions. Don't use these functions to write to files that are being visited; that could cause confusion in the mechanisms for visiting.

Command: **append-to-file** *start end filename*

This function appends the contents of the region delimited by start and end in the current buffer to the end of file filename. If that file does not exist, it is created. This function returns `nil`.

An error is signaled if filename specifies a nonwritable file, or a nonexistent file in a directory where files cannot be created.

Command: **write-region** *start end filename &optional append visit*

This function writes the region (of the current buffer) delimited by start and end into the file specified by filename.

If start is a string, then `write-region` writes or appends that string, rather than text from the buffer.

If append is non-`nil`, then the region is appended to the existing file contents (if any).

If visit is `t`, then Emacs establishes an association between the buffer and the file: the buffer is then visiting that file. It also sets the last file modification time for the current buffer to filename's modtime, and marks the buffer as not modified. This feature is used by `write-file` and you should probably not use it yourself.

If visit is a string, it specifies the file name to visit. This way, you can write the data to one file (filename) while recording the buffer as visiting another file (visit). The argument visit is used in the echo area message and also for file locking; visit is stored in `buffer-file-name`. This feature is used to implement `file-precious-flag`; don't use it yourself unless you really know what you're doing.

Normally, `write-region` displays a message `Wrote file filename' in the echo area. If visit is neither `t` nor `nil` nor a string, then this message is inhibited. This feature is useful for programs that use files for internal purposes, files which the user does not need to know about.

File Locks

When two users edit the same file at the same time, they are likely to interfere with each other. Emacs tries to prevent this situation from arising by recording a file lock when a file is being modified. Emacs can then detect the first attempt to modify a buffer visiting a file that is locked by another Emacs job, and ask the user what to do.

File locks do not work properly when multiple machines can share file systems, such as with NFS. Perhaps a better file locking system will be implemented in the future. When file locks do not work, it is possible for two users to make changes simultaneously, but Emacs can still warn the user who saves second. Also, the detection of modification of a buffer visiting a file changed on disk catches some cases of simultaneous editing; see section Comparison of Modification Time.

Function: **file-locked-p** *filename*

This function returns `nil` if the file filename is not locked by this Emacs process. It returns `t` if it is locked by this Emacs, and it returns the name of the user who has locked it if it is locked by someone else.

```
(file-locked-p "foo")
     => nil
```

Function: **lock-buffer** *&optional filename*

This function locks the file filename, if the current buffer is modified. The argument filename defaults to the current buffer's visited file. Nothing is done if the current buffer is not visiting a file, or is not

modified.

Function: **unlock-buffer**

This function unlocks the file being visited in the current buffer, if the buffer is modified. If the buffer is not modified, then the file should not be locked, so this function does nothing. It also does nothing if the current buffer is not visiting a file.

Function: **ask-user-about-lock** *file other-user*

This function is called when the user tries to modify file, but it is locked by another user name other-user. The value it returns tells Emacs what to do next:

- A value of `t` tells Emacs to grab the lock on the file. Then this user may edit the file and other-user loses the lock.
- A value of `nil` tells Emacs to ignore the lock and let this user edit the file anyway.
- This function may instead signal a `file-locked` error, in which case the change to the buffer which the user was about to make does not take place.

  The error message for this error looks like this:

  ```
  error--> File is locked: file other-user
  ```

  where `file` is the name of the file and other-user is the name of the user who has locked the file.

The default definition of this function asks the user to choose what to do. If you wish, you can replace the `ask-user-about-lock` function with your own version that decides in another way. The code for its usual definition is in `` `userlock.el' ``.

Information about Files

The functions described in this section are similar in as much as they all operate on strings which are interpreted as file names. All have names that begin with the word `file'. These functions all return information about actual files or directories, so their arguments must all exist as actual files or directories unless otherwise noted.

Most of the file-oriented functions take a single argument, filename, which must be a string. The file name is expanded using `expand-file-name`, so `` `~' `` is handled correctly, as are relative file names (including `../'). Environment variable substitutions, such as `$HOME', are not recognized by these functions. See section Functions that Expand Filenames.

Testing Accessibility

These functions test for permission to access a file in specific ways.

Function: **file-exists-p** *filename*

This function returns `t` if a file named filename appears to exist. This does not mean you can necessarily

read the file, only that you can find out its attributes. (On Unix, this is true if the file exists and you have execute permission on the containing directories, regardless of the protection of the file itself.)

If the file does not exist, or if fascist access control policies prevent you from finding the attributes of the file, this function returns `nil`.

Function: **file-readable-p** *filename*

This function returns `t` if a file named filename exists and you can read it. It returns `nil` otherwise.

```
(file-readable-p "files.texi")
     => t
(file-exists-p "/usr/spool/mqueue")
     => t
(file-readable-p "/usr/spool/mqueue")
     => nil
```

Function: **file-executable-p** *filename*

This function returns `t` if a file named filename exists and you can execute it. It returns `nil` otherwise. If the file is a directory, execute permission means you can access files inside the directory.

Function: **file-writable-p** *filename*

This function returns `t` if filename can be written or created by you. It is writable if the file exists and you can write it. It is creatable if the file does not exist, but the specified directory does exist and you can write in that directory. `file-writable-p` returns `nil` otherwise.

In the third example below, `` `foo' `` is not writable because the parent directory does not exist, even though the user could create it.

```
(file-writable-p "~rms/foo")
     => t
(file-writable-p "/foo")
     => nil
(file-writable-p "~rms/no-such-dir/foo")
     => nil
```

Function: **file-accessible-directory-p** *dirname*

This function returns `t` if you have permission to open existing files in directory dirname; otherwise (and if there is no such directory), it returns `nil`. The value of dirname may be either a directory name or the file name of a directory.

Example: after the following,

```
(file-accessible-directory-p "/foo")
     => nil
```

we can deduce that any attempt to read a file in `/foo/' will give an error.

Function: **file-newer-than-file-p** *filename1 filename2*

This functions returns `t` if the file filename1 is newer than file filename2. If filename1 does not exist, it returns `nil`. If filename2 does not exist, it returns `t`.

You can use `file-attributes` to get a file's last modification time as a list of two numbers. See section Other Information about Files.

In the following example, assume that the file `aug-19' was written on the 19th, and `aug-20' was written on the 20th. The file `no-file' doesn't exist at all.

```
(file-newer-than-file-p "aug-19" "aug-20")
     => nil
(file-newer-than-file-p "aug-20" "aug-19")
     => t
(file-newer-than-file-p "aug-19" "no-file")
     => t
(file-newer-than-file-p "no-file" "aug-19")
     => nil
```

Distinguishing Kinds of Files

This section describes how to distinguish directories and symbolic links from ordinary files.

Function: **file-symlink-p** *filename*

If filename is a symbolic link, the `file-symlink-p` function returns the file name to which it is linked. This may be the name of a text file, a directory, or even another symbolic link, or of no file at all.

If filename is not a symbolic link (or there is no such file), `file-symlink-p` returns `nil`.

```
(file-symlink-p "foo")
     => nil
(file-symlink-p "sym-link")
     => "foo"
(file-symlink-p "sym-link2")
     => "sym-link"
(file-symlink-p "/bin")
     => "/pub/bin"
```

Function: **file-directory-p** *filename*

This function returns `t` if filename is the name of an existing directory, `nil` otherwise.

```
(file-directory-p "~rms")
     => t
```

```
(file-directory-p "~rms/lewis/files.texi")
     => nil
(file-directory-p "~rms/lewis/no-such-file")
     => nil
(file-directory-p "$HOME")
     => nil
(file-directory-p
 (substitute-in-file-name "$HOME"))
     => t
```

Truenames

The truename of a file is the name that you get by following symbolic links until none remain, then expanding to get rid of `.' and `..' as components. Strictly speaking, a file need not have a unique truename; the number of distinct truenames a file has is equal to the number of hard links to the file. However, truenames are useful because they eliminate symbolic links as a cause of name variation.

Function: **file-truename** *filename*

The function `file-truename` returns the true name of the file filename. This is the name that you get by following symbolic links until none remain. The argument must be an absolute file name.

See section Buffer File Name, for related information.

Other Information about Files

This section describes the functions for getting detailed information about a file, other than its contents. This information includes the mode bits that control access permission, the owner and group numbers, the number of names, the inode number, the size, and the times of access and modification.

Function: **file-modes** *filename*

This function returns the mode bits of filename, as an integer. The mode bits are also called the file permissions, and they specify access control in the usual Unix fashion. If the low-order bit is 1, then the file is executable by all users, if the second lowest-order bit is 1, then the file is writable by all users, etc.

The highest value returnable is 4095 (7777 octal), meaning that everyone has read, write, and execute permission, that the SUID bit is set for both others and group, and that the sticky bit is set.

```
(file-modes "~/junk/diffs")
     => 492               ; Decimal integer.
(format "%o" 492)
     => 754               ; Convert to octal.

(set-file-modes "~/junk/diffs" 438)
     => nil
```

```
(format "%o" 438)
     => 666               ; Convert to octal.

% ls -l diffs
  -rw-rw-rw-  1 lewis 0 3063 Oct 30 16:00 diffs
```

Function: **file-nlinks** *filename*

This functions returns the number of names (i.e., hard links) that file filename has. If the file does not exist, then this function returns `nil`. Note that symbolic links have no effect on this function, because they are not considered to be names of the files they link to.

```
% ls -l foo*
-rw-rw-rw-  2 rms       4 Aug 19 01:27 foo
-rw-rw-rw-  2 rms       4 Aug 19 01:27 foo1

(file-nlinks "foo")
     => 2
(file-nlinks "doesnt-exist")
     => nil
```

Function: **file-attributes** *filename*

This function returns a list of attributes of file filename. If the specified file cannot be opened, it returns `nil`.

The elements of the list, in order, are:

1. `t` for a directory, a string for a symbolic link (the name linked to), or `nil` for a text file.
2. The number of names the file has. Alternate names, also known as hard links, can be created by using the `add-name-to-file` function (see section Changing File Names and Attributes).
3. The file's UID.
4. The file's GID.
5. The time of last access, as a list of two integers. The first integer has the high-order 16 bits of time, the second has the low 16 bits. (This is similar to the value of `current-time`; see section Time of Day.)
6. The time of last modification as a list of two integers (as above).
7. The time of last status change as a list of two integers (as above).
8. The size of the file in bytes.
9. The file's modes, as a string of ten letters or dashes as in `ls -l'.
10. `t` if the file's GID would change if file were deleted and recreated; `nil` otherwise.
11. The file's inode number.
12. The file system number of the file system that the file is in. This element together with the file's inode number, give enough information to distinguish any two files on the system--no two files can have the same values for both of these numbers.

For example, here are the file attributes for `files.texi':

```
(file-attributes "files.texi")
     =>  (nil
          1
          2235
          75
          (8489 20284)
          (8489 20284)
          (8489 20285)
          14906
          "-rw-rw-rw-"
          nil
          129500
          -32252)
```

and here is how the result is interpreted:

`nil`
: is neither a directory nor a symbolic link.

`1`
: has only one name (the name `files.texi' in the current default directory).

`2235`
: is owned by the user with UID 2235.

`75`
: is in the group with GID 75.

`(8489 20284)`
: was last accessed on Aug 19 00:09. Unfortunately, you cannot convert this number into a time string in Emacs.

`(8489 20284)`
: was last modified on Aug 19 00:09.

`(8489 20285)`
: last had its inode changed on Aug 19 00:09.

`14906`
: is 14906 characters long.

`"-rw-rw-rw-"`
: has a mode of read and write access for the owner, group, and world.

`nil`
: would retain the same GID if it were recreated.

`129500`
: has an inode number of 129500.

`-32252`

is on file system number -32252.

Contents of Directories

A directory is a kind of file that contains other files entered under various names. Directories are a feature of the file system.

Emacs can list the names of the files in a directory as a Lisp list, or display the names in a buffer using the `ls` shell command. In the latter case, it can optionally display information about each file, depending on the value of switches passed to the `ls` command.

Function: **directory-files** *directory &optional full-name match-regexp nosort*

This function returns a list of the names of the files in the directory directory. By default, the list is in alphabetical order.

If full-name is non-`nil`, the function returns the files' absolute file names. Otherwise, it returns just the names relative to the specified directory.

If match-regexp is non-`nil`, this function returns only those file names that contain that regular expression--the other file names are discarded from the list.

If nosort is non-`nil`, that inhibits sorting the list, so you get the file names in no particular order. Use this if you want the utmost possible speed and don't care what order the files are processed in. If the order of processing is visible to the user, then the user will probably be happier if you do sort the names.

```
(directory-files "~lewis")
     => ("#foo#" "#foo.el#" "." ".."
         "dired-mods.el" "files.texi"
         "files.texi.~1~")
```

An error is signaled if directory is not the name of a directory that can be read.

Function: **file-name-all-versions** *file dirname*

This function returns a list of all versions of the file named file in directory dirname.

Function: **insert-directory** *file switches &optional wildcard full-directory-p*

This function inserts a directory listing for directory dir, formatted according to switches. It leaves point after the inserted text.

The argument dir may be either a directory name or a file specification including wildcard characters. If wildcard is non-`nil`, that means treat file as a file specification with wildcards.

If full-directory-p is non-`nil`, that means file is a directory and switches do not contain `d', so that a full listing is expected.

This function works by running a directory listing program whose name is in the variable `insert-directory-program`. If wildcard is non-`nil`, it also runs the shell specified by `shell-file-name`, to expand the wildcards.

Variable: **insert-directory-program**

This variable's value is the program to run to generate a directory listing for the function `insert-directory`.

Creating and Deleting Directories

Function: **make-directory** *dirname*

This function creates a directory named dirname.

Function: **delete-directory** *dirname*

This function deletes the directory named dirname. The function `delete-file` does not work for files that are directories; you must use `delete-directory` in that case.

Changing File Names and Attributes

The functions in this section rename, copy, delete, link, and set the modes of files.

In the functions that have an argument newname, if a file by the name of newname already exists, the actions taken depend on the value of the argument ok-if-already-exists:

- A `file-already-exists` error is signaled if ok-if-already-exists is `nil`.
- Confirmation is requested if ok-if-already-exists is a number.
- No confirmation is requested if ok-if-already-exists is any other value, in which case the old file is removed.

Function: **add-name-to-file** *oldname newname &optional ok-if-already-exists*

This function gives the file named oldname the additional name newname. This means that newname becomes a new "hard link" to oldname.

In the first part of the following example, we list two files, `` `foo' `` and `` `foo3' ``.

```
% ls -l fo*
-rw-rw-rw-  1 rms       29 Aug 18 20:32 foo
-rw-rw-rw-  1 rms       24 Aug 18 20:31 foo3
```

Then we evaluate the form `(add-name-to-file "~/lewis/foo" "~/lewis/foo2")`. Again we list the files. This shows two names, `` `foo' `` and `` `foo2' ``.

```
(add-name-to-file "~/lewis/foo1" "~/lewis/foo2")
```

```
     => nil

% ls -l fo*
-rw-rw-rw-  2 rms       29 Aug 18 20:32 foo
-rw-rw-rw-  2 rms       29 Aug 18 20:32 foo2
-rw-rw-rw-  1 rms       24 Aug 18 20:31 foo3
```

Finally, we evaluate the following:

```
(add-name-to-file "~/lewis/foo" "~/lewis/foo3" t)
```

and list the files again. Now there are three names for one file: `foo', `foo2', and `foo3'. The old contents of `foo3' are lost.

```
(add-name-to-file "~/lewis/foo1" "~/lewis/foo3")
     => nil

% ls -l fo*
-rw-rw-rw-  3 rms       29 Aug 18 20:32 foo
-rw-rw-rw-  3 rms       29 Aug 18 20:32 foo2
-rw-rw-rw-  3 rms       29 Aug 18 20:32 foo3
```

This function is meaningless on VMS, where multiple names for one file are not allowed.

See also `file-nlinks` in section Other Information about Files.

Command: **rename-file** *filename newname &optional ok-if-already-exists*

This command renames the file filename as newname.

If filename has additional names aside from filename, it continues to have those names. In fact, adding the name newname with `add-name-to-file` and then deleting filename has the same effect as renaming, aside from momentary intermediate states.

In an interactive call, this function prompts for filename and newname in the minibuffer; also, it requests confirmation if newname already exists.

Command: **copy-file** *oldname newname &optional ok-if-exists time*

This command copies the file oldname to newname. An error is signaled if oldname does not exist.

If time is non-`nil`, then this functions gives the new file the same last-modified time that the old one has. (This works on only some operating systems.)

In an interactive call, this function prompts for filename and newname in the minibuffer; also, it requests confirmation if newname already exists.

Command: **delete-file** *filename*

This command deletes the file filename, like the shell command `rm filename'. If the file has multiple

names, it continues to exist under the other names.

A suitable kind of `file-error` error is signaled if the file does not exist, or is not deletable. (In Unix, a file is deletable if its directory is writable.)

See also `delete-directory` in section Creating and Deleting Directories.

Command: **make-symbolic-link** *filename newname &optional ok-if-exists*

This command makes a symbolic link to filename, named newname. This is like the shell command `ln -s filename newname'.

In an interactive call, filename and newname are read in the minibuffer, and ok-if-exists is set to the numeric prefix argument.

Function: **define-logical-name** *varname string*

This function defines the logical name name to have the value string. It is available only on VMS.

Function: **set-file-modes** *filename mode*

This function sets mode bits of filename to mode (which must be an integer). Only the 12 low bits of mode are used.

Function: **set-default-file-modes** *mode*

This function sets the default file protection for new files created by Emacs and its subprocesses. Every file created with Emacs initially has this protection. On Unix, the default protection is the bitwise complement of the "umask" value.

The argument mode must be an integer. Only the 9 low bits of mode are used.

Saving a modified version of an existing file does not count as creating the file; it does not change the file's mode, and does not use the default file protection.

Function: **default-file-modes**

This function returns the current default protection value.

File Names

Files are generally referred to by their names, in Emacs as elsewhere. File names in Emacs are represented as strings. The functions that operate on a file all expect a file name argument.

In addition to operating on files themselves, Emacs Lisp programs often need to operate on the names; i.e., to take them apart and to use part of a name to construct related file names. This section describes how to manipulate file names.

The functions in this section do not actually access files, so they can operate on file names that do not refer to an existing file or directory.

On VMS, all these functions understand both VMS file name syntax and Unix syntax. This is so that the standard Lisp libraries can specify file names in Unix syntax and work properly on VMS without change.

File Name Components

The operating system groups files into directories. To specify a file, you must specify the directory, and the file's name in that directory. Therefore, a file name in Emacs is considered to have two main parts: the directory name part, and the nondirectory part (or file name within the directory). Either part may be empty. Concatenating these two parts reproduces the original file name.

On Unix, the directory part is everything up to and including the last slash; the nondirectory part is the rest. The rules in VMS syntax are complicated.

For some purposes, the nondirectory part is further subdivided into the name proper and the version number. On Unix, only backup files have version numbers in their names; on VMS, every file has a version number, but most of the time the file name actually used in Emacs omits the version number. Version numbers are found mostly in directory lists.

Function: **file-name-directory** *filename*

This function returns the directory part of filename (or `nil` if filename does not include a directory part). On Unix, the function returns a string ending in a slash. On VMS, it returns a string ending in one of the three characters `:', `]', or `>'.

```
(file-name-directory "lewis/foo")  ; Unix example
     => "lewis/"
(file-name-directory "foo")        ; Unix example
     => nil
(file-name-directory "[X]FOO.TMP") ; VMS example
     => "[X]"
```

Function: **file-name-nondirectory** *filename*

This function returns the nondirectory part of filename.

```
(file-name-nondirectory "lewis/foo")
     => "foo"
(file-name-nondirectory "foo")
     => "foo"
;; The following example is accurate only on VMS.
(file-name-nondirectory "[X]FOO.TMP")
     => "FOO.TMP"
```

Function: **file-name-sans-versions** *filename*

This function returns filename without any file version numbers, backup version numbers, or trailing tildes.

```
(file-name-sans-versions "~rms/foo.~1~")
     => "~rms/foo"
(file-name-sans-versions "~rms/foo~")
     => "~rms/foo"
(file-name-sans-versions "~rms/foo")
     => "~rms/foo"
;; The following example applies to VMS only.
(file-name-sans-versions "foo;23")
     => "foo"
```

Directory Names

A directory name is the name of a directory. A directory is a kind of file, and it has a file name, which is related to the directory name but not identical to it. (This is not quite the same as the usual Unix terminology.) These two different names for the same entity are related by a syntactic transformation. On Unix, this is simple: a directory name ends in a slash, whereas the directory's name as a file lacks that slash. On VMS, the relationship is more complicated.

The difference between a directory name and its name as a file is subtle but crucial. When an Emacs variable or function argument is described as being a directory name, a file name of a directory is not acceptable.

These two functions take a single argument, filename, which must be a string. Environment variable substitutions such as `$HOME', and the symbols `~', and `..', are *not* expanded. Use `expand-file-name` or `substitute-in-file-name` for that (see section Functions that Expand Filenames).

Function: **file-name-as-directory** *filename*

This function returns a string representing filename in a form that the operating system will interpret as the name of a directory. In Unix, this means that a slash is appended to the string. On VMS, the function converts a string of the form `` `[X]Y.DIR.1' `` to the form `` `[X.Y]' ``.

```
(file-name-as-directory "~rms/lewis")
     => "~rms/lewis/"
```

Function: **directory-file-name** *dirname*

This function returns a string representing dirname in a form that the operating system will interpret as the name of a file. On Unix, this means removing a final slash from the string. On VMS, the function converts a string of the form `` `[X.Y]' `` to `` `[X]Y.DIR.1' ``.

```
(directory-file-name "~lewis/")
     => "~lewis"
```

Directory name abbreviations are useful for directories that are normally accessed through symbolic

links. Sometimes the users recognize primarily the link's name as "the name" of the directory, and fi
annoying to see the directory's "real" name. If you define the link name as an abbreviation for the "re
name, Emacs shows users the abbreviation instead.

If you wish to convert a directory name to its abbreviation, use this function:

Function: **abbreviate-file-name** *dirname*

This function applies abbreviations from `directory-abbrev-alist` to its argument, and substitutes `~' for the user's home directory.

Variable: **directory-abbrev-alist**

The variable `directory-abbrev-alist` contains an alist of abbreviations to use for file directories. Each element has the form `(from . to)`, and says to replace from with to when it appears in a directory name. The from string is actually a regular expression; it should always start with `^'. The function `abbreviate-file-name` performs these substitutions.

You can set this variable in `site-init.el' to describe the abbreviations appropriate for your site.

Here's an example, from a system on which file system `/home/fsf' and so on are normally accessed through symbolic links named `/fsf' and so on.

```
(("^/home/fsf" . "/fsf")
 ("^/home/gp" . "/gp")
 ("^/home/gd" . "/gd"))
```

Absolute and Relative File Names

All the directories in the file system form a tree starting at the root directory. A file name can specify all the directory names starting from the root of the tree; then it is called an absolute file name. Or it can specify the position of the file in the tree relative to a default directory; then it is called an relative file name. On Unix, an absolute file name starts with a slash or a tilde (`~'), and a relative one does not. The rules on VMS are complicated.

Function: **file-name-absolute-p** *filename*

This function returns `t` if file filename is an absolute file name, `nil` otherwise. On VMS, this function understands both Unix syntax and VMS syntax.

```
(file-name-absolute-p "~rms/foo")
     => t
(file-name-absolute-p "rms/foo")
     => nil
(file-name-absolute-p "/user/rms/foo")
     => t
```

Functions that Expand Filenames

Expansion of a file name means converting a relative file name to an absolute one. Since this is done relative to a default directory, you must specify the default directory name as well as the file name to be expanded. Expansion also simplifies file names by eliminating redundancies such as `./' and `name/../'.

Function: **expand-file-name** *filename &optional directory*

This function converts filename to an absolute file name. If directory is supplied, it is the directory to start with if filename is relative. (The value of directory should itself be an absolute, expanded file name; it should not start with `~'.) Otherwise, the current buffer's value of `default-directory` is used. For example:

```
(expand-file-name "foo")
     => "/xcssun/users/rms/lewis/foo"
(expand-file-name "../foo")
     => "/xcssun/users/rms/foo"
(expand-file-name "foo" "/usr/spool/")
     => "/usr/spool/foo"
(expand-file-name "$HOME/foo")
     => "/xcssun/users/rms/lewis/$HOME/foo"
```

Filenames containing `.' or `..' are simplified to their canonical form:

```
(expand-file-name "bar/../foo")
     => "/xcssun/users/rms/lewis/foo"
```

`~/' is expanded into the user's home directory. A `/' or `~' following a `/' is taken to be the start of an absolute file name that overrides what precedes it, so everything before that `/' or `~' is deleted. For example:

```
(expand-file-name
 "/a1/gnu//usr/local/lib/emacs/etc/MACHINES")
     => "/usr/local/lib/emacs/etc/MACHINES"
(expand-file-name "/a1/gnu/~/foo")
     => "/xcssun/users/rms/foo"
```

In both cases, `/a1/gnu/' is discarded because an absolute file name follows it.

Note that `expand-file-name` does *not* expand environment variables; that is done only by `substitute-in-file-name`.

Function: **file-relative-name** *filename directory*

This function does the inverse of expansion--it tries to return a relative name which is equivalent to filename when interpreted relative to directory. (If such a relative name would be longer than the

absolute name, it returns the absolute name instead.)

```
(file-relative-name "/foo/bar" "/foo/")
     => "bar")
(file-relative-name "/foo/bar" "/hack/")
     => "/foo/bar")
```

Variable: **default-directory**

The value of this buffer-local variable is the default directory for the current buffer. It is local in every buffer. `expand-file-name` uses the default directory when its second argument is `nil`.

On Unix systems, the value is always a string ending with a slash.

```
default-directory
     => "/user/lewis/manual/"
```

Function: **substitute-in-file-name** *filename*

This function replaces environment variables names in filename with the values to which they are set by the operating system. Following standard Unix shell syntax, `$' is the prefix to substitute an environment variable value.

The environment variable name is the series of alphanumeric characters (including underscores) that follow the `$'. If the character following the `$' is a `{', then the variable name is everything up to the matching `}'.

Here we assume that the environment variable `HOME`, which holds the user's home directory name, has the value `/xcssun/users/rms'.

```
(substitute-in-file-name "$HOME/foo")
     => "/xcssun/users/rms/foo"
```

If a `~' or a `/' appears following a `/', after substitution, everything before the following `/' is discarded:

```
(substitute-in-file-name "bar/~/foo")
     => "~/foo"
(substitute-in-file-name "/usr/local/$HOME/foo")
     => "/xcssun/users/rms/foo"
```

On VMS, `$' substitution is not done, so this function does nothing on VMS except discard superfluous initial components as shown above.

Generating Unique File Names

Some programs need to write temporary files. Here is the usual way to construct a name for such a file:

```
(make-temp-name (concat "/tmp/" name-of-application))
```

Here we use the directory `/tmp/' because that is the standard place on Unix for temporary files. The job of `make-temp-name` is to prevent two different users or two different jobs from trying to use the same name.

Function: **make-temp-name** *string*

This function generates string that can be used as a unique name. The name starts with the prefix string, and ends with a number that is different in each Emacs job.

```
(make-temp-name "/tmp/foo")
     => "/tmp/foo021304"
```

To prevent conflicts among different application libraries run in the same Emacs, each application should have its own string. The number added to the end of the name distinguishes between the same application running in different Emacs jobs.

File Name Completion

This section describes low-level subroutines for completing a file name. For other completion functions, see section Completion.

Function: **file-name-all-completions** *partial-filename directory*

This function returns a list of all possible completions for a file whose name starts with partial-filename in directory directory. The order of the completions is the order of the files in the directory, which is unpredictable and conveys no useful information.

The argument partial-filename must be a file name containing no directory part and no slash. The current buffer's default directory is prepended to directory, if directory is not an absolute file name.

In the following example, suppose that the current default directory, `~rms/lewis', has five files whose names begin with `f': `foo', `file~', `file.c', `file.c.~1~', and `file.c.~2~'.

```
(file-name-all-completions "f" "")
     => ("foo" "file~" "file.c.~2~"
               "file.c.~1~" "file.c")

(file-name-all-completions "fo" "")
     => ("foo")
```

Function: **file-name-completion** *filename directory*

This function completes the file name filename in directory directory. It returns the longest prefix common to all file names in directory directory that start with filename.

If only one match exists and filename matches it exactly, the function returns `t`. The function returns `nil` if directory directory contains no name starting with filename.

In the following example, suppose that the current default directory has five files whose names begin with `f': `foo', `file~', `file.c', `file.c.~1~', and `file.c.~2~'.

```
(file-name-completion "fi" "")
     => "file"

(file-name-completion "file.c.~1" "")
     => "file.c.~1~"

(file-name-completion "file.c.~1~" "")
     => t

(file-name-completion "file.c.~3" "")
     => nil
```

User Option: **completion-ignored-extensions**

`file-name-completion` usually ignores file names that end in any string in this list. It does not ignore them when all the possible completions end in one of these suffixes or when a buffer showing all possible completions is displayed.

A typical value might look like this:

```
completion-ignored-extensions
     => (".o" ".elc" "~" ".dvi")
```

Making Certain File Names "Magic"

You can implement special handling for certain file names. This is called making those names magic. You must supply a regular expression to define the class of names (all those which match the regular expression), plus a handler that implements all the primitive Emacs file operations for file names that do match.

The value of `file-name-handler-alist` is a list of handlers, together with regular expressions that decide when to apply each handler. Each element has this form:

```
(regexp . handler)
```

All the Emacs primitives for file access and file name transformation check the given file name against `file-name-handler-alist`. If the file name matches regexp, the primitives handle that file by calling handler.

The first argument given to handler is the name of the primitive; the remaining arguments are the arguments that were passed to that operation. (The first of these arguments is typically the file name itself.) For example, if you do this:

```
(file-exists-p filename)
```

and filename has handler handler, then handler is called like this:

```
(funcall handler 'file-exists-p filename)
```

Here are the operations that you can handle for a magic file name:

```
add-name-to-file, copy-file, delete-directory,
delete-file, directory-file-name, directory-files,
dired-compress-file, dired-uncache,
expand-file-name, file-accessible-directory-p,
file-attributes, file-directory-p,
file-executable-p, file-exists-p, file-local-copy,
file-modes, file-name-all-completions,
file-name-as-directory, file-name-completion,
file-name-directory, file-name-nondirectory,
file-name-sans-versions, file-newer-than-file-p,
file-readable-p, file-symlink-p, file-writable-p,
insert-directory, insert-file-contents,
make-directory, make-symbolic-link, rename-file,
set-file-modes, set-visited-file-modtime,
unhandled-file-name-directory,
verify-visited-file-modtime, write-region.
```

The handler function must handle all of the above operations, and possibly others to be added in the future. Therefore, it should always reinvoke the ordinary Lisp primitive when it receives an operation it does not recognize. Here's one way to do this:

```
(defun my-file-handler (operation &rest args)
  ;; First check for the specific operations
  ;; that we have special handling for.
  (cond ((eq operation 'insert-file-contents) ...)
        ((eq operation 'write-region) ...)
        ...
        ;; Handle any operation we don't know about.
        (t (let (file-name-handler-alist)
             (apply operation args)))))
```

Function: **find-file-name-handler** *file*

This function returns the handler function for file name file, or `nil` if there is none.

Function: **file-local-copy** *filename*

This function copies file filename to the local site, if it isn't there already. If filename specifies a "magic" file name which programs outside Emacs cannot directly read or write, this copies the contents to an

ordinary file and returns that file's name.

If filename is an ordinary file name, not magic, then this function does nothing and returns `nil`.

Function: **unhandled-file-name-directory** *filename*

This function returns the name of a directory that is not magic. It uses the directory part of filename if that is not magic. Otherwise, it asks the handler what to do.

This is used for running a subprocess; any subprocess must have a non-magic directory to serve as its current directory.

Go to the previous, next section.

Go to the previous, next section.

Backups and Auto-Saving

Backup files and auto-save files are two methods by which Emacs tries to protect the user from the consequences of crashes or of the user's own errors. Auto-saving preserves the text from earlier in the current editing session; backup files preserve file contents prior to the current session.

Backup Files

A backup file is a copy of the old contents of a file you are editing. Emacs makes a backup file the first time you save a buffer into its visited file. Normally, this means that the backup file contains the contents of the file as it was before the current editing session. The contents of the backup file normally remain unchanged once it exists.

Backups are usually made by renaming the visited file to a new name. Optionally, you can specify that backup files should be made by copying the visited file. This choice makes a difference for files with multiple names; it also can affect whether the edited file remains owned by the original owner or becomes owned by the user editing it.

By default, Emacs makes a single backup file for each file edited. You can alternatively request numbered backups; then each new backup file gets a new name. You can delete old numbered backups when you don't want them any more, or Emacs can delete them automatically.

Making Backup Files

Function: **backup-buffer**

This function makes a backup of the file visited by the current buffer, if appropriate. It is called by `save-buffer` before saving the buffer the first time.

Variable: **buffer-backed-up**

This buffer-local variable indicates whether this buffer's file has been backed up on account of this buffer. If it is non-`nil`, then the backup file has been written. Otherwise, the file should be backed up when it is next saved (if backup files are enabled). This is a permanent local; `kill-local-variables` does not alter it.

User Option: **make-backup-files**

This variable determines whether or not to make backup files. If it is non-`nil`, then Emacs creates a backup of each file when it is saved for the first time.

The following example shows how to change the `make-backup-files` variable only in the `` `RMAIL' `` buffer and not elsewhere. Setting it `nil` stops Emacs from making backups of the `` `RMAIL' `` file, which may save disk space. (You would put this code in your `` `.emacs' `` file.)

```
(add-hook 'rmail-mode-hook
          (function (lambda ()
                      (make-local-variable
                       'make-backup-files)
                      (setq make-backup-files nil))))
```

Variable: **backup-enable-predicate** *filename*

This variable's value is a function to be called on certain occasions to decide whether a there should be backup files for file name filename. If it returns `nil`, backups are disabled. Otherwise, backups are enabled (if `make-backup-files` is true).

Backup by Renaming or by Copying?

There are two ways that Emacs can make a backup file:

- Emacs can rename the original file so that it becomes a backup file, and then write the buffer being saved into a new file. After this procedure, any other names (i.e., hard links) of the original file now refer to the backup file. The new file is owned by the user doing the editing, and its group is the default for new files written by the user in that directory.
- Emacs can copy the original file into a backup file, and then overwrite the original file with new contents. After this procedure, any other names (i.e., hard links) of the original file still refer to the current version of the file. The file's owner and group will be unchanged.

The first method, renaming, is the default.

The variable `backup-by-copying`, if non-`nil`, says to use the second method, which is to copy the original file and overwrite it with the new buffer contents. The variable `file-precious-flag`, if non-`nil`, also has this effect (as a sideline of its main significance). See section Saving Buffers.

The following two variables, when non-`nil`, cause the second method to be used in certain special cases. They have no effect on the treatment of files that don't fall into the special cases.

Variable: **backup-by-copying**

This variable controls whether to make backup files by copying. If it is non-`nil`, then Emacs always copies the current contents of the file into the backup file before writing the buffer to be saved to the file. (In many circumstances, this has the same effect as `file-precious-flag`.)

Variable: **backup-by-copying-when-linked**

This variable controls whether to make backups by copying for files with multiple names (hard links). If it is non-`nil`, then Emacs uses copying to create backups for those files.

This variable is significant only if `backup-by-copying` is `nil`, since copying is always used when that variable is non-`nil`.

Variable: **backup-by-copying-when-mismatch**

This variable controls whether to make backups by copying in cases where renaming would change either the owner or the group of the file. If it is non-`nil` then Emacs creates backups by copying in s cases.

The value has no effect when renaming would not alter the owner or group of the file; that is, for files which are owned by the user and whose group matches the default for a new file created there by the user.

This variable is significant only if `backup-by-copying` is `nil`, since copying is always used when that variable is non-`nil`.

Making and Deleting Numbered Backup Files

If a file's name is `` `foo' ``, the names of its numbered backup versions are `` `foo.~v~' ``, for various integers v, like this: `` `foo.~1~' ``, `` `foo.~2~' ``, `` `foo.~3~' ``, ..., `` `foo.~259~' ``, and so on.

User Option: **version-control**

This variable controls whether to make a single non-numbered backup file or multiple numbered backups.

`nil`
: Make numbered backups if the visited file already has numbered backups; otherwise, do not.

`never`
: Do not make numbered backups.

anything else
: Do make numbered backups.

The use of numbered backups ultimately leads to a large number of backup versions, which must then be deleted. Emacs can do this automatically.

User Option: **kept-new-versions**

The value of this variable is the number of oldest versions to keep when a new numbered backup is made. The newly made backup is included in the count. The default value is 2.

User Option: **kept-old-versions**

The value of this variable is the number of oldest versions to keep when a new numbered backup is made. The default value is 2.

User Option: **dired-kept-versions**

This variable plays a role in Dired's `dired-clean-directory` (.) command like that played by `kept-old-versions` when a backup file is made. The default value is 2.

If there are backups numbered 1, 2, 3, 5, and 7, and both of these variables have the value 2, then the backups numbered 1 and 2 are kept as old versions and those numbered 5 and 7 are kept as new versions; backup version 3 is deleted. The function `find-backup-file-name` (see section Naming Backup

Files) is responsible for determining which backup versions to delete, but does not delete them itself.

User Option: **trim-versions-without-asking**

If this variable is non-`nil`, then saving a file deletes excess backup versions silently. Otherwise, it asks the user whether to delete them.

Naming Backup Files

The functions in this section are documented mainly because you can customize the naming conventions for backup files by redefining them. If you change one, you probably need to change the rest.

Function: **backup-file-name-p** *filename*

This function returns a non-`nil` value if filename is a possible name for a backup file. A file with the name filename need not exist; the function just checks the name.

```
(backup-file-name-p "foo")
     => nil
(backup-file-name-p "foo~")
     => 3
```

The standard definition of this function is as follows:

```
(defun backup-file-name-p (file)
  "Return non-nil if FILE is a backup file \
name (numeric or not)..."
  (string-match "~$" file))
```

Thus, the function returns a non-`nil` value if the file name ends with a `~'. (We use a backslash to split the documentation string's first line into two lines in the text, but produce just one line in the string itself.)

This simple expression is placed in a separate function to make it easy to redefine for customization.

Function: **make-backup-file-name** *filename*

This function returns a string which is the name to use for a non-numbered backup file for file filename. On Unix, this is just filename with a tilde appended.

The standard definition of this function is as follows:

```
(defun make-backup-file-name (file)
  "Create the non-numeric backup file name for FILE..."
  (concat file "~"))
```

You can change the backup file naming convention by redefining this function. In the following example, `make-backup-file-name` is redefined to prepend a `.' as well as to append a tilde.

```
(defun make-backup-file-name (filename)
  (concat "." filename "~"))

(make-backup-file-name "backups.texi")
     => ".backups.texi~"
```

Function: **find-backup-file-name** *filename*

This function computes the file name for a new backup file for filename. It may also propose certain existing backup files for deletion. `find-backup-file-name` returns a list whose CAR is the name for the new backup file and whose CDR is a list of backup files whose deletion is proposed.

Two variables, `kept-old-versions` and `kept-new-versions`, determine which old backup versions should be kept (by excluding them from the list of backup files ripe for deletion). See section Making and Deleting Numbered Backup Files.

In this example, the value says that `` `~rms/foo.~5~' `` is the name to use for the new backup file, and `` `~rms/foo.~3~' `` is an "excess" version that the caller should consider deleting now.

```
(find-backup-file-name "~rms/foo")
     => ("~rms/foo.~5~" "~rms/foo.~3~")
```

Function: **file-newest-backup** *filename*

This function returns the name of the most recent backup file for filename, or `nil` that file has no backup files.

Some file comparison commands use this function in order to compare a file by default with its most recent backup.

Auto-Saving

Emacs periodically saves all files that you are visiting; this is called auto-saving. Auto-saving prevents you from losing more than a limited amount of work if the system crashes. By default, auto-saves happen every 300 keystrokes, or after around 30 seconds of idle time. See section 'Auto-Saving: Protection Against Disasters' in The GNU Emacs Manual, for information on auto-save for users. Here we describe the functions used to implement auto-saving and the variables that control them.

Variable: **buffer-auto-save-file-name**

This buffer-local variable is the name of the file used for auto-saving the current buffer. It is `nil` if the buffer should not be auto-saved.

```
buffer-auto-save-file-name
=> "/xcssun/users/rms/lewis/#files.texi#"
```

Command: **auto-save-mode** *arg*

When used interactively without an argument, this command is a toggle switch: it turns on auto-saving in the current buffer if it is off, and vice-versa. With an argument arg, the command turns auto-saving on if the value of arg is `t`, a nonempty list, or a positive integer. Otherwise, it turns auto-saving off.

Function: **auto-save-file-name-p** *filename*

This function returns a non-`nil` value if filename is a string that could be the name of an auto-save file. It works based on knowledge of the naming convention for auto-save files: a name that begins and ends with hash marks (`#') is a possible auto-save file name. The argument filename should not contain a directory part.

```
(make-auto-save-file-name)
     => "/xcssun/users/rms/lewis/#files.texi#"
(auto-save-file-name-p "#files.texi#")
     => 0
(auto-save-file-name-p "files.texi")
     => nil
```

The standard definition of this function is as follows:

```
(defun auto-save-file-name-p (filename)
  "Return non-nil if FILENAME can be yielded by..."
  (string-match "^#.*#$" filename))
```

This function exists so that you can customize it if you wish to change the naming convention for auto-save files. If you redefine it, be sure to redefine the function `make-auto-save-file-name` correspondingly.

Function: **make-auto-save-file-name**

This function returns the file name to use for auto-saving the current buffer. This is just the file name with hash marks (`#') appended and prepended to it. This function does not look at the variable `auto-save-visited-file-name`; that should be checked before this function is called.

```
(make-auto-save-file-name)
     => "/xcssun/users/rms/lewis/#backup.texi#"
```

The standard definition of this function is as follows:

```
(defun make-auto-save-file-name ()
  "Return file name to use for auto-saves \
of current buffer..."
  (if buffer-file-name
      (concat
       (file-name-directory buffer-file-name)
       "#"
       (file-name-nondirectory buffer-file-name)
```

```
    "#")
  (expand-file-name
   (concat "#%" (buffer-name) "#"))))
```

This exists as a separate function so that you can redefine it to customize the naming convention for auto-save files. Be sure to change `auto-save-file-name-p` in a corresponding way.

Variable: **auto-save-visited-file-name**

If this variable is non-`nil`, Emacs auto-saves buffers in the files they are visiting. That is, the auto-save is done in the same file which you are editing. Normally, this variable is `nil`, so auto-save files have distinct names that are created by `make-auto-save-file-name`.

When you change the value of this variable, the value does not take effect until the next time auto-save mode is reenabled in any given buffer. If auto-save mode is already enabled, auto-saves continue to go in the same file name until `auto-save-mode` is called again.

Function: **recent-auto-save-p**

This function returns `t` if the current buffer has been auto-saved since the last time it was read in or saved.

Function: **set-buffer-auto-saved**

This function marks the current buffer as auto-saved. The buffer will not be auto-saved again until the buffer text is changed again. The function returns `nil`.

User Option: **auto-save-interval**

The value of this variable is the number of characters that Emacs reads from the keyboard between auto-saves. Each time this many more characters are read, auto-saving is done for all buffers in which it is enabled.

User Option: **auto-save-timeout**

The value of this variable is the number of seconds of idle time that should cause auto-saving. Each time the user pauses for this long, Emacs auto-saves any buffers that need it. (Actually, the specified timeout is multiplied by a factor depending on the size of the current buffer.)

Variable: **auto-save-hook**

This normal hook is run whenever an auto-save is about to happen.

User Option: **auto-save-default**

If this variable is non-`nil`, buffers that are visiting files have auto-saving enabled by default. Otherwise, they do not.

Command: **do-auto-save** *&optional no-message*

This function auto-saves all buffers that need to be auto-saved. This is all buffers for which auto-saving is enabled and that have been changed since the last time they were auto-saved.

Normally, if any buffers are auto-saved, a message `Auto-saving...' is displayed in the echo area while auto-saving is going on. However, if no-message is non-`nil`, the message is inhibited.

Function: **delete-auto-save-file-if-necessary**

This function deletes the current buffer's auto-save file if `delete-auto-save-files` is non-`nil`. It is called every time a buffer is saved.

Variable: **delete-auto-save-files**

This variable is used by the function `delete-auto-save-file-if-necessary`. If it is non-`nil`, Emacs deletes auto-save files when a true save is done (in the visited file). This saves on disk space and unclutters your directory.

Function: **rename-auto-save-file**

This function adjusts the current buffer's auto-save file name if the visited file name has changed. It also renames an existing auto-save file. If the visited file name has not changed, this function does nothing.

Reverting

If you have made extensive changes to a file and then change your mind about them, you can get rid of them by reading in the previous version of the file with the `revert-buffer` command. See section 'Reverting a Buffer' in The GNU Emacs Manual.

Command: **revert-buffer** *&optional check-auto-save noconfirm*

This command replaces the buffer text with the text of the visited file on disk. This action undoes all changes since the file was visited or saved.

If the argument check-auto-save is non-`nil`, and the latest auto-save file is more recent than the visited file, `revert-buffer` asks the user whether to use that instead. Otherwise, it always uses the text of the visited file itself. Interactively, check-auto-save is set if there is a numeric prefix argument.

When the value of the noconfirm argument is non-`nil`, `revert-buffer` does not ask for confirmation for the reversion action. This means that the buffer contents are deleted and replaced by the text from the file on the disk, with no further opportunities for the user to prevent it.

Since reverting works by deleting the entire text of the buffer and inserting the file contents, all the buffer's markers are relocated to point at the beginning of the buffer. This is not "correct", but then, there is no way to determine what would be correct. It is not possible to determine, from the text before and after, which characters after reversion correspond to which characters before.

If the value of the `revert-buffer-function` variable is non-`nil`, it is called as a function with no arguments to do the work.

Variable: **revert-buffer-function**

The value of this variable is the function to use to revert this buffer; but if the value of this variable is `nil`, then the `revert-buffer` function carries out its default action. Modes such as Dired mode, in

which the text being edited does not consist of a file's contents but can be regenerated in some other fashion, give this variable a buffer-local value that is a function to regenerate the contents.

Variable: **revert-buffer-insert-file-contents-function**

The value of this variable, if non-`nil`, is the function to use to insert contents when reverting this buffer. The function receives two arguments, first the file name to use, and second, `t` if the user has asked to read the auto-save file.

Command: **recover-file** *filename*

This function visits filename, but gets the contents from its last auto-save file. This is useful after the system has crashed, to resume editing the same file without losing all the work done in the previous session.

An error is signaled if there is no auto-save file for filename, or if filename is newer than its auto-save file. If filename does not exist, but its auto-save file does, then the auto-save file is read as usual. This last situation may occur if you visited a nonexistent file and never actually saved it.

Go to the previous, next section.

Go to the previous, next section.

Buffers

A buffer is a Lisp object containing text to be edited. Buffers are used to hold the contents of files that are being visited; there may also be buffers which are not visiting files. While several buffers may exist at one time, exactly one buffer is designated the current buffer at any time. Most editing commands act on the contents of the current buffer. Each buffer, including the current buffer, may or may not be displayed in any windows.

Buffer Basics

Buffers in Emacs editing are objects which have distinct names and hold text that can be edited. Buffers appear to Lisp programs as a special data type. The contents of a buffer may be viewed as an extendable string; insertions and deletions may occur in any part of the buffer. See section Text.

A Lisp buffer object contains numerous pieces of information. Some of this information is directly accessible to the programmer through variables, while other information is only accessible through special-purpose functions. For example, the width of a tab character is directly accessible through a variable, while the value of point is accessible only through a primitive function.

Buffer-specific information that is directly accessible is stored in buffer-local variable bindings, which are variable values that are effective only in a particular buffer. This feature allows each buffer to override the values of certain variables. Most major modes override variables such as `fill-column` or `comment-column` in this way. For more information about buffer-local variables and functions related to them, see section Buffer-Local Variables.

For functions and variables related to visiting files in buffers, see section Visiting Files and section Saving Buffers. For functions and variables related to the display of buffers in windows, see section Buffers and Windows.

Function: **bufferp** *object*

This function returns `t` if object is a buffer, `nil` otherwise.

Buffer Names

Each buffer has a unique name, which is a string. Many of the functions that work on buffers accept either a buffer or a buffer name as an argument. Any argument called buffer-or-name is of this sort, and an error is signaled if it is neither a string nor a buffer. Any argument called buffer is required to be an actual buffer object, not a name.

Buffers that are ephemeral and generally uninteresting to the user have names starting with a space, which prevents them from being listed by the `list-buffers` or `buffer-menu` commands. (A name

starting with space also initially disables recording undo information; see section Undo.)

Function: **buffer-name** *&optional buffer*

This function returns the name of buffer as a string. If buffer is not supplied, it defaults to the current buffer.

If `buffer-name` returns `nil`, it means that buffer has been killed. See section Killing Buffers.

```
(buffer-name)
     => "buffers.texi"

(setq foo (get-buffer "temp"))
     => #<buffer temp>
(kill-buffer foo)
     => nil
(buffer-name foo)
     => nil
foo
     => #<killed buffer>
```

Command: **rename-buffer** *newname &optional unique*

This function renames the current buffer to newname. An error is signaled if newname is not a string, or if there is already a buffer with that name. The function returns `nil`.

Ordinarily, `rename-buffer` signals an error if newname is already in use. However, if unique is non-`nil`, it modifies newname to make a name that is not in use. Interactively, you can make unique non-`nil` with a numeric prefix argument.

One application of this command is to rename the `*shell*' buffer to some other name, thus making it possible to create a second shell buffer under the name `*shell*'.

Function: **get-buffer** *buffer-or-name*

This function returns the buffer specified by buffer-or-name. If buffer-or-name is a string and there is no buffer with that name, the value is `nil`. If buffer-or-name is a buffer, it is returned as given. (That is not very useful, so the argument is usually a name.) For example:

```
(setq b (get-buffer "lewis"))
     => #<buffer lewis>
(get-buffer b)
     => #<buffer lewis>
(get-buffer "Frazzle-nots")
     => nil
```

See also the function `get-buffer-create` in section Creating Buffers.

Function: **generate-new-buffer-name** *starting-name*

This function returns a name that would be unique for a new buffer--but does not create the buffer. It starts with starting-name, and produces a name not currently in use for any buffer by appending a number inside of `<...>'.

See the related function `generate-new-buffer` in section Creating Buffers.

Buffer File Name

The buffer file name is the name of the file that is visited in that buffer. When a buffer is not visiting a file, its buffer file name is `nil`. Most of the time, the buffer name is the same as the nondirectory part of the buffer file name, but the buffer file name and the buffer name are distinct and can be set independently. See section Visiting Files.

Function: **buffer-file-name** *&optional buffer*

This function returns the absolute file name of the file that buffer is visiting. If buffer is not visiting any file, `buffer-file-name` returns `nil`. If buffer is not supplied, it defaults to the current buffer.

```
(buffer-file-name (other-buffer))
     => "/usr/user/lewis/manual/files.texi"
```

Variable: **buffer-file-name**

This buffer-local variable contains the name of the file being visited in the current buffer, or `nil` if it is not visiting a file. It is a permanent local, unaffected by `kill-local-variables`.

```
buffer-file-name
     => "/usr/user/lewis/manual/buffers.texi"
```

It is risky to change this variable's value without doing various other things. See the definition of `set-visited-file-name` in `files.el`; some of the things done there, such as changing the buffer name, are not strictly necessary, but others are essential to avoid confusing Emacs.

Variable: **buffer-file-truename**

This buffer-local variable holds the truename of the file visited in the current buffer, or `nil` if no file is visited. It is a permanent local, unaffected by `kill-local-variables`. See section Truenames.

Variable: **buffer-file-number**

This buffer-local variable holds the file number and directory device number of the file visited in the current buffer, or `nil` if no file or a nonexistent file is visited. It is a permanent local, unaffected by `kill-local-variables`. See section Truenames.

The value is normally a list of the form `(filenum devnum)`. This pair of numbers uniquely identifies the file among all files accessible on the system. See the function `file-attributes`, in section Other Information about Files, for more information about them.

TOC

Function: **get-file-buffer** *filename*

This function returns the buffer visiting file filename. If there is no such buffer, it returns `nil`. The argument filename, which must be a string, is expanded (see section Functions that Expand Filenames), then compared against the visited file names of all live buffers.

```
(get-file-buffer "buffers.texi")
    => #<buffer buffers.texi>
```

In unusual circumstances, there can be more than one buffer visiting the same file name. In such cases, this function returns the first such buffer in the buffer list.

Command: **set-visited-file-name** *filename*

If filename is a non-empty string, this function changes the name of the file visited in current buffer to filename. (If the buffer had no visited file, this gives it one.) The *next time* the buffer is saved it will go in the newly-specified file. This command marks the buffer as modified, since it does not (as far as Emacs knows) match the contents of filename, even if it matched the former visited file.

If filename is `nil` or the empty string, that stands for "no visited file". In this case, `set-visited-file-name` marks the buffer as having no visited file.

When the function `set-visited-file-name` is called interactively, it prompts for filename in the minibuffer.

See also `clear-visited-file-modtime` and `verify-visited-file-modtime` in section Buffer Modification.

Variable: **list-buffers-directory**

This buffer-local variable records a string to display in a buffer listing in place of the visited file name, for buffers that don't have a visited file name. Dired buffers use this variable.

Buffer Modification

Emacs keeps a flag called the modified flag for each buffer, to record whether you have changed the text of the buffer. This flag is set to `t` whenever you alter the contents of the buffer, and cleared to `nil` when you save it. Thus, the flag shows whether there are unsaved changes. The flag value is normally shown in the mode line (see section Variables Used in the Mode Line), and controls saving (see section Saving Buffers) and auto-saving (see section Auto-Saving).

Some Lisp programs set the flag explicitly. For example, the function `set-visited-file-name` sets the flag to `t`, because the text does not match the newly-visited file, even if it is unchanged from the file formerly visited.

The functions that modify the contents of buffers are described in section Text.

Function: **buffer-modified-p** *&optional buffer*

This function returns `t` if the buffer buffer has been modified since it was last read in from a file or saved, or `nil` otherwise. If buffer is not supplied, the current buffer is tested.

Function: **set-buffer-modified-p** *flag*

This function marks the current buffer as modified if flag is non-`nil`, or as unmodified if the flag is `nil`.

Another effect of calling this function is to cause unconditional redisplay of the mode line for the current buffer. In fact, the function `force-mode-line-update` works by doing this:

```
(set-buffer-modified-p (buffer-modified-p))
```

Command: **not-modified**

This command marks the current buffer as unmodified, and not needing to be saved. Don't use this function in programs, since it prints a message in the echo area; use `set-buffer-modified-p` (above) instead.

Function: **buffer-modified-tick** *&optional buffer*

This function returns buffer`s modification-count. This is a counter that increments every time the buffer is modified. If buffer is `nil` (or omitted), the current buffer is used.

Comparison of Modification Time

Suppose that you visit a file and make changes in its buffer, and meanwhile the file itself is changed on disk. At this point, saving the buffer would overwrite the changes in the file. Occasionally this may be what you want, but usually it would lose valuable information. Emacs therefore checks the file's modification time using the functions described below before saving the file.

Function: **verify-visited-file-modtime** *buffer*

This function compares Emacs's record of the modification time for the file that the buffer is visiting against the actual modification time of the file as recorded by the operating system. The two should be the same unless some other process has written the file since Emacs visited or saved it.

The function returns `t` if the last actual modification time and Emacs's recorded modification time are the same, `nil` otherwise.

Function: **clear-visited-file-modtime**

This function clears out the record of the last modification time of the file being visited by the current buffer. As a result, the next attempt to save this buffer will not complain of a discrepancy in file modification times.

This function is called in `set-visited-file-name` and other exceptional places where the usual test to avoid overwriting a changed file should not be done.

Function: **set-visited-file-modtime** *&optional time*

This function updates the buffer's record of the last modification time of the visited file, to the value specified by time if time is not `nil`, and otherwise to the last modification time of the visited file.

If time is not `nil`, it should have the form `(high . low)` or `(high low)`, in either case containing two integers, each of which holds 16 bits of the time. (This is the same format that `file-attributes` uses to return time values; see section Other Information about Files.)

This function is useful if the buffer was not read from the file normally, or if the file itself has been changed for some known benign reason.

Function: **visited-file-modtime**

This function returns the buffer's recorded last file modification time, as a list of the form `(high . low)`. Note that this is not identical to the last modification time of the file that is visited (though under normal circumstances the values are equal).

Function: **ask-user-about-supersession-threat** *fn*

This function is used to ask a user how to proceed after an attempt to modify an obsolete buffer. An obsolete buffer is an unmodified buffer for which the associated file on disk is newer than the last save-time of the buffer. This means some other program has probably altered the file.

This function is called automatically by Emacs on the proper occasions. It exists so you can customize Emacs by redefining it. See the file `` `userlock.el' `` for the standard definition.

Depending on the user's answer, the function may return normally, in which case the modification of the buffer proceeds, or it may signal a `file-supersession` error with data `(fn)`, in which case the proposed buffer modification is not allowed.

See also the file locking mechanism in section File Locks.

Read-Only Buffers

A buffer may be designated as read-only. This means that the buffer's contents may not be modified, although you may change your view of the contents by scrolling, narrowing, or widening, etc.

Read-only buffers are used in two kinds of situations:

- A buffer visiting a file is made read-only if the file is write-protected.

  Here, the purpose is to show the user that editing the buffer with the aim of saving it in the file may be futile or undesirable. The user who wants to change the buffer text despite this can do so after clearing the read-only flag with the function `toggle-read-only`.
- Modes such as Dired and Rmail make buffers read-only when altering the contents with the usual editing commands is probably a mistake.

  The special commands of the mode in question bind `buffer-read-only` to `nil` (with `let`) around the places where they change the text.

Variable: **buffer-read-only**

This buffer-local variable specifies whether the buffer is read-only. The buffer is read-only if this variable is non-`nil`.

Command: **toggle-read-only**

This command changes whether the current buffer is read-only. It is intended for interactive use; don't use it in programs. At any given point in a program, you should know whether you want the read-only flag on or off; so you can set `buffer-read-only` explicitly to the proper value, `t` or `nil`.

Function: **barf-if-buffer-read-only**

This function signals a `buffer-read-only` error if the current buffer is read-only. See section Interactive Call, for another way to signal an error if the current buffer is read-only.

The Buffer List

The buffer list is a list of all buffers that have not been killed. The order of the buffers in the list is based primarily on how recently each buffer has been displayed in the selected window. Several functions, notably `other-buffer`, make use of this ordering.

Function: **buffer-list**

This function returns a list of all buffers, including those whose names begin with a space. The elements are actual buffers, not their names.

```
(buffer-list)
     => (#<buffer buffers.texi>
         #<buffer  *Minibuf-1*> #<buffer buffer.c>
         #<buffer *Help*> #<buffer TAGS>)

;; Note that the name of the minibuffer
;;   begins with a space!

(mapcar (function buffer-name) (buffer-list))
    => ("buffers.texi" " *Minibuf-1*"
         "buffer.c" "*Help*" "TAGS")
```

Buffers appear earlier in the list if they were current more recently.

This list is a copy of a list used inside Emacs; modifying it has no effect on the buffers.

Function: **other-buffer** *&optional buffer-or-name visible-ok*

This function returns the first buffer in the buffer list other than buffer-or-name. Usually this is the buffer most recently shown in the selected window, aside from buffer-or-name. Buffers are moved to the front of the list when they are selected and to the end when they are buried. Buffers whose names start with a

space are not even considered.

If buffer-or-name is not supplied (or if it is not a buffer), then `other-buffer` returns the first buffer on the buffer list that is not visible in any window.

Normally, `other-buffer` avoids returning a buffer visible in any window, except as a last resort. However, if visible-ok is non-`nil`, then a buffer displayed in some window is admissible to return.

If no suitable buffer exists, the buffer `*scratch*' is returned (and created, if necessary).

Command: **list-buffers** *&optional files-only*

This function displays a listing of the names of existing buffers. It clears the buffer `*Buffer List*', then inserts the listing into that buffer and displays it in a window. `list-buffers` is intended for interactive use, and is described fully in The GNU Emacs Manual. It returns `nil`.

Command: **bury-buffer** *&optional buffer-or-name*

This function puts buffer-or-name at the end of the buffer list without changing the order of any of the other buffers on the list. This buffer therefore becomes the least desirable candidate for `other-buffer` to return, and appears last in the list displayed by `list-buffers`.

If buffer-or-name is `nil` or omitted, this means to bury the current buffer. In addition, this switches to some other buffer (obtained using `other-buffer`) in the selected window. If the buffer is displayed in a window other than the selected one, it remains there.

If you wish to remove a buffer from all the windows that display it, you can do so with a loop that uses `get-buffer-window`. See section Buffers and Windows.

Creating Buffers

This section describes the two primitives for creating buffers. `get-buffer-create` creates a buffer if it finds no existing buffer; `generate-new-buffer` always creates a new buffer, and gives it a unique name.

Other functions you can use to create buffers include `with-output-to-temp-buffer` (see section Temporary Displays) and `create-file-buffer` (see section Visiting Files).

Function: **get-buffer-create** *name*

This function returns a buffer named name. If such a buffer already exists, it is returned. If such a buffer does not exist, one is created and returned. The buffer does not become the current buffer--this function does not change which buffer is current.

An error is signaled if name is not a string.

```
(get-buffer-create "foo")
     => #<buffer foo>
```

The major mode for the new buffer is set by the value of `default-major-mode`. See section How Emacs Chooses a Major Mode.

Function: **generate-new-buffer** *name*

This function returns a newly created, empty buffer, but does not make it current. If there is no buffer named name, then that is the name of the new buffer. If that name is in use, this function adds suffixes of the form `<n>' are added to name, where n is an integer. It tries successive integers starting with 2 until it finds an available name.

An error is signaled if name is not a string.

```
(generate-new-buffer "bar")
     => #<buffer bar>
(generate-new-buffer "bar")
     => #<buffer bar<2>>
(generate-new-buffer "bar")
     => #<buffer bar<3>>
```

The major mode for the new buffer is set by the value of `default-major-mode`. See section How Emacs Chooses a Major Mode.

See the related function `generate-new-buffer-name` in section Buffer Names.

Killing Buffers

Killing a buffer makes its name unknown to Emacs and makes its space available for other use.

The buffer object for the buffer which has been killed remains in existence as long as anything refers to it, but it is specially marked so that you cannot make it current or display it. Killed buffers retain their identity, however; two distinct buffers, when killed, remain distinct according to `eq`.

If you kill a buffer that is current or displayed in a window, Emacs automatically selects or displays some other buffer instead. This means that killing a buffer can in general change the current buffer. Therefore, when you kill a buffer, you should also take the precautions associated with changing the current buffer (unless you happen to know that the buffer being killed isn't current). See section The Current Buffer.

The `buffer-name` of a killed buffer is `nil`. You can use this feature to test whether a buffer has been killed:

```
(defun killed-buffer-p (buffer)
  "Return t if BUFFER is killed."
  (not (buffer-name buffer)))
```

Command: **kill-buffer** *buffer-or-name*

This function kills the buffer buffer-or-name, freeing all its memory for use as space for other buffers.

(Emacs version 18 and older was unable to return the memory to the operating system.) It returns `nil`.

Any processes that have this buffer as the `process-buffer` are sent the `SIGHUP` signal, which normally causes them to terminate. (The usual meaning of `SIGHUP` is that a dialup line has been disconnected.) See section Deleting Processes.

If the buffer is visiting a file when `kill-buffer` is called and the buffer has not been saved since it was last modified, the user is asked to confirm before the buffer is killed. This is done even if `kill-buffer` is not called interactively. To prevent the request for confirmation, clear the modified flag before calling `kill-buffer`. See section Buffer Modification.

Just before actually killing the buffer, after asking all questions, `kill-buffer` runs the normal hook `kill-buffer-hook`. The buffer to be killed is current when the hook functions run. See section Hooks.

Killing a buffer that is already dead has no effect.

```
(kill-buffer "foo.unchanged")
     => nil
(kill-buffer "foo.changed")

---------- Buffer: Minibuffer ----------
Buffer foo.changed modified; kill anyway? (yes or no) yes
---------- Buffer: Minibuffer ----------

     => nil
```

The Current Buffer

There are, in general, many buffers in an Emacs session. At any time, one of them is designated as the current buffer. This is the buffer in which most editing takes place, because most of the primitives for examining or changing text in a buffer operate implicitly on the current buffer (see section Text). Normally the buffer that is displayed on the screen in the selected window is the current buffer, but this is not always so: a Lisp program can designate any buffer as current temporarily in order to operate on its contents, without changing what is displayed on the screen.

The way to designate a current buffer in a Lisp program is by calling `set-buffer`. The specified buffer remains current until a new one is designated.

When an editing command returns to the editor command loop, the command loop designates the buffer displayed in the selected window as current, to prevent confusion: the buffer that the cursor is in, when Emacs reads a command, is the one to which the command will apply. (See section Command Loop.) Therefore, `set-buffer` is not usable for switching visibly to a different buffer so that the user can edit it. For this, you must use the functions described in section Displaying Buffers in Windows.

However, Lisp functions that change to a different current buffer should not leave it to the command loop

to set it back afterwards. Editing commands written in Emacs Lisp can be called from other programs as well as from the command loop. It is convenient for the caller if the subroutine does not change which buffer is current (unless, of course, that is the subroutine's purpose). Therefore, you should normally use `set-buffer` within a `save-excursion` that will restore the current buffer when your program is done (see section Excursions). Here is an example, the code for the command `append-to-buffer` (with the documentation string abridged):

```
(defun append-to-buffer (buffer start end)
  "Append to specified buffer the text of the region..."
  (interactive "BAppend to buffer: \nr")
  (let ((oldbuf (current-buffer)))
    (save-excursion
      (set-buffer (get-buffer-create buffer))
      (insert-buffer-substring oldbuf start end))))
```

This function binds a local variable to the current buffer, and then `save-excursion` records the values of point, the mark, and the original buffer. Next, `set-buffer` makes another buffer current. Finally, `insert-buffer-substring` copies the string from the original current buffer to the new current buffer.

If the buffer appended to happens to be displayed in some window, then the next redisplay will show how its text has changed. Otherwise, you will not see the change immediately on the screen. The buffer becomes current temporarily during the execution of the command, but this does not cause it to be displayed.

Changing the current buffer between the binding and unbinding of a buffer-local variable can cause it to be bound in one buffer, and then unbound in another! You can avoid this problem by using save-excursion to make sure that the buffer from which the variable was bound is current again whenever the variable is unbound.

```
(let (buffer-read-only)
  (save-excursion
    (set-buffer ...)
    ...))
```

Function: **current-buffer**

This function returns the current buffer.

```
(current-buffer)
     => #<buffer buffers.texi>
```

Function: **set-buffer** *buffer-or-name*

This function makes buffer-or-name the current buffer. However, it does not display the buffer in the currently selected window or in any other window. This means that the user cannot necessarily see the buffer, but Lisp programs can in any case work on it.

TOC

This function returns the buffer identified by buffer-or-name. An error is signaled if buffer-or-name does not identify an existing buffer.

Go to the previous, next section.

Go to the previous, next section.

Windows

This chapter describes most of the functions and variables related to Emacs windows. See section Emacs Display, for information on how text is displayed in windows.

Basic Concepts of Emacs Windows

A window is the physical area of the screen in which a buffer is displayed. The term is also used to refer to a Lisp object which represents that screen area in Emacs Lisp. It should be clear from the context which is meant.

There is always at least one window displayed on the screen, and there is exactly one window that we call the selected window. The cursor is in the selected window. The selected window's buffer is usually the current buffer (except when `set-buffer` has been used.) See section The Current Buffer.

For all intents, a window only exists while it is displayed on the terminal. Once removed from the display, the window is effectively deleted and should not be used, *even though there may still be references to it* from other Lisp objects. Restoring a saved window configuration is the only way for a window no longer on the screen to come back to life. (See section Deleting Windows.)

Each window has the following attributes:

- containing frame
- window height
- window width
- window edges with respect to the screen or frame
- the buffer it displays
- position within the buffer at the upper left of the window
- the amount of horizontal scrolling, in columns
- point
- the mark
- how recently the window was selected

Applications use multiple windows for a variety of reasons, but most often to give different views of the same information. In Rmail, for example, you can move through a summary buffer in one window while the other window shows messages one at a time as they are reached.

The term "window" in Emacs means something similar to what it means in the context of general puprpose window systems such as X, but not identical. The X Window System subdivides the screen into X windows; Emacs uses one or more X windows, called frames in Emacs terminology, and subdivides each of them into (nonoverlapping) Emacs windows. When you use Emacs on an ordinary display

terminal, Emacs subdivides the terminal screen into Emacs windows.

Most window systems support arbitrarily located overlapping windows. In contrast, Emacs windows are tiled; they never overlap, and together they fill the whole of the screen or frame. Because of the way in which Emacs creates new windows and resizes them, you can't create every conceivable tiling on an Emacs screen. See section Splitting Windows. Also, see section The Size of a Window.

See section Emacs Display, for information on how the contents of the window's buffer are displayed in the window.

Function: **windowp** *object*

This function returns `t` if object is a window.

Splitting Windows

The functions described here are the primitives used to split a window into two windows. Two higher level functions sometimes split a window, but not always: `pop-to-buffer` and `display-buffer` (see section Displaying Buffers in Windows).

The functions described here do not accept a buffer as an argument. They let the two "halves" of the split window display the same buffer previously visible in the window that was split.

Function: **one-window-p** *&optional no-mini*

This function returns non-`nil` if there is only one window. The argument no-mini, if non-`nil`, means don't count the minibuffer even if it is active; otherwise, the minibuffer window is included, if active, in the total number of windows which is compared against one.

Command: **split-window** *&optional window size horizontal*

This function splits window into two windows. The original window window remains the selected window, but occupies only part of its former screen area. The rest is occupied by a newly created window which is returned as the value of this function.

If horizontal is non-`nil`, then window splits side by side, keeping the leftmost size columns and giving the rest of the columns to the new window. Otherwise, it splits into halves one above the other, keeping the upper size lines and giving the rest of the lines to the new window. The original window is therefore the right-hand or upper of the two, and the new window is the left-hand or lower.

If window is omitted or `nil`, then the selected window is split. If size is omitted or `nil`, then window is divided evenly into two parts. (If there is an odd line, it is allocated to the new window.) When `split-window` is called interactively, all its arguments are `nil`.

The following example starts with one window on a screen that is 50 lines high by 80 columns wide; then the window is split.

```
(setq w (selected-window))
     => #<window 8 on windows.texi>
```

```
(window-edges)          ; Edges in order:
     => (0 0 80 50)     ;   left--top--right--bottom

;; Returns window created
(setq w2 (split-window w 15))
     => #<window 28 on windows.texi>
(window-edges w2)
     => (0 15 80 50)    ; Bottom window;
                        ;   top is line 15
(window-edges w)
     => (0 0 80 15)     ; Top window
```

The screen looks like this:

```
          ___________
         |           |  line 0
         |     w     |
         |___________|
         |           |  line 15
         |     w2    |
         |___________|
                       line 50
 column 0   column 80
```

Next, the top window is split horizontally:

```
(setq w3 (split-window w 35 t))
     => #<window 32 on windows.texi>
(window-edges w3)
     => (35 0 80 15)  ; Left edge at column 35
(window-edges w)
     => (0 0 35 15)   ; Right edge at column 35
(window-edges w2)
     => (0 15 80 50)  ; Bottom window unchanged
```

Now, the screen looks like this:

```
     column 35
          ___________
         |   |       |  line 0
         | w |  w3   |
         |___|_______|
         |           |  line 15
         |     w2    |
         |___________|
                       line 50
```

```
column 0   column 80
```

Command: **split-window-vertically** *size*

This function splits the selected window into two windows, one above the other, leaving the selected window with size lines.

This function is simply an interface to `split-windows`. Here is the complete function definition for it:

```
(defun split-window-vertically (&optional arg)
  "Split selected window into two windows,
one above the other..."
  (interactive "P")
  (split-window nil (and arg (prefix-numeric-value arg))))
```

Command: **split-window-horizontally** *size*

This function splits the selected window into two windows side-by-side, leaving the selected window with size columns.

This function is simply an interface to `split-windows`. Here is the complete definition for `split-window-horizontally` (except for part of the documentation string):

```
(defun split-window-horizontally (&optional arg)
  "Split selected window into two windows
side by side..."
  (interactive "P")
  (split-window nil (and arg (prefix-numeric-value arg)) t))
```

Deleting Windows

A window remains visible on its frame unless you delete it by calling certain functions that delete windows. A deleted window cannot appear on the screen, but continues to exist as a Lisp object until there are no references to it. There is no way to cancel the deletion of a window aside from restoring a saved window configuration (see section Window Configurations). Restoring a window configuration also deletes any windows that aren't part of that configuration.

When you delete a window, the space it took up is given to one adjacent sibling. (In Emacs version 18, the space was divided evenly among all the siblings.)

Function: **window-live-p** *window*

This function returns `nil` if window is deleted, and `t` otherwise.

Warning: erroneous information or fatal errors may result from using a deleted window as if it were live.

Command: **delete-window** *&optional window*

This function removes window from the display. If window is omitted, then the selected window is deleted. An error is signaled if there is only one window when `delete-window` is called.

This function returns `nil`.

When `delete-window` is called interactively, window defaults to the selected window.

Command: **delete-other-windows** *&optional window*

This function makes window the only window on its frame, by deleting all the other windows. If window is omitted or `nil`, then the selected window is used by default.

The result is `nil`.

Command: **delete-windows-on** *buffer*

This function deletes all windows showing buffer. If there are no windows showing buffer, then this function does nothing. If all windows in some frame are showing buffer (including the case where there is only one window), then the frame reverts to having a single window showing the buffer chosen by `other-buffer`. See section The Buffer List.

If there are several windows showing different buffers, then those showing buffer are removed, and the others are expanded to fill the void.

The result is `nil`.

Selecting Windows

When a window is selected, the buffer in the window becomes the current buffer, and the cursor will appear in it.

Function: **selected-window**

This function returns the selected window. This is the window in which the cursor appears and to which many commands apply.

Function: **select-window** *window*

This function makes window the selected window. The cursor then appears in window (on redisplay). The buffer being displayed in window is immediately designated the current buffer.

The return value is window.

```
(setq w (next-window))
(select-window w)
     => #<window 65 on windows.texi>
```

The following functions choose one of the windows on the screen, offering various criteria for the choice.

Function: **get-lru-window** *&optional all-frames*

This function returns the window least recently "used" (that is, selected). The selected window is always the most recently used window.

The selected window can be the least recently used window if it is the only window. A newly created window becomes the least recently used window until it is selected. The minibuffer window is not considered a candidate.

The argument all-frames controls which set of windows are considered. If it is non-`nil`, then all windows on all frames are considered. Otherwise, only windows in the selected frame are considered.

Function: **get-largest-window** *&optional all-frames*

This function returns the window with the largest area (height times width). If there are no side-by-side windows, then this is the window with the most lines. The minibuffer window is not considered a candidate.

If there are two windows of the same size, then the function returns the window which is first in the cyclic ordering of windows (see following section), starting from the selected window.

The argument all-frames controls which set of windows are considered. If it is non-`nil`, then all windows on all frames are considered. Otherwise, only windows in the selected frame are considered.

Cycling Ordering of Windows

When you use the command C-x o (`other-window`) to select the next window, it moves through all the windows on the screen in a specific cyclic order. For any given configuration of windows, this order never varies. It is called the cyclic ordering of windows.

This ordering generally goes from top to bottom, and from left to right. But it may go down first or go right first, depending on the order in which the windows were split.

If the first split was vertical (into windows one above each other), and then the subwindows were split horizontally, then the ordering is left to right in the top, and then left to right in the next lower part of the frame, and so on. If the first split was horizontal, the ordering is top to bottom in the left part, and so on. In general, within each set of siblings at any level in the window tree, the order is left to right, or top to bottom.

Function: **next-window** *window &optional minibuf all-frames*

This function returns the window following window in the cyclic ordering of windows. This is the window which C-x o would select if done when window is selected. If window is the only window visible, then this function returns window.

The value of the argument minibuf determines whether the minibuffer is included in the window order. Normally, when minibuf is `nil`, the minibuffer is included if it is currently active; this is the behavior of C-x o.

If minibuf is `t`, then the cyclic ordering includes the minibuffer window even if it is not active.

If minibuf is neither `t` nor `nil`, then the minibuffer window is not included even if it is active. (The minibuffer window is active while the minibuffer is in use. See section Minibuffers.)

When there are multiple frames, this functions normally cycles through all the windows in the selected frame, plus the minibuffer used by the selected frame even if it lies in some other frame.

If all-frames is `t`, then it cycles through all the windows in all the frames that currently exist.

If all-frames is neither `t` nor `nil`, then it cycles through precisely the windows in the selected frame, excluding the minibuffer in use if it lies in some other frame.

This example shows two windows, which both happen to be displaying the same buffer:

```
(selected-window)
     => #<window 56 on windows.texi>
(next-window (selected-window))
     => #<window 52 on windows.texi>
(next-window (next-window (selected-window)))
     => #<window 56 on windows.texi>
```

Function: **previous-window** *window &optional minibuf all-frames*

This function returns the window preceding window in the cyclic ordering of windows. The other arguments affect which windows are included in the cycle, as in `next-window`.

Command: **other-window** *count*

This function selects the countth next window in the cyclic order. If count is negative, then it selects the -countth preceding window. It returns `nil`.

In an interactive call, count is the numeric prefix argument.

Function: **walk-windows** *proc &optional minibuf all-frames*

This function cycles through all visible windows, calling `proc` once for each window with the window as its sole argument.

The optional argument minibuf says whether to include minibuffer windows. A value of `t` means count the minibuffer window even if not active. A value of `nil` means count it only if active. Any other value means not to count the minibuffer even if it is active.

If the optional third argument all-frames is `t`, that means include all windows in all frames. If all-frames is `nil`, it means to cycle within the selected frame, but include the minibuffer window (if minibuf says so) that that frame uses, even if it is on another frame. If all-frames is neither `nil` nor `t`, `walk-windows` sticks strictly to the selected frame.

Buffers and Windows

This section describes low-level functions to examine windows or to show buffers in windows in a precisely controlled fashion. See the following section for related functions that find a window to use and specify a buffer for it. The functions described there are easier to use than these, but they employ heuristics in choosing or creating a window; use these functions when you need complete control.

Function: **set-window-buffer** *window buffer-or-name*

This function makes window display buffer-or-name as its contents. It returns `nil`.

```
(set-window-buffer (selected-window) "foo")
     => nil
```

Function: **window-buffer** *&optional window*

This function returns the buffer that window is displaying. If window is omitted, then this function returns the buffer for the selected window.

```
(window-buffer)
     => #<buffer windows.texi>
```

Function: **get-buffer-window** *buffer-or-name &optional all-frames*

This function returns a window currently displaying buffer-or-name, or `nil` if there is none. If there are several such windows, then the function returns the first one in the cyclic ordering of windows, starting from the selected window. See section Cycling Ordering of Windows.

The argument all-frames controls which set of windows are considered. If it is non-`nil`, then all windows on all frames are considered. Otherwise, only windows in the selected frame are considered.

Command: **replace-buffer-in-windows** *buffer*

This function replaces buffer with some other buffer in all windows displaying it. The other buffer used is chosen with `other-buffer`. In the usual applications of this function, you don't care which other buffer is used; you just want to make sure that buffer is no longer displayed.

This function returns `nil`.

Displaying Buffers in Windows

In this section we describe convenient functions that choose a window automatically and use it to display a specified buffer. These functions can also split an existing window in certain circumstances. We also describe variables that parameterize the heuristics used for choosing a window. See the preceding section for low-level functions that give you more precise control.

Do not use the functions in this section in order to make a buffer current so that a Lisp program can

access or modify it; they are too drastic for that purpose, since they change the display of buffers in windows, which is gratuitous and will surprise the user. Instead, use `set-buffer` (see section The Current Buffer) and `save-excursion` (see section Excursions), which designate buffers as current for programmed access without affecting the display of buffers in windows.

Command: **switch-to-buffer** *buffer-or-name &optional norecord*

This function makes buffer-or-name the current buffer, and also displays the buffer in the selected window. This means that a human can see the buffer and subsequent keyboard commands will apply to it. Contrast this with `set-buffer`, which makes buffer-or-name the current buffer but does not display it in the selected window. See section The Current Buffer.

If buffer-or-name does not identify an existing buffer, then a new buffer by that name is created.

Normally the specified buffer is put at the front of the buffer list. This affects the operation of `other-buffer`. However, if norecord is non-`nil`, this is not done. See section The Buffer List.

The `switch-to-buffer` function is often used interactively, as the binding of C-x b. It is also used frequently in programs. It always returns `nil`.

Command: **switch-to-buffer-other-window** *buffer-or-name*

This function makes buffer-or-name the current buffer and displays it in a window not currently selected. It then selects that window. The handling of the buffer is the same as in `switch-to-buffer`.

The previously selected window is absolutely never used to display the buffer. If it is the only window, then it is split to make a distinct window for this purpose. If the selected window is already displaying the buffer, then it continues to do so, but another window is nonetheless found to display it in as well.

Function: **pop-to-buffer** *buffer-or-name &optional other-window*

This function makes buffer-or-name the current buffer and switches to it in some window, preferably not the window previously selected. The "popped-to" window becomes the selected window.

If the variable `pop-up-frames` is non-`nil`, `pop-to-buffer` creates a new frame to display the buffer in. Otherwise, if the variable `pop-up-windows` is non-`nil`, windows may be split to create a new window that is different from the original window. For details, see section Choosing a Window.

If other-window is non-`nil`, `pop-to-buffer` finds or creates another window even if buffer-or-name is already visible in the selected window. Thus buffer-or-name could end up displayed in two windows. On the other hand, if buffer-or-name is already displayed in the selected window and other-window is `nil`, then the selected window is considered sufficient display for buffer-or-name, so that nothing needs to be done.

If buffer-or-name is a string that does not name an existing buffer, a buffer by that name is created.

An example use of this function is found at the end of section Process Filter Functions.

Choosing a Window

This section describes the basic facility which chooses a window to display a buffer in---`display-buffer`. All the higher-level functions and commands use this subroutine. Here we describe how to use `display-buffer` and how to customize it.

Function: **display-buffer** *buffer-or-name &optional not-this-window*

This function makes buffer-or-name appear in some window, like `pop-to-buffer`, but it does not select that window and does not make the buffer current. The identity of the selected window is unaltered by this function.

If not-this-window is non-`nil`, it means that the specified buffer should be displayed in a window other than the selected one, even if it is already on display in the selected window. This can cause the buffer to appear in two windows at once. Otherwise, if buffer-or-name is already being displayed in any window, that is good enough, so this function does nothing.

`display-buffer` returns the window chosen to display buffer-or-name.

Precisely how `display-buffer` finds or creates a window depends on the variables described below.

A window can be marked as "dedicated" to its buffer. Then `display-buffer` does not try to use that window.

Function: **window-dedicated-p** *window*

This function returns `t` if window is marked as dedicated; otherwise `nil`.

Function: **set-window-dedicated-p** *window flag*

This function marks window as dedicated if flags is non-`nil`, and nondedicated otherwise.

User Option: **pop-up-windows**

This variable controls whether `display-buffer` makes new windows. If it is non-`nil` and there is only one window, then that window is split. If it is `nil`, then `display-buffer` does not split the single window, but rather replaces its buffer.

User Option: **split-height-threshold**

This variable determines when `display-buffer` may split a window, if there are multiple windows. `display-buffer` splits the largest window if it has at least this many lines.

If there is only one window, it is split regardless of this value, provided `pop-up-windows` is non-`nil`.

User Option: **pop-up-frames**

This variable controls whether `display-buffer` makes new frames. If it is non-`nil`, `display-buffer` makes a new frame. If it is `nil`, then `display-buffer` either splits a window or reuses one.

If this is non-`nil`, the variables `pop-up-windows` and `split-height-threshold` do not matter.

See section Frames, for more information.

Variable: **pop-up-frame-function**

This variable specifies how to make a new frame if `pop-up-frame` is non-`nil`.

Its value should be a function of no arguments. When `display-buffer` makes a new frame, it does so by calling that function, which should return a frame. The default value of the variable is a function which creates a frame using parameters from `pop-up-frame-alist`.

Variable: **pop-up-frame-alist**

This variable holds an alist specifying frame parameters used when `display-buffer` makes a new frame. See section Frame Parameters, for more information about frame parameters.

Variable: **display-buffer-function**

This variable is the most flexible way to customize the behavior of `display-buffer`. If it is non-`nil`, it should be a function that `display-buffer` calls to do the work. The function should accept two arguments, the same two arguments that `display-buffer` received. It should choose or create a window, display the specified buffer, and then return the window.

This hook takes precedence over all the other options and hooks described above.

Window Point

Each window has its own value of point, independent of the value of point in other windows displaying the same buffer. This makes it useful to have multiple windows showing one buffer.

- The window point is established when a window is first created; it is initialized from the buffer's point, or from the window point of another window opened on the buffer if such a window exists.
- Selecting a window sets the value of point in its buffer to the window's value of point. Conversely, deselecting a window sets the window's value of point from that of the buffer. Thus, when you switch between windows that display a given buffer, the point value for the selected window is in effect in the buffer, while the point values for the other windows are stored in those windows.
- As long as the selected window displays the current buffer, the window's point and the buffer's point always move together; they remain equal.
- See section Positions, for more details on positions.

As far as the user is concerned, point is where the cursor is, and when the user switches to another buffer, the cursor jumps to the position of point in that buffer.

Function: **window-point** *window*

This function returns the current position of point in window. For a nonselected window, this is the value point would have (in that window's buffer) if that window were selected.

When window is the selected window and its buffer is also the current buffer, the value returned is the same as point in that buffer.

Strictly speaking, it would be more correct to return the "top-level" value of point, outside of any `save-excursion` forms. But that value is hard to find.

Function: **set-window-point** *window position*

This function positions point in window at position position in window's buffer.

The Window Start Position

Each window contains a marker used to keep track of a buffer position which specifies where in the buffer display should start. This position is called the display-start position of the window (or just the start). The character after this position is the one that appears at the upper left corner of the window. It is usually, but not inevitably, at the beginning of a text line.

Function: **window-start** *&optional window*

This function returns the display-start position of window window. If window is `nil`, the selected window is used.

```
(window-start)
     => 7058
```

For a more complicated example of use, see the description of `count-lines` in section Motion by Text Lines.

Function: **window-end** *&optional window*

This function returns the position of the end of the display in window window. If window is `nil`, the selected window is used.

Function: **set-window-start** *window position &optional noforce*

This function sets the display-start position of window to position in window's buffer.

The display routines insist that the position of point be visible when a buffer is displayed. Normally, they change the display-start position (that is, scroll the window) whenever necessary to make point visible. However, if you specify the start position with this function with `nil` for noforce, it means you want display to start at position even if that would put the location of point off the screen. What the display routines do in this case is move point instead, to the left margin on the middle line in the window.

For example, if point is 1 and you attempt to set the start of the window to 2, then the position of point would be "above" the top of the window. The display routines would automatically move point if it is still 1 when redisplay occurs. Here is an example:

```
;; Here is what `foo' looks like before executing
```

```
;;   the set-window-start expression.

---------- Buffer: foo ----------
-!-This is the contents of buffer foo.
2
3
4
5
6
---------- Buffer: foo ----------

(set-window-start
 (selected-window)
 (1+ (window-start)))

;; Here is what `foo' looks like after executing
;;   the set-window-start expression.

---------- Buffer: foo ----------
his is the contents of buffer foo.
2
3
-!-4
5
6
---------- Buffer: foo ----------

     => 2
```

However, when noforce is non-`nil`, `set-window-start` does nothing if the specified start position would make point invisible.

This function returns position, regardless of whether the noforce option caused that position to be overruled.

Function: **pos-visible-in-window-p** *&optional position window*

This function returns `t` if position is within the range of text currently visible on the screen in window. It returns `nil` if position is scrolled vertically out of view. The argument position defaults to the current position of point; window, to the selected window. Here is an example:

```
(or
(pos-visible-in-window-p
 (point) (selected-window))
   (recenter 0))
```

The `pos-visible-in-window-p` function considers only vertical scrolling. It returns `t` if position

is out of view only because window has been scrolled horizontally. See section Horizontal Scrolling.

Vertical Scrolling

Vertical scrolling means moving the text up or down in a window. It works by changing the value of the window's display-start location. It may also change the value of `window-point` to keep it on the screen.

In the commands `scroll-up` and `scroll-down`, the directions "up" and "down" refer to the motion of the text in the buffer at which you are looking through the window. Imagine that the text is written on a long roll of paper and that the scrolling commands move the paper up and down. Thus, if you are looking at text in the middle of a buffer and repeatedly call `scroll-down`, you will eventually see the beginning of the buffer.

Some people have urged that the opposite convention be used: they imagine that the window moves over text that remains in place. Then "down" commands would take you to the end of the buffer. This view is more consistent with the actual relationship between windows and the text in the buffer, but it is less like what the user sees. The position of a window on the terminal does not move, and short scrolling commands clearly move the text up or down on the screen. We have chosen names that fit the user's point of view.

The scrolling functions (aside from `scroll-other-window`) will have unpredictable results if the current buffer is different from the buffer that is displayed in the selected window. See section The Current Buffer.

Command: **scroll-up** *&optional count*

This function scrolls the text in the selected window upward count lines. If count is negative, scrolling is actually downward.

If count is `nil` (or omitted), then the length of scroll is `next-screen-context-lines` lines less than the usable height of the window (not counting its mode line).

`scroll-up` returns `nil`.

Command: **scroll-down** *&optional count*

This function scrolls the text in the selected window downward count lines. If count is negative, scrolling is actually upward.

If count is omitted or `nil`, then the length of the scroll is `next-screen-context-lines` lines less than the usable height of the window.

`scroll-down` returns `nil`.

Command: **scroll-other-window** *&optional count*

This function scrolls the text in another window upward count lines. Negative values of count, or `nil`, are handled as in `scroll-up`.

The window that is scrolled is normally the one following the selected window in the cyclic ordering of windows--the window that `next-window` would return. See section Cycling Ordering of Windows.

If the selected window is the minibuffer, the next window is normally the one at the top left corner. However, you can specify the window to scroll by binding the variable `minibuffer-scroll-window`. This variable has no effect when any other window is selected. See section Minibuffer Miscellany.

When the minibuffer is active, it is the next window if the selected window is the one at the bottom right corner. In this case, `scroll-other-window` attempts to scroll the minibuffer. If the minibuffer contains just one line, it has nowhere to scroll to, so the line reappears after the echo area momentarily displays the message "Beginning of buffer".

Variable: **other-window-scroll-buffer**

If this variable is non-`nil`, it tells `scroll-other-window` which buffer to scroll.

User Option: **scroll-step**

This variable controls how scrolling is done automatically when point moves off the screen. If the value is zero, then the text is scrolled so that point is centered vertically in the window. If the value is a positive integer n, then if it is possible to bring point back on screen by scrolling n lines in either direction, that is done; otherwise, point is centered vertically as usual. The default value is zero.

User Option: **next-screen-context-lines**

The value of this variable is the number of lines of continuity to retain when scrolling by full screens. For example, when `scroll-up` executes, this many lines that were visible at the bottom of the window move to the top of the window. The default value is `2`.

Command: **recenter** *&optional count*

This function scrolls the selected window to put the text where point is located at a specified vertical position within the window.

If count is a nonnegative number, it puts the line containing point count lines down from the top of the window. If count is a negative number, then it counts upward from the bottom of the window, so that -1 stands for the last usable line in the window. If count is a non-`nil` list, then it stands for the line in the middle of the window.

If count is `nil`, then it puts the line containing point in the middle of the window, then clears and redisplays the entire selected frame.

When `recenter` is called interactively, Emacs sets count to the raw prefix argument. Thus, typing C-u as the prefix sets the count to a non-`nil` list, while typing C-u 4 sets count to 4, which positions the current line four lines from the top.

Typing C-u 0 C-l positions the current line at the top of the window. This action is so handy that some people bind the command to a function key. For example,

```
(defun line-to-top-of-window ()
  "Scroll current line to top of window.
Replaces three keystroke sequence C-u 0 C-l."
  (interactive)
  (recenter 0))

(global-set-key "\C-cl" 'line-to-top-of-window)
```

Horizontal Scrolling

Because we read English first from top to bottom and second from left to right, horizontal scrolling is not like vertical scrolling. Vertical scrolling involves selection of a contiguous portion of text to display. Horizontal scrolling causes part of each line to go off screen. The amount of horizontal scrolling is therefore specified as a number of columns rather than as a position in the buffer. It has nothing to do with the display-start position returned by `window-start`.

Usually, no horizontal scrolling is in effect; then the leftmost column is at the left edge of the window. In this state, scrolling to the right is meaningless, since there is no data to the left of the screen to be revealed by it, so it is not allowed. Scrolling to the left is allowed; it causes the first columns of text to go off the edge of the window and can reveal additional columns on the right that were truncated before. Once a window has a nonzero amount of leftward horizontal scrolling, you can scroll it back to the right, but only so far as to reduce the net horizontal scroll to zero. There is no limit to how far left you can scroll, but eventually all the text will disappear off the left edge.

Command: **scroll-left** *count*

This function scrolls the selected window count columns to the left (or to the right if count is negative). The return value is the total amount of leftward horizontal scrolling in effect after the change--just like the value returned by `window-hscroll`.

Command: **scroll-right** *count*

This function scrolls the selected window count columns to the right (or to the left if count is negative). The return value is the total amount of leftward horizontal scrolling in effect after the change--just like the value returned by `window-hscroll`.

Once you scroll a window as far right as it can go, back to its normal position where the total leftward scrolling is zero, attempts to scroll any farther have no effect.

Function: **window-hscroll** *&optional window*

This function returns the total leftward horizontal scrolling of window---the number of columns by which the text in window is scrolled left past the left margin.

The value is never negative. It is zero when no horizontal scrolling has been done in window (which is usually the case).

If window is `nil`, the selected window is used.

```
(window-hscroll)
     => 0
(scroll-left 5)
     => 5
(window-hscroll)
     => 5
```

Function: **set-window-hscroll** *window columns*

This function sets the number of columns from the left margin that window is scrolled to the value of columns. The argument columns should be zero or positive; if not, it is taken as zero.

The value returned is columns.

```
(set-window-hscroll (selected-window) 10)
     => 10
```

Here is how you can determine whether a given position position is off the screen due to horizontal scrolling:

```
(save-excursion
  (goto-char position)
  (and
   (>= (- (current-column) (window-hscroll window)) 0)
   (< (- (current-column) (window-hscroll window))
      (window-width window))))
```

The Size of a Window

An Emacs window is rectangular, and its size information consists of the height (the number of lines) and the width (the number of character positions in each line). The mode line is included in the height. For a window that does not abut the right hand edge of the screen, the column of `|' characters that separates it from the window on the right is included in the width.

The following three functions return size information about a window:

Function: **window-height** *&optional window*

This function returns the number of lines in window, including its mode line. If window fills its entire frame, this is one less than the value of `frame-height` on that frame (since the last line is always reserved for the minibuffer).

If window is `nil`, the function uses the selected window.

```
(window-height)
     => 23
```

```
(split-window-vertically)
     => #<window 4 on windows.texi>
(window-height)
     => 11
```

Function: **window-width** *&optional window*

This function returns the number of columns in window. If window fills its entire frame, this is the same as the value of `frame-width` on that frame.

If window is `nil`, the function uses the selected window.

```
(window-width)
     => 80
```

Function: **window-edges** *&optional window*

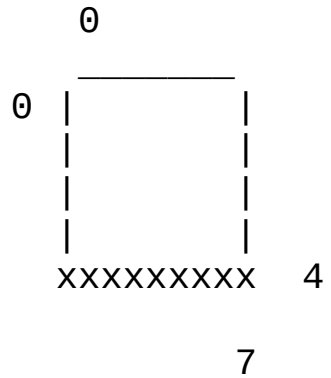
This function returns a list of the edge coordinates of window. If window is `nil`, the selected window is used.

The order of the list is `(left top right bottom)`, all elements relative to 0, 0 at the top left corner of the frame. The element right of the value is one more than the rightmost column used by window, and bottom is one more than the bottommost row used by window and its mode-line.

Here is the result obtained on a typical 24-line terminal with just one window:

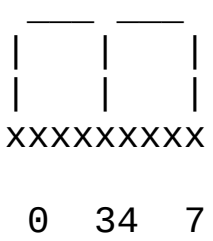
```
(window-edges (selected-window))
     => (0 0 80 23)
```

If window is at the upper left corner of its frame, right and bottom are the same as the values returned by `(window-width)` and `(window-height)` respectively, and top and bottom are zero. For example, the edges of the following window are `0 0 5 8'. Assuming that the frame has more than 8 columns, the last column of the window (column 7) holds a border rather than text. The last row (row 4) holds the mode line, shown here with `xxxxxxxxx'.



When there are side-by-side windows, any window not at the right edge of its frame has a border in its last column. This border counts as one column in the width of the window. A window never includes a border on its left, since the border there belongs to the window to the left.

In the following example, let's imagine that the frame is 7 columns wide. Then the edges of the left window are `0 0 4 3' and the edges of the right window are `4 0 7 3'.



Changing the Size of a Window

The window size functions fall into two classes: high-level commands that change the size of windows and low-level functions that access window size. Emacs does not permit overlapping windows or gaps between windows, so resizing one window affects other windows.

Command: **enlarge-window** *size &optional horizontal*

This function makes the selected window size lines bigger, stealing lines from neighboring windows. It takes the lines from one window at a time until that window is used up, then takes from another. If a window from which lines are stolen shrinks below `window-min-height` lines, then that window disappears.

If horizontal is non-`nil`, then this function makes window wider by size columns, stealing columns instead of lines. If a window from which columns are stolen shrinks below `window-min-width` columns, then that window disappears.

If the window's frame is smaller than size lines (or columns), then the function makes the window occupy the entire height (or width) of the frame.

If size is negative, this function shrinks the window by -size lines. If it becomes shorter than `window-min-height`, it disappears.

`enlarge-window` returns `nil`.

Command: **enlarge-window-horizontally** *columns*

This function makes the selected window columns wider. It could be defined as follows:

```
(defun enlarge-window-horizontally (columns)
  (enlarge-window columns t))
```

Command: **shrink-window** *size &optional horizontal*

This function is like `enlarge-window` but negates the argument size, making the selected window smaller by giving lines (or columns) to the other windows. If the window shrinks below `window-min-height` or `window-min-width`, then it disappears.

If size is negative, the window is enlarged by -size lines.

Command: **shrink-window-horizontally** *columns*

This function makes the selected window columns narrower. It could be defined as follows:

```
(defun shrink-window-horizontally (columns)
  (shrink-window columns t))
```

The following two variables constrain the window size changing functions to a minimum height and width.

User Option: **window-min-height**

The value of this variable determines how short a window may become before it disappears. A window disappears when it becomes smaller than `window-min-height`, and no window may be created that is smaller. The absolute minimum height is two (allowing one line for the mode line, and one line for the buffer display). Actions which change window sizes reset this variable to two if it is less than two. The default value is 4.

User Option: **window-min-width**

The value of this variable determines how narrow a window may become before it disappears. A window disappears when it becomes narrower than `window-min-width`, and no window may be created that is narrower. The absolute minimum width is one; any value below that is ignored. The default value is 10.

Coordinates and Windows

This section describes how to compare screen coordinates with windows.

Function: **window-at** *x y &optional frame*

This function returns the window containing the specified cursor position in the frame frame. The coordinates x and y are measured in characters and count from the top left corner of the screen or frame.

If you omit frame, the selected frame is used.

Function: **coordinates-in-window-p** *coordinates window*

This function checks whether a particular frame position falls within the window window.

The argument coordinates is a cons cell of this form:

```
(x . y)
```

The coordinates x and y are measured in characters, and count from the top left corner of the screen or frame.

The value of `coordinates-in-window-p` is non-`nil` if the coordinates are inside window. The

value also indicates what part of the window the position is in, as follows:

`(relx . rely)`
: The coordinates are inside window. The numbers relx and rely are the equivalent window-relative coordinates for the specified position, counting from 0 at the top left corner of the window.

`mode-line`
: The coordinates are in the mode line of window.

`vertical-split`
: The coordinates are in the vertical line between window and its neighbor to the right.

`nil`
: The coordinates are not in any sense within window.

The function `coordinates-in-window-p` does not require a frame as argument because it always uses the frame that window window is on.

Window Configurations

A window configuration records the entire layout of a frame--all windows, their sizes, which buffers they contain, what part of each buffer is displayed, and the values of point and the mark. You can bring back an entire previous layout by restoring a window configuration previously saved.

If you want to record all frames instead of just one, use a frame configuration instead of a window configuration. See section Frame Configurations.

Function: **current-window-configuration**

This function returns a new object representing Emacs's current window configuration, namely the number of windows, their sizes and current buffers, which window is the selected window, and for each window the displayed buffer, the display-start position, and the positions of point and the mark. An exception is made for point in the current buffer, whose value is not saved.

Function: **set-window-configuration** *configuration*

This function restores the configuration of Emacs's windows and buffers to the state specified by configuration. The argument configuration must be a value that was previously returned by `current-window-configuration`.

Here is a way of using this function to get the same effect as `save-window-excursion`:

```
(let ((config (current-window-configuration)))
  (unwind-protect
      (progn (split-window-vertically nil)
             ...)
    (set-window-configuration config)))
```

Special Form: **save-window-excursion** *forms...*

This special form executes forms in sequence, preserving window sizes and contents, including the w of point and the portion of the buffer which is visible. It also preserves the choice of selected windo However, it does not restore the value of point in the current buffer; use `save-excursion` for that.

The return value is the value of the final form in forms. For example:

```
(split-window)
     => #<window 25 on control.texi>
(setq w (selected-window))
     => #<window 19 on control.texi>
(save-window-excursion
  (delete-other-windows w)
  (switch-to-buffer "foo")
  'do-something)
     => do-something
     ;; The screen is now split again.
```

Function: **window-configuration-p** *object*

This function returns `t` if object is a window configuration.

Primitives to look inside of window configurations would make sense, but none are implemented. It is not clear they are useful enough to be worth implementing.

Go to the previous, next section.

Go to the previous, next section.

Frames

A frame is a rectangle on the screen that contains one or more Emacs windows. A frame initially contains a single main window (plus perhaps a minibuffer window) which you can subdivide vertically or horizontally into smaller windows.

When Emacs runs on a text-only terminal, it has just one frame, a terminal frame. There is no way to create another terminal frame after startup. If Emacs has an X display, it does not make a terminal frame; instead, it initially creates a single X window frame. You can create more; see section Creating Frames.

Function: **framep** *object*

This predicate returns `t` if object is a frame, and `nil` otherwise.

See section Emacs Display, for related information.

Creating Frames

To create a new frame, call the function `make-frame`.

Function: **make-frame** *alist*

This function creates a new frame, if the display mechanism permits creation of frames. (An X server does; an ordinary terminal does not.)

The argument is an alist specifying frame parameters. Any parameters not mentioned in alist default according to the value of the variable `default-frame-alist`; parameters not specified there either default from the standard X defaults file and X resources.

The set of possible parameters depends in principle on what kind of window system Emacs uses to display its the frames. See section X Window Frame Parameters, for documentation of individual parameters you can specify when creating an X window frame.

Variable: **default-frame-alist**

An alist specifying default values of frame parameters. Each element has the form:

```
(parameter . value)
```

If you use options that specify window appearance when you invoke Emacs, they take effect by adding elements to `default-frame-alist`.

Frame Parameters

A frame has many parameters that control how it displays.

Access to Frame Parameters

These functions let you read and change the parameter values of a frame.

Function: **frame-parameters** *frame*

The function `frame-parameters` returns an alist of all the parameters of frame.

Function: **modify-frame-parameters** *frame alist*

This function alters the parameters of frame frame based on the elements of alist. Each element of alist has the form `(parm . value)`, where parm is a symbol naming a parameter. If you don't mention a parameter in alist, its value doesn't change.

Initial Frame Parameters

You can specify the parameters for the initial startup frame by setting `initial-frame-alist` in your `` `.emacs' `` file.

Variable: **initial-frame-alist**

This variable's value is an alist of parameter values to when creating the initial X window frame.

If these parameters specify a separate minibuffer-only frame, and you have not created one, Emacs creates one for you.

Variable: **minibuffer-frame-alist**

This variable's value is an alist of parameter values to when creating an initial minibuffer-only frame--if such a frame is needed, according to the parameters for the main initial frame.

X Window Frame Parameters

Just what parameters a frame has depends on what display mechanism it uses. Here is a table of the parameters of an X window frame:

`name`
: The name of the frame.

`left`
: The screen position of the left edge, in pixels.

`top`
: The screen position of the top edge, in pixels.

`height`

The height of the frame contents, in pixels.

`width`

The width of the frame contents, in pixels.

`window-id`

The number of the X window for the frame.

`minibuffer`

Whether this frame has its own minibuffer. The value `t` means yes, `nil` means no, `only` means this frame is just a minibuffer, a minibuffer window (in some other frame) means the new frame uses that minibuffer.

`font`

The name of the font for text in the frame. This is a string.

`auto-raise`

Whether selecting the frame raises it (non-`nil` means yes).

`auto-lower`

Whether deselecting the frame lowers it (non-`nil` means yes).

`vertical-scroll-bars`

Whether the frame has a scroll bar for vertical scrolling (non-`nil` means yes).

`horizontal-scroll-bars`

Whether the frame has a scroll bar for horizontal scrolling (non-`nil` means yes). (Horizontal scroll bars are not currently implemented.)

`icon-type`

The type of icon to use for this frame when it is iconified. Non-`nil` specifies a bitmap icon, `nil` a text icon.

`foreground-color`

The color to use for the inside of a character. We use strings to designate colors; the X server defines the meaningful color names.

`background-color`

The color to use for the background of text.

`mouse-color`

The color for the mouse cursor.

`cursor-color`

The color for the cursor that shows point.

`border-color`

The color for the border of the frame.

`cursor-type`

The way to display the cursor. There are two legitimate values: `bar` and `box`. The value `bar` specifies a vertical bar between characters as the cursor. The value `box` specifies an ordinary black box overlaying the character after point; that is the default.

`border-width`

The width in pixels of the window border.

`internal-border-width`

The distance in pixels between text and border.

`unsplittable`

If non-`nil`, this frame's window is never split automatically.

`visibility`

The state of visibility of the frame. There are three possibilities: `nil` for invisible, `t` for visible, and `icon` for iconified. See section Visibility of Frames.

`menu-bar-lines`

The number of lines to allocate at the top of the frame for a menu bar. The default is zero. See section The Menu Bar.

`parent-id`

The X Window number of the window that should be the parent of this one. Specifying this lets you create an Emacs window inside some other application's window. (It is not certain this will be implemented; try it and see if it works.)

Frame Size And Position

You can read or change the size and position of a frame using the frame parameters `left`, `top`, `height` and `width`. When you create a frame, you must specify either both size parameters or neither. Likewise, you must specify either both position parameters or neither. Whatever geometry parameters you don't specify are chosen by the window manager in its usual fashion.

Here are some special features for working with sizes and positions:

Function: **set-frame-position** *frame left top*

This function sets the position of the top left corner of frame---to left and top. These arguments are measured in pixels, counting from the top left corner of the screen.

Function: **frame-height** *&optional frame*

Function: **frame-width** *&optional frame*

These functions return the height and width of frame, measured in characters. If you don't supply frame, they use the selected frame.

Function: **frame-pixel-height** *&optional frame*

Function: **frame-pixel-width** *&optional frame*

These functions return the height and width of frame, measured in pixels. If you don't supply frame, they use the selected frame.

Function: **frame-char-height** *&optional frame*

Function: **frame-char-width** *&optional frame*

These functions return the height and width, respectively, of a character in frame, measured in pixels. The values depend on the choice of font. If you don't supply frame, these functions use the selected frame.

Function: **set-frame-size** *frame cols rows*

This function sets the size of frame, measured in characters; cols and rows specify the new width and height.

To set the size with values measured in pixels, use `modify-frame-parameters` to set the `width` and `height` parameters. See section X Window Frame Parameters.

The old-fashioned functions `set-screen-height` and `set-screen-width`, which were used to specify the height and width of the screen in Emacs versions that did not support multiple frames, are still usable. They apply to the selected frame. See section Screen Size.

Function: **x-parse-geometry** *geom*

The function `x-parse-geometry` converts a standard X windows geometry string to an alist which you can use as part of the argument to `x-create-frame`.

The alist describes which parameters were specified in geom, and gives the values specified for them. Each element looks like `(parameter . value)`. The possible parameter values are `left`, `top`, `width`, and `height`.

```
(x-geometry "35x70+0-0")
     => ((width . 35) (height . 70) (left . 0) (top . -1))
```

Deleting Frames

Frames remain potentially visible until you explicitly delete them. A deleted frame cannot appear on the screen, but continues to exist as a Lisp object until there are no references to it. There is no way to cancel the deletion of a frame aside from restoring a saved frame configuration (see section Frame Configurations); this is similar to the way windows behave.

Command: **delete-frame** *&optional frame*

This function deletes the frame frame. By default, frame is the selected frame.

Function: **frame-live-p** *frame*

The function `frame-live-p` returns non-`nil` if the frame frame has not been deleted.

Finding All Frames

Function: **frame-list**

The function `frame-list` returns a list of all the frames that have not been deleted. It is analogous to `buffer-list` for buffers. The list that you get is newly created, so modifying the list doesn't have any effect on the internals of Emacs.

Function: **visible-frame-list**

This function returns a list of just the currently visible frames.

Function: **next-frame** *&optional frame minibuf*

The function `next-frame` lets you cycle conveniently through all the frames from an arbitrary starting point. It returns the "next" frame after frame in the cycle. If frame is omitted or `nil`, it defaults to the selected frame.

The second argument, minibuf, says which frames to consider:

`nil`
: Exclude minibuffer-only frames.

a window
: Consider only the frames using that particular window as their minibuffer.

anything else
: Consider all frames.

Frames and Windows

All the non-minibuffer windows in a frame are arranged in a tree of subdivisions; the root of this tree is available via the function `frame-root-window`. Each window is part of one and only one frame; you can get the frame with `window-frame`.

Function: **frame-root-window** *frame*

This returns the root window of frame frame.

Function: **window-frame** *window*

This function returns the frame that window is on.

At any time, exactly one window on any frame is selected within the frame. The significance of this designation is that selecting the frame also selects this window. You can get the frame's current selected window with `frame-selected-window`.

Function: **frame-selected-window** *frame*

This function returns the window on frame which is selected within frame.

Conversely, selecting a window for Emacs with `select-window` also makes that window selected within its frame. See section Selecting Windows.

Minibuffers and Frames

Normally, each frame has its own minibuffer window at the bottom, which is used whenever that frame is selected. If the frame has a minibuffer, you can get it with `minibuffer-window` (see section Minibuffer Miscellany).

However, you can also create a frame with no minibuffer. Such a frame must use the minibuffer window of some other frame. When you create the frame, you can specify explicitly the frame on which to find the minibuffer to use. If you don't, then the minibuffer is found in the frame which is the value of the variable `default-minibuffer-frame`. Its value should be a frame which does have a minibuffer.

Input Focus

At any time, one frame in Emacs is the selected frame. The selected window always resides on the selected frame.

Function: **selected-frame**

This function returns the selected frame.

The X server normally directs keyboard input to the X window that the mouse is in. Some window managers use mouse clicks or keyboard events to shift the focus to various X windows, overriding the normal behavior of the server.

Lisp programs can switch frames "temporarily" by calling the function `select-frame`. This does not override the window manager; rather, it escapes from the window manager's control until that control is somehow reasserted.

Function: **select-frame** *frame*

This function selects frame frame, temporarily disregarding the X Windows focus. The selection of frame lasts until the next time the user does something to select a different frame, or until the next time this function is called.

Emacs cooperates with the X server and the window managers by arranging to select frames according to what the server and window manager ask for. It does so by generating a special kind of input event, called a focus event. The command loop handles a focus event by calling `internal-select-frame`. See section Focus Events.

Function: **internal-select-frame** *frame*

This function selects frame frame, assuming that the X server focus already points to frame.

Focus events normally do their job by invoking this command. Don't call it for any other reason.

Visibility of Frames

A frame may be visible, invisible, or iconified. If it is visible, you can see its contents. If it is iconified, the frame's contents do not appear on the screen, but an icon does. If the frame is invisible, it doesn't show in the screen, not even as an icon.

Command: **make-frame-visible** *&optional frame*

This function makes frame frame visible. If you omit frame, it makes the selected frame visible.

Command: **make-frame-invisible** *&optional frame*

This function makes frame frame invisible. If you omit frame, it makes the selected frame invisible.

Command: **iconify-frame** *&optional frame*

This function iconifies frame frame. If you omit frame, it iconifies the selected frame.

Function: **frame-visible-p** *frame*

This returns the visibility status of frame frame. The value is `t` if frame is visible, `nil` if it is invisible, and `icon` if it is iconified.

The visibility status of a frame is also available as a frame parameter. You can read or change it as such. See section X Window Frame Parameters.

Raising and Lowering Frames

The X window system uses a desktop metaphor. Part of this metaphor is the idea that windows are stacked in a notional third dimension perpendicular to the screen surface, and thus ordered from "highest" to "lowest". Where two windows overlap, the one higher up covers the one underneath. Even a window at the bottom of the stack can be seen if no other window overlaps it.

A window's place in this ordering is not fixed; in fact, users tend to change the order frequently. Raising a window means moving it "up", to the top of the stack. Lowering a window means moving it to the bottom of the stack. This motion is in the notional third dimension only, and does not change the position of the window on the screen.

You can raise and lower Emacs's X windows with these functions:

Function: **raise-frame** *frame*

This function raises frame frame.

Function: **lower-frame** *frame*

This function lowers frame frame.

You can also specify auto-raise (raising automatically when a frame is selected) or auto-lower (lowering automatically when it is deselected) for any frame using frame parameters. See section X Window Frame

Parameters.

Frame Configurations

Function: **current-frame-configuration**

This function returns a frame configuration list which describes the current arrangement of frames, all their properties, and the window configuration of each one.

Function: **set-frame-configuration** *configuration*

This function restores the state of frames described in configuration.

Mouse Tracking

Sometimes it is useful to track the mouse, which means, to display something to indicate where the mouse is and move the indicator as the mouse moves. For efficient mouse tracking, you need a way to wait until the mouse actually moves.

The convenient way to track the mouse is to ask for events to represent mouse motion. Then you can wait for motion by waiting for an event. In addition, you can easily handle any other sorts of events that may occur. That is useful, because normally you don't want to track the mouse forever--only until some other event, such as the release of a button.

Special Form: **track-mouse** *body...*

Execute body, meanwhile generating input events for mouse motion. The code in body can read these events with `read-event` or `read-key-sequence`. See section Motion Events, for the format of mouse motion events.

The value of `track-mouse` is that of the last form in body.

The usual purpose of tracking mouse motion is to indicate on the screen the consequences of pushing or releasing a button at the current position.

Mouse Position

The new functions `mouse-position` and `set-mouse-position` give access to the current position of the mouse.

Function: **mouse-position**

This function returns a description of the position of the mouse. The value looks like `(frame x . y)`, where x and y are integers giving the position in pixels relative to the top left corner of the inside of frame.

Function: **set-mouse-position** *frame x y*

Thus function warps the mouse to position x, y in frame frame. The arguments x and y are integers, giving the position in pixels relative to the top left corner of the inside of frame.

Warping the mouse means changing the screen position of the mouse as if the user had moved the physical mouse--thus simulating the effect of actual mouse motion.

Pop-Up Menus

Function: **x-popup-menu** *position menu*

This function displays a pop-up menu and returns an indication of what selection the user makes.

The argument position specifies where on the screen to put the menu. It can be either a mouse button event (which says to put the menu where the user actuated the button) or a list of this form:

```
((xoffset yoffset) window)
```

where xoffset and yoffset are positions measured in characters, counting from the top left corner of window's frame.

The argument menu says what to display in the menu. It can be a keymap or a list of keymaps (see section Menu Keymaps). Alternatively, it can have the following form:

```
(title pane1 pane2...)
```

where each pane is a list of form

```
(title (line item)...)
```

Each line should be a string, and each item should be the value to return if that line is chosen.

X Selections

The X server records a set of selections which permit transfer of data between application programs. The various selections are distinguished by selection types, represented in Emacs by symbols. X clients including Emacs can read or set the selection for any given type.

Function: **x-set-selection** *type data*

This function sets a "selection" in the X server. It takes two arguments: a selection type type, and the value to assign to it, data. If data is `nil`, it means to clear out the selection. Otherwise, data may be a string, a symbol, an integer (or a cons of two integers or list of two integers), or a cons of two markers pointing to the same buffer. In the last case, the selection is considered to be the text between the markers. The data may also be a vector of valid non-vector selection values.

Each possible type has its own selection value, which changes independently. The usual values of type are `PRIMARY` and `SECONDARY`; these are symbols with upper-case names, in accord with X Windows

conventions. The default is `PRIMARY`.

Function: **x-get-selection** *type data-type*

This function accesses selections set up by Emacs or by other X clients. It takes two optional arguments, type and data-type. The default for type, the selection type, is `PRIMARY`.

The data-type argument specifies the form of data conversion to use, to convert the raw data obtained from another X client into Lisp data. Meaningful values include `TEXT`, `STRING`, `TARGETS`, `LENGTH`, `DELETE`, `FILE_NAME`, `CHARACTER_POSITION`, `LINE_NUMBER`, `COLUMN_NUMBER`, `OWNER_OS`, `HOST_NAME`, `USER`, `CLASS`, `NAME`, `ATOM`, and `INTEGER`. (These are symbols with upper-case names in accord with X conventions.) The default for data-type is `STRING`.

The X server also has a set of numbered cut buffers which can store text or other data being moved between applications. Cut buffers are considered obsolete, but Emacs supports them for the sake of X clients that still use them.

Function: **x-get-cut-buffer** *n*

This function returns the contents of cut buffer number n.

Function: **x-set-cut-buffer** *string*

This function stores string into the first cut buffer (cut buffer 0), moving the other values down through the series of cut buffers, kill-ring-style.

X Server

This section describes how to access and change the overall status of the X server Emacs is using.

X Connections

You can close the connection with the X server with the function `x-close-current-connection`, and open a new one with `x-open-connection` (perhaps with a different server and display).

Function: **x-close-current-connection**

This function closes the connection to the X server. It deletes all frames, making Emacs effectively inaccessible to the user; therefore, a Lisp program that closes the connection should open another one.

Function: **x-open-connection** *display &optional resource-string*

This function opens a connection to an X server, for use of display display.

The optional argument resource-string is a string of resource names and values, in the same format used in the `` `.Xresources' `` file. The values you specify override the resource values recorded in the X server itself. Here's an example of what this string might look like:

```
"*BorderWidth: 3\n*InternalBorder: 2\n"
```

Function: **x-color-display-p**

This returns `t` if the connected X display has color, and `nil` otherwise.

Function: **x-color-defined-p** *color*

This function reports whether a color name is meaningful and supported on the X display Emacs is using. It returns `t` if the display supports that color; otherwise, `nil`.

Black-and-white displays support just two colors, `"black"` or `"white"`. Color displays support many other colors.

Function: **x-synchronize** *flag*

The function `x-synchronize` enables or disables synchronous communication with the X server. It enables synchronous communication if flag is non-`nil`, and disables it if flag is `nil`.

In synchronous mode, Emacs waits for a response to each X protocol command before doing anything else. This is useful for debugging Emacs, because protocol errors are reported right away, which helps you find the erroneous command. Synchronous mode is not the default because it is much slower.

Resources

Function: **x-get-resource** *attribute &optional name class*

The function `x-get-resource` retrieves a resource value from the X Windows defaults database.

Resources are indexed by a combination of a key and a class. This function searches using a key of the form `instance.attribute', where instance is the name under which Emacs was invoked, and uses `Emacs' as the class.

The optional arguments component and subclass add to the key and the class, respectively. You must specify both of them or neither. If you specify them, the key is `instance.component.attribute', and the class is `Emacs.subclass'.

Rebinding X Server Keys

The X server allows each client to specify what sequence of characters each keyboard key should generate, depending on the set of shift keys held down. Emacs has functions to redefine these sequences in the X server. Redefinitions via `x-rebind-key` apply only to Emacs. Other clients using the same X server are not affected.

Function: **x-rebind-key** *keysym modifiers newstring*

This function redefines a keyboard key in the X server. keysym is a string which conforms to the X keysym definitions found in `` `X11/keysymdef.h' ``, but without the prefix `XK_`. modifiers is either `nil`, meaning no modifier keys, or a list of names of modifier keys, again using the names from `` `X11/keysymdef.h' `` but without the `XK_` prefix.

The third argument, newstring, is the new definition of the key. It is the sequence of characters that the

key should produce as input.

For example,

```
(x-rebind-key "F1" nil "abc")
```

causes the F1 function key to generate the string `"abc"`. Similarly,

```
(x-rebind-key "BackSpace"
              (list "Shift" "Control_L" "c-s-BackSpace")
```

makes the BS key send the string `"c-s-BackSpace"` if either the shift key or the left-hand control key is held down.

Function: **x-rebind-keys** *keysym strings*

This function redefines the complete meaning of a single keyboard key, specifying the behavior for each of the 16 shift masks independently.

The argument keysym specifies the key to rebind, as in `x-rebind-key`.

The argument strings is a list of 16 elements, one for each possible shift mask value; the nth element says how to redefine the key keycode with shift mask value n. If element n is a string, it is the new definition for shift mask n. If element n is `nil`, the definition for shift mask n is unchanged.

Data about the X Server

This section describes functions and a variable that you can use to get information about the capabilities and origin of the X server that Emacs is displaying its frames on.

Function: **x-display-screens**

This function returns the number of screens associated with the current display.

Function: **x-server-version**

This function returns the list of version numbers of the X server in use.

Function: **x-server-vendor**

This function returns the vendor supporting the X server in use.

Function: **x-display-pixel-height**

This function returns the height of this X screen in pixels.

Function: **x-display-mm-height**

This function returns the height of this X screen in millimeters.

Function: **x-display-pixel-width**

This function returns the width of this X screen in pixels.

Function: **x-display-mm-width**

This function returns the width of this X screen in millimeters.

Function: **x-display-backing-store**

This function returns the backing store capability of this screen. Values can be the symbols `always`, `when-mapped`, or `not-useful`.

Function: **x-display-save-under**

This function returns non-`nil` if this X screen supports the SaveUnder feature.

Function: **x-display-planes**

This function returns the number of planes this display supports.

Function: **x-display-visual-class**

This function returns the visual class for this X screen. The value is one of the symbols `static-gray`, `gray-scale`, `static-color`, `pseudo-color`, `true-color`, and `direct-color`.

Function: **x-display-color-p**

This function returns `t` if the X screen in use is a color screen.

Function: **x-display-color-cells**

This function returns the number of color cells this X screen supports.

Variable: **x-no-window-manager**

This variable's value is is `t` if no X window manager is in use.

Go to the previous, next section.

Go to the previous, next section.

Positions

A position is the index of a character in the text of buffer. More precisely, a position identifies the place between two characters (or before the first character, or after the last character), so we can speak of the character before or after a given position. However, the character after a position is often said to be "at" that position.

Positions are usually represented as integers starting from 1, but can also be represented as markers---special objects which relocate automatically when text is inserted or deleted so they stay with the surrounding characters. See section Markers.

Point

Point is a special buffer position used by many editing commands, including the self-inserting typed characters and text insertion functions. Other commands move point through the text to allow editing and insertion at different places.

Like other positions, point designates a place between two characters (or before the first character, or after the last character), rather than a particular character. Many terminals display the cursor over the character that immediately follows point; on such terminals, point is actually before the character on which the cursor sits.

The value of point is a number between 1 and the buffer size plus 1. If narrowing is in effect (see section Narrowing), then point is constrained to fall within the accessible portion of the buffer (possibly at one end of it).

Each buffer has its own value of point, which is independent of the value of point in other buffers. Each window also has a value of point, which is independent of the value of point in other windows on the same buffer. This is why point can have different values in various windows that display the same buffer. When a buffer appears in only one window, the buffer's point and the window's point normally have the same value, so the distinction is rarely important. See section Window Point, for more details.

Function: **point**

This function returns the position of point in the current buffer, as an integer.

```
(point)
     => 175
```

Function: **point-min**

This function returns the minimum accessible value of point in the current buffer. This is 1, unless narrowing is in effect, in which case it is the position of the start of the region that you narrowed to. (See section Narrowing.)

Function: **point-max**

This function returns the maximum accessible value of point in the current buffer. This is `(1+ (buffer-size))`, unless narrowing is in effect, in which case it is the position of the end of the region that you narrowed to. (See section Narrowing).

Function: **buffer-end** *flag*

This function returns `(point-min)` if flag is less than 1, `(point-max)` otherwise. The argument flag must be a number.

Function: **buffer-size**

This function returns the total number of characters in the current buffer. In the absence of any narrowing (see section Narrowing), `point-max` returns a value one larger than this.

```
(buffer-size)
     => 35
(point-max)
     => 36
```

Variable: **buffer-saved-size**

The value of this buffer-local variable is the former length of the current buffer, as of the last time it was read in, saved or auto-saved.

Motion

Motion functions change the value of point, either relative to the current value of point, relative to the beginning or end of the buffer, or relative to the edges of the selected window. See section Point.

Motion by Characters

These functions move point based on a count of characters. `goto-char` is a fundamental primitive because it is the way to move point to a specified position.

Command: **goto-char** *position*

This function sets point in the current buffer to the value position. If position is less than 1, then point is set to the beginning of the buffer. If it is greater than the length of the buffer, then point is set to the end of the buffer.

If narrowing is in effect, then the position is still measured from the beginning of the buffer, but point cannot be moved outside of the accessible portion. Therefore, if position is too small, point is set to the beginning of the accessible portion of the text; if position is too large, point is set to the end.

When this function is called interactively, position is the numeric prefix argument, if provided; otherwise it is read from the minibuffer.

`goto-char` returns position.

Command: **forward-char** *&optional count*

This function moves point forward, towards the end of the buffer, count characters (or backward, towards the beginning of the buffer, if count is negative). If the function attempts to move point past the beginning or end of the buffer (or the limits of the accessible portion, when narrowing is in effect), an error is signaled with error code `beginning-of-buffer` or `end-of-buffer`.

In an interactive call, count is the numeric prefix argument.

Command: **backward-char** *&optional count*

This function moves point backward, towards the beginning of the buffer, count characters (or forward, towards the end of the buffer, if count is negative). If the function attempts to move point past the beginning or end of the buffer (or the limits of the accessible portion, when narrowing is in effect), an error is signaled with error code `beginning-of-buffer` or `end-of-buffer`.

In an interactive call, count is the numeric prefix argument.

Motion by Words

These functions for parsing words use the syntax table to decide whether a given character is part of a word. See section Syntax Tables.

Command: **forward-word** *count*

This function moves point forward count words (or backward if count is negative). Normally it returns `t`. If this motion encounters the beginning or end of the buffer, or the limits of the accessible portion when narrowing is in effect, point stops there and the value is `nil`.

In an interactive call, count is set to the numeric prefix argument.

Command: **backward-word** *count*

This function just like `forward-word`, except that it moves backward until encountering the front of a word, rather than forward.

In an interactive call, count is set to the numeric prefix argument.

This function is rarely used in programs, as it is more efficient to call `forward-word` with negative argument.

Variable: **words-include-escapes**

This variable affects the behavior of `forward-word` and everything that uses it. If it is non-`nil`, then characters in the "escape" and "character quote" syntax classes count as part of words. Otherwise, they do not.

Motion to an End of the Buffer

To move point to the beginning of the buffer, write:

```
(goto-char (point-min))
```

Likewise, to move to the end of the buffer, use:

```
(goto-char (point-max))
```

Here are two commands which users use to do these things. They are documented here to warn you not to use them in Lisp programs, because they set the mark and display messages in the echo area.

Command: **beginning-of-buffer** *&optional n*

This function moves point to the beginning of the buffer (or the limits of the accessible portion, when narrowing is in effect), setting the mark at the previous position. If n is non-`nil`, then it puts point n tenths of the way from the beginning of the buffer.

In an interactive call, n is the numeric prefix argument, if provided; otherwise n defaults to `nil`.

Don't use this function in Lisp programs!

Command: **end-of-buffer** *&optional n*

This function moves point to the end of the buffer (or the limits of the accessible portion, when narrowing is in effect), setting the mark at the previous position. If n is non-`nil`, then it puts point n tenths of the way from the end.

In an interactive call, n is the numeric prefix argument, if provided; otherwise n defaults to `nil`.

Don't use this function in Lisp programs!

Motion by Text Lines

Text lines are portions of the buffer delimited by newline characters, which are regarded as part of the previous line. The first text line begins at the beginning of the buffer, and the last text line ends at the end of the buffer whether or not the last character is a newline. The division of the buffer into text lines is not affected by the width of the window, or by how tabs and control characters are displayed.

Command: **goto-line** *line*

This function moves point to the front of the lineth line, counting from line 1 at beginning of buffer. If line is less than 1, then point is set to the beginning of the buffer. If line is greater than the number of lines in the buffer, then point is set to the *end of the last line* of the buffer.

If narrowing is in effect, then line still counts from the beginning of the buffer, but point cannot go outside the accessible portion. So point is set at the beginning or end of the accessible portion of the text if the line number specifies a position that is inaccessible.

The return value of `goto-line` is the difference between line and the line number of the line to wh point actually was able move (before taking account of any narrowing). Thus, the value is positive if scan encounters the end of the buffer.

In an interactive call, line is the numeric prefix argument if one has been provided. Otherwise line is read in the minibuffer.

Command: **beginning-of-line** *&optional count*

This function moves point to the beginning of the current line. With an argument count not `nil` or 1, it moves forward count-1 lines and then to the beginning of the line.

If this function reaches the end of the buffer (or of the accessible portion, if narrowing is in effect), it positions point at the beginning of the last line. No error is signaled.

Command: **end-of-line** *&optional count*

This function moves point to the end of the current line. With an argument count not `nil` or 1, it moves forward count-1 lines and then to the end of the line.

If this function reaches the end of the buffer (or of the accessible portion, if narrowing is in effect), it positions point at the end of the last line. No error is signaled.

Command: **forward-line** *&optional count*

This function moves point forward count lines, to the beginning of the line. If count is negative, it moves point -count lines backward, to the beginning of the line.

If the beginning or end of the buffer (or of the accessible portion) is encountered before that many lines are found, then point stops at the beginning or end. No error is signaled.

`forward-line` returns the difference between count and the number of lines actually moved. If you attempt to move down five lines from the beginning of a buffer that has only three lines, point will positioned at the end of the last line, and the value will be 2.

In an interactive call, count is the numeric prefix argument.

Function: **count-lines** *start end*

This function returns the number of lines between the positions start and end in the current buffer. If start and end are equal, then it returns 0. Otherwise it returns at least 1, even if start and end are on the same line. This is because the text between them, considered in isolation, must contain at least one line unless it is empty.

Here is an example of using `count-lines`:

```
(defun current-line ()
  "Return the vertical position of point
in the selected window.  Top line is 0.
Counts each text line only once, even if it wraps."
  (+ (count-lines (window-start) (point))
```

```
    (if (= (current-column) 0) 1 0)
    -1))
```

Also see the functions `bolp` and `eolp` in section Examining Text Near Point. These functions do not move point, but test whether it is already at the beginning or end of a line.

Motion by Screen Lines

The line functions in the previous section count text lines, delimited only by newline characters. By contrast, these functions count screen lines, which are defined by the way the text appears on the screen. A text line is a single screen line if it is short enough to fit the width of the selected window, but otherwise it may occupy several screen lines.

In some cases, text lines are truncated on the screen rather than continued onto additional screen lines. Then `vertical-motion` moves point just like `forward-line`. See section Truncation.

Because the width of a given string depends on the flags which control the appearance of certain characters, `vertical-motion` will behave differently on a given piece of text found in different buffers. It will even act differently in different windows showing the same buffer, because the width may differ and so may the truncation flag. See section Usual Display Conventions.

Function: **vertical-motion** *count*

This function moves point to the start of the screen line count screen lines down from the screen line containing point. If count is negative, it moves up instead.

This function returns the number of lines moved. The value may be less in absolute value than count if the beginning or end of the buffer was reached.

Command: **move-to-window-line** *count*

This function moves point with respect to the text currently displayed in the selected window. Point is moved to the beginning of the screen line count screen lines from the top of the window. If count is negative, point moves either to the beginning of the line -count lines from the bottom or else to the last line of the buffer if the buffer ends above the specified screen position.

If count is `nil`, then point moves to the beginning of the line in the middle of the window. If the absolute value of count is greater than the size of the window, then point moves to the place which would appear on that screen line if the window were tall enough. This will probably cause the next redisplay to scroll to bring that location onto the screen.

In an interactive call, count is the numeric prefix argument.

The value returned is the window line number, with the top line in the window numbered 0.

The User-Level Vertical Motion Commands

A goal column is useful if you want to edit text such as a table in which you want to move point to a certain column on each line. The goal column affects the vertical text line motion commands, `next-line` and `previous-line`. See section 'Basic Editing Commands' in The GNU Emacs Manual.

User Option: **goal-column**

This variable holds an explicitly specified goal column for vertical line motion commands. If it is an integer, it specifies a column, and these commands try to move to that column on each line. If it is `nil`, then the commands set their own goal columns. Any other value is invalid.

Variable: **temporary-goal-column**

This variable holds the temporary goal column during a sequence of consecutive vertical line motion commands. It is overridden by `goal-column` if that is non-`nil`. It is set each time a vertical motion command is invoked, unless the previous command was also a vertical motion command.

User Option: **track-eol**

This variable controls how the vertical line motion commands operate when starting at the end of a line. If `track-eol` is non-`nil`, then vertical motion starting at the end of a line will keep to the ends of lines. This means moving to the end of each line moved onto. The value of `track-eol` has no effect if point is not at the end of a line when the first vertical motion command is given.

`track-eol` has its effect by causing `temporary-goal-column` to be set to 9999 instead of to the current column.

Command: **set-goal-column** *unset*

This command sets the variable `goal-column` to specify a permanent goal column for the vertical line motion commands. If unset is `nil`, then `goal-column` is set to the current column of point. If unset is non-`nil`, then `goal-column` is set to `nil`.

This function is intended for interactive use; and in an interactive call, unset is the raw prefix argument.

Moving over Balanced Expressions

Here are several functions concerned with balanced-parenthesis expressions (also called sexps in connection with moving across them in Emacs). The syntax table controls how these functions interpret various characters; see section Syntax Tables. See section Parsing Balanced Expressions, for lower-level primitives for scanning sexps or parts of sexps. For user-level commands, see section 'Lists and Sexps' in GNU Emacs Manual.

Command: **forward-list** *arg*

Move forward across arg balanced groups of parentheses. (Other syntactic entities such as words or paired string quotes are ignored.)

Command: **backward-list** *arg*

Move backward across arg balanced groups of parentheses. (Other syntactic entities such as words or paired string quotes are ignored.)

Command: **up-list** *arg*

Move forward out of arg levels of parentheses. A negative argument means move backward but still to a less deep spot.

Command: **down-list** *arg*

Move forward down arg levels of parentheses. A negative argument means move backward but still go down arg level.

Command: **forward-sexp** *arg*

Move forward across arg balanced expressions. Balanced expressions include both those delimited by parentheses and other kinds, such as words and string constants. For example,

```
---------- Buffer: foo ----------
(concat-!- "foo " (car x) y z)
---------- Buffer: foo ----------

(forward-sexp 3)
     => nil

---------- Buffer: foo ----------
(concat "foo " (car x) y-!- z)
---------- Buffer: foo ----------
```

Command: **backward-sexp** *arg*

Move backward across arg balanced expressions.

Skipping Characters

The following two functions move point over a specified set of characters. For example, they are often used to skip whitespace. For related functions, see section Motion and Syntax.

Function: **skip-chars-forward** *character-set &optional limit*

This function moves point in the current buffer forward, skipping over a given set of characters. Emacs first examines the character following point; if it matches character-set, then point is advanced and the next character is examined. This continues until a character is found that does not match. The function returns `nil`.

The argument character-set is like the inside of a `[...]' in a regular expression except that `]' is never special and `\' quotes `^', `-' or `\'. Thus, `"a-zA-Z"` skips over all letters, stopping before the first

nonletter, and "^a-zA-Z" skips nonletters stopping before the first letter. See section Regular Expressions.

If limit is supplied (it must be a number or a marker), it specifies the maximum position in the buffer that point can be skipped to. Point will stop at or before limit.

In the following example, point is initially located directly before the `T'. After the form is evaluated, point is located at the end of that line (between the `t' of `hat' and the newline). The function skips all letters and spaces, but not newlines.

```
---------- Buffer: foo ----------
I read "-!-The cat in the hat
comes back" twice.
---------- Buffer: foo ----------

(skip-chars-forward "a-zA-Z ")
     => nil

---------- Buffer: foo ----------
I read "The cat in the hat-!-
comes back" twice.
---------- Buffer: foo ----------
```

Function: **skip-chars-backward** *character-set &optional limit*

This function moves point backward, skipping characters that match character-set. It just like `skip-chars-forward` except for the direction of motion.

Excursions

It is often useful to move point "temporarily" within a localized portion of the program, or to switch buffers temporarily. This is called an excursion, and it is done with the `save-excursion` special form. This construct saves the current buffer and its values of point and the mark so they can be restored after the completion of the excursion.

The forms for saving and restoring the configuration of windows are described elsewhere (see section Window Configurations, and see section Frame Configurations).

Special Form: **save-excursion** *forms...*

The `save-excursion` special form saves the identity of the current buffer and the values of point and the mark in it, evaluates forms, and finally restores the buffer and its saved values of point and the mark. All three saved values are restored even in case of an abnormal exit via throw or error (see section Nonlocal Exits).

The `save-excursion` special form is the standard way to switch buffers or move point within one part of a program and avoid affecting the rest of the program. It is used more than 500 times in the Lisp

sources of Emacs.

The values of point and the mark for other buffers are not saved by `save-excursion`, so any changes made to point and the mark in the other buffers will remain in effect after `save-excursion` exits.

Likewise, `save-excursion` does not restore window-buffer correspondences altered by functions such as `switch-to-buffer`. One way to restore these correspondences, and the selected window, is to use `save-window-excursion` inside `save-excursion` (see section Window Configurations).

The value returned by `save-excursion` is the result of the last of forms, or `nil` if no forms are given.

```
(save-excursion
  forms)
==
(let ((old-buf (current-buffer))
      (old-pnt (point-marker))
      (old-mark (copy-marker (mark-marker))))
  (unwind-protect
      (progn forms)
    (set-buffer old-buf)
    (goto-char old-pnt)
    (set-marker (mark-marker) old-mark)))
```

Narrowing

Narrowing means limiting the text addressable by Emacs editing commands to a limited range of characters in a buffer. The text that remains addressable is called the accessible portion of the buffer.

Narrowing is specified with two buffer positions which become the beginning and end of the accessible portion. For most editing commands these positions replace the values of the beginning and end of the buffer. While narrowing is in effect, no text outside the accessible portion is displayed, and point cannot move outside the accessible portion.

Values such as positions or line numbers which usually count from the beginning of the buffer continue to do so, but the functions which use them will refuse to operate on text that is inaccessible.

The commands for saving buffers are unaffected by narrowing; the entire buffer is saved regardless of the any narrowing.

Command: **narrow-to-region** *start end*

This function sets the accessible portion of the current buffer to start at start and end at end. Both arguments should be character positions.

In an interactive call, start and end are set to the bounds of the current region (point and the mark, with the smallest first).

Command: **narrow-to-page** *move-count*

This function sets the accessible portion of the current buffer to include just the current page. An optional first argument move-count non-`nil` means to move forward or backward by move-count pages and then narrow.

In an interactive call, move-count is set to the numeric prefix argument.

Command: **widen**

This function cancels any narrowing in the current buffer, so that the entire contents are accessible. This is called widening. It is equivalent to the following expression:

```
(narrow-to-region 1 (1+ (buffer-size)))
```

Special Form: **save-restriction** *body...*

This special form saves the current bounds of the accessible portion, evaluates the body forms, and finally restores the saved bounds, thus restoring the same state of narrowing (or absence thereof) formerly in effect. The state of narrowing is restored even in the event of an abnormal exit via throw or error (see section Nonlocal Exits). Therefore, this construct is a clean way to narrow a buffer temporarily.

The value returned by `save-restriction` is that returned by the last form in body, or `nil` if no body forms were given.

Caution: it is easy to make a mistake when using the `save-restriction` function. Read the entire description here before you try it.

If body changes the current buffer, `save-restriction` still restores the restrictions on the original buffer (the buffer they came from), but it does not restore the identity of the current buffer.

Point and the mark are *not* restored by this special form; use `save-excursion` for that. If you use both `save-restriction` and `save-excursion` together, `save-excursion` should come first (on the outside). Otherwise, the old point value would be restored with temporary narrowing still in effect. If the old point value were outside the limits of the temporary narrowing, this would fail to restore it accurately.

The `save-restriction` special form records the values of the beginning and end of the accessible portion as distances from the beginning and end of the buffer. In other words, it records the amount of inaccessible text before and after the accessible portion.

This technique yields correct results if body does further narrowing. However, `save-restriction` can become confused if they widen and then make changes outside the area of the saved narrowing. When this is what you want to do, `save-restriction` is not the right tool for the job. Here is what you must use instead:

```
(let ((beg (point-min-marker))
      (end (point-max-marker)))
```

```
  (unwind-protect
      (progn body)
    (save-excursion
      (set-buffer (marker-buffer beg))
      (narrow-to-region beg end))))
```

Here is a simple example of correct use of `save-restriction`:

```
---------- Buffer: foo ----------
This is the contents of foo
This is the contents of foo
This is the contents of foo-!-
---------- Buffer: foo ----------

(save-excursion
  (save-restriction
    (goto-char 1)
    (forward-line 2)
    (narrow-to-region 1 (point))
    (goto-char (point-min))
    (replace-string "foo" "bar")))

---------- Buffer: foo ----------
This is the contents of bar
This is the contents of bar
This is the contents of foo-!-
---------- Buffer: foo ----------
```

Markers

A marker is a Lisp object used to specify a position in a buffer relative to the surrounding text. A marker changes its offset from the beginning of the buffer automatically whenever text is inserted or deleted, so that it stays with the two characters on either side of it.

Overview of Markers

A marker specifies a buffer and a position in that buffer. The marker can be used to represent a position in the functions that require one, just as an integer could be used. See section Positions, for a complete description of positions.

A marker has two attributes: the marker position, and the marker buffer. The marker position is an integer which is equivalent (at the moment) to the marker as a position in that buffer; however, as text is inserted or deleted in the buffer, the marker is relocated, so that its integer equivalent changes. The idea is that a marker positioned between two characters in a buffer will remain between those two characters despite any changes made to the contents of the buffer; thus, a marker's offset from the beginning of a buffer may change often during the life of the marker.

If the text around a marker is deleted, the marker is repositioned between the characters immediately before and after the deleted text. If text is inserted at the position of a marker, the marker remains in front of the new text unless it is inserted with `insert-before-markers` (see section Insertion). When text is inserted or deleted somewhere before the marker position (not next to the marker), the marker moves back and forth with the two neighboring characters.

When a buffer is modified, all of its markers must be checked so that they can be relocated if necessary. This slows processing in a buffer with a large number of markers. For this reason, it is a good idea to make a marker point nowhere if you are sure you don't need it any more. Unreferenced markers will eventually be garbage collected, but until then will continue to be updated if they do point somewhere.

Because it is quite common to perform arithmetic operations on a marker position, most of the arithmetic operations (including `+` and `-`) accept markers as arguments. In such cases, the current position of the marker is used.

Here are examples of creating markers, setting markers, and moving point to markers:

```
;; Make a new marker that initially does not point anywhere:
(setq m1 (make-marker))
     => #<marker in no buffer>

;; Set m1 to point between the 100th and 101st characters
;;   in the current buffer:
(set-marker m1 100)
```

```
     => #<marker at 100 in markers.texi>

;; Now insert one character at the beginning of the buffer:
(goto-char (point-min))
     => 1
(insert "Q")
     => nil

;; m1 is updated appropriately.
m1
     => #<marker at 101 in markers.texi>

;; Two markers that point to the same position
;;   are not eq, but they are equal.
(setq m2 (copy-marker m1))
     => #<marker at 101 in markers.texi>
(eq m1 m2)
     => nil
(equal m1 m2)
     => t

;; When you are finished using a marker, make it point nowhere.
(set-marker m1 nil)
     => #<marker in no buffer>
```

Predicates on Markers

You can test an object to see whether it is a marker, or whether it is either an integer or a marker. The latter test is useful when you are using the arithmetic functions that work with both markers and integers.

Function: **markerp** *object*

This function returns `t` if object is a marker, `nil` otherwise. In particular, integers are not markers, even though many functions will accept either a marker or an integer.

Function: **integer-or-marker-p** *object*

This function returns `t` if object is an integer or a marker, `nil` otherwise.

Function: **number-or-marker-p** *object*

This function returns `t` if object is a number (of any type) or a marker, `nil` otherwise.

Functions That Create Markers

When you create a new marker, you can make it point nowhere, or point to the present position of point, or to the beginning or end of the accessible portion of the buffer, or to the same place as another given marker.

Function: **make-marker**

This functions returns a newly allocated marker that does not point anywhere.

```
(make-marker)
     => #<marker in no buffer>
```

Function: **point-marker**

This function returns a new marker that points to the present position of point in the current buffer. See section Point. For an example, see `copy-marker`, below.

Function: **point-min-marker**

This function returns a new marker that points to the beginning of the accessible portion of the buffer. This will be the beginning of the buffer unless narrowing is in effect. See section Narrowing.

Function: **point-max-marker**

This function returns a new marker that points to the end of the accessible portion of the buffer. This will be the end of the buffer unless narrowing is in effect. See section Narrowing.

Here are examples of this function and `point-min-marker`, shown in a buffer containing a version of the source file for the text of this chapter.

```
(point-min-marker)
     => #<marker at 1 in markers.texi>
(point-max-marker)
     => #<marker at 15573 in markers.texi>

(narrow-to-region 100 200)
     => nil
(point-min-marker)
     => #<marker at 100 in markers.texi>
(point-max-marker)
     => #<marker at 200 in markers.texi>
```

Function: **copy-marker** *marker-or-integer*

If passed a marker as its argument, `copy-marker` returns a new marker that points to the same place and the same buffer as does marker-or-integer. If passed an integer as its argument, `copy-marker` returns a new marker that points to position marker-or-integer in the current buffer.

If passed an argument that is an integer whose value is less than 1, `copy-marker` returns a new marker that points to the beginning of the current buffer. If passed an argument that is an integer whose value is greater than the length of the buffer, then `copy-marker` returns a new marker that points to the end of the buffer.

An error is signaled if marker is neither a marker nor an integer.

```
(setq p (point-marker))
     => #<marker at 2139 in markers.texi>

(setq q (copy-marker p))
     => #<marker at 2139 in markers.texi>

(eq p q)
     => nil

(equal p q)
     => t

(copy-marker 0)
     => #<marker at 1 in markers.texi>

(copy-marker 20000)
     => #<marker at 7572 in markers.texi>
```

Information from Markers

This section describes the functions for accessing the components of a marker object.

Function: **marker-position** *marker*

This function returns the position that marker points to, or `nil` if it points nowhere.

Function: **marker-buffer** *marker*

This function returns the buffer that marker points into, or `nil` if it points nowhere.

```
(setq m (make-marker))
     => #<marker in no buffer>
(marker-position m)
     => nil
(marker-buffer m)
     => nil

(set-marker m 3770 (current-buffer))
     => #<marker at 3770 in markers.texi>
```

```
(marker-buffer m)
     => #<buffer markers.texi>
(marker-position m)
     => 3770
```

Two distinct markers will be found `equal` (even though not `eq`) to each other if they have the same position and buffer, or if they both point nowhere.

Changing Markers

This section describes how to change the position of an existing marker. When you do this, be sure you know whether the marker is used outside of your program, and, if so, what effects will result from moving it--otherwise, confusing things may happen in other parts of Emacs.

Function: **set-marker** *marker position &optional buffer*

This function moves marker to position in buffer. If buffer is not provided, it defaults to the current buffer.

If position is less than 1, `set-marker` moves marker to the beginning of the buffer. If the value of position is greater than the size of the buffer, `set-marker` moves marker to the end of the buffer. If position is `nil` or a marker that points nowhere, then marker is set to point nowhere.

The value returned is marker.

```
(setq m (point-marker))
     => #<marker at 4714 in markers.texi>
(set-marker m 55)
     => #<marker at 55 in markers.texi>
(setq b (get-buffer "foo"))
     => #<buffer foo>
(set-marker m 0 b)
     => #<marker at 1 in foo>
```

Function: **move-marker** *marker position &optional buffer*

This is another name for `set-marker`.

The Mark

A special marker in each buffer is designated the mark. It records a position for the user for the sake of commands such as C-w and C-x TAB. Lisp programs should set the mark only to values that have a potential use to the user, and never for their own internal purposes. For example, the `replace-regexp` command sets the mark to the value of point before doing any replacements, because this enables the user to move back there conveniently after the replace is finished.

Many commands are designed so that when called interactively they operate on the text between point

and the mark. If you are writing such a command, don't examine the mark directly; instead, use `interactive` with the `r' specification. This will provide the values of point and the mark as arguments to the command in an interactive call, but will permit other Lisp programs to specify arguments explicitly. See section Code Characters for `interactive`.

Each buffer has its own value of the mark that is independent of the value of the mark in other buffers. When a buffer is created, the mark exists but does not point anywhere. We consider this state as "the absence of a mark in that buffer".

Once the mark "exists" in a buffer, it normally never ceases to exist. However, it may become inactive, if Transient Mark mode is enabled. The variable `mark-active`, which is always local in all buffers, indicates whether the mark is active: non-`nil` means yes. A command can request deactivation of the mark upon return to the editor command loop by setting `deactivate-mark` to a non-`nil` value (but this deactivation only follows if Transient Mark mode is enabled).

The main motivation for using Transient Mark mode is that this mode also enables highlighting of the region when the mark is active. See section Emacs Display.

In addition to the mark, each buffer has a mark ring which is a list of markers that are the previous values of the mark. When editing commands change the mark, they should normally save the old value of the mark on the mark ring. The mark ring may contain no more than the maximum number of entries specified by the variable `mark-ring-max`; excess entries are discarded on a first-in-first-out basis.

Function: **mark** *&optional force*

This function returns the position of the current buffer's mark as an integer.

Normally, if the mark is inactive `mark` signals an error. However, if force is non-`nil`, then it returns the mark position anyway--or `nil`, if the mark is not yet set for this buffer.

Function: **mark-marker**

This function returns the current buffer's mark. This is the very marker which records the mark location inside Emacs, not a copy. Therefore, changing this marker's position will directly affect the position of the mark. Don't do it unless that is the effect you want.

```
(setq m (mark-marker))
     => #<marker at 3420 in markers.texi>
(set-marker m 100)
     => #<marker at 100 in markers.texi>
(mark-marker)
     => #<marker at 100 in markers.texi>
```

Like any marker, this marker can be set to point at any buffer you like. We don't recommend that you make it point at any buffer other than the one of which it is the mark. If you do, it will yield perfectly consistent, if rather odd, results.

Function: **set-mark** *position*

This function sets the mark to position, and activates the mark. The old value of the mark is *not* pushed onto the mark ring.

Please note: use this function only if you want the user to see that the mark has moved, and you want the previous mark position to be lost. Normally, when a new mark is set, the old one should go on the `mark-ring`. For this reason, most applications should use `push-mark` and `pop-mark`, not `set-mark`.

Novice Emacs Lisp programmers often try to use the mark for the wrong purposes. The mark saves a location for the user's convenience. An editing command should not alter the mark unless altering the mark is part of the user-level functionality of the command. (And, in that case, this effect should be documented.) To remember a location for internal use in the Lisp program, store it in a Lisp variable. For example:

```
(let ((beg (point)))
  (forward-line 1)
  (delete-region beg (point))).
```

Variable: **mark-ring**

The value of this buffer-local variable is the list of saved former marks of the current buffer, most recent first.

```
mark-ring
=> (#<marker at 11050 in markers.texi>
    #<marker at 10832 in markers.texi>
    ...)
```

User Option: **mark-ring-max**

The value of this variable is the maximum size of `mark-ring`. If more marks than this are pushed onto the `mark-ring`, it discards marks on a first-in, first-out basis.

Function: **push-mark** *&optional position nomsg activate*

This function sets the current buffer's mark to position, and pushes a copy of the previous mark onto `mark-ring`. If position is `nil`, then the value of point is used. `push-mark` returns `nil`.

The function `push-mark` normally *does not* activate the mark. To do that, specify `t` for the argument activate.

A `Mark set' message is displayed unless nomsg is non-`nil`.

Function: **pop-mark**

This function pops off the top element of `mark-ring` and makes that mark become the buffer's actual mark. This does not change the buffer's point, and does nothing if `mark-ring` is empty. It deactivates the mark.

The return value is not useful.

User Option: **transient-mark-mode**

This variable enables Transient Mark mode, in which every buffer-modifying primitive sets `deactivate-mark`. The consequence of this is that commands that modify the buffer normally cause the mark to become inactive.

Variable: **deactivate-mark**

If an editor command sets this variable non-`nil`, then the editor command loop deactivates the mark after the command returns.

Variable: **mark-active**

The mark is active when this variable is non-`nil`. This variable is always local in each buffer.

Variable: **activate-mark-hook**

Variable: **deactivate-mark-hook**

These normal hooks are run, respectively, when the mark becomes active and when it becomes inactive. The hook `activate-mark-hook` is also run at the end of a command if the mark is active and the region may have changed.

The Region

The text between point and the mark is known as the region. Various functions operate on text delimited by point and the mark, but only those functions specifically related to the region itself are described here.

Function: **region-beginning**

This function returns the position of the beginning of the region (as an integer). This is the position of either point or the mark, whichever is smaller.

If the mark does not point anywhere, an error is signaled.

Function: **region-end**

This function returns the position of the end of the region (as an integer). This is the position of either point or the mark, whichever is larger.

If the mark does not point anywhere, an error is signaled.

Few programs need to use the `region-beginning` and `region-end` functions. A command designed to operate on a region should instead use `interactive` with the `r' specification, so that the same function can be called with explicit bounds arguments from programs. (See section Code Characters for `interactive`.)

Go to the previous, next section.

Go to the previous, next section.

Text

This chapter describes the functions that deal with the text in a buffer. Most examine, insert or delete text in the current buffer, often in the vicinity of point. Many are interactive. All the functions that change the text provide for undoing the changes (see section Undo).

Many text-related functions operate on a region of text defined by two buffer positions passed in arguments named start and end. These arguments should be either markers (see section Markers) or or numeric character positions (see section Positions). The order of these arguments does not matter; it is all right for start to be the end of the region and end the beginning. For example, `(delete-region 1 10)` and `(delete-region 10 1)` perform identically. An `args-out-of-range` error is signaled if either start or end is outside the accessible portion of the buffer. In an interactive call, point and the mark are used for these arguments.

Throughout this chapter, "text" refers to the characters in the buffer.

Examining Text Near Point

Many functions are provided to look at the characters around point. Several simple functions are described here. See also `looking-at` in section Regular Expression Searching.

Function: **char-after** *position*

This function returns the character in the current buffer at (i.e., immediately after) position position. If position is out of range for this purpose, either before the beginning of the buffer, or at or beyond the end, then the value is `nil`.

Remember that point is always between characters, and the terminal cursor normally appears over the character following point. Therefore, the character returned by `char-after` is the character the cursor is over.

In the following example, assume that the first character in the buffer is `@':

```
(char-to-string (char-after 1))
     => "@"
```

Function: **following-char**

This function returns the character following point in the current buffer. This is similar to `(char-after (point))`. However, if point is at the end of the buffer, then the result of `following-char` is 0.

In this example, point is between the `a' and the `c'.

```
---------- Buffer: foo ----------
Gentlemen may cry "Pea-!-ce! Peace!,"
but there is no peace.
---------- Buffer: foo ----------

(char-to-string (preceding-char))
     => "a"
(char-to-string (following-char))
     => "c"
```

Function: **preceding-char**

This function returns the character preceding point in the current buffer. See above, under `following-char`, for an example. If point is at the beginning of the buffer, then the result of `preceding-char` is 0.

Function: **bobp**

This function returns `t` if point is at the beginning of the buffer. If narrowing is in effect, this means the beginning of the accessible portion of the text. See also `point-min` in section Point.

Function: **eobp**

This function returns `t` if point is at the end of the buffer. If narrowing is in effect, this means the end of accessible portion of the text. See also `point-max` in See section Point.

Function: **bolp**

This function returns `t` if point is at the beginning of a line. See section Motion by Text Lines.

Function: **eolp**

This function returns `t` if point is at the end of a line. The end of the buffer is always considered the end of a line.

Examining Buffer Contents

This section describes two functions that allow a Lisp program to convert any portion of the text in the buffer into a string.

Function: **buffer-substring** *start end*

This function returns a string containing a copy of the text of the region defined by positions start and end in the current buffer. If the arguments are not positions in the accessible portion of the buffer, Emacs signals an `args-out-of-range` error.

It is not necessary for start to be less than end; the arguments can be given in either order. But most often the smaller argument is written first.

```
---------- Buffer: foo ----------
This is the contents of buffer foo

---------- Buffer: foo ----------

(buffer-substring 1 10)
=> "This is t"
(buffer-substring (point-max) 10)
=> "he contents of buffer foo
"
```

Function: **buffer-string**

This function returns the contents of the accessible portion of the current buffer as a string. This is the portion between `(point-min)` and `(point-max)` (see section Narrowing).

```
---------- Buffer: foo ----------
This is the contents of buffer foo

---------- Buffer: foo ----------

(buffer-string)
     => "This is the contents of buffer foo
"
```

Comparing Text

This function lets you compare portions of the text in a buffer, without copying them into strings first.

Function: **compare-buffer-substrings** *buffer1 start1 end1 buffer2 start2 end2*

This function lets you compare two substrings of the same buffer or two different buffers. The first three arguments specify one substring, giving a buffer and two positions within the buffer. The last three arguments specify the other substring in the same way. You can use `nil` for buffer1, buffer2 or both to stand for the current buffer.

The value is negative if the first substring is less, positive if the first is greater, and zero if they are equal. The absolute value of the result is one plus the index of the first differing characters within the substrings.

This function ignores case when comparing characters if `case-fold-search` is non-`nil`.

Suppose the current buffer contains the text `foobarbar haha!rara!'; then in this example the two substrings are `rbar ' and `rara!'. The value is 2 because the first substring is greater at the second character.

```
(compare-buffer-substring nil 6 11 nil 16 21)
```

```
=> 2
```

This function does not exist in Emacs version 18 and earlier.

Insertion

Insertion takes place at point. Markers pointing at positions after the insertion point are relocated with the surrounding text (see section Markers). When a marker points at the place of insertion, it is normally not relocated, so that it points to the beginning of the inserted text; however, when `insert-before-markers` is used, all such markers are relocated to point after the inserted text.

Point may end up either before or after inserted text, depending on the function used. If point is left after the inserted text, we speak of insertion before point.

Each of these functions signals an error if the current buffer is read-only.

Function: **insert** *&rest args*

This function inserts the strings and/or characters args into the current buffer, at point, moving point forward. An error is signaled unless all args are either strings or characters. The value is `nil`.

Function: **insert-before-markers** *&rest args*

This function inserts the strings and/or characters args into the current buffer, at point, moving point forward. An error is signaled unless all args are either strings or characters. The value is `nil`.

This function is unlike the other insertion functions in that a marker whose position initially equals point is relocated to come after the newly inserted text.

Function: **insert-char** *character count*

This function inserts count instances of character into the current buffer before point. count must be a number, and character must be a character. The value is `nil`.

Function: **insert-buffer-substring** *from-buffer-or-name &optional start end*

This function inserts a substring of the contents of buffer from-buffer-or-name (which must already exist) into the current buffer before point. The text inserted consists of the characters in the region defined by start and end (These arguments default to the beginning and end of the accessible portion of that buffer). The function returns `nil`.

In this example, the form is executed with buffer `bar' as the current buffer. We assume that buffer `bar' is initially empty.

```
---------- Buffer: foo ----------
We hold these truths to be self-evident, that all
---------- Buffer: foo ----------

(insert-buffer-substring "foo" 1 20)
```

```
     => nil

---------- Buffer: bar ----------
We hold these truth
---------- Buffer: bar ----------
```

User-Level Insertion Commands

This section describes higher-level commands for inserting text, commands intended primarily for the user but useful also in Lisp programs.

Command: **insert-buffer** *from-buffer-or-name*

This function inserts the entire contents of from-buffer-or-name (which must exist) into the current buffer after point. It leaves the mark after the inserted text. The value is `nil`.

Command: **self-insert-command** *count*

This function inserts the last character typed count times and returns `nil`. Most printing characters are bound to this command. In routine use, `self-insert-command` is the most frequently called function in Emacs, but programs rarely use it except to install it on a keymap.

In an interactive call, count is the numeric prefix argument.

This function calls `auto-fill-function` if the current column number is greater than the value of `fill-column` and the character inserted is a space (see section Auto Filling).

This function performs abbrev expansion if Abbrev mode is enabled and the inserted character does not have word-constituent syntax. (See section Abbrevs And Abbrev Expansion, and section Table of Syntax Classes.)

This function is also responsible for calling `blink-paren-function` when the inserted character has close parenthesis syntax (see section Blinking).

Command: **newline** *&optional number-of-newlines*

This function inserts newlines into the current buffer before point. If number-of-newlines is supplied, that many newline characters are inserted.

In Auto Fill mode, `newline` can break the preceding line if number-of-newlines is not supplied. When this happens, it actually inserts two newlines at different places: one at point, and another earlier in the line. `newline` does not auto-fill if number-of-newlines is non-`nil`.

The value returned is `nil`. In an interactive call, count is the numeric prefix argument.

Command: **split-line**

This function splits the current line, moving the portion of the line after point down vertically, so that it is on the next line directly below where it was before. Whitespace is inserted as needed at the beginning of

the lower line, using the `indent-to` function. `split-line` returns the position of point.

Programs hardly ever use this function.

Variable: **overwrite-mode**

This variable controls whether overwrite mode is in effect: a non-`nil` value enables the mode. It is automatically made buffer-local when set in any fashion.

Deletion of Text

All of the deletion functions operate on the current buffer, and all return a value of `nil`. In addition to these functions, you can also delete text using the "kill" functions that save it in the kill ring; some of these functions save text in the kill ring in some cases but not in the usual case. See section The Kill Ring.

Function: **erase-buffer**

This function deletes the entire text of the current buffer, leaving it empty. If the buffer is read-only, it signals a `buffer-read-only` error. Otherwise, it deletes the text without asking for any confirmation. The value is always `nil`.

Normally, deleting a large amount of text from a buffer inhibits further auto-saving of that buffer "because it has shrunk". However, `erase-buffer` does not do this, the idea being that the future text is not really related to the former text, and its size should not be compared with that of the former text.

Command: **delete-region** *start end*

This function deletes the text in the current buffer in the region defined by start and end. The value is `nil`.

Command: **delete-char** *count &optional killp*

This function deletes count characters directly after point, or before point if count is negative. If killp is non-`nil`, then it saves the deleted characters in the kill ring.

In an interactive call, count is the numeric prefix argument, and killp is the unprocessed prefix argument. Therefore, if a prefix argument is supplied, the text is saved in the kill ring. If no prefix argument is supplied, then one character is deleted, but not saved in the kill ring.

The value returned is always `nil`.

Command: **delete-backward-char** *count &optional killp*

This function deletes count characters directly before point, or after point if count is negative. If killp is non-`nil`, then it saves the deleted characters in the kill ring.

In an interactive call, count is the numeric prefix argument, and killp is the unprocessed prefix argument. Therefore, if a prefix argument is supplied, the text is saved in the kill ring. If no prefix argument is supplied, then one character is deleted, but not saved in the kill ring.

The value returned is always `nil`.

Command: **backward-delete-char-untabify** *count &optional killp*

This function deletes count characters backward, changing tabs into spaces. When the next character to be deleted is a tab, it is first replaced with the proper number of spaces to preserve alignment and then one of those spaces is deleted instead of the tab. If killp is non-`nil`, then the command saves the deleted characters in the kill ring.

If count is negative, then tabs are not changed to spaces, and the characters are deleted by calling `delete-backward-char` with count.

In an interactive call, count is the numeric prefix argument, and killp is the unprocessed prefix argument. Therefore, if a prefix argument is supplied, the text is saved in the kill ring. If no prefix argument is supplied, then one character is deleted, but not saved in the kill ring.

The value returned is always `nil`.

User-Level Deletion Commands

This section describes higher-level commands for deleting text, commands intended primarily for the user but useful also in Lisp programs.

Command: **delete-horizontal-space**

This function deletes all spaces and tabs around point. It returns `nil`.

In the following examples, assume that `delete-horizontal-space` is called four times, once on each line, with point between the second and third characters on the line.

```
---------- Buffer: foo ----------
I -!-thought
I -!-     thought
We-!- thought
Yo-!-u thought
---------- Buffer: foo ----------

(delete-horizontal-space)   ; Four times.
     => nil

---------- Buffer: foo ----------
Ithought
Ithought
Wethought
You thought
---------- Buffer: foo ----------
```

Command: **delete-indentation** *&optional join-following-p*

This function joins the line point is on to the previous line, deleting any whitespace at the join and in some cases replacing it with one space. If join-following-p is non-`nil`, `delete-indentation` joins this line to the following line instead. The value is `nil`.

If there is a fill prefix, and the second of the lines being joined starts with the prefix, then `delete-indentation` deletes the fill prefix before joining the lines.

In the example below, point is located on the line starting `events', and it makes no difference if there are trailing spaces in the preceding line.

```
---------- Buffer: foo ----------
When in the course of human
-!-    events, it becomes necessary
---------- Buffer: foo ----------

(delete-indentation)
     => nil

---------- Buffer: foo ----------
When in the course of human-!- events, it becomes necessary
---------- Buffer: foo ----------
```

After the lines are joined, the function `fixup-whitespace` is responsible for deciding whether to leave a space at the junction.

Function: **fixup-whitespace**

This function replaces white space between the objects on either side of point with either one space or no space as appropriate. It returns `nil`.

The appropriate amount of space is none at the beginning or end of the line. Otherwise, it is one space except when point is before a character with close parenthesis syntax or after a character with open parenthesis or expression-prefix syntax. See section Table of Syntax Classes.

In the example below, when `fixup-whitespace` is called the first time, point is before the word `spaces' in the first line. It is located directly after the `(' for the second invocation.

```
---------- Buffer: foo ----------
This has too many     -!-spaces
This has too many spaces at the start of (-!-   this list)
---------- Buffer: foo ----------

(fixup-whitespace)
     => nil
(fixup-whitespace)
     => nil
```

```
---------- Buffer: foo ----------
This has too many spaces
This has too many spaces at the start of (this list)
---------- Buffer: foo ----------
```

Command: **just-one-space**

This command replaces any spaces and tabs around point with a single space. It returns `nil`.

Command: **delete-blank-lines**

This function deletes blank lines surrounding point. If point is on a blank line with one or more blank lines before or after it, then all but one of them are deleted. If point is on an isolated blank line, then it is deleted. If point is on a nonblank line, the command deletes all blank lines following it.

A blank line is defined as a line containing only tabs and spaces.

`delete-blank-lines` returns `nil`.

The Kill Ring

Kill functions delete text like the deletion functions, but save it so that the user can reinsert it by yanking. Most of these functions have `kill-' in their name. By contrast, the functions whose names start with `delete-' normally do not save text for yanking (though they can still be undone); these are "deletion" functions.

Most of the kill commands are primarily for interactive use, and are not described here. What we do describe are the functions provided for use in writing such commands. When deleting text for internal purposes within a Lisp function, you should normally use deletion functions, so as not to disturb the kill ring contents. See section Deletion of Text.

Emacs saves the last several batches of killed text in a list. We call it the kill ring because, in yanking, the elements are considered to be in a cyclic order. The list is kept in the variable `kill-ring`, and can be operated on with the usual functions for lists; there are also specialized functions, described in this section, which treat it as a ring.

Some people think use of the word "kill" in Emacs is unfortunate, since it refers to processes which specifically *do not* destroy the entities "killed". This is in sharp contrast to ordinary life, in which death is permanent and "killed" entities do not come back to life. Therefore, other metaphors have been proposed. For example, the term "cut ring" makes sense to people who, in pre-computer days, used scissors and paste to cut up and rearrange manuscripts. However, it would be difficult to change now.

Kill Ring Concepts

The kill ring records killed text as strings in a list. A short kill ring, for example, might look like this:

```
("some text" "a different piece of text" "yet more text")
```

New entries in the kill ring go at the front of the list. When the list reaches `kill-ring-max` entries in length, adding a new entry automatically deletes the last entry.

When kill commands are interwoven with other commands, the killed portions of text are put into separate entries in the kill ring. But when two or more kill commands are executed in succession, the text they kill forms a single entry, because the second and subsequent consecutive kill commands append to the entry made by the first one.

The user can reinsert or yank text from any element in the kill ring. One of the entries in the ring is considered the "front", and the simplest yank command yanks that entry. Other yank commands "rotate" the ring by designating other entries as the "front".

Functions for Killing

`kill-region` is the usual subroutine for killing text. Any command that calls this function is a "kill command" (and should probably have `kill' in its name). `kill-region` puts the newly killed text in a new element at the beginning of the kill ring or adds it to the most recent element. It uses the `last-command` variable to keep track of whether the previous was a kill command, and in such cases appends the killed text to the most recent entry.

Command: **kill-region** *start end*

This function kills the text in the region defined by start and end. The text is deleted but saved in the kill ring. The value is always `nil`.

In an interactive call, start and end are point and the mark.

If the buffer is read-only, `kill-region` modifies the kill ring just the same, then signals an error without modifying the buffer. This is convenient because it lets the user use all the kill commands to copy text into the kill ring from a read-only buffer.

Command: **copy-region-as-kill** *start end*

This function saves the region defined by start and end on the kill ring, but does not delete the text from the buffer. It returns `nil`. It also indicates the extent of the text copied by moving the cursor momentarily, or by displaying a message in the echo area.

Don't use this command in Lisp programs; use `kill-new` or `kill-append` instead. See section Low Level Kill Ring.

In an interactive call, start and end are point and the mark.

Functions for Yanking

Command: **yank** *&optional arg*

This function inserts the text in the first entry in the kill ring directly before point. After the yank, the mark is positioned at the beginning and point is positioned after the end of the inserted text.

If arg is a list (which occurs interactively when the user types C-u with no digits), then `yank` inserts text as described above, but puts point before the yanked text and puts the mark after it. If arg is a number, then `yank` inserts the argth most recently killed text.

`yank` does not alter the contents of the kill ring or rotate it. It returns `nil`.

Command: **yank-pop** *arg*

This function replaces the just-yanked text with another batch of killed text--another element of the kill ring.

This command is allowed only immediately after a `yank` or a `yank-pop`. At such a time, the region contains text that was just inserted by the previous `yank`. `yank-pop` deletes that text and inserts in its place a different stretch of killed text. The text that is deleted is not inserted into the kill ring, since it is already in the kill ring somewhere.

If arg is `nil`, then the existing region contents are replaced with the previous element of the kill ring. If arg is numeric, then the argth previous kill is the replacement. If arg is negative, a more recent kill is the replacement.

The sequence of kills in the kill ring wraps around, so that after the oldest one comes the newest one, and before the newest one goes the oldest.

The value is always `nil`.

Low Level Kill Ring

These functions and variables provide access to the kill ring at a lower level, but still convenient for use in Lisp programs. They take care of interaction with X Window selections. They do not exist in Emacs version 18.

Function: **current-kill** *n &optional do-not-move*

The function `current-kill` rotates the yanking pointer in the kill ring by n places, and returns the text at that place in the ring.

If the optional second argument do-not-move is non-`nil`, then `current-kill` doesn't alter the yanking pointer; it just returns the nth kill forward from the current yanking pointer.

If n is zero, indicating a request for the latest kill, `current-kill` calls the value of `interprogram-paste-function` (documented below) before consulting the kill ring.

Function: **kill-new** *string*

This function puts the text string into the kill ring as a new entry at the front of the ring. It also discards the oldest entry if appropriate. It also invokes the value of `interprogram-cut-function` (see below).

Function: **kill-append** *string before-p*

This function appends the text string to the first entry in the kill ring. Normally string goes at the end of

the entry, but if before-p is non-`nil`, it goes at the beginning. This function also invokes the value of `interprogram-cut-function` (see below).

Variable: **interprogram-paste-function**

This variable provides a way of transferring killed text from other programs, when you are using a window system. Its value should be `nil` or a function of no arguments.

If the value is a function, it is called when the "most recent kill" value is called for. If the function returns a non-`nil` values, then that value is used as the "most recent kill". If it returns `nil`, then the first element of the kill ring is used.

Variable: **interprogram-cut-function**

This variable provides a way of communicating killed text to and from other programs, when you are using a window system. Its value should be `nil` or a function of one argument.

If the value is a function, it is called whenever the "most recent kill" is changed, with the new string of killed text as an argument.

Internals of the Kill Ring

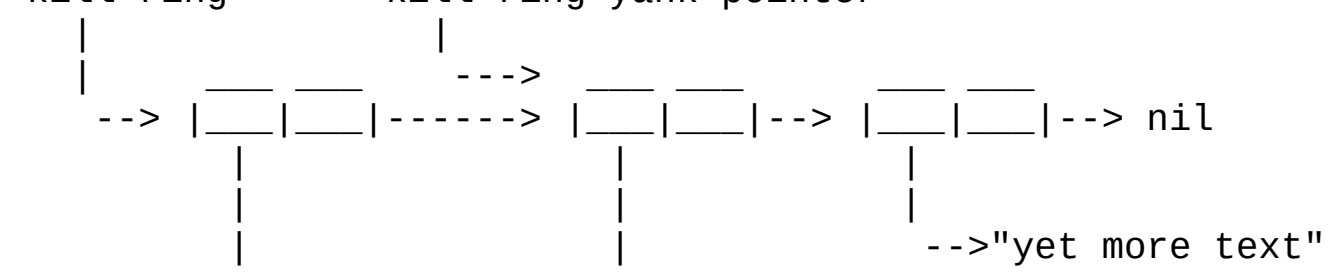
The variable `kill-ring` holds the kill ring contents, in the form of a list of strings. The most recent kill is always at the front of the list.

The `kill-ring-yank-pointer` variable points to a link in the kill ring list, whose CAR is the text that yank functions should copy. Moving `kill-ring-yank-pointer` to a different link is called rotating the kill ring. We call the kill ring a "ring" because the functions that move the yank pointer wrap around from the end of the list to the beginning, or vice-versa. Rotating the ring does not change the value of `kill-ring`.

Both `kill-ring` and `kill-ring-yank-pointer` are Lisp variables whose values are normally lists. The word "pointer" in the name of the `kill-ring-yank-pointer` indicates that the variable's purpose is to identify one element of the list for use by the next yank command.

The value of `kill-ring-yank-pointer` is always `eq` to one of the links in the kill ring list. The element it identifies is the CAR of that link. Commands which change the text in the kill ring also set this variable from `kill-ring`. The effect is to rotate the ring so that the newly killed text is at front.

Here is a diagram that shows the variable `kill-ring-yank-pointer` pointing to the second entry in the kill ring `("some text" "a different piece of text" "yet more text")`.



```
        |                  |
        |                   --> "a different piece of text"
        |
         --> "some text"
```

This circumstance might occur after C-y (`yank`) immediately followed by M-y (`yank-pop`).

Variable: **kill-ring**

List of killed text sequences, most recently killed first.

Variable: **kill-ring-yank-pointer**

This variable's value indicates which element of the kill ring is at the "front" of the ring for yanking. More precisely, the value is a sublist of the value of `kill-ring`, and its CAR is the kill string that C-y should yank.

User Option: **kill-ring-max**

The value of this variable is the maximum length to which the kill ring can grow, before elements are thrown away at the end. The default value for `kill-ring-max` is 30.

Undo

Most buffers have an undo list which records all changes made to the buffer's text so that they can be undone. (The buffers which don't have one are usually special-purpose buffers for which Emacs assumes that undoing is not useful.) All the primitives which modify the text in the buffer automatically add elements to the front of the undo list, which you can find in the variable `buffer-undo-list`.

Variable: **buffer-undo-list**

This variable's value is the undo list of the current buffer. A value of `t` disables the recording of undo information.

Here are the kinds of elements an undo list can have:

`integer`
: This kind of element records a previous value of point. Ordinary cursor motion does not get any sort of undo record, but these entries are used to record where point was before a deletion.

`(beg . end)`
: This kind of element indicates how to delete text that was inserted. Upon insertion, the text occupied the range beg--end in the buffer.

`(pos . deleted)`
: This kind of element indicates how to reinsert text that was deleted. The deleted text itself is the string deleted. The place to reinsert it is pos.

`(t high . low)`
: This kind of element indicates that an unmodified buffer became modified. The elements high and

low are two integers, each recording 16 bits of the visited file's modification time as of when it previously visited or saved. `primitive-undo` uses those values to determine whether to ma the buffer as unmodified once again; it does so only if the file's modification time matches those numbers.

`(nil property value beg . end)`

This kind of element records a change in a text property. Here's how you might undo the change:

```
(put-text-property beg end
                   property value)
```

`nil`

This element is a boundary. The function `undo-boundary` adds these elements. The elements between two boundaries are called a change group; normally, each change group corresponds to one keyboard command, and undo commands normally undo an entire group as a unit.

Function: **undo-boundary**

This function places a boundary element in the undo list. The undo command stops at such a boundary, and successive undo commands undo to earlier and earlier boundaries. This function returns `nil`.

The editor command loop automatically creates an undo boundary between keystroke commands. Thus, each undo normally undoes the effects of one command. Calling this function explicitly is useful for splitting the effects of a command into more than one unit. For example, `query-replace` calls this function after each replacement so that the user can undo individual replacements one by one.

Function: **primitive-undo** *count list*

This is the basic function for undoing elements of an undo list. It undoes the first count elements of list, returning the rest of list. You could write this function in Lisp, but it is convenient to have it in C.

`primitive-undo` adds elements to the buffer's undo list. Undo commands avoid confusion by saving the undo list value at the beginning of a sequence of undo operations. Then the undo operations use and update the saved value. The new elements added by undoing never get into the saved value, so they don't cause any trouble.

Maintaining Undo Lists

This section describes how to enable and disable undo information for a given buffer. It also explains how data from the undo list is discarded automatically so it doesn't get too big.

Recording of undo information in a newly created buffer is normally enabled to start with; but if the buffer name starts with a space, the undo recording is initially disabled. You can explicitly enable or disable undo recording with the following two functions, or by setting `buffer-undo-list` yourself.

Command: **buffer-enable-undo** *&optional buffer-or-name*

This function enables recording undo information for buffer buffer-or-name, so that subsequent changes can be undone. If no argument is supplied, then the current buffer is used. This function does nothing if

undo recording is already enabled in the buffer. It returns `nil`.

In an interactive call, buffer-or-name is the current buffer. You cannot specify any other buffer.

Function: **buffer-disable-undo** *buffer*

Function: **buffer-flush-undo** *buffer*

This function discards the undo list of buffer, and disables further recording of undo information. As a result, it is no longer possible to undo either previous changes or any subsequent changes. If the undo list of buffer is already disabled, this function has no effect.

This function returns `nil`. It cannot be called interactively.

The name `buffer-flush-undo` is not considered obsolete, but the preferred name `buffer-disable-undo` was not provided in Emacs versions 18 and earlier.

As editing continues, undo lists get longer and longer. To prevent them from using up all available memory space, garbage collection trims them back to size limits you can set. (For this purpose, the "size" of an undo list measures the cons cells that make up the list, plus the strings of deleted text.) Two variables control the range of acceptable sizes: `undo-limit` and `undo-strong-limit`.

Variable: **undo-limit**

This is the soft limit for the acceptable size of an undo list. The change group at which this size is exceeded is the last one kept.

Variable: **undo-strong-limit**

The upper limit for the acceptable size of an undo list. The change group at which this size is exceeded is discarded itself (along with all subsequent changes). There is one exception: garbage collection always keeps the very last change group no matter how big it is.

Filling

Filling means adjusting the lengths of lines (by moving words between them) so that they are nearly (but no greater than) a specified maximum width. Additionally, lines can be justified, which means that spaces are inserted between words to make the line exactly the specified width. The width is controlled by the variable `fill-column`. For ease of reading, lines should be no longer than 70 or so columns.

You can use Auto Fill mode (see section Auto Filling) to fill text automatically as you insert it, but changes to existing text may leave it improperly filled. Then you must fill the text explicitly.

Most of the functions in this section return values that are not meaningful.

Command: **fill-paragraph** *justify-flag*

This function fills the paragraph at or after point. If justify-flag is non-`nil`, each line is justified as well. It uses the ordinary paragraph motion commands to find paragraph boundaries.

Command: **fill-region** *start end &optional justify-flag*

This function fills each of the paragraphs in the region from start to end. It justifies as well if justify-flag is non-`nil`. (In an interactive call, this is true if there is a prefix argument.)

The variable `paragraph-separate` controls how to distinguish paragraphs.

Command: **fill-individual-paragraphs** *start end &optional justify-flag mail-flag*

This function fills each paragraph in the region according to its individual fill prefix. Thus, if the lines of a paragraph are indented with spaces, the filled paragraph will continue to be indented in the same fashion.

The first two arguments, start and end, are the beginning and end of the region that will be filled. The third and fourth arguments, justify-flag and mail-flag, are optional. If justify-flag is non-`nil`, the paragraphs are justified as well as filled. If mail-flag is non-`nil`, the function is told that it is operating on a mail message and therefore should not fill the header lines.

Ordinarily, `fill-individual-paragraphs` regards each change in indentation as starting a new paragraph. If `fill-individual-varying-indent` is non-`nil`, then only separator lines separate paragraphs. That mode can handle paragraphs with extra indentation on the first line.

User Option: **fill-individual-varying-indent**

This variable alters the action of `fill-individual-paragraphs` as described above.

Command: **fill-region-as-paragraph** *start end &optional justify-flag*

This function considers a region of text as a paragraph and fills it. If the region was made up of many paragraphs, the blank lines between paragraphs are removed. This function justifies as well as filling when justify-flag is non-`nil`. In an interactive call, any prefix argument requests justification.

In Adaptive Fill mode, which is enabled by default, `fill-region-as-paragraph` on an indented paragraph when there is no fill prefix uses the indentation of the second line of the paragraph as the fill prefix.

Command: **justify-current-line**

This function inserts spaces between the words of the current line so that the line ends exactly at `fill-column`. It returns `nil`.

User Option: **fill-column**

This buffer-local variable specifies the maximum width of filled lines. Its value should be an integer, which is a number of columns. All the filling, justification and centering commands are affected by this variable, including Auto Fill mode (see section Auto Filling).

As a practical matter, if you are writing text for other people to read, you should set `fill-column` to no more than 70. Otherwise the line will be too long for people to read comfortably, and this can make the text seem clumsy.

Variable: **default-fill-column**

The value of this variable is the default value for `fill-column` in buffers that do not override it. This is the same as `(default-value 'fill-column)`.

The default value for `default-fill-column` is 70.

Auto Filling

Filling breaks text into lines that are no more than a specified number of columns wide. Filled lines end between words, and therefore may have to be shorter than the maximum width.

Auto Fill mode is a minor mode in which Emacs fills lines automatically as text as inserted. This section describes the hook and the two variables used by Auto Fill mode. For a description of functions that you can call manually to fill and justify text, see section Filling.

Variable: **auto-fill-function**

The value of this variable should be a function (of no arguments) to be called after self-inserting a space at a column beyond `fill-column`. It may be `nil`, in which case nothing special is done.

The default value for `auto-fill-function` is `do-auto-fill`, a function whose sole purpose is to implement the usual strategy for breaking a line.

> In older Emacs versions, this variable was named `auto-fill-hook`, but since it is not called with the standard convention for hooks, it was renamed to `auto-fill-function` in version 19.

Sorting Text

The sorting commands described in this section all rearrange text in a buffer. This is in contrast to the function `sort`, which rearranges the order of the elements of a list (see section Functions that Rearrange Lists). The values returned by these commands are not meaningful.

Command: **sort-regexp-fields** *reverse record-regexp key-regexp start end*

This command sorts the region between start and end alphabetically as specified by record-regexp and key-regexp. If reverse is a negative integer, then sorting is in reverse order.

Alphabetical sorting means that two sort keys are compared by comparing the first characters of each, the second characters of each, and so on. If a mismatch is found, it means that the sort keys are unequal; the sort key whose character is less at the point of first mismatch is the lesser sort key. The individual characters are compared according to their numerical values. Since Emacs uses the ASCII character set, the ordering in that set determines alphabetical order.

The value of the record-regexp argument specifies the textual units or records that should be sorted. At the end of each record, a search is done for this regular expression, and the text that matches it is the next record. For example, the regular expression `\^.+$', which matches lines with at least one character besides a newline, would make each such line into a sort record. See section Regular Expressions, for a description of the syntax and meaning of regular expressions.

The value of the key-regexp argument specifies what part of each record is to be compared against the other records. The key-regexp could match the whole record, or only a part. In the latter case, the rest of the record has no effect on the sorted order of records, but it is carried along when the record moves to its new position.

The key-regexp argument can refer to the text matched by a subexpression of record-regexp, or it can be a regular expression on its own.

If key-regexp is:

`\digit'

then the text matched by the digitth `\(...\)' parenthesis grouping in record-regexp is used for sorting.

`\&'

then the whole record is used for sorting.

a regular expression

then the function searches for a match for the regular expression within the record. If such a match is found, it is used for sorting. If a match for key-regexp is not found within a record then that record is ignored, which means its position in the buffer is not changed. (The other records may move around it.)

For example, if you plan to sort all the lines in the region by the first word on each line starting with the letter `f', you should set record-regexp to `^.*$' and set key-regexp to `\<f\w*\>'. The resulting expression looks like this:

```
(sort-regexp-fields nil "^.*$" "\\<f\\w*\\>"
                    (region-beginning)
                    (region-end))
```

If you call `sort-regexp-fields` interactively, you are prompted for record-regexp and key-regexp in the minibuffer.

Command: **sort-subr** *reverse nextrecfun endrecfun &optional startkeyfun endkeyfun*

This command is the general text sorting routine that divides a buffer into records and sorts them. The functions `sort-lines`, `sort-paragraphs`, `sort-pages`, `sort-fields`, `sort-regexp-fields` and `sort-numeric-fields` all use `sort-subr`.

To understand how `sort-subr` works, consider the whole accessible portion of the buffer as being divided into disjoint pieces called sort records. A portion of each sort record (perhaps all of it) is designated as the sort key. The records are rearranged in the buffer in order by their sort keys. The records may or may not be contiguous.

Usually, the records are rearranged in order of ascending sort key. If the first argument to the `sort-subr` function, reverse, is non-`nil`, the sort records are rearranged in order of descending sort key.

The next four arguments to `sort-subr` are functions that are called to move point across a sort re
They are called many times from within `sort-subr`.

1. nextrecfun is called with point at the end of a record. This function moves point to the start of the next record. The first record is assumed to start at the position of point when `sort-subr` is called. (Therefore, you should usually move point to the beginning of the buffer before calling `sort-subr`.)

   This function can indicate there are no more sort records by leaving point at the end of the buffer.
2. endrecfun is called with point within a record. It moves point to the end of the record.
3. startkeyfun is called to move point from the start of a record to the start of the sort key. This argument is optional. If supplied, the function should either return a non-`nil` value to be used as the sort key, or return `nil` to indicate that the sort key is in the buffer starting at point. In the latter case, endkeyfun is called to find the end of the sort key.
4. endkeyfun is called to move point from the start of the sort key to the end of the sort key. This argument is optional. If startkeyfun returns `nil` and this argument is omitted (or `nil`), then the sort key extends to the end of the record. There is no need for endkeyfun if startkeyfun returns a non-`nil` value.

As an example of `sort-subr`, here is the complete function definition for `sort-lines`:

```
;; Note that the first two lines of doc string
;; are effectively one line when viewed by a user.
(defun sort-lines (reverse beg end)
  "Sort lines in region alphabetically;\
 argument means descending order.
Called from a program, there are three arguments:
REVERSE (non-nil means reverse order),
and BEG and END (the region to sort)."
  (interactive "P\nr")
  (save-restriction
    (narrow-to-region beg end)
    (goto-char (point-min))
    (sort-subr reverse
               'forward-line
               'end-of-line)))
```

Here `forward-line` moves point to the start of the next record, and `end-of-line` moves point to the end of record. We do not pass the arguments startkeyfun and endkeyfun, because the entire record is used as the sort key.

The `sort-paragraphs` function is very much the same, except that its `sort-subr` call looks like this:

```
(sort-subr reverse
           (function
```

```
     (lambda ()
       (skip-chars-forward "\n \t\f")))
   'forward-paragraph)
```

Command: **sort-lines** *reverse start end*

This command sorts lines in the region between start and end alphabetically. If reverse is non-`nil`, the sort is in reverse order.

Command: **sort-paragraphs** *reverse start end*

This command sorts paragraphs in the region between start and end alphabetically. If reverse is non-`nil`, the sort is in reverse order.

Command: **sort-pages** *reverse start end*

This command sorts pages in the region between start and end alphabetically. If reverse is non-`nil`, the sort is in reverse order.

Command: **sort-fields** *field start end*

This command sorts lines in the region between start and end, comparing them alphabetically by the fieldth field of each line. Fields are separated by whitespace and numbered starting from 1. If field is negative, sorting is by the -fieldth field from the end of the line. This command is useful for sorting tables.

Command: **sort-numeric-fields** *field start end*

This command sorts lines in the region between start and end, comparing them numerically by the fieldth field of each line. Fields are separated by whitespace and numbered starting from 1. The specified field must contain a number in each line of the region. If field is negative, sorting is by the -fieldth field from the end of the line. This command is useful for sorting tables.

Command: **sort-columns** *reverse &optional beg end*

This command sorts the lines in the region between beg and end, comparing them alphabetically by a certain range of columns. The column positions of beg and end bound the range of columns to sort on.

If reverse is non-`nil`, the sort is in reverse order.

One unusual thing about this command is that the entire line containing position beg, and the entire line containing position end, are included in the region sorted.

Note that `sort-columns` uses the `sort` utility program, and so cannot work properly on text containing tab characters. Use M-x `untabify` to convert tabs to spaces before sorting.

The `sort-columns` function did not work on VMS prior to Emacs 19.

Indentation

The indentation functions are used to examine, move to, and change whitespace that is at the beginning of a line. Some of the functions can also change whitespace elsewhere on a line. Indentation always counts from zero at the left margin.

Indentation Primitives

This section describes the primitive functions used to count and insert indentation. The functions in the following sections use these primitives.

Function: **current-indentation**

This function returns the indentation of the current line, which is the horizontal position of the first nonblank character. If the contents are entirely blank, then this is the horizontal position of the end of the line.

Command: **indent-to** *column &optional minimum*

This function indents from point with tabs and spaces until column is reached. If minimum is specified and non-`nil`, then at least that many spaces are inserted even if this requires going beyond column. The value is the column at which the inserted indentation ends.

User Option: **indent-tabs-mode**

If this variable is non-`nil`, indentation functions can insert tabs as well as spaces. Otherwise, they insert only spaces. Setting this variable automatically makes it local to the current buffer.

Indentation Controlled by Major Mode

An important function of each major mode is to customize the TAB key to indent properly for the language being edited. This section describes the mechanism of the TAB key and how to control it. The functions in this section return unpredictable values.

Variable: **indent-line-function**

This variable's value is the function to be used by TAB (and various commands) to indent the current line. The command `indent-according-to-mode` does no more than call this function.

In Lisp mode, the value is the symbol `lisp-indent-line`; in C mode, `c-indent-line`; in Fortran mode, `fortran-indent-line`. In Fundamental mode, Text mode, and many other modes with no standard for indentation, the value is `indent-to-left-margin` (which is the default value).

Command: **indent-according-to-mode**

This command calls the function in `indent-line-function` to indent the current line in a way appropriate for the current major mode.

Command: **indent-for-tab-command**

This command calls the function in `indent-line-function` to indent the current line, except that that function is `indent-to-left-margin`, `insert-tab` is called instead. (That is a trivial command which inserts a tab character.)

Variable: **left-margin**

This variable is the column to which the default `indent-line-function` will indent. (That function is `indent-to-left-margin`.) In Fundamental mode, LFD indents to this column. This variable automatically becomes buffer-local when set in any fashion.

Function: **indent-to-left-margin**

This is the default `indent-line-function`, used in Fundamental mode, Text mode, etc. Its effect is to adjust the indentation at the beginning of the current line to the value specified by the variable `left-margin`. This may involve either inserting or deleting whitespace.

Command: **newline-and-indent**

This function inserts a newline, then indents the new line (the one following the newline just inserted) according to the major mode.

Indentation is done using the current `indent-line-function`. In programming language modes, this is the same thing TAB does, but in some text modes, where TAB inserts a tab, `newline-and-indent` indents to the column specified by `left-margin`.

Command: **reindent-then-newline-and-indent**

This command reindents the current line, inserts a newline at point, and then reindents the new line (the one following the newline just inserted).

Indentation of both lines is done according to the current major mode; this means that the current value of `indent-line-function` is called. In programming language modes, this is the same thing TAB does, but in some text modes, where TAB inserts a tab, `reindent-then-newline-and-indent` indents to the column specified by `left-margin`.

Indenting an Entire Region

This section describes commands which indent all the lines in the region. They return unpredictable values.

Command: **indent-region** *start end to-column*

This command indents each nonblank line starting between start (inclusive) and end (exclusive). If to-column is `nil`, `indent-region` indents each nonblank line by calling the current mode's indentation function, the value of `indent-line-function`.

If to-column is non-`nil`, it should be an integer specifying the number of columns of indentation; then this function gives each line exactly that much indentation, by either adding or deleting whitespace.

If there is a fill prefix, `indent-region` indents each line by making it start with the fill prefix.

Variable: **indent-region-function**

The value of this variable is a function that can be used by `indent-region` as a short cut. You should design the function so that it will produce the same results as indenting the lines of the region one by one (but presumably faster).

If the value is `nil`, there is no short cut, and `indent-region` actually works line by line.

A short cut function is useful in modes such as C mode and Lisp mode, where the `indent-line-function` must scan from the beginning of the function: applying it to each line would be quadratic in time. The short cut can update the scan information as it moves through the lines indenting them; this takes linear time. If indenting a line individually is fast, there is no need for a short cut.

`indent-region` with a non-`nil` argument has a different definition and does not use this variable.

Command: **indent-rigidly** *start end count*

This command indents all lines starting between start (inclusive) and end (exclusive) sideways by `count` columns. This "preserves the shape" of the affected region, moving it as a rigid unit. Consequently, this command is useful not only for indenting regions of unindented text, but also for indenting regions of formatted code.

For example, if count is 3, this command adds 3 columns of indentation to each of the lines beginning in the region specified.

In Mail mode, C-c C-y (`mail-yank-original`) uses `indent-rigidly` to indent the text copied from the message being replied to.

Function: **indent-code-rigidly** *start end columns &optional nochange-regexp*

This is like `indent-rigidly`, except that it doesn't alter lines that start within strings or comments.

In addition, it doesn't alter a line if nochange-regexp matches at the beginning of the line (if nochange-regexp is non-`nil`).

Indentation Relative to Previous Lines

This section describes two commands which indent the current line based on the contents of previous lines.

Command: **indent-relative** *&optional unindented-ok*

This function inserts whitespace at point, extending to the same column as the next indent point of the previous nonblank line. An indent point is a non-whitespace character following whitespace. The next indent point is the first one at a column greater than the current column of point. For example, if point is underneath and to the left of the first non-blank character of a line of text, it moves to that column by inserting whitespace.

If the previous nonblank line has no next indent point (i.e., none at a great enough column position), this function either does nothing (if unindented-ok is non-`nil`) or calls `tab-to-tab-stop`. Thus, if point

is underneath and to the right of the last column of a short line of text, this function moves point to th next tab stop by inserting whitespace.

This command returns an unpredictable value.

In the following example, point is at the beginning of the second line:

```
            This line is indented twelve spaces.
-!-The quick brown fox jumped.
```

Evaluation of the expression `(indent-relative nil)` produces the following:

```
            This line is indented twelve spaces.
            -!-The quick brown fox jumped.
```

In this example, point is between the `m' and `p' of `jumped':

```
            This line is indented twelve spaces.
The quick brown fox jum-!-ped.
```

Evaluation of the expression `(indent-relative nil)` produces the following:

```
            This line is indented twelve spaces.
The quick brown fox jum  -!-ped.
```

Command: **indent-relative-maybe**

This command indents the current line like the previous nonblank line. The function consists of a call to `indent-relative` with a non-`nil` value passed to the unindented-ok optional argument. The value is unpredictable.

If the previous line has no indentation, the current line is given no indentation (any existing indentation is deleted); if the previous nonblank line has no indent points beyond the column at which point starts, nothing is changed.

Adjustable "Tab Stops"

This section explains the mechanism for user-specified "tab stops" and the mechanisms which use and set them. The name "tab stops" is used because the feature is similar to that of the tab stops on a typewriter. The feature works by inserting an appropriate number of spaces and tab characters to reach the designated position, like the other indentation functions; it does not affect the display of tab characters in the buffer (see section Usual Display Conventions). Note that the TAB character as input uses this tab stop feature only in a few major modes, such as Text mode.

Function: **tab-to-tab-stop**

This function inserts spaces or tabs up to the next tab stop column defined by `tab-stop-list`. It searches the list for an element greater than the current column number, and uses that element as the

column to indent to. If no such element is found, then nothing is done.

User Option: **tab-stop-list**

This variable is the list of tab stop columns used by `tab-to-tab-stops`. The elements should be integers in increasing order. The tab stop columns need not be evenly spaced.

Use M-x edit-tab-stops to edit the location of tab stops interactively.

Indentation-Based Motion Commands

These commands, primarily for interactive use, act based on the indentation in the text.

Command: **back-to-indentation**

This command moves point to the first non-whitespace character in the current line (which is the line in which point is located). It returns `nil`.

Command: **backward-to-indentation** *arg*

This command moves point backward arg lines and then to the first nonblank character on that line. It returns `nil`.

Command: **forward-to-indentation** *arg*

This command moves point forward arg lines and then to the first nonblank character on that line. It returns `nil`.

Counting Columns

The column functions convert between a character position (counting characters from the beginning of the buffer) and a column position (counting screen characters from the beginning of a line).

Column number computations ignore the width of the window and the amount of horizontal scrolling. Consequently, a column value can be arbitrarily high. The first (or leftmost) column is numbered 0.

A character counts according to the number of columns it occupies on the screen. This means control characters count as occupying 2 or 4 columns, depending upon the value of `ctl-arrow`, and tabs count as occupying a number of columns that depends on the value of `tab-width` and on the column where the tab begins. See section Usual Display Conventions.

Function: **current-column**

This function returns the horizontal position of point, measured in columns, counting from 0 at the left margin. The column count is calculated by adding together the widths of all the displayed representations of the characters between the start of the current line and point.

For a more complicated example of the use of `current-column`, see the description of `count-lines` in section Motion by Text Lines.

Function: **move-to-column** *column &optional force*

This function moves point to column in the current line. The calculation of column takes into account the widths of all the displayed representations of the characters between the start of the line and point.

If the argument column is greater than the column position of the end of the line, point moves to the end of the line. If column is negative, point moves to the beginning of the line.

If it is impossible to move to column column because that is in the middle of a multicolumn character such as a tab, point moves to the end of that character. However, if force is non-`nil`, and column is in the middle of a tab, then `move-to-column` converts the tab into spaces so that it can move precisely to column column.

The argument force also has an effect if the line isn't long enough to reach column column; in that case, it says to indent at the end of the line to reach that column.

If column is not an integer, an error is signaled.

The return value is the column number actually moved to.

Case Changes

The case change commands described here work on text in the current buffer. See section Character Case, for case conversion commands that work on strings and characters. See section The Case Table, for how to customize which characters are upper or lower case and how to convert them.

Command: **capitalize-region** *start end*

This function capitalizes all words in the region defined by start and end. To capitalize means to convert each word's first character to upper case and convert the rest of each word to lower case. The function returns `nil`.

If one end of the region is in the middle of a word, the part of the word within the region is treated as an entire word.

When `capitalize-region` is called interactively, start and end are point and the mark, with the smallest first.

```
---------- Buffer: foo ----------
This is the contents of the 5th foo.
---------- Buffer: foo ----------

(capitalize-region 1 44)
=> nil

---------- Buffer: foo ----------
This Is The Contents Of The 5th Foo.
---------- Buffer: foo ----------
```

Command: **downcase-region** *start end*

This function converts all of the letters in the region defined by start and end to lower case. The function returns `nil`.

When `downcase-region` is called interactively, start and end are point and the mark, with the smallest first.

Command: **upcase-region** *start end*

This function converts all of the letters in the region defined by start and end to upper case. The function returns `nil`.

When `upcase-region` is called interactively, start and end are point and the mark, with the smallest first.

Command: **capitalize-word** *count*

This function capitalizes count words after point, moving point over as it does. To capitalize means to convert each word's first character to upper case and convert the rest of each word to lower case. If count is negative, the function capitalizes the -count previous words but does not move point. The value is `nil`.

If point is in the middle of a word, the part of word the before point (if moving forward) or after point (if operating backward) is ignored. The rest is treated as an entire word.

When `capitalize-word` is called interactively, count is set to the numeric prefix argument.

Command: **downcase-word** *count*

This function converts the count words after point to all lower case, moving point over as it does. If count is negative, it converts the -count previous words but does not move point. The value is `nil`.

When `downcase-word` is called interactively, count is set to the numeric prefix argument.

Command: **upcase-word** *count*

This function converts the count words after point to all upper case, moving point over as it does. If count is negative, it converts the -count previous words but does not move point. The value is `nil`.

When `upcase-word` is called interactively, count is set to the numeric prefix argument.

Text Properties

Each character position in a buffer or a string can have a text property list, much like the property list of a symbol. The properties belong to a particular character at a particular place, such as, the letter `T' at the beginning of this sentence or the first `o' in `foo'---if the same character occurs in two different places, the two occurrences generally have different properties.

Each property has a name, which is usually a symbol, and an associated value, which can be any Lisp

object--just as for properties of symbols (see section Property Lists).

If a character has a `category` property, we call it the category of the character. It should be a symbol. The properties of the symbol serve as defaults for the properties of the character.

Copying text between strings and buffers preserves the properties along with the characters; this includes such diverse functions as `substring`, `insert`, and `buffer-substring`.

Examining Text Properties

The simplest way to examine text properties is to ask for the value of a particular property of a particular character. For that, use `get-text-property`. Use `text-properties-at` to get the entire property list of a character. See section Property Search Functions, for functions to examine the properties of a number of characters at once.

These functions handle both strings and buffers. Keep in mind that positions in a string start from 0, whereas positions in a buffer start from 1.

Function: **get-text-property** *pos prop &optional object*

This function returns the value of the prop property of the character after position pos in object (a buffer or string). The argument object is optional and defaults to the current buffer.

If there is no prop property strictly speaking, but the character has a category which is a symbol, then `get-text-property` returns the prop property of that symbol.

Function: **text-properties-at** *position &optional object*

This function returns the list of properties held by the character at position in the string or buffer object. If object is `nil`, it defaults to the current buffer.

Changing Text Properties

The primitives for changing properties apply to a specified range of text. The function `set-text-properties` (see end of section) sets the entire property list of the text in that range; more often, it is useful to add, change, or delete just certain properties specified by name.

Since text properties are considered part of the buffer's contents, and can affect how the buffer looks on the screen, any change in the text properties is considered a buffer modification. Buffer text property changes are undoable.

Function: **add-text-properties** *start end props &optional object*

This function modifies the text properties for the text between start and end in the string or buffer object. If object is `nil`, it defaults to the current buffer.

The argument props specifies which properties to change. It should have the form of a property list (see section Property Lists): a list whose elements include the property names followed alternately by the corresponding values.

The return value is `t` if the function actually changed some property's value; `nil` otherwise (if props is `nil` or its values agree with those in the text).

For example, here is how to set the `comment` property to `t` for a range of text:

```
(add-text-properties (region-beginning)
                     (region-end)
                     (list 'comment t))
```

Function: **put-text-property** *start end prop value &optional object*

This function sets the prop property to value for the text between start and end in the string or buffer object. If object is `nil`, it defaults to the current buffer.

Function: **remove-text-properties** *start end props &optional object*

This function deletes specified text properties from the text between start and end in the string or buffer object. If object is `nil`, it defaults to the current buffer.

The argument props specifies which properties to delete. It should have the form of a property list (see section Property Lists): a list whose elements include the property names followed by the corresponding values. The property names mentioned in props are the ones deleted from the text. The values associated in props with these names do not matter.

The return value is `t` if the function actually changed some property's value; `nil` otherwise (if props is `nil` or if none of the text had any of those properties).

Function: **set-text-properties** *start end props &optional object*

This function completely replaces the text property list for the text between start and end in the string or buffer object. If object is `nil`, it defaults to the current buffer.

The argument props is the new property list. It should have the form of a list whose elements include the property names followed by the corresponding values.

After `set-text-properties` returns, all the characters in the specified range have identical properties.

If props is `nil`, the effect is to get rid of all properties from the specified range of text. Here's an example:

```
(set-text-properties (region-beginning)
                     (region-end)
                     nil)
```

Property Search Functions

In typical use of text properties, most of the time several or many consecutive characters have the same value for a property. Rather than writing your programs to examine characters one by one, it is much faster to process chunks of text that have the same property value.

Here are functions you can use to do this. In all cases, object defaults to the current buffer.

Function: **next-property-change** *pos &optional object*

The function scans the text forward from position pos in the string or buffer object till it finds a change in some text property, then returns the position of the change. In other words, it returns the position of the first character beyond pos whose properties are not identical to those of the character just after pos.

The value is `nil` if the properties remain unchanged all the way to the end of object. If the value is non-`nil`, it is a position greater than pos, never equal.

Here is an example of how to scan the buffer by chunks of text within which all properties are constant:

```
(while (not (eobp))
  (let ((plist (text-properties-at (point)))
        (next-change
         (or (next-property-change (point) (current-buffer))
             (point-max))))
    Process text from point to next-change...
    (goto-char next-change)))
```

Function: **next-single-property-change** *pos prop &optional object*

The function scans the text forward from position pos in the string or buffer object till it finds a change in the prop property, then returns the position of the change. In other words, it returns the position of the first character beyond pos whose prop property differs from that of the character just after pos.

The value is `nil` if the properties remain unchanged all the way to the end of object. If the value is non-`nil`, it is a position greater than pos, never equal.

Function: **previous-property-change** *pos &optional object*

This is like `next-property-change`, but scans back from pos instead of forward. If the value is non-`nil`, it is a position always strictly less than pos.

Function: **previous-single-property-change** *pos prop &optional object*

This is like `next-property-change`, but scans back from pos instead of forward. If the value is non-`nil`, it is a position always strictly less than pos.

Special Properties

If a character has a `category` property, we call it the category of the character. It should be a symbol. The properties of the symbol serve as defaults for the properties of the character.

You can use the property `face` to control the font and color of text. See section Faces, for more information. This feature is temporary; in the future, we may replace it with other ways of specifying how to display text.

The property `mouse-face` is used instead of `face` when the mouse is on or near the character. For this purpose, "near" means that all text between the character and where the mouse is have the same `mouse-face` property value.

You can specify a different keymap for a portion of the text by means of a `local-map` property. The property's value, for the character after point, replaces the buffer's local map. See section Active Keymaps.

If a character has the property `read-only`, then modifying that character is not allowed. Any command that would do so gets an error.

If a character has the property `modification-hooks`, then its value should be a list of functions; modifying that character calls all of those functions. Each function receives two arguments: the beginning and end of the part of the buffer being modified. Note that if a particular modification hook function appears on several characters being modified by a single primitive, you can't predict how many times the function will be called.

Insertion of text does not, strictly speaking, change any existing character, so there is a special rule for insertion. It compares the `read-only` properties of the two surrounding characters; if they are non-`nil` and `eq` to each other, then the insertion is not allowed. Assuming insertion is allowed, it then gets the `modification-hooks` properties of those characters and calls all the functions in each of them. (If a function appears on both characters, it may be called once or twice.)

See also section Change Hooks, for other hooks that are called when you change text in a buffer.

The special properties `point-entered` and `point-left` record hook functions that report motion of point. Each time point moves, Emacs compares these two property values:

- the `point-left` property of the character after the old location, and
- the `point-entered` property of the character after the new location.

If these two values differ, each of them is called (if not `nil`) with two arguments: the old value of point, and the new one.

The same comparison is made for the characters before the old and new locations. The result may be to execute two `point-left` functions (which may be the same function) and/or two `point-entered` functions (which may be the same function). The `point-left` functions are always called before the `point-entered` functions.

A primitive function may examine characters at various positions without moving point to those

positions. Only an actual change in the value of point runs these hook functions.

Why Text Properties are not Intervals

Some editors that support adding attributes to text in the buffer do so by letting the user specify "intervals" within the text, and adding the properties to the intervals. Those editors permit the user or the programmer to determine where individual intervals start and end. We deliberately provided a different sort of interface in Emacs Lisp to avoid certain paradoxical behavior associated with text modification.

If the actual subdivision into intervals is meaningful, that means you can distinguish between a buffer that is just one interval with a certain property, and a buffer containing the same text subdivided into two intervals, both of which have that property.

Suppose you take the buffer with just one interval and kill part of the text. The text remaining in the buffer is one interval, and the copy in the kill ring (and the undo list) becomes a separate interval. Then if you undo the kill, you get two intervals with the same properties. Thus, the distinction can't be preserved when editing happens.

But suppose we "fix" this problem by coalescing the two intervals when the text is inserted. That works fine if the buffer originally was a single interval. But if it was two intervals, and the killed text equals one of them, then undoing the kill yields just one interval. Again, the distinction can't be preserved.

Insertion of text at the border between intervals also raises questions that have no satisfactory answer.

However, it is easy to arrange for editing to behave consistently for questions of the form, "What are the properties of this character?" So we have decided these are the only questions that make sense; we have not implemented asking questions about where intervals start or end.

For practical purposes, the property search functions serve in place of explicit interval boundaries. You can think of them as finding the boundaries of intervals, assuming that intervals are always coalesced whenever possible. See section Property Search Functions.

Emacs also provides explicit intervals as a presentation feature; see section Overlays.

Substituting for a Character Code

The following functions replace characters within a specified region based on their character codes.

Function: **subst-char-in-region** *start end old-char new-char &optional noundo*

This function replaces all occurrences of the character old-char with the character new-char in the region of the current buffer defined by start and end.

If noundo is non-`nil`, then `subst-char-in-region` does not record the change for undo and does not mark the buffer as modified. This feature is useful for changes which are not considered significant, such as when Outline mode changes visible lines to invisible lines and vice versa.

`subst-char-in-region` does not move point and returns `nil`.

```
---------- Buffer: foo ----------
This is the contents of the buffer before.
---------- Buffer: foo ----------

(subst-char-in-region 1 20 ?i ?X)
     => nil

---------- Buffer: foo ----------
ThXs Xs the contents of the buffer before.
---------- Buffer: foo ----------
```

Function: **translate-region** *start end table*

This function applies a translation table to the characters in the buffer between positions start and end.

The translation table table is a string; `(aref table ochar)` gives the translated character corresponding to ochar. If the length of table is less than 256, any characters with codes larger than the length of table are not altered by the translation.

The return value of `translate-region` is the number of characters which were actually changed by the translation. This does not count characters which were mapped into themselves in the translation table.

This function is available in Emacs versions 19 and later.

Underlining

The underlining commands are somewhat obsolete. The `underline-region` function actually inserts `_^H' before each appropriate character in the region. This command provides a minimal text formatting feature that might work on your printer; however, we recommend instead that you use more powerful text formatting facilities, such as Texinfo.

Command: **underline-region** *start end*

This function underlines all nonblank characters in the region defined by start and end. That is, an underscore character and a backspace character are inserted just before each non-whitespace character in the region. The backspace characters are intended to cause overstriking, but in Emacs they display as either `\010' or `^H', depending on the setting of `ctl-arrow`. There is no way to see the effect of the overstriking within Emacs. The value is `nil`.

Command: **ununderline-region** *start end*

This function removes all underlining (overstruck underscores) in the region defined by start and end. The value is `nil`.

Registers

A register is a sort of variable used in Emacs editing that can hold a marker, a string, a rectangle, a window configuration (of one frame), or a frame configuration (of all frames). Each register is named by a single character. All characters, including control and meta characters (but with the exception of C-g), can be used to name registers. Thus, there are 255 possible registers. A register is designated in Emacs Lisp by a character which is its name.

The functions in this section return unpredictable values unless otherwise stated.

Variable: **register-alist**

This variable is an alist of elements of the form `(name . contents)`. Normally, there is one element for each Emacs register that has been used.

The object name is a character (an integer) identifying the register. The object contents is a string, marker, or list representing the register contents. A string represents text stored in the register. A marker represents a position. A list represents a rectangle; its elements are strings, one per line of the rectangle.

Command: **view-register** *reg*

This command displays what is contained in register reg.

Function: **get-register** *reg*

This function returns the contents of the register reg, or `nil` if it has no contents.

Function: **set-register** *reg value*

This function sets the contents of register reg to value. A register can be set to any value, but the other register functions expect only certain data types. The return value is value.

Command: **point-to-register** *reg*

This command stores both the current location of point and the current buffer in register reg as a marker.

Command: **jump-to-register** *reg*

Command: **register-to-point** *reg*

This command restores the status recorded in register reg.

If reg contains a marker, it moves point to the position stored in the marker. Since both the buffer and the location within the buffer are stored by the `point-to-register` function, this command can switch you to another buffer.

If reg contains a window configuration or a frame configuration. `jump-to-register` restores that configuration.

Command: **insert-register** *reg &optional beforep*

This command inserts contents of register reg into the current buffer.

Normally, this command puts point before the inserted text, and the mark after it. However, if the optional second argument beforep is non-`nil`, it puts the mark before and point after. You can pass a non-`nil` second argument beforep to this function interactively by supplying any prefix argument.

If the register contains a rectangle, then the rectangle is inserted with its upper left corner at point. This means that text is inserted in the current line and underneath it on successive lines.

If the register contains something other than saved text (a string) or a rectangle (a list), currently useless things happen. This may be changed in the future.

Command: **copy-to-register** *reg start end &optional delete-flag*

This command copies the region from start to end into register reg. If delete-flag is non-`nil`, it deletes the region from the buffer after copying it into the register.

Command: **prepend-to-register** *reg start end &optional delete-flag*

This command prepends the region from start to end into register reg. If delete-flag is non-`nil`, it deletes the region from the buffer after copying it to the register.

Command: **append-to-register** *reg start end &optional delete-flag*

This command appends the region from start to end to the text already in register reg. If delete-flag is non-`nil`, it deletes the region from the buffer after copying it to the register.

Command: **copy-rectangle-to-register** *reg start end &optional delete-flag*

This command copies a rectangular region from start to end into register reg. If delete-flag is non-`nil`, it deletes the region from the buffer after copying it to the register.

Command: **window-configuration-to-register** *reg*

This function stores the window configuration of the selected frame in register reg.

Command: **frame-configuration-to-register** *reg*

This function stores the current frame configuration in register reg.

Change Hooks

These hook variables let you arrange to take notice of all changes in all buffers (or in a particular buffer, if you make them buffer-local). See also section Special Properties, for how to detect changes to specific parts of the text.

Variable: **before-change-function**

If this variable is non-`nil`, then it should be a function; the function is called before any buffer modification. Its arguments are the beginning and end of the region that is going to change, represented as integers. The buffer that's about to change is always the current buffer.

Variable: **after-change-function**

If this variable is non-`nil`, then it should be a function; the function is called after any buffer modification. It receives three arguments: the beginning and end of the region just changed, and the length of the text that existed before the change. (To get the current length, subtract the region beginning from the region end.) All three arguments are integers. The buffer that's about to change is always the current buffer.

Both of these variables are temporarily bound to `nil` during the time that either of these hooks is running. This means that if one of these functions changes the buffer, that change won't run these functions. If you do want the hook function to be run recursively, write your hook functions to bind these variables back to their usual values.

Variable: **first-change-hook**

This variable is a normal hook; its hook functions are run using `run-hooks` whenever a buffer is changed that was previously in the unmodified state.

The variables described in this section are meaningful only starting with Emacs version 19.

Go to the previous, next section.

Go to the previous, next section.

Searching and Matching

GNU Emacs provides two ways to search through a buffer for specified text: exact string searches and regular expression searches. After a regular expression search, you can identify the text matched by parts of the regular expression by examining the match data.

Searching for Strings

These are the primitive functions for searching through the text in a buffer. They are meant for use in programs, but you may call them interactively. If you do so, they prompt for the search string; limit and noerror are set to `nil`, and repeat is set to 1.

Command: **search-forward** *string &optional limit noerror repeat*

This function searches forward from point for an exact match for string. If successful, it sets point to the end of the occurrence found, and returns the new value of point. If no match is found, the value and side effects depend on noerror (see below).

In the following example, point is positioned at the beginning of the line. Then `(search-forward "fox")` is evaluated in the minibuffer and point is left after the last letter of `fox':

```
---------- Buffer: foo ----------
-!-The quick brown fox jumped over the lazy dog.
---------- Buffer: foo ----------

(search-forward "fox")
     => t

---------- Buffer: foo ----------
The quick brown fox-!- jumped over the lazy dog.
---------- Buffer: foo ----------
```

The argument limit specifies the upper bound to the search. (It must be a position in the current buffer.) No match extending after that position is accepted. If limit is omitted or `nil`, it defaults to the end of the accessible portion of the buffer.

What happens when the search fails depends on the value of noerror. If noerror is `nil`, a `search-failed` error is signaled. If noerror is `t`, `search-forward` returns `nil` and does nothing. If noerror is neither `nil` nor `t`, then `search-forward` moves point to the upper bound and returns `nil`. (It would be more consistent now to return the new position of point in that case, but some programs may depend on a value of `nil`.)

If repeat is non-`nil`, then the search is repeated that many times. Point is positioned at the end of the last

match.

Command: **search-backward** *string &optional limit noerror repeat*

This function searches backward from point for string. It is just like `search-forward` except that it searches backwards and leaves point at the beginning of the match.

Command: **word-search-forward** *string &optional limit noerror repeat*

This function searches forward from point for a "word" match for string. If it finds a match, it sets point to the end of the match found, and returns the new value of point.

A word search differs from a simple string search in that a word search **requires** that the words it searches for are present as entire words (searching for the word `ball' does not match the word `balls'), and punctuation and spacing are ignored (searching for `ball boy' does match `ball. Boy!').

In this example, point is first placed at the beginning of the buffer; the search leaves it between the y and the !.

```
---------- Buffer: foo ----------
-!-He said "Please!  Find
the ball boy!"
---------- Buffer: foo ----------

(word-search-forward "Please find the ball, boy.")
     => t

---------- Buffer: foo ----------
He said "Please!  Find
the ball boy-!-!"
---------- Buffer: foo ----------
```

If limit is non-`nil` (it must be a position in the current buffer), then it is the upper bound to the search. The match found must not extend after that position.

If noerror is `t`, then `word-search-forward` returns `nil` when a search fails, instead of signaling an error. If noerror is neither `nil` nor `t`, then `word-search-forward` moves point to limit (or the end of the buffer) and returns `nil`.

If repeat is non-`nil`, then the search is repeated that many times. Point is positioned at the end of the last match.

Command: **word-search-backward** *string &optional limit noerror repeat*

This function searches backward from point for a word match to string. This function is just like `word-search-forward` except that it searches backward and normally leaves point at the beginning of the match.

Regular Expressions

A regular expression (regexp, for short) is a pattern that denotes a (possibly infinite) set of strings. Searching for matches for a regexp is a very powerful operation. This section explains how to write regexps; the following section says how to search for them.

Syntax of Regular Expressions

Regular expressions have a syntax in which a few characters are special constructs and the rest are ordinary. An ordinary character is a simple regular expression which matches that character and nothing else. The special characters are `$', `^', `.', `*', `+', `?', `[', `]' and `\'; no new special characters will be defined in the future. Any other character appearing in a regular expression is ordinary, unless a `\' precedes it.

For example, `f' is not a special character, so it is ordinary, and therefore `f' is a regular expression that matches the string `f' and no other string. (It does *not* match the string `ff'.) Likewise, `o' is a regular expression that matches only `o'.

Any two regular expressions a and b can be concatenated. The result is a regular expression which matches a string if a matches some amount of the beginning of that string and b matches the rest of the string.

As a simple example, we can concatenate the regular expressions `f' and `o' to get the regular expression `fo', which matches only the string `fo'. Still trivial. To do something more powerful, you need to use one of the special characters. Here is a list of them:

. (Period)

is a special character that matches any single character except a newline. Using concatenation, we can make regular expressions like `a.b' which matches any three-character string which begins with `a' and ends with `b'.

*

is not a construct by itself; it is a suffix that means the preceding regular expression is to be repeated as many times as possible. In `fo*', the `*' applies to the `o', so `fo*' matches one `f' followed by any number of `o's. The case of zero `o's is allowed: `fo*' does match `f'.

`*' always applies to the *smallest* possible preceding expression. Thus, `fo*' has a repeating `o', not a repeating `fo'.

The matcher processes a `*' construct by matching, immediately, as many repetitions as can be found. Then it continues with the rest of the pattern. If that fails, backtracking occurs, discarding some of the matches of the `*'-modified construct in case that makes it possible to match the rest of the pattern. For example, matching `ca*ar' against the string `caaar', the `a*' first tries to match all three `a's; but the rest of the pattern is `ar' and there is only `r' left to match, so this try fails. The next alternative is for `a*' to match only two `a's. With this choice, the rest of the regexp matches successfully.

+

is a suffix character similar to `*' except that it must match the preceding expression at least once. So, for example, `ca+r' will match the strings `car' and `caaaar' but not the string `cr', whereas `ca*r' would match all three strings.

?

is a suffix character similar to `*' except that it can match the preceding expression either once or not at all. For example, `ca?r' will match `car' or `cr'; nothing else.

[...]

`[' begins a character set, which is terminated by a `]'. In the simplest case, the characters between the two form the set. Thus, `[ad]' matches either one `a' or one `d', and `[ad]*' matches any string composed of just `a's and `d's (including the empty string), from which it follows that `c[ad]*r' matches `cr', `car', `cdr', `caddaar', etc.

Character ranges can also be included in a character set, by writing two characters with a `-' between them. Thus, `[a-z]' matches any lower case letter. Ranges may be intermixed freely with individual characters, as in `[a-z$%.]', which matches any lower case letter or `$', `%' or a period.

Note that the usual special characters are not special any more inside a character set. A completely different set of special characters exists inside character sets: `]', `-' and `^'.

To include a `]' in a character set, make it the first character. For example, `[]a]' matches `]' or `a'. To include a `-', write `-' as the first or last character in the range.

To include `^', make it other than the first character in the set.

[^ ...]

`[^' begins a complement character set, which matches any character except the ones specified. Thus, `[^a-z0-9A-Z]' matches all characters *except* letters and digits.

`^' is not special in a character set unless it is the first character. The character following the `^' is treated as if it were first (thus, `-' and `]' are not special there).

Note that a complement character set can match a newline, unless newline is mentioned as one of the characters not to match.

^

is a special character that matches the empty string, but only at the beginning of a line in the text being matched. Otherwise it fails to match anything. Thus, `^foo' matches a `foo' which occurs at the beginning of a line.

When matching a string, `^' matches at the beginning of the string or after a newline character `\n'.

$

is similar to `^' but matches only at the end of a line. Thus, `x+$' matches a string of one `x' or more at the end of a line.

When matching a string, `$' matches at the end of the string or before a newline character `\n'.

\

has two functions: it quotes the special characters (including `\'), and it introduces additional special constructs.

Because `\' quotes special characters, `\$' is a regular expression which matches only `$', and `\[' a regular expression which matches only `[', and so on.

Note that `\' also has special meaning in the read syntax of Lisp strings (see section String Type), and must be quoted with `\'. For example, the regular expression that matches the `\' character is `\\'. To write a Lisp string that contains the characters `\\', Lisp syntax requires you to quote each `\' with another `\'. Therefore, the read syntax for a regular expression matching `\' is `"\\\\"'.

Please note: for historical compatibility, special characters are treated as ordinary ones if they are in contexts where their special meanings make no sense. For example, `*foo' treats `*' as ordinary since there is no preceding expression on which the `*' can act. It is poor practice to depend on this behavior; better to quote the special character anyway, regardless of where it appears.

For the most part, `\' followed by any character matches only that character. However, there are several exceptions: characters which, when preceded by `\', are special constructs. Such characters are always ordinary when encountered on their own. Here is a table of `\' constructs:

\|

specifies an alternative. Two regular expressions a and b with `\|' in between form an expression that matches anything that either a or b matches.

Thus, `foo\|bar' matches either `foo' or `bar' but no other string.

`\|' applies to the largest possible surrounding expressions. Only a surrounding `\(... \)' grouping can limit the grouping power of `\|'.

Full backtracking capability exists to handle multiple uses of `\|'.

\(... \)

is a grouping construct that serves three purposes:

To enclose a set of `\|' alternatives for other operations. Thus, `\(foo\|bar\)x' matches either `foox' or `barx'.

To enclose a complicated expression for a suffix character such as `*' to operate on. Thus, `ba\(na\)*' matches `bananana', etc., with any (zero or more) number of `na' strings.

To record a matched substring for future reference.

This last application is not a consequence of the idea of a parenthetical grouping; it is a separate feature which happens to be assigned as a second meaning to the same `\(... \)' construct because there is no conflict in practice between the two meanings. Here is an explanation of this feature:

\digit

matches the same text which is matched the digitth time by a previous `\(... \)' construct.

In other words, after the end of a `\( ... \)' construct. the matcher remembers the beginning and end of the text matched by that construct. Then, later on in the regular expression, you can use `\' followed by digit to mean "match the same text matched the digitth time by the `\(... \)' construct."

The strings matching the first nine `\(... \)' constructs appearing in a regular expression are assigned numbers 1 through 9 in the order that the open parentheses appear in the regular

expression. So you can use `\1' through `\9' to refer to the text matched by the corresponding `\(\)' constructs.

For example, `\(.*\)\1' matches any newline-free string that is composed of two identical halves. The `\(.*\)' matches the first half, which may be anything, but the `\1' that follows must match the same exact text.

\`

matches the empty string, provided it is at the beginning of the buffer.

\'

matches the empty string, provided it is at the end of the buffer.

\=

matches the empty string, provided it is at point.

\b

matches the empty string, provided it is at the beginning or end of a word. Thus, `\bfoo\b' matches any occurrence of `foo' as a separate word. `\bballs?\b' matches `ball' or `balls' as a separate word.

\B

matches the empty string, provided it is *not* at the beginning or end of a word.

\<

matches the empty string, provided it is at the beginning of a word.

\>

matches the empty string, provided it is at the end of a word.

\w

matches any word-constituent character. The editor syntax table determines which characters these are. See section Syntax Tables.

\W

matches any character that is not a word-constituent.

\scode

matches any character whose syntax is code. Here code is a character which represents a syntax code: thus, `w' for word constituent, `-' for whitespace, `(' for open parenthesis, etc. See section Syntax Tables, for a list of the codes.

\Scode

matches any character whose syntax is not code.

Not every string is a valid regular expression. For example, any string with unbalanced square brackets is invalid, and so is a string that ends with a single `\'. If an invalid regular expression is passed to any of the search functions, an `invalid-regexp` error is signaled.

Function: **regexp-quote** *string*

This function returns a regular expression string which matches exactly string and nothing else. This allows you to request an exact string match when calling a function that wants a regular expression.

```
(regexp-quote "^The cat$")
     => "\\^The cat\\$"
```

One use of `regexp-quote` is to combine an exact string match with context described as a regular expression. For example, this searches for the string which is the value of `string`, surrounded by whitespace:

```
(re-search-forward
 (concat "\\s " (regexp-quote string) "\\s "))
```

Complex Regexp Example

Here is a complicated regexp, used by Emacs to recognize the end of a sentence together with any whitespace that follows. It is the value of the variable `sentence-end`.

First, we show the regexp as a string in Lisp syntax to enable you to distinguish the spaces from the tab characters. The string constant begins and ends with a double-quote. `\"' stands for a double-quote as part of the string, `\\' for a backslash as part of the string, `\t' for a tab and `\n' for a newline.

```
"[.?!][]\"')}]*\\($\\|\t\\|  \\)[ \t\n]*"
```

In contrast, if you evaluate the variable `sentence-end`, you will see the following:

```
sentence-end
=>
"[.?!][]\"')}]*\\($\\|  \\|  \\)[
]*"
```

In this case, the tab and carriage return are the actual characters.

This regular expression contains four parts in succession and can be deciphered as follows:

`[.?!]`

The first part of the pattern consists of three characters, a period, a question mark and an exclamation mark, within square brackets. The match must begin with one of these three characters.

`[]\"')}]*`

The second part of the pattern matches any closing braces and quotation marks, zero or more of them, that may follow the period, question mark or exclamation mark. The `\"` is Lisp syntax for a double-quote in a string. The `*' at the end indicates that the immediately preceding regular expression (a character set, in this case) may be repeated zero or more times.

`\\($\\|\t\\| \\)`

The third part of the pattern matches the whitespace that follows the end of a sentence: the end of a line, or a tab, or two spaces. The double backslashes are needed to prevent Emacs from reading the parentheses and vertical bars as part of the search pattern; the parentheses are used to mark the

group and the vertical bars are used to indicated that the patterns to either side of them are alternatives. The dollar sign is used to match the end of a line. The tab character is written using `\t' and the two spaces are written as themselves.

`[ \t\n]*`

Finally, the last part of the pattern indicates that the end of the line or the whitespace following the period, question mark or exclamation mark may, but need not, be followed by additional whitespace.

Regular Expression Searching

In GNU Emacs, you can search for the next match for a regexp either incrementally or not. Incremental search commands are described in the The GNU Emacs Manual. See section 'Regular Expression Search' in The GNU Emacs Manual. Here we describe only the search functions useful in programs. The principal one is `re-search-forward`.

Command: **re-search-forward** *regexp &optional limit noerror repeat*

This function searches forward in the current buffer for a string of text that is matched by the regular expression regexp. The function skips over any amount of text that is not matched by regexp, and leaves point at the end of the first string found that does match.

If the search is successful (i.e., if text matching regexp is found), then point moves to the end of that text, and the function returns the new value of point.

What happens when the search fails depends on the value of noerror. If noerror is `nil`, a `search-failed` error is signaled. If noerror is `t`, `re-search-forward` does nothing and returns `nil`. If noerror is neither `nil` nor `t`, then `re-search-forward` moves point to limit (or the end of the buffer) and returns `nil`.

If limit is non-`nil` (it must be a position in the current buffer), then it is the upper bound to the search. No match extending after that position is accepted.

If repeat is supplied (it must be a positive number), then the search is repeated that many times (each time starting at the end of the previous time's match). The call succeeds if all these searches succeeded, and point is left at the end of the match found by the last search. Otherwise the search fails.

In the following example, point is initially located directly before the `T'. After evaluating the form, point is located at the end of that line (between the `t' of `hat' and before the newline).

```
---------- Buffer: foo ----------
I read "-!-The cat in the hat
comes back" twice.
---------- Buffer: foo ----------

(re-search-forward "[a-z]+" nil t 5)
     => t
```

```
---------- Buffer: foo ----------
I read "The cat in the hat-!-
comes back" twice.
---------- Buffer: foo ----------
```

Command: **re-search-backward** *regexp &optional limit noerror repeat*

This function searches backward in the current buffer for a string of text that is matched by the regular expression regexp, leaving point at the beginning of the first text found.

This function is analogous to `re-search-forward`, but they are not simple mirror images. `re-search-forward` finds the match whose beginning is as close as possible. If `re-search-backward` were a perfect mirror image, it would find the match whose end is as close as possible. However, in fact it finds the match whose beginning is as close as possible. The reason is that matching a regular expression at a given spot always works from beginning to end, and is done at a specified beginning position. Thus, true mirror-image behavior would require a special feature for matching regexps from end to beginning.

Function: **string-match** *regexp string &optional start*

This function returns the index of the start of the first match for the regular expression regexp in string, or `nil` if there is no match. If start is non-`nil`, the search starts at that index in string.

For example,

```
(string-match
 "quick" "The quick brown fox jumped quickly.")
     => 4
(string-match
 "quick" "The quick brown fox jumped quickly." 8)
     => 27
```

The index of the first character of the string is 0, the index of the second character is 1, and so on.

After this function returns, the index of the first character beyond the match is available as `(match-end 0)`. See section The Match Data.

```
(string-match
 "quick" "The quick brown fox jumped quickly." 8)
     => 27

(match-end 0)
     => 32
```

The `match-beginning` and `match-end` functions are described together; see section The Match Data.

Function: **looking-at** *regexp*

This function determines whether the text in the current buffer directly following point matches the regular expression regexp. "Directly following" means precisely that: the search is "anchored" and it must succeed starting with the first character following point. The result is `t` if so, `nil` otherwise.

This function does not move point, but it updates the match data, which you can access using `match-beginning` or `match-end`. See section The Match Data.

In this example, point is located directly before the `T'. If it were anywhere else, the result would be `nil`.

```
---------- Buffer: foo ----------
I read "-!-The cat in the hat
comes back" twice.
---------- Buffer: foo ----------

(looking-at "The cat in the hat$")
     => t
```

Replacement

Function: **perform-replace** *from-string replacements query-flag regexp-flag delimited-flag &optional repeat-count map*

This function is the guts of `query-replace` and related commands. It searches for occurrences of from-string and replaces some or all of them. If query-flag is `nil`, it replaces all occurrences; otherwise, it asks the user what to do about each one.

If regexp-flag is non-`nil`, then from-string is considered a regular expression; otherwise, it must match literally. If delimited-flag is non-`nil`, then only replacements surrounded by word boundaries are considered.

The argument replacements specifies what to replace occurrences with. If it is a string, that string is used. It can also be a list of strings, to be used in cyclic order.

If repeat-count is non-`nil`, it should be an integer, the number of occurrences to consider. In this case, `perform-replace` returns after considering that many occurrences.

Normally, the keymap `query-replace-map` defines the possible user responses. The argument map, if non-`nil`, is a keymap to use instead of `query-replace-map`.

Variable: **query-replace-map**

This variable holds a special keymap that defines the valid user responses for `query-replace` and related functions, as well as `y-or-n-p` and `map-y-or-n-p`. It is special in two ways:

- The "key bindings" are not commands, just symbols that are meaningful to the functions that use this map.
- Prefix keys are not supported; each key binding must be for a single event key sequence. This is because the functions don't use read key sequence to get the input; instead, they read a single event

and look it up "by hand."

Here are the meaningful "bindings" for `query-replace-map`. Several of them are meaningful only for `query-replace` and friends.

`act`
: Do take the action. The action being considered--in other words, "yes."

`skip`
: Do not take action for this question--in other words, "no."

`exit`
: Answer this question "no," and don't ask any more.

`act-and-exit`
: Answer this question "yes," and don't ask any more.

`act-and-show`
: Answer this question "yes," but show the results--don't advance yet.

`automatic`
: Answer this question and all subsequent questions in the series with "yes," without further user interaction.

`backup`
: Move back to the previous place that a question was asked about.

`edit`
: Enter a recursive edit to deal with this item--instead of any other answer.

`delete-and-edit`
: Delete the text being considered, then enter a recursive edit to replace it.

`recenter`
: Redisplay and center the window, then ask the same question again.

`quit`
: Perform a quit right away. Only the `y-or-n-p` functions use this answer.

`help`
: Display some help, then ask again.

The Match Data

Emacs keeps track of the positions of the start and end of segments of text found during a regular expression search. This means, for example, that you can search for a complex pattern, such as a date in an Rmail message, and extract parts of it.

Because the match data normally describe the most recent search only, you must be careful not to do another search inadvertently between the search you wish to refer back to and the use of the match data. If you can't avoid another intervening search, you must save and restore the match data around it, to

prevent it from being overwritten.

Simple Match Data Access

This section explains how to use the match data to find the starting point or ending point of the text that was matched by a particular search, or by a particular parenthetical subexpression of a regular expression.

Function: **match-beginning** *count*

This function returns the position of the start of text matched by the last regular expression searched for. count, a number, specifies a subexpression whose start position is the value. If count is zero, then the value is the position of the text matched by the whole regexp. If count is greater than zero, then the value is the position of the beginning of the text matched by the countth subexpression, regardless of whether it was used in the final match.

Subexpressions of a regular expression are those expressions grouped inside of parentheses, `\(...\)'. The countth subexpression is found by counting occurrences of `\(' from the beginning of the whole regular expression. The first subexpression is numbered 1, the second 2, and so on.

The value is `nil` for a parenthetical grouping inside of a `\|' alternative that wasn't used in the match.

The `match-end` function is similar to the `match-beginning` function except that it returns the position of the end of the matched text.

Here is an example, with a comment showing the numbers of the positions in the text:

```
(string-match
 "\\(qu\\)\\(ick\\)" "The quick fox jumped quickly.")
     => 4            ;^^^^^^^^^^
                     ;0123456789

(match-beginning 1)              ; The beginning of the match
     => 4                        ;   with `qu' is at index 4.

(match-beginning 2)              ; The beginning of the match
     => 6                        ;   with `ick' is at index 6.

(match-end 1)                    ; The end of the match
     => 6                        ;   with `qu' is at index 6.

(match-end 2)                    ; The end of the match
     => 9                        ;   with `ick' is at index 9.
```

Here is another example. Before the form is evaluated, point is located at the beginning of the line. After evaluating the search form, point is located on the line between the space and the word `in'. The beginning of the entire match is at the 9th character of the buffer (`T'), and the beginning of the match for the first subexpression is at the 13th character (`c').

```
(list
  (re-search-forward "The \\(cat \\)")
  (match-beginning 0)
  (match-beginning 1))
    => (t 9 13)

---------- Buffer: foo ----------
I read "The cat -!-in the hat comes back" twice.
        ^   ^
        9  13
---------- Buffer: foo ----------
```

(Note that in this case, the index returned is a buffer position; the first character of the buffer counts as 1.)

Function: **match-end** *count*

This function returns the position of the end of text matched by the last regular expression searched for. This function is otherwise similar to `match-beginning`.

Replacing the Text That Matched

Function: **replace-match** *replacement &optional fixedcase literal*

This function replaces the text matched by the last search with replacement.

If fixedcase is non-`nil`, then the case of the replacement text is not changed; otherwise, the replacement text is converted to a different case depending upon the capitalization of the text to be replaced. If the original text is all upper case, the replacement text is converted to upper case, except when all of the words in the original text are only one character long. In that event, the replacement text is capitalized. If *all* of the words in the original text are capitalized, then all of the words in the replacement text are capitalized.

If literal is non-`nil`, then replacement is inserted exactly as it is, the only alterations being case changes as needed. If it is `nil` (the default), then the character `\' is treated specially. If a `\' appears in replacement, then it must be part of one of the following sequences:

`\&'

: `\&' stands for the entire text being replaced.

`\n'

: `\n' stands for the nth subexpression in the original regexp. Subexpressions are those expressions grouped inside of `\(...\)'. n is a digit.

`\\'

: `\\' stands for a single `\' in the replacement text.

`replace-match` leaves point at the end of the replacement text, and returns `t`.

Accessing the Entire Match Data

The functions `match-data` and `store-match-data` let you read or write the entire match data, all at once.

Function: **match-data**

This function returns a new list containing all the information on what text the last search matched. Element zero is the position of the beginning of the match for the whole expression; element one is the position of the end of the match for the expression. The next two elements are the positions of the beginning and end of the match for the first subexpression. In general, element corresponds to `(match-beginning n)`; and element corresponds to `(match-end n)`.

All the elements are markers or `nil` if matching was done on a buffer, and all are integers or `nil` if matching was done on a string with `string-match`. (In Emacs 18 and earlier versions, markers were used even for matching on a string, except in the case of the integer 0.)

As always, there must be no possibility of intervening searches between the call to a search function and the call to `match-data` that is intended to access the match-data for that search.

```
(match-data)
     =>  (#<marker at 9 in foo>
          #<marker at 17 in foo>
          #<marker at 13 in foo>
          #<marker at 17 in foo>)
```

Function: **store-match-data** *match-list*

This function sets the match data from the elements of match-list, which should be a list that was the value of a previous call to `match-data`.

If match-list refers to a buffer that doesn't exist, you don't get an error; that sets the match data in a meaningless but harmless way.

Saving and Restoring the Match Data

All asynchronous process functions (filters and sentinels) and functions that use `recursive-edit` should save and restore the match data if they do a search or if they let the user type arbitrary commands. Saving the match data is useful in other cases as well--whenever you want to access the match data resulting from an earlier search, notwithstanding another intervening search.

This example shows the problem that can arise if you fail to attend to this requirement:

```
(re-search-forward "The \\(cat \\)")
     => 48
(foo)                   ; Perhaps foo does
                        ;   more searching.
```

```
(match-end 0)
     => 61               ; Unexpected result--not 48!
```

In Emacs versions 19 and later, you can save and restore the match data with `save-match-data`:

Special Form: **save-match-data** *body...*

This special form executes body, saving and restoring the match data around it. This is useful if you wish to do a search without altering the match data that resulted from an earlier search.

You can use `store-match-data` together with `match-data` to imitate the effect of the special form `save-match-data`. This is useful for writing code that can run in Emacs 18. Here is how:

```
(let ((data (match-data)))
  (unwind-protect
      ...   ; May change the original match data.
    (store-match-data data)))
```

Standard Regular Expressions Used in Editing

Here are the regular expressions standardly used in editing:

Variable: **page-delimiter**

This is the regexp describing line-beginnings that separate pages. The default value is `"^\014"` (i.e., `"^^L"` or `"^\C-l"`).

Variable: **paragraph-separate**

This is the regular expression for recognizing the beginning of a line that separates paragraphs. (If you change this, you may have to change `paragraph-start` also.) The default value is `"^[ \t\f]*$"`, which is a line that consists entirely of spaces, tabs, and form feeds.

Variable: **paragraph-start**

This is the regular expression for recognizing the beginning of a line that starts *or* separates paragraphs. The default value is `"^[ \t\n\f]"`, which matches a line starting with a space, tab, newline, or form feed.

Variable: **sentence-end**

This is the regular expression describing the end of a sentence. (All paragraph boundaries also end sentences, regardless.) The default value is:

```
"[.?!][]\"')}]*\\($\\|\t\\| \\)[ \t\n]*"
```

This means a period, question mark or exclamation mark, followed by a closing brace, followed by tabs, spaces or new lines.

For a detailed explanation of this regular expression, see section Complex Regexp Example.

Searching and Case

By default, searches in Emacs ignore the case of the text they are searching through; if you specify searching for `FOO', then `Foo' or `foo' is also considered a match. Regexps, and in particular character sets, are included: thus, `[aB]' would match `a' or `A' or `b' or `B'.

If you do not want this feature, set the variable `case-fold-search` to `nil`. Then all letters must match exactly, including case. This is a per-buffer-local variable; altering the variable affects only the current buffer. (See section Introduction to Buffer-Local Variables.) Alternatively, you may change the value of `default-case-fold-search`, which is the default value of `case-fold-search` for buffers that do not override it.

User Option: **case-replace**

This variable determines whether `query-replace` should preserve case in replacements. If the variable is `nil`, then case need not be preserved.

User Option: **case-fold-search**

This buffer-local variable determines whether searches should ignore case. If the variable is `nil` they do not ignore case; otherwise they do ignore case.

Variable: **default-case-fold-search**

The value of this variable is the default value for `case-fold-search` in buffers that do not override it. This is the same as `(default-value 'case-fold-search)`.

Go to the previous, next section.

Go to the previous, next section.

Syntax Tables

A syntax table provides Emacs with the information that determines the syntactic use of each character in a buffer. This information is used by the parsing commands, the complex movement commands, and others to determine where words, symbols, and other syntactic constructs begin and end. The current syntax table controls the meaning of the word motion functions (see section Motion by Words) and the list motion functions (see section Moving over Balanced Expressions) as well as the functions in this chapter.

A syntax table is a vector of 256 elements; it contains one entry for each of the 256 ASCII characters of an 8-bit byte. Each element is an integer that encodes the syntax of the character in question.

Syntax tables are used only for moving across text, not for the GNU Emacs Lisp reader. GNU Emacs Lisp uses built-in syntactic rules when reading Lisp expressions, and these rules cannot be changed.

Each buffer has its own major mode, and each major mode has its own idea of the syntactic class of various characters. For example, in Lisp mode, the character `;' begins a comment, but in C mode, it terminates a statement. To support these variations, Emacs makes the choice of syntax table local to each buffer. Typically, each major mode has its own syntax table and installs that table in each buffer which uses that mode. Changing this table alters the syntax in all those buffers as well as in any buffers subsequently put in that mode. Occasionally several similar modes share one syntax table. See section Major Mode Examples, for an example of how to set up a syntax table.

Function: **syntax-table-p** *object*

This function returns `t` if object is a vector of length 256 elements. This means that the vector may be a syntax table. However, according to this test, any vector of length 256 is considered to be a syntax table, no matter what its contents.

Syntax Descriptors

This section describes the syntax classes and flags that denote the syntax of a character, and how they are represented as a syntax descriptor, which is a Lisp string that you pass to `modify-syntax-entry` to specify the desired syntax.

Emacs defines twelve syntax classes. Each syntax table puts each character into one class. There is no necessary relationship between the class of a character in one syntax table and its class in any other table.

Each class is designated by a mnemonic character which serves as the name of the class when you need to specify a class. Usually the designator character is one which is frequently put in that class; however, its meaning as a designator is unvarying and independent of how it is actually classified.

A syntax descriptor is a Lisp string which specifies a syntax class, a matching character (unused except for parenthesis classes) and flags. The first character is the designator for a syntax class. The second

character is the character to match; if it is unused, put a space there. Then come the characters for any desired flags. If no matching character or flags are needed, one character is sufficient.

Thus, the descriptor for the character `*' in C mode is `. 23' (i.e., punctuation, matching character slot unused, second character of a comment-starter, first character of an comment-ender), and the entry for `/' is `. 14' (i.e., punctuation, matching character slot unused, first character of a comment-starter, second character of a comment-ender).

Table of Syntax Classes

Here is a summary of the classes, the characters that stand for them, their meanings, and examples of their use.

Syntax class: **whitespace character**

Whitespace characters (designated with ` ' or `-') separate symbols and words from each other. Typically, whitespace characters have no other syntactic use, and multiple whitespace characters are syntactically equivalent to a single one. Space, tab, newline and formfeed are almost always considered whitespace.

Syntax class: **word constituent**

Word constituents (designated with `w') are parts of normal English words and are typically used in variable and command names in programs. All upper and lower case letters and the digits are typically word constituents.

Syntax class: **symbol constituent**

Symbol constituents (designated with `_') are the extra characters that are used in variable and command names along with word constituents. For example, the symbol constituents class is used in Lisp mode to indicate that certain characters may be part of symbol names even though they are not part of English words. These characters are `$&*+-_<>'. In standard C, the only non-word-constituent character that is valid in symbols is underscore (`_').

Syntax class: **punctuation character**

Punctuation characters (`.') are those characters that are used as punctuation in English, or are used in some way in a programming language to separate symbols from one another. Most programming language modes, including Emacs Lisp mode, have no characters in this class since the few characters that are not symbol or word constituents all have other uses.

Syntax class: **open parenthesis character**

Syntax class: **close parenthesis character**

Open and close parenthesis characters are characters used in dissimilar pairs to surround sentences or expressions. Such a grouping is begun with an open parenthesis character and terminated with a close. Each open parenthesis character matches a particular close parenthesis character, and vice versa. Normally, Emacs indicates momentarily the matching open parenthesis when you insert a close parenthesis. See section Blinking.

The class of open parentheses is designated with `(', and that of close parentheses with `)'.

In English text, and in C code, the parenthesis pairs are `()', `[]', and `{}'. In Emacs Lisp, the delimiters for lists and vectors (`()' and `[]') are classified as parenthesis characters.

Syntax class: **string quote**

String quote characters (designated with `"') is used to delimit string constants in many languages, including Lisp and C. The same string quote character appears at the beginning and the end of a string. Such quoted strings do not nest.

The parsing facilities of Emacs consider a string as a single token. The usual syntactic meanings of the characters in the string are suppressed.

The Lisp modes have two string quote characters: double-quote (`"') and vertical bar (`|'). `|' is not used in Emacs Lisp, but it is used in Common Lisp. C also has two string quote characters: double-quote for strings, and single-quote (`') for character constants.

English text has no string quote characters because English is not a programming language. Although quotation marks are used in English, we do not want them to turn off the usual syntactic properties of other characters in the quotation.

Syntax class: **escape**

An escape character (designated with `\') starts an escape sequence such as is used in C string and character constants. The character `\' belongs to this class in both C and Lisp. (In C, it is used thus only inside strings, but it turns out to cause no trouble to treat it this way throughout C code.)

Characters in this class count as part of words if `words-include-escapes` is non-`nil`. See section Motion by Words.

Syntax class: **character quote**

A character quote character (designated with `/') quotes the following character so that it loses its normal syntactic meaning. This differs from an escape character in that only the character immediately following is ever affected.

Characters in this class count as part of words if `words-include-escapes` is non-`nil`. See section Motion by Words.

This class is not currently used in any standard Emacs modes.

Syntax class: **paired delimiter**

Paired delimiter characters (designated with `$') are like string quote characters except that the syntactic properties of the characters between the delimiters are not suppressed. Only TeX mode uses a paired identical delimiter presently--the `$' that begins and ends math mode.

Syntax class: **expression prefix**

An expression prefix operator (designated with `') is used for syntactic operators that are part of an expression if they appear next to one but are not part of an adjoining symbol. These characters in Lisp

include the apostrophe, `'' (used for quoting), the comma, `,' (used in macros), and `#' (used in the rea syntax for certain data types).

Syntax class: **comment starter**

Syntax class: **comment ender**

The comment starter and comment ender characters are used in different languages to delimit comments. These classes are designated with `<' and `>', respectively.

English text has no comment characters. In Lisp, the semicolon (`;') starts a comment and a newline or formfeed ends one.

Syntax Flags

In addition to the classes, entries for characters in a syntax table can include flags. There are six possible flags, represented by the characters `1', `2', `3', `4', `b' and `p'.

All the flags except `p' are used to describe multi-character comment delimiters. The digit flags indicate that a character can *also* be part of a comment sequence, in addition to the syntactic properties associated with its character class. The flags are independent of the class and each other for the sake of characters such as `*' in C mode, which is a punctuation character, *and* the second character of a start-of-comment sequence (`/*'), *and* the first character of an end-of-comment sequence (`*/').

The flags for a character c are:

- `1' means c is the start of a two-character comment start sequence.
- `2' means c is the second character of such a sequence.
- `3' means c is the start of a two-character comment end sequence.
- `4' means c is the second character of such a sequence.
- `b' means that c as a comment delimiter belongs to the alternative "b" comment style.

  Emacs can now supports two comment styles simultaneously. (This is for the sake of C++.) More specifically, it can recognize two different comment-start sequences. Both must share the same first character; only the second character may differ. Mark the second character of the "b"-style comment start sequence with the `b' flag.

  The two styles of comment can have different comment-end sequences. A comment-end sequence (one or two characters) applies to the "b" style if its first character has the `b' flag set; otherwise, it applies to the "a" style.

  The appropriate comment syntax settings for C++ are as follows:
  `/'
  `124b'
  `*'
  `23'
  newline

`>b'

Thus `/*' is a comment-start sequence for "a" style, `//' is a comment-start sequence for "b" style, `*/' is a comment-end sequence for "a" style, and newline is a comment-end sequence for "b" style.

- `p' identifies an additional "prefix character" for Lisp syntax. These characters are treated as whitespace when they appear between expressions. When they appear within an expression, they are handled according to their usual syntax codes.

  The function `backward-prefix-chars` moves back over these characters, as well as over characters whose primary syntax class is prefix (`').

Syntax Table Functions

In this section we describe functions for creating, accessing and altering syntax tables.

Function: **make-syntax-table** *&optional table*

This function constructs a copy of table and returns it. If table is not supplied (or is `nil`), it returns a copy of the current syntax table. Otherwise, an error is signaled if table is not a syntax table.

Function: **copy-syntax-table** *&optional table*

This function is identical to `make-syntax-table`.

Command: **modify-syntax-entry** *char syntax-descriptor &optional table*

This function sets the syntax entry for char according to syntax-descriptor. The syntax is changed only for table, which defaults to the current buffer's syntax table, and not in any other syntax table. The argument syntax-descriptor specifies the desired syntax; this is a string beginning with a class designator character, and optionally containing a matching character and flags as well. See section Syntax Descriptors.

This function always returns `nil`. The old syntax information in the table for this character is discarded.

An error is signaled if the first character of the syntax descriptor is not one of the twelve syntax class designator characters. An error is also signaled if char is not a character.

```
Examples:

;; Put the space character in class whitespace.
(modify-syntax-entry ?\  " ")
     => nil

;; Make `$' an open parenthesis character,
;;   with `^' as its matching close.
(modify-syntax-entry ?$ "(^")
     => nil
```

```
;; Make `^' a close parenthesis character,
;;   with `$' as its matching open.
(modify-syntax-entry ?^ ")$")
     => nil

;; Make `/' a punctuation character,
;;   the first character of a start-comment sequence,
;;   and the second character of an end-comment sequence.
;;   This is used in C mode.
(modify-syntax-entry ?/ ".13")
     => nil
```

Function: **char-syntax** *character*

This function returns the syntax class of character, represented by its mnemonic designator character. This *only* returns the class, not any matching parenthesis or flags.

An error is signaled if char is not a character.

The first example shows that the syntax class of space is whitespace (represented by a space). The second example shows that the syntax of `/' is punctuation in C-mode. This does not show the fact that it is also a comment sequence character. The third example shows that open parenthesis is in the class of open parentheses. This does not show the fact that it has a matching character, `)'.

```
(char-to-string (char-syntax ?\ ))
     => " "

(char-to-string (char-syntax ?/))
     => "."

(char-to-string (char-syntax ?\())
     => "("
```

Function: **set-syntax-table** *table*

This function makes table the syntax table for the current buffer. It returns table.

Function: **syntax-table**

This function returns the current syntax table, which is the table for the current buffer.

Motion and Syntax

This section describes functions for moving across characters in certain syntax classes. None of these functions exists in Emacs version 18 or earlier.

Function: **skip-syntax-forward** *syntaxes &optional limit*

This function moves point forward across characters whose syntax classes are mentioned in syntaxes stops when it encounters the end of the buffer, or position lim (if specified), or a character it is not supposed to skip.

The return value is the distance traveled, which is a nonnegative integer.

Function: **skip-syntax-backward** *syntaxes &optional limit*

This function moves point backward across characters whose syntax classes are mentioned in syntaxes. It stops when it encounters the beginning of the buffer, or position lim (if specified), or a character it is not supposed to skip.

The return value indicates the distance traveled. It is an integer that is zero or less.

Function: **backward-prefix-chars**

This function moves point backward over any number of chars with expression prefix syntax. This includes both characters in the expression prefix syntax class, and characters with the `p' flag.

Parsing Balanced Expressions

Here are several functions for parsing and scanning balanced expressions. The syntax table controls the interpretation of characters, so these functions can be used for Lisp expressions when in Lisp mode and for C expressions when in C mode. See section Moving over Balanced Expressions, for convenient higher-level functions for moving over balanced expressions.

Function: **parse-partial-sexp** *start limit &optional target-depth stop-before state stop-comment*

This function parses an expression in the current buffer starting at start, not scanning past limit. Parsing stops at limit or when certain criteria described below are met; point is set to the location where parsing stops. The value returned is a description of the status of the parse at the point where it stops.

Normally, start is assumed to be the top level of an expression to be parsed, such as the beginning of a function definition. Alternatively, you might wish to resume parsing in the middle of an expression. To do this, you must provide a state argument that describes the initial status of parsing. If state is omitted (or `nil`), parsing assumes that start is the beginning of a new parse at level 0.

If the third argument target-depth is non-`nil`, parsing stops if the depth in parentheses becomes equal to target-depth. The depth starts at 0, or at whatever is given in state.

If the fourth argument stop-before is non-`nil`, parsing stops when it comes to any character that starts a sexp. If stop-comment is non-`nil`, parsing stops when it comes to the start of a comment.

The fifth argument state is a seven-element list of the same form as the value of this function, described below. The return value of one call may be used to initialize the state of the parse on another call to `parse-partial-sexp`.

The result is a list of seven elements describing the final state of the parse:

1. The depth in parentheses, starting at 0.

2. The character position of the start of the innermost containing parenthetical grouping; `nil` if r
3. The character position of the start of the last complete subexpression terminated; `nil` if none.
4. Non-`nil` if inside a string. (It is the character that will terminate the string.)
5. `t` if inside a comment.
6. `t` if point is just after a quote character.
7. The minimum parenthesis depth encountered during this scan.

Elements 1, 4, 5, and 6 are significant in the argument state.

This function is used to determine how to indent lines in programs written in languages that have nested parentheses.

Function: **scan-lists** *from count depth*

This function scans forward count balanced parenthetical groupings from character number from. It returns the character number of the position thus found.

If depth is nonzero, parenthesis depth counting begins from that value. The only candidates for stopping are places where the depth in parentheses becomes zero; `scan-lists` counts count such places and then stops. Thus, a positive value for depth means go out levels of parenthesis.

Comments are ignored if `parse-sexp-ignore-comments` is non-`nil`.

If the beginning or end of the buffer (or its accessible portion) is reached and the depth is not zero, an error is signaled. If the depth is zero but the count is not used up, `nil` is returned.

Function: **scan-sexps** *from count*

Scan from character number from by count balanced expressions. It returns the character number of the position thus found.

Comments are ignored if `parse-sexp-ignore-comments` is non-`nil`.

If the beginning or end of (the accessible part of) the buffer is reached in the middle of a parenthetical grouping, an error is signaled. If the beginning or end is reached between groupings but before count is used up, `nil` is returned.

Variable: **parse-sexp-ignore-comments**

If the value is non-`nil`, then comments are treated as whitespace by the functions in this section and by `forward-sexp`.

In older Emacs versions, this feature worked only when the comment terminator is something like `*/', and appears only to end a comment. In languages where newlines terminate comments, it was necessary make this variable `nil`, since not every newline is the end of a comment. This limitation no longer exists.

You can use `forward-comment` to move forward or backward over one comment or several comments.

Function: **forward-comment** *count*

This function moves point forward across count comments (backward, if count is negative). If it finds anything other than a comment or whitespace, it stops, leaving point at the place where it stopped. It also stops after satisfying count.

To move forward over all comments and whitespace following point, use `(forward-comment (buffer-size))`. `(buffer-size)` is a good argument to use, because the number of comments to skip cannot exceed that many.

Some Standard Syntax Tables

Each of the major modes in Emacs has its own syntax table. Here are several of them:

Function: **standard-syntax-table**

This function returns the standard syntax table, which is the syntax table used in Fundamental mode.

Variable: **text-mode-syntax-table**

The value of this variable is the syntax table used in Text mode.

Variable: **c-mode-syntax-table**

The value of this variable is the syntax table in use in C-mode buffers.

Variable: **emacs-lisp-mode-syntax-table**

The value of this variable is the syntax table used in Emacs Lisp mode by editing commands. (It has no effect on the Lisp `read` function.)

Syntax Table Internals

Each element of a syntax table is an integer that translates into the full meaning of the entry: class, possible matching character, and flags. However, it is not common for a programmer to work with the entries directly in this form since the Lisp-level syntax table functions usually work with syntax descriptors (see section Syntax Descriptors).

The low 8 bits of each element of a syntax table indicates the syntax class.

Integer
: *Class*

0
: whitespace

1
: punctuation

2

word

3

symbol

4

open parenthesis

5

close parenthesis

6

expression prefix

7

string quote

8

paired delimiter

9

escape

10

character quote

11

comment-start

12

comment-end

The next 8 bits are the matching opposite parenthesis (if the character has parenthesis syntax); otherwise, they are not meaningful. The next 6 bits are the flags.

Go to the previous, next section.

Go to the previous, next section.

Abbrevs And Abbrev Expansion

An abbreviation or abbrev is a string of characters that may be expanded to a longer string. The user can insert the abbrev string and find it replaced automatically with the expansion of the abbrev. This saves typing.

The set of abbrevs currently in effect is recorded in an abbrev table. Each buffer has a local abbrev table, but normally all buffers in the same major mode share one abbrev table. There is also a global abbrev table. Normally both are used.

An abbrev table is represented as an obarray containing a symbol for each abbreviation. The symbol's name is the abbreviation. Its value is the expansion; its function definition is the hook; its property list cell contains the use count, the number of times the abbreviation has been expanded. Because these symbols are not interned in the usual obarray, they will never appear as the result of reading a Lisp expression; in fact, they will never be used except by the code that handles abbrevs. Therefore, it is safe to use them in an extremely nonstandard way. See section Creating and Interning Symbols.

For the user-level commands for abbrevs, see section 'Abbrev Mode' in The GNU Emacs Manual.

Setting Up Abbrev Mode

Abbrev mode is a minor mode controlled by the value of the variable `abbrev-mode`.

Variable: **abbrev-mode**

A non-`nil` value of this variable turns on the automatic expansion of abbrevs when their abbreviations are inserted into a buffer. If the value is `nil`, abbrevs may be defined, but they are not expanded automatically.

This variable automatically becomes local when set in any fashion.

Variable: **default-abbrev-mode**

This is the value `abbrev-mode` for buffers that do not override it. This is the same as `(default-value 'abbrev-mode)`.

Abbrev Tables

This section describes how to create and manipulate abbrev tables.

Function: **make-abbrev-table**

This function creates and returns a new, empty abbrev table--an obarray containing no symbols. It is a vector filled with `nil`s.

Function: **clear-abbrev-table** *table*

This function undefines all the abbrevs in abbrev table table, leaving it empty. The function returns `nil`.

Function: **define-abbrev-table** *tabname definitions*

This function defines tabname (a symbol) as an abbrev table name, i.e., as a variable whose value is an abbrev table. It defines abbrevs in the table according to definitions, a list of elements of the form `(abbrevname expansion hook usecount)`. The value is always `nil`.

Variable: **abbrev-table-name-list**

This is a list of symbols whose values are abbrev tables. `define-abbrev-table` adds the new abbrev table name to this list.

Function: **insert-abbrev-table-description** *name &optional human*

This function inserts before point a description of the abbrev table named name. The argument name is a symbol whose value is an abbrev table. The value is always `nil`.

If human is non-`nil`, a human-oriented description is inserted. Otherwise the description is a Lisp expression--a call to `define-abbrev-table` which would define name exactly as it is currently defined.

Defining Abbrevs

These functions define an abbrev in a specified abbrev table. `define-abbrev` is the low-level basic function, while `add-abbrev` is used by commands that ask for information from the user.

Function: **add-abbrev** *table type arg*

This function adds an abbreviation to abbrev table table. The argument type is a string describing in English the kind of abbrev this will be (typically, `"global"` or `"mode-specific"`); this is used in prompting the user. The argument arg is the number of words in the expansion.

The return value is the symbol which internally represents the new abbrev, or `nil` if the user declines to redefine an existing abbrev.

Function: **define-abbrev** *table name expansion hook*

This function defines an abbrev in table named name, to expand to expansion, and call hook. The return value is an uninterned symbol which represents the abbrev inside Emacs; its name is name.

The argument name should be a string. The argument expansion should be a string, or `nil`, to undefine the abbrev.

The argument hook is a function or `nil`. If hook is non-`nil`, then it is called with no arguments after the abbrev is replaced with expansion; point is located at the end of expansion.

The use count of the abbrev is initialized to zero.

User Option: **only-global-abbrevs**

If this variable is non-`nil`, it means that the user plans to use global abbrevs only. This tells the commands that define mode-specific abbrevs to define global ones instead. This variable does not alter the functioning of the functions in this section; it is examined by their callers.

Saving Abbrevs in Files

A file of saved abbrev definitions is actually a file of Lisp code. The abbrevs are saved in the form of a Lisp program to define the same abbrev tables with the same contents. Therefore, you can load the file with `load` (see section How Programs Do Loading). However, the function `quietly-read-abbrev-file` is provided as a more convenient interface.

User-level facilities such as `save-some-buffers` can save abbrevs in a file automatically, under the control of variables described here.

User Option: **abbrev-file-name**

This is the default file name for reading and saving abbrevs.

Function: **quietly-read-abbrev-file** *filename*

This function reads abbrev definitions from a file named filename, previously written with `write-abbrev-file`. If filename is `nil`, the file specified in `abbrev-file-name` is used. `save-abbrevs` is set to `t` so that changes will be saved.

This function does not display any messages. It returns `nil`.

User Option: **save-abbrevs**

A non-`nil` value for `save-abbrev` means that Emacs should save abbrevs when files are saved. `abbrev-file-name` specifies the file to save the abbrevs in.

Variable: **abbrevs-changed**

This variable is set non-`nil` by defining or altering any abbrevs. This serves as a flag for various Emacs commands to offer to save your abbrevs.

Command: **write-abbrev-file** *filename*

Save all abbrev definitions, in all abbrev tables, in the file filename, in the form of a Lisp program which when loaded will define the same abbrevs. This function returns `nil`.

Looking Up and Expanding Abbreviations

Abbrevs are usually expanded by commands for interactive use, including `self-insert-command`. This section describes the subroutines used in writing such functions, as well as the variables they use for communication.

Function: **abbrev-symbol** *abbrev &optional table*

This function returns the symbol representing the abbrev named abbrev. The value returned is `nil` if that abbrev is not defined. The optional second argument table is the abbrev table to look it up in. By default, this function tries first the current buffer's local abbrev table, and second the global abbrev table.

User Option: **abbrev-all-caps**

When this is set non-`nil`, an abbrev entered entirely in upper case is expanded using all upper case. Otherwise, an abbrev entered entirely in upper case is expanded by capitalizing each word of the expansion.

Function: **abbrev-expansion** *abbrev &optional table*

This function returns the string that abbrev would expand into (as defined by the abbrev tables used for the current buffer). The optional argument table specifies the abbrev table to use; if it is specified, the abbrev is looked up in that table only.

Variable: **abbrev-start-location**

This is the buffer position for `expand-abbrev` to use as the start of the next abbrev to be expanded. (`nil` means use the word before point instead.) `abbrev-start-location` is set to `nil` each time `expand-abbrev` is called. This variable is also set by `abbrev-prefix-mark`.

Variable: **abbrev-start-location-buffer**

The value of this variable is the buffer for which `abbrev-start-location` has been set. Trying to expand an abbrev in any other buffer clears `abbrev-start-location`. This variable is set by `abbrev-prefix-mark`.

Variable: **last-abbrev**

This is the `abbrev-symbol` of the last abbrev expanded. This information is left by `expand-abbrev` for the sake of the `unexpand-abbrev` command.

Variable: **last-abbrev-location**

This is the location of the last abbrev expanded. This contains information left by `expand-abbrev` for the sake of the `unexpand-abbrev` command.

Variable: **last-abbrev-text**

This is the exact expansion text of the last abbrev expanded, as results from case conversion. Its value is `nil` if the abbrev has already been unexpanded. This contains information left by `expand-abbrev` for the sake of the `unexpand-abbrev` command.

Variable: **pre-abbrev-expand-hook**

This is a normal hook whose functions are executed, in sequence, just before any expansion of an abbrev. See section Hooks. Since it is a normal hook, the hook functions receive no arguments. However, they can find the abbrev to be expanded by looking in the buffer before point.

The following sample code shows a simple use of `pre-abbrev-expand-hook`. If the user termir an abbrev with a punctuation character, the function issues a prompt. Thus, this hook allows the user t decide whether the abbrev should be expanded, and to abort expansion if it is not desired.

```
(add-hook 'pre-abbrev-expand-hook 'query-if-not-space)

;; This is the function invoked by pre-abbrev-expand-hook.

;; If the user terminated the abbrev with a space, the function does
;; nothing (that is, it returns so that the abbrev can expand).  If the
;; user entered some other character, this function asks whether
;; expansion should continue.

;; If the user enters the prompt with y, the function returns
;; nil (because of the not function), but that is
;; acceptable; the return value has no effect on expansion.

(defun query-if-not-space ()
  (if (/= ?\  (preceding-char))
      (if (not (y-or-n-p "Do you want to expand this abbrev? "))
          (error "Not expanding this abbrev"))))
```

Standard Abbrev Tables

Here we list the variables that hold the abbrev tables for the preloaded major modes of Emacs.

Variable: **global-abbrev-table**

This is the abbrev table for mode-independent abbrevs. The abbrevs defined in it apply to all buffers. Each buffer may also have a local abbrev table, whose abbrev definitions take precedence over those in the global table.

Variable: **local-abbrev-table**

The value of this buffer-local variable is the (mode-specific) abbreviation table of the current buffer.

Variable: **fundamental-mode-abbrev-table**

This is the local abbrev table used in Fundamental mode. It is the local abbrev table in all buffers in Fundamental mode.

Variable: **text-mode-abbrev-table**

This is the local abbrev table used in Text mode.

Variable: **c-mode-abbrev-table**

This is the local abbrev table used in C mode.

Variable: **lisp-mode-abbrev-table**

This is the local abbrev table used in Lisp mode and Emacs Lisp mode.

Go to the previous, next section.

Go to the previous, next section.

Processes

In the terminology of operating systems, a process is a space in which a program can execute. Emacs runs in a process. Emacs Lisp programs can invoke other programs in processes of their own. These are called subprocesses or child processes of the Emacs process, which is their parent process.

A subprocess of Emacs may be synchronous or asynchronous, depending on how it is created. When you create a synchronous subprocess, the Lisp program waits for the subprocess to terminate before continuing execution. When you create an asynchronous subprocess, it can run in parallel with the Lisp program. This kind of subprocess is represented within Emacs by a Lisp object which is also called a "process". Lisp programs can use this object to communicate with the subprocess or to control it. For example, you can send signals, obtain status information, receive output from the process, or send input to it.

Function: **processp** *object*

This function returns `t` if object is a process, `nil` otherwise.

Functions that Create Subprocesses

There are three functions that create a new subprocess in which to run a program. One of them, `start-process`, creates an asynchronous process and returns a process object (see section Creating an Asynchronous Process). The other two, `call-process` and `call-process-region`, create a synchronous process and do not return a process object (see section Creating a Synchronous Process).

Synchronous and asynchronous processes are explained in following sections. Since the three functions are all called in a similar fashion, their common arguments are described here.

In all cases, the function's program argument specifies the program to be run. An error is signaled if the file is not found or cannot be executed. The actual file containing the program is found by following normal system rules: if the file name is absolute, then the program must be found in the specified file; if the name is relative, then the directories in `exec-path` are searched sequentially for a suitable file. The variable `exec-path` is initialized when Emacs is started, based on the value of the environment variable `PATH`. The standard file name constructs, `~', `.', and `..', are interpreted as usual in `exec-path`, but environment variable substitutions (`$HOME', etc.) are not recognized; use `substitute-in-file-name` to perform them (see section Functions that Expand Filenames).

Each of the subprocess-creating functions has a buffer-or-name argument which specifies where the standard output from the program will go. If buffer-or-name is `nil`, that says to discard the output unless a filter function handles it. (See section Process Filter Functions, and section Reading and Printing Lisp Objects.) Normally, you should avoid having multiple processes send output to the same buffer because their output would be intermixed randomly.

All three of the subprocess-creating functions have a `&rest` argument, args. The args must all be strings, and they are supplied to program as separate command line arguments. Wildcard characters and other shell constructs are not allowed in these strings, since they are passed directly to the specified program.

Please note: the argument program contains only the name of the program; it may not contain any command-line arguments. Such arguments must be provided via args.

The subprocess gets its current directory from the value of `default-directory` (see section Functions that Expand Filenames).

The subprocess inherits its environment from Emacs; but you can specify overrides for it with `process-environment`. See section Operating System Environment.

Variable: **exec-directory**

The value of this variable is the name of a directory (a string) that contains programs that come with GNU Emacs, that are intended for Emacs to invoke. The program `wakeup` is an example of such a program; the `display-time` command uses it to get a reminder once per minute.

The default value is the name of a directory whose name ends in `` `arch-lib' ``. We call the directory `` `emacs/arch-lib' ``, since its name usually ends that way. We sometimes refer to "the directory `` `emacs/arch-lib' ``," when strictly speaking we ought to say, "the directory named by the variable `exec-directory`." Most of the time, there is no difference.

(In earlier Emacs versions, prior to version 19, these files lived in the directory `` `emacs/etc' `` instead of in `` `emacs/arch-lib' ``.)

User Option: **exec-path**

The value of this variable is a list of directories to search for programs to run in subprocesses. Each element is either the name of a directory (i.e., a string), or `nil`, which stands for the default directory (which is the value of `default-directory`).

The value of `exec-path` is used by `call-process` and `start-process` when the program argument is not an absolute file name.

Creating a Synchronous Process

After a synchronous process is created, Emacs waits for the process to terminate before continuing. Starting Dired is an example of this: it runs `ls` in a synchronous process, then modifies the output slightly. Because the process is synchronous, the entire directory listing arrives in the buffer before Emacs tries to do anything with it.

While Emacs waits for the synchronous subprocess to terminate, the user can quit by typing C-g, and the process is killed by sending it a `SIGKILL` signal. See section Quitting.

The synchronous subprocess functions return `nil` in version 18. In version 19, they will return an indication of how the process terminated.

Function: **call-process** *program &optional infile buffer-or-name display &rest args*

This function calls program in a separate process and waits for it to finish.

The standard input for the process comes from file infile if infile is not `nil` and from `` `/dev/null' `` otherwise. The process output gets inserted in buffer buffer-or-name before point, if that argument names a buffer. If buffer-or-name is `t`, output is sent to the current buffer; if buffer-or-name is `nil`, output is discarded.

If buffer-or-name is the integer 0, `call-process` returns `nil` immediately and discards any output. In this case, the process is not truly synchronous, since it can run in parallel with Emacs; but you can think of it as synchronous in that Emacs is essentially finished with the subprocess as soon as this function returns.

If display is non-`nil`, then `call-process` redisplays the buffer as output is inserted. Otherwise the function does no redisplay, and the results become visible on the screen only when Emacs redisplays that buffer in the normal course of events.

The remaining arguments, args, are strings that are supplied as the command line arguments for the program.

The value returned by `call-process` (unless you told it not to wait) indicates the reason for process termination. A number gives the exit status of the subprocess; 0 means success, and any other value means failure. If the process terminated with a signal, `call-process` returns a string describing the signal.

The examples below are both run with the buffer `foo' current.

```
(call-process "pwd" nil t)
     => nil

---------- Buffer: foo ----------
/usr/user/lewis/manual
---------- Buffer: foo ----------

(call-process "grep" nil "bar" nil "lewis" "/etc/passwd")
     => nil

---------- Buffer: bar ----------
lewis:5LTsHm66CSWKg:398:21:Bil Lewis:/user/lewis:/bin/csh

---------- Buffer: bar ----------
```

The `dired-readin` function contains a good example of the use of `call-process`:

```
(call-process
 "ls" nil buffer nil dired-listing-switches dirname)
```

Function: **call-process-region** *start end program &optional delete buffer-or-name display &rest arg*

This function sends the text between start to end as standard input to a process running program. It deletes the text sent if delete is non-`nil`, which may be useful when the output is going to be inserted back in the current buffer.

If buffer-or-name names a buffer, the output is inserted in that buffer at point. If buffer-or-name is `t`, the output is sent to the current buffer. If buffer-or-name is `nil`, the output is discarded. If buffer-or-name is the integer 0, the output is discarded and `call-process` returns `nil` immediately, just as `call-process` would.

If display is non-`nil`, then `call-process-region` redisplays the buffer as output is inserted. Otherwise the function does no redisplay, and the results become visible on the screen only when Emacs redisplays that buffer in the normal course of events.

The remaining arguments, args, are strings that are supplied as the command line arguments for the program.

The return value of `call-process-region` is just like that of `call-process`: `nil` if you told it to return without waiting; otherwise, a number or string which indicates how the subprocess terminated.

In the following example, we use `call-process-region` to run the `cat` utility, with standard input being the first five characters in buffer `foo' (the word `input'). `cat` copies its standard input into its standard output. Since the argument buffer-or-name is `t`, this output is inserted in the current buffer.

```
---------- Buffer: foo ----------
input-!-
---------- Buffer: foo ----------

(call-process-region 1 6 "cat" nil t)
     => nil

---------- Buffer: foo ----------
inputinput-!-
---------- Buffer: foo ----------
```

The `shell-command-on-region` command uses `call-process-region` like this:

```
(call-process-region
 start end
 shell-file-name      ; Name of program.
 nil                  ; Do not delete region.
 buffer               ; Send output to buffer.
 nil                  ; No redisplay during output.
 "-c" command)        ; Arguments for the shell.
```

Creating an Asynchronous Process

After an asynchronous process is created, Emacs and the Lisp program can continue running immediately. The process may thereafter run in parallel with Emacs, and the two may communicate with each other using the functions described in following sections. Here we describe how to create an asynchronous process, with `start-process`.

Function: **start-process** *name buffer-or-name program &rest args*

This function creates a new asynchronous subprocess and starts the program program running in it. It returns a process object that stands for the new subprocess for Emacs Lisp programs. The argument name specifies the name for the process object; if a process with this name already exists, then name is modified (by adding `<1>', etc.) to be unique. The buffer buffer-or-name is the buffer to associate with the process.

The remaining arguments, args, are strings that are supplied as the command line arguments for the program.

In the example below, the first process is started and runs (rather, sleeps) for 100 seconds. Meanwhile, the second process is started, given the name `my-process<1>' for the sake of uniqueness. It inserts the directory listing at the end of the buffer `foo', before the first process finishes. Then it finishes, and a message to that effect is inserted in the buffer. Much later, the first process finishes, and another message is inserted in the buffer for it.

```
(start-process "my-process" "foo" "sleep" "100")
     => #<process my-process>

(start-process "my-process" "foo" "ls" "-l" "/user/lewis/bin")
     => #<process my-process<1>>

---------- Buffer: foo ----------
total 2
lrwxrwxrwx  1 lewis     14 Jul 22 10:12 gnuemacs --> /emacs
-rwxrwxrwx  1 lewis     19 Jul 30 21:02 lemon

Process my-process<1> finished

Process my-process finished
---------- Buffer: foo ----------
```

Function: **start-process-shell-command** *name buffer-or-name command &rest command-args*

This function is like `start-process` except that it uses a shell to execute the specified command. The argument command is a shell command name, and command-args are the arguments for the shell command.

Variable: **process-connection-type**

This variable controls the type of device used to communicate with asynchronous subprocesses. If it is `nil`, then pipes are used. If it is `t`, then PTYs are used (or pipes if PTYs are not supported).

PTYs are usually preferable for processes visible to the user, as in Shell mode, because they allow job control (C-c, C-z, etc.) to work between the process and its children whereas pipes do not. For subprocesses used for internal purposes by programs, it is often better to use a pipe, because they are more efficient. In addition, the total number of PTYs is limited on many systems and it is good not to waste them.

The value `process-connection-type` is used when `start-process` is called, so in order to change it for just one call of `start-process`, temporarily rebind it with `let`.

```
(let ((process-connection-type nil))  ; Use a pipe.
  (start-process ...))
```

Deleting Processes

Deleting a process disconnects Emacs immediately from the subprocess, and removes it from the list of active processes. It sends a signal to the subprocess to make the subprocess terminate, but this is not guaranteed to happen immediately. (The process object itself continues to exist as long as other Lisp objects point to it.)

You can delete a process explicitly at any time. Processes are deleted automatically after they terminate, but not necessarily right away. If you delete a terminated process explicitly before it is deleted automatically, no harm results.

Variable: **delete-exited-processes**

This variable controls automatic deletion of processes that have terminated (due to calling `exit` or to a signal). If it is `nil`, then they continue to exist until the user runs `list-processes`. Otherwise, they are deleted immediately after they exit.

Function: **delete-process** *name*

This function deletes the process associated with name. The argument name may be a process, the name of a process, a buffer, or the name of a buffer. The subprocess is killed with a `SIGHUP` signal.

```
(delete-process "*shell*")
     => nil
```

Function: **process-kill-without-query** *process*

This function declares that Emacs need not query the user if process is still running when Emacs is exited. The process will be deleted silently. The value is `t`.

```
(process-kill-without-query (get-process "shell"))
     => t
```

Process Information

Several functions return information about processes. `list-processes` is provided for interactive use.

Command: **list-processes**

This command displays a listing of all living processes. (Any processes listed as `Exited' or `Signaled' are actually eliminated after the listing is made.) This function returns `nil`.

Function: **process-list**

This function returns a list of all processes that have not been deleted.

```
(process-list)
     => (#<process display-time> #<process shell>)
```

Function: **get-process** *name*

This function returns the process named name, or `nil` if there is none. An error is signaled if name is not a string.

```
(get-process "shell")
     => #<process shell>
```

Function: **process-command** *process*

This function returns the command that was executed to start process. This is a list of strings, the first string being the program executed and the rest of the strings being the arguments that were given to the program.

```
(process-command (get-process "shell"))
     => ("/bin/csh" "-i")
```

Function: **process-exit-status** *process*

This function returns the exit status of process or the signal number that killed it. (Use the result of `process-status` to determine which of those it is.) If process has not yet terminated, the value is 0.

Function: **process-id** *process*

This function returns the PID of process. This is an integer which distinguishes the process process from all other processes running on the same computer at the current time. The PID of a process is chosen by the operating system kernel when the process is started and remains constant as long as the process exists.

Function: **process-name** *process*

This function returns the name of process.

Function: **process-status** *process-name*

This function returns the status of process-name as a symbol. The argument process-name must be either a process or a string. If it is a string, it need not name an actual process.

The possible values for an actual subprocess are:

`run`
: for a process that is running.

`stop`
: for a process that is stopped but continuable.

`exit`
: for a process that has exited.

`signal`
: for a process that has received a fatal signal.

`open`
: for a network connection that is open.

`closed`
: for a network connection that is closed. Once a connection is closed, you cannot reopen it, though you might be able to open a new connection to the same place.

`nil`
: if process-name is not the name of an existing process.

```
(process-status "shell")
     => run
(process-status "never-existed")
     => nil
x
     => #<process xx<1>>
(process-status x)
     => exit
```

For a network connection, `process-status` returns one of the symbols `open` or `closed`. The latter means that the other side closed the connection, or Emacs did `delete-process`.

In earlier Emacs versions (prior to version 19), the status of a network connection was `run` if open, and `exit` if closed.

Sending Input to Processes

Asynchronous subprocesses receive input when it is sent to them by Emacs, which is done with the functions in this section. You must specify the process to send input to, and the input data to send. The data appears on the "standard input" of the subprocess.

Some operating systems have limited space for buffered input in a PTY. On these systems, the subprocess will cease to read input correctly if you send an input line longer than the system can handle. You cannot avoid the problem by breaking the input into pieces and sending them separately, for the operating system will still have to put all the pieces together in the input buffer before it lets the subprocess read the line. The only solution is to put the input in a temporary file, and send the process a brief command to read that file.

Function: **process-send-string** *process-name string*

This function sends process-name the contents of string as standard input. The argument process-name must be a process or the name of a process.

The function returns `nil`.

```
(process-send-string "shell<1>" "ls\n")
     => nil

---------- Buffer: *shell* ----------
...
introduction.texi              syntax-tables.texi~
introduction.texi~             text.texi
introduction.txt               text.texi~
...
---------- Buffer: *shell* ----------
```

Command: **process-send-region** *process-name start end*

This function sends the text in the region defined by start and end as standard input to process-name, which is a process or a process name.

An error is signaled unless both start and end are integers or markers that indicate positions in the current buffer. (It is unimportant which number is larger.)

Function: **process-send-eof** *&optional process-name*

This function makes process-name see an end-of-file in its input. The EOF comes after any text already sent to it.

If process-name is not supplied, or if it is `nil`, then this function sends the EOF to the current buffer's process. An error is signaled if the current buffer has no process.

The function returns process-name.

```
(process-send-eof "shell")
     => "shell"
```

Sending Signals to Processes

Sending a signal to a subprocess is a way of interrupting its activities. There are several different signals, each with its own meaning. For example, the signal `SIGINT` means that the user has typed C-c, or that some analogous thing has happened.

Each signal has a standard effect on the subprocess. Most signals kill the subprocess, but some stop or resume execution instead. Most signals can optionally be handled by programs; if the program handles the signal, then we can say nothing in general about its effects.

The set of signals and their names is defined by the operating system; Emacs has facilities for sending only a few of the signals that are defined. Emacs can send signals only to its own subprocesses.

You can send signals explicitly by calling the functions in this section. Emacs also sends signals automatically at certain times: killing a buffer sends a `SIGHUP` signal to all its associated processes; killing Emacs sends a `SIGHUP` signal to all remaining processes. (`SIGHUP` is a signal that usually indicates that the user hung up the phone.)

Each of the signal-sending functions takes two optional arguments: process-name and current-group.

The argument process-name must be either a process, the name of one, or `nil`. If it is `nil`, the process defaults to the process associated with the current buffer. An error is signaled if process-name does not identify a process.

The argument current-group is a flag that makes a difference when you are running a job-control shell as an Emacs subprocess. If it is non-`nil`, then the signal is sent to the current process-group of the terminal which Emacs uses to communicate with the subprocess. If the process is a job-control shell, this means the shell's current subjob. If it is `nil`, the signal is sent to the process group of the immediate subprocess of Emacs. If the subprocess is a job-control shell, this is the shell itself.

The flag current-group has no effect when a pipe is used to communicate with the subprocess, because the operating system does not support the distinction in the case of pipes. For the same reason, job-control shells won't work when a pipe is used. See `process-connection-type` in section Creating an Asynchronous Process.

Function: **interrupt-process** *&optional process-name current-group*

This function interrupts the process process-name by sending the signal `SIGINT`. Outside of Emacs, typing the "interrupt character" (normally C-c on some systems, and `DEL` on others) sends this signal. When the argument current-group is non-`nil`, you can think of this function as "typing C-c" on the terminal by which Emacs talks to the subprocess.

Function: **kill-process** *&optional process-name current-group*

This function kills the process process-name by sending the signal `SIGKILL`. This signal kills the subprocess immediately, and cannot be handled by the subprocess.

Function: **quit-process** *&optional process-name current-group*

This function sends the signal `SIGQUIT` to the process process-name. This signal is the one sent by the "quit character" (usually C-b or C-\) when you are not inside Emacs.

Function: **stop-process** *&optional process-name current-group*

This function stops the process process-name by sending the signal `SIGTSTP`. Use `continue-process` to resume its execution.

On systems with job control, the "stop character" (usually C-z) sends this signal (outside of Emacs). When current-group is non-`nil`, you can think of this function as "typing C-z" on the terminal Emacs uses to communicate with the subprocess.

Function: **continue-process** *&optional process-name current-group*

This function resumes execution of the process process by sending it the signal `SIGCONT`. This presumes that process-name was stopped previously.

Function: **signal-process** *pid signal*

This function sends a signal to process pid, which need not be a child of Emacs. The argument signal specifies which signal to send; it should be an integer.

Receiving Output from Processes

There are two ways to receive the output that a subprocess writes to its standard output stream. The output can be inserted in a buffer, which is called the associated buffer of the process, or a function called the filter function can be called to act on the output.

Process Buffers

A process can (and usually does) have an associated buffer, which is an ordinary Emacs buffer that is used for two purposes: storing the output from the process, and deciding when to kill the process. You can also use the buffer to identify a process to operate on, since in normal practice only one process is associated with any given buffer. Many applications of processes also use the buffer for editing input to be sent to the process, but this is not built into Emacs Lisp.

Unless the process has a filter function (see section Process Filter Functions), its output is inserted in the associated buffer. The position to insert the output is determined by the `process-mark` (see section Process Information), which is then updated to point to the end of the text just inserted. Usually, but not always, the `process-mark` is at the end of the buffer. If the process has no buffer and no filter function, its output is discarded.

Function: **process-buffer** *process*

This function returns the associated buffer of the process process.

```
(process-buffer (get-process "shell"))
     => #<buffer *shell*>
```

Function: **process-mark** *process*

This function returns the marker which controls where additional output from the process will be inserted in the process buffer. When output is inserted, the marker is updated to point at the end of the output. This causes successive batches of output to be inserted consecutively.

If process does not insert its output into a buffer, then `process-mark` returns a marker that points nowhere.

Filter functions normally should use this marker in the same fashion as is done by direct insertion of output in the buffer. A good example of a filter function that uses `process-mark` is found at the end of the following section.

When the user is expected to enter input in the process buffer for transmission to the process, the process marker is useful for distinguishing the new input from previous output.

Function: **set-process-buffer** *process buffer*

This function sets the buffer associated with process to buffer. If buffer is `nil`, the process will not be associated with any buffer.

Function: **get-buffer-process** *buffer-or-name*

This function returns the process associated with buffer-or-name. If there are several processes associated with it, then one is chosen. (Presently, the one chosen is the one most recently created.) It is usually a bad idea to have more than one process associated with the same buffer.

```
(get-buffer-process "*shell*")
     => #<process shell>
```

If the process's buffer is killed, the actual child process is killed with a `SIGHUP` signal (see section Sending Signals to Processes).

Process Filter Functions

A process filter function is a function that receives the standard output from the associated process. If a process has a filter, then *all* output from that process, that would otherwise have been in a buffer, is passed to the filter. The process buffer is used for output from the process only when there is no filter.

A filter function must accept two arguments: the associated process and a string, which is the output. The function is then free to do whatever it chooses with the output.

A filter function runs only while Emacs is waiting (e.g., for terminal input, or for time to elapse, or for process output). This avoids the timing errors that could result from running filters at random places in the middle of other Lisp programs. You may explicitly cause Emacs to wait, so that filter functions will run, by calling `sit-for`, `sleep-for` or `accept-process-output` (see section Accepting Output from Processes). Emacs is also waiting when the command loop is reading input.

Quitting is normally inhibited within a filter function--otherwise, the effect of typing C-g at command

level or to quit a user command would be unpredictable. If you want to permit quitting inside a filter function, bind `inhibit-quit` to `nil`. See section Quitting.

Many filter functions sometimes or always insert the text in the process's buffer, mimicking the actions of Emacs when there is no filter. Such filter functions need to use `set-buffer` in order to be sure to insert in that buffer. To avoid setting the current buffer semipermanently, these filter functions must use `unwind-protect` to make sure to restore the previous current buffer. They should also update the process marker, and in some cases update the value of point. Here is how to do these things:

```
(defun ordinary-insertion-filter (proc string)
  (let ((old-buffer (current-buffer)))
    (unwind-protect
        (let (moving)
          (set-buffer (process-buffer proc))
          (setq moving (= (point) (process-mark proc)))
          (save-excursion
            ;; Insert the text, moving the process-marker.
            (goto-char (process-mark proc))
            (insert string)
            (set-marker (process-mark proc) (point)))
          (if moving (goto-char (process-mark proc))))
      (set-buffer old-buffer))))
```

The reason to use an explicit `unwind-protect` rather than letting `save-excursion` restore the current buffer is so as to preserve the change in point made by `goto-char`.

To make the filter force the process buffer to be visible whenever new text arrives, insert the following line just before the `unwind-protect`:

```
(display-buffer (process-buffer proc))
```

To force point to move to the end of the new output no matter where it was previously, eliminate the variable `moving` and call `goto-char` unconditionally.

All filter functions that do regexp searching or matching should save and restore the match data. Otherwise, a filter function that runs during a call to `sit-for` might clobber the match data of the program that called `sit-for`. See section The Match Data.

The output to the function may come in chunks of any size. A program that produces the same output twice in a row may send it as one batch of 200 characters one time, and five batches of 40 characters the next.

Function: **set-process-filter** *process filter*

This function gives process the filter function filter. If filter is `nil`, then the process will have no filter.

Function: **process-filter** *process*

This function returns the filter function of process, or `nil` if it has none.

Here is an example of use of a filter function:

```
(defun keep-output (process output)
   (setq kept (cons output kept)))
     => keep-output
(setq kept nil)
     => nil
(set-process-filter (get-process "shell") 'keep-output)
     => keep-output
(process-send-string "shell" "ls ~/other\n")
     => nil
kept
     => ("lewis@slug[8] % "
"FINAL-W87-SHORT.MSS    backup.otl              kolstad.mss~
address.txt             backup.psf              kolstad.psf
backup.bib~             david.mss               resume-Dec-86.mss~
backup.err              david.psf               resume-Dec.psf
backup.mss              dland                   syllabus.mss
"
"#backups.mss#          backup.mss~             kolstad.mss
")
```

Here is another, more realistic example, which demonstrates how to use the process mark to do insertion in the same fashion as is done when there is no filter function:

```
;; Insert input in the buffer specified by my-shell-buffer
;;   and make sure that buffer is shown in some window.
(defun my-process-filter (proc str)
    (let ((cur (selected-window))
          (pop-up-windows t))
      (pop-to-buffer my-shell-buffer)
      (goto-char (point-max))
      (insert str)
      (set-marker (process-mark proc) (point-max))
      (select-window cur)))
```

Accepting Output from Processes

Output from asynchronous subprocesses normally arrives only while Emacs is waiting for some sort of external event, such as elapsed time or terminal input. Occasionally it is useful in a Lisp program to explicitly permit output to arrive at a specific point, or even to wait until output arrives from a process.

Function: **accept-process-output** *&optional process seconds millisec*

This function allows Emacs to read pending output from processes. The output is inserted in the associated buffers or given to their filter functions. If process is non-`nil` then this function does not return until some output has been received from process.

The arguments seconds and millisec let you specify timeout periods. The former specifies a period measured in seconds and the latter specifies one measured in milliseconds. The two time periods thus specified are added together, and `accept-process-output` returns after that much time whether or not there has been any subprocess output.

Not all operating systems support waiting periods other than multiples of a second; on those that do not, you get an error if you specify nonzero millisec.

The function `accept-process-output` returns non-`nil` if it did get some output, or `nil` if the timeout expired before output arrived.

Sentinels: Detecting Process Status Changes

A process sentinel is a function that is called whenever the associated process changes status for any reason, including signals (whether sent by Emacs or caused by the process's own actions) that terminate, stop, or continue the process. The process sentinel is also called if the process exits. The sentinel receives two arguments: the process for which the event occurred, and a string describing the type of event.

The string describing the event looks like one of the following:

- `"finished\n"`.
- `"exited abnormally with code exitcode\n"`.
- `"name-of-signal\n"`.
- `"name-of-signal (core dumped)\n"`.

A sentinel runs only while Emacs is waiting (e.g., for terminal input, or for time to elapse, or for process output). This avoids the timing errors that could result from running them at random places in the middle of other Lisp programs. You may explicitly cause Emacs to wait, so that sentinels will run, by calling `sit-for`, `sleep-for` or `accept-process-output` (see section Accepting Output from Processes). Emacs is also waiting when the command loop is reading input.

Quitting is normally inhibited within a sentinel--otherwise, the effect of typing C-g at command level or to quit a user command would be unpredictable. If you want to permit quitting inside a sentinel, bind `inhibit-quit` to `nil`. See section Quitting.

All sentinels that do regexp searching or matching should save and restore the match data. Otherwise, a sentinel that runs during a call to `sit-for` might clobber the match data of the program that called `sit-for`. See section The Match Data.

Function: **set-process-sentinel** *process sentinel*

This function associates sentinel with process. If sentinel is `nil`, then the process will have no sentinel. The default behavior when there is no sentinel is to insert a message in the process's buffer when the process status changes.

```
(defun msg-me (process event)
   (princ
     (format "Process: %s had the event `%s'" process event)))
(set-process-sentinel (get-process "shell") 'msg-me)
     => msg-me
(kill-process (get-process "shell"))
     -| Process: #<process shell> had the event `killed'
     => #<process shell>
```

Function: **process-sentinel** *process*

This function returns the sentinel of process, or `nil` if it has none.

Function: **waiting-for-user-input-p**

While a sentinel or filter function is running, this function returns non-`nil` if Emacs was waiting for keyboard input from the user at the time the sentinel or filter function was called, `nil` if it was not.

Transaction Queues

You can use a transaction queue for more convenient communication with subprocesses using transactions. First use `tq-create` to create a transaction queue communicating with a specified process. Then you can call `tq-enqueue` to send a transaction.

Function: **tq-create** *process*

This function creates and returns a transaction queue communicating with process. The argument process should be a subprocess capable of sending and receiving streams of bytes. It may be a child process, or it may be a TCP connection to a server possibly on another machine.

Function: **tq-enqueue** *queue question regexp closure fn*

This function sends a transaction to queue queue. Specifying the queue has the effect of specifying the subprocess to talk to.

The argument question is the outgoing message which starts the transaction. The argument fn is the function to call when the corresponding answer comes back; it is called with two arguments: closure, and the answer received.

The argument regexp is a regular expression to match the entire answer; that's how `tq-enqueue` tells where the answer ends.

The return value of `tq-enqueue` itself is not meaningful.

Function: **tq-close** *queue*

Shut down transaction queue queue, waiting for all pending transactions to complete, and then terminate the connection or child process.

Transaction queues are implemented by means of a filter function. See section Process Filter Functio

TCP

Emacs Lisp programs can open TCP connections to other processes on the same machine or other machines. A network connection is handled by Lisp much like a subprocess, and is represented by a process object. However, the process you are communicating with is not a child of the Emacs process, so you can't kill it or send it signals. All you can do is send and receive data. `delete-process` closes the connection, but does not kill the process at the other end; that process must decide what to do about closure of the connection.

You can distinguish process objects representing network connections from those representing subprocesses with the `process-status` function. See section Process Information.

Function: **open-network-stream** *name buffer-or-name host service*

This function opens a TCP connection for a service to a host. It returns a process object to represent the connection.

The name argument specifies the name for the process object. It is modified as necessary to make it unique.

The buffer-or-name argument is the buffer to associate with the connection. Output from the connection is inserted in the buffer, unless you specify a filter function to handle the output. If buffer-or-name is `nil`, it means that the connection is not associated with any buffer.

The arguments host and service specify where to connect to; host is the host name (a string), and service is the name of a defined network service (a string) or a port number (an integer).

Operating System Interface

This chapter is about starting and getting out of Emacs, access to values in the operating system environment, and terminal input, output and flow control.

See section Building Emacs, for related information. See also section Emacs Display, for additional operating system status information pertaining to the terminal and the screen.

Starting Up Emacs

This section describes what Emacs does when it is started, and how you can customize these actions.

Summary: Sequence of Actions at Start Up

The order of operations performed (in `startup.el') by Emacs when it is started up is as follows:

1. It runs the normal hook `before-init-hook`.
2. It loads `.emacs' unless `-q' was specified on command line. (This is not done in `-batch' mode.) `.emacs' is found in the user's home directory; the `-u' option can specify the user name whose home directory should be used.
3. It loads `default.el' unless `inhibit-default-init` is non-`nil`. (This is not done in `-batch' mode or if `-q' was specified on command line.)
4. It runs the normal hook `after-init-hook`.
5. It loads the terminal-specific Lisp file, if any, except when in batch mode.
6. It runs `term-setup-hook`.
7. It runs `window-setup-hook`. See section Window Systems.
8. It displays copyleft and nonwarranty, plus basic use information, unless the value of the variable `inhibit-startup-message` is non-`nil`.

   This display is also inhibited in batch mode, and if the current buffer is not `*scratch*'.
9. It processes any remaining command line arguments.

User Option: **inhibit-startup-message**

This variable inhibits the initial startup messages (the nonwarranty, etc.). If it is non-`nil`, then the messages are not printed.

This variable exists so you can set it in your personal init file, once you are familiar with the contents of the startup message. Do not set this variable in the init file of a new user, or in a way that affects more than one user, because that would prevent new users from receiving the information they are supposed to see.

The Init File: `.emacs'

When you start Emacs, it normally attempts to load the file `.emacs' from your home directory. This file, if it exists, must contain Lisp code. It is called your init file. The command line switches `-q' and `-u' can be used to control the use of the init file; `-q' says not to load an init file, and `-u' says to load a specified user's init file instead of yours. See section 'Entering Emacs' in The GNU Emacs Manual.

Emacs may also have a default init file, which is the library named `default.el'. Emacs finds the `default.el' file through the standard search path for libraries (see section How Programs Do Loading). The Emacs distribution does not have any such file; you may create one at your site for local customizations. If the default init file exists, it is loaded whenever you start Emacs, except in batch mode or if `-q' is specified. But your own personal init file, if any, is loaded first; if it sets `inhibit-default-init` to a non-`nil` value, then Emacs will not subsequently load the `default.el' file.

If there is a great deal of code in your `.emacs' file, you should move it into another file named `something.el', byte-compile it (see section Byte Compilation), and make your `.emacs' file load the other file using `load` (see section Loading).

See section 'Init File Examples' in The GNU Emacs Manual, for examples of how to make various commonly desired customizations in your `.emacs' file.

User Option: **inhibit-default-init**

This variable prevents Emacs from loading the default initialization library file for your session of Emacs. If its value is non-`nil`, then the default library is not loaded. The default value is `nil`.

Variable: **before-init-hook**

Variable: **after-init-hook**

These two normal hooks are run just before, and just after, loading of the user's init file or `default.el'.

Terminal-Specific Initialization

Each terminal type can have its own Lisp library that Emacs loads when run on that type of terminal. For a terminal type named termtype, the library is called `term/termtype'. Emacs finds the file by searching the `load-path` directories as it does for other files, and trying the `.elc' and `.el' suffixes. Normally, terminal-specific Lisp library is located in `emacs/lisp/term', a subdirectory of the `emacs/lisp' directory in which most Emacs Lisp libraries are kept.

The library's name is constructed by concatenating the value of the variable `term-file-prefix` and the terminal type. Normally, `term-file-prefix` has the value `"term/"`; changing this is not recommended.

The usual function of a terminal-specific library is to enable special keys to send sequences that Emacs can recognize. It may also need to set or add to `function-key-map` if the Termcap entry does not

fully explain what should go in it. See section Terminal Input.

When the name of the terminal type contains a hyphen, only the part of the name before the first hyphen is significant in choosing the library name. Thus, terminal types `aaa-48' and `aaa-30-rv' both use the `term/aaa' library. If necessary, the library can evaluate `(getenv "TERM")` to find the full name of the terminal type.

Your `.emacs' file can prevent the loading of the terminal-specific library by setting the variable `term-file-prefix` to `nil`. This feature is very useful when experimenting with your own peculiar customizations.

You can also arrange to override some of the actions of the terminal-specific library by setting the variable `term-setup-hook`. This is a normal hook which Emacs runs using `run-hooks` at the end of Emacs initialization, after loading both your `.emacs' file and any terminal-specific libraries. You can use this variable to define initializations for terminals that do not have their own libraries. See section Hooks.

Variable: **term-file-prefix**

If the `term-file-prefix` variable is non-`nil`, Emacs loads a terminal-specific initialization file as follows:

```
(load (concat term-file-prefix (getenv "TERM")))
```

You may set the `term-file-prefix` variable to `nil` in your `.emacs' file if you do not wish to load the terminal-initialization file. To do this, put the following in your `.emacs' file: `(setq term-file-prefix nil)`.

Variable: **term-setup-hook**

This variable is a normal hook which Emacs runs after loading your `.emacs' file, the default initialization file (if any) and after loading terminal-specific Lisp files. arguments.

You can use `term-setup-hook` to override the definitions made by a terminal-specific file.

See `window-setup-hook` in section Window Systems, for a related feature.

Command Line Arguments

You can use command line arguments to request various actions when you start Emacs. Since you do not need to start Emacs more than once per day, and will often leave your Emacs session running longer than that, command line arguments are hardly ever used. As a practical matter, it is best to avoid making the habit of using them, since this habit would encourage you to kill and restart Emacs unnecessarily often. These options exist for two reasons: to be compatible with other editors (for invocation by other programs) and to enable shell scripts to run specific Lisp programs.

Function: **command-line**

This function parses the command line which Emacs was called with, processes it, loads the user's

`.emacs' file and displays the initial nonwarranty information, etc.

Variable: **command-line-processed**

The value of this variable is `t` once the command line has been processed.

If you redump Emacs by calling `dump-emacs`, you may wish to set this variable to `nil` first in order to cause the new dumped Emacs to process its new command line arguments.

Variable: **command-switch-alist**

The value of this variable is an alist of user-defined command-line options and associated handler functions. This variable exists so you can add elements to it.

A command line option is an argument on the command line of the form:

```
-option
```

The elements of the `command-switch-alist` look like this:

```
(option . handler-function)
```

The handler-function is called to handle option and receives the option name as its sole argument.

In some cases, the option is followed in the command line by an argument. In these cases, the handler-function can find all the remaining command-line arguments in the variable `command-line-args-left`. (The entire list of command-line arguments is in `command-line-args`.)

The command line arguments are parsed by the `command-line-1` function in the `startup.el' file. See also section 'Command Line Switches and Arguments' in The GNU Emacs Manual.

Variable: **command-line-args**

The value of this variable is the arguments passed by the shell to Emacs, as a list of strings.

Getting out of Emacs

There are two ways to get out of Emacs: you can kill the Emacs job, which exits permanently, or you can suspend it, which permits you to reenter the Emacs process later. As a practical matter, you seldom kill Emacs--only when you are about to log out. Suspending is much more common.

Killing Emacs

Killing Emacs means ending the execution of the Emacs process. The parent process normally resumes control.

All the information in the Emacs process, aside from files that have been saved, is lost when the Emacs is killed. Because killing Emacs inadvertently can lose a lot of work, Emacs queries for confirmation before

actually terminating if you have buffers that need saving or subprocesses that are running.

Function: **kill-emacs** *&optional no-query*

This function exits the Emacs process and kills it.

Normally, if there are modified files or if there are running processes, `kill-emacs` asks the user for confirmation before exiting. However, if no-query is supplied and non-`nil`, then Emacs exits without confirmation.

If no-query is an integer, then it is used as the exit status of the Emacs process. (This is useful primarily in batch operation; see section Batch Mode.)

If no-query is a string, its contents are stuffed into the terminal input buffer so that the shell (or whatever program next reads input) can read them.

Variable: **kill-emacs-hook**

This variable is a normal hook (a list of functions); the first thing `kill-emacs` does is to run this hook with `run-hooks`. That calls each of the functions in the list, with no arguments.

Suspending Emacs

Suspending Emacs means stopping Emacs temporarily and returning control to its superior process, which is usually the shell. This allows you to resume editing later in the same Emacs process, with the same buffers, the same kill ring, the same undo history, and so on. To resume Emacs, use the appropriate command in the parent shell--most likely `fg`.

Some operating systems do not support suspension of jobs; on these systems, "suspension" actually creates a new shell temporarily as a subprocess of Emacs. Then you would exit the shell to return to Emacs.

Suspension is not useful with window systems such as X, because the Emacs job may not have a parent that can resume it again, and in any case you can give input to some other job such as a shell merely by moving to a different window. Therefore, suspending is not allowed when Emacs is an X client.

Function: **suspend-emacs** *string*

This function stops Emacs and returns to the superior process. It returns `nil`.

If string is non-`nil`, its characters are sent to be read as terminal input by Emacs's superior shell. The characters in string are not echoed by the superior shell; only the results appear.

Before suspending, `suspend-emacs` runs the normal hook `suspend-hook`. In Emacs version 18, `suspend-hook` was not a normal hook; its value was a single function, and if its value was non-`nil`, then `suspend-emacs` returned immediately without actually suspending anything.

After the user resumes Emacs, it runs the normal hook `suspend-resume-hook` using `run-hooks`. See section Hooks.

The next redisplay after resumption will redraw the entire screen, unless the variable

`no-redraw-on-reenter` is non-`nil` (see section Refreshing the Screen).

In the following example, note that `pwd' is not echoed after Emacs is suspended. But it is read and executed by the shell.

```
(suspend-emacs)
     => nil

(add-hook 'suspend-hook
          (function (lambda ()
                      (or (y-or-n-p
                            "Really suspend? ")
                          (error "Suspend cancelled")))))
     => (lambda nil
          (or (y-or-n-p "Really suspend? ")
              (error "Suspend cancelled")))
(add-hook 'suspend-resume-hook
          (function (lambda () (message "Resumed!"))))
     => (lambda nil (message "Resumed!"))
(suspend-emacs "pwd")
     => nil
---------- Buffer: Minibuffer ----------
Really suspend? y
---------- Buffer: Minibuffer ----------

---------- Parent Shell ----------
lewis@slug[23] % /user/lewis/manual
lewis@slug[24] % fg

---------- Echo Area ----------
Resumed!
```

Variable: **suspend-hook**

This variable is a normal hook run before suspending.

Variable: **suspend-resume-hook**

This variable is a normal hook run after suspending.

Operating System Environment

Emacs provides access to variables in the operating system environment through various functions. These variables include the name of the system, the user's UID, and so on.

Variable: **system-type**

The value of this variable is a symbol indicating the type of operating system Emacs is operating on. Here is a table of the symbols for the operating systems that Emacs can run on up to version 19.1.

`aix-v3`
: AIX version 3.

`berkeley-unix`
: Berkeley BSD 4.1, 4.2, or 4.3.

`hpux`
: Hewlett-Packard operating system, version 5, 6, or 7.

`irix`
: Silicon Graphics Irix system.

`rtu`
: RTU 3.0, UCB universe.

`unisoft-unix`
: UniSoft's UniPlus 5.0 or 5.2.

`usg-unix-v`
: AT&T's System V.0, System V Release 2.0, 2.2, or 3.

`vax-vms`
: VAX VMS version 4 or 5.

`xenix`
: SCO Xenix 386 Release 2.2.

We do not wish to add new symbols to make finer distinctions unless it is absolutely necessary! In fact, it would be nice to eliminate some of these alternatives in the future.

Function: **system-name**

This function returns the name of the machine you are running on.

```
(system-name)
     => "prep.ai.mit.edu"
```

Function: **getenv** *var*

This function returns the value of the environment variable var, as a string. If the variable `process-environment` specifies a value for var, that overrides the actual environment.

```
(getenv "USER")
     => "lewis"

lewis@slug[10] % printenv
PATH=.:/user/lewis/bin:/usr/bin:/usr/local/bin
USER=lewis
```

```
TERM=ibmapa16
SHELL=/bin/csh
HOME=/user/lewis
```

Command: **setenv** *variable value*

This command sets the value of the environment variable named variable to value. Both arguments should be strings. This works by modifying `process-environment`; binding that variable with `let` is also reasonable practice.

Variable: **process-environment**

This variable is a list of strings to append to the environment of processes as they are created. Each string assigns a value to a shell environment variable. (This applies both to asynchronous and synchronous processes.) The function `getenv` also looks at this variable.

```
process-environment
=> ("l=/usr/stanford/lib/gnuemacs/lisp"
    "PATH=.:/user/lewis/bin:/usr/class:/nfsusr/local/bin"
    "USER=lewis"
    "TERM=ibmapa16"
    "SHELL=/bin/csh"
    "HOME=/user/lewis")
```

Function: **load-average**

This function returns the current 1 minute, 5 minute and 15 minute load averages in a list. The values are integers that are 100 times the system load averages. (The load averages indicate the number of processes trying to run.)

```
(load-average)
     => (169 48 36)

lewis@rocky[5] % uptime
 11:55am  up 1 day, 19:37,  3 users,
 load average: 1.69, 0.48, 0.36
```

Function: **setprv** *privilege-name &optional setp getprv*

This function sets or resets a VMS privilege. (It does not exist on Unix.) The first arg is the privilege name, as a string. The second argument, setp, is `t` or `nil`, indicating whether the privilege is to be turned on or off. Its default is `nil`. The function returns `t` if success, `nil` if not.

If the third argument, getprv, is non-`nil`, `setprv` does not change the privilege, but returns `t` or `nil` indicating whether the privilege is currently enabled.

User Identification

Function: **user-login-name**

This function returns the name under which the user is logged in. This is based on the effective UID, not the real UID.

```
(user-login-name)
     => "lewis"
```

Function: **user-real-login-name**

This function returns the name under which the user logged in. This is based on the real UID, not the effective UID. This differs from `user-login-name` only when running with the setuid bit.

Function: **user-full-name**

This function returns the full name of the user.

```
(user-full-name)
     => "Bil Lewis"
```

Function: **user-real-uid**

This function returns the real UID of the user.

```
(user-real-uid)
     => 19
```

Function: **user-uid**

This function returns the effective UID of the user.

Time of Day

This section explains how to determine the current time and the time zone.

Function: **current-time-string** *&optional time-value*

This function returns the current time and date as a humanly-readable string. The format of the string is unvarying; the number of characters used for each part is always the same, so you can reliably use `substring` to extract pieces of it. However, it would be wise to count the characters from the beginning of the string rather than from the end, as additional information may be added at the end.

The argument time-value, if given, specifies a time to format instead of the current time. The argument should be a cons cell containing two integers, or a list whose first two elements are integers. Thus, you can use times obtained from `current-time` (see below) and from `file-attributes` (see section Other Information about Files).

```
(current-time-string)
     => "Wed Oct 14 22:21:05 1987"
```

Function: **current-time**

This function returns the system's time value as a list of three integers: `(high low microsec)`. The integers high and low combine to give the number of seconds since 0:00 January 1, 1970, which is high * 2**16 + low.

The third element, microsec, gives the microseconds since the start of the current second (or 0 for systems that return time only on the resolution of a second).

The first two elements can be compared with file time values such as you get with the function `file-attributes`. See section Other Information about Files.

Function: **current-time-zone** *&optional time-value*

This function returns a list describing the time zone that the user is in.

The value has the form `(offset name)`. Here offset is an integer giving the number of seconds ahead of UTC (east of Greenwich). A negative value means west of Greenwich. The second element, name is a string giving the name of the time zone. Both elements change when daylight savings time begins or ends; if the user has specified a time zone that does not use a seasonal time adjustment, then the value is constant through time.

If the operating system doesn't supply all the information necessary to compute the value, both elements of the list are `nil`.

The argument time-value, if given, specifies a time to analyze instead of the current time. The argument should be a cons cell containing two integers, or a list whose first two elements are integers. Thus, you can use times obtained from `current-time` (see below) and from `file-attributes` (see section Other Information about Files).

Timers

You can set up a timer to call a function at a specified future time.

Function: **run-at-time** *time repeat function &rest args*

This function arranges to call function with arguments args at time time. The argument function is a function to call later, and args are the arguments to give it when it is called. The time time is specified as a string.

Absolute times may be specified in a wide variety of formats; The form `hour:min:sec timezone month/day/year', where all fields are numbers, works; the format that `current-time-string` returns is also allowed.

To specify a relative time, use numbers followed by units. For example:

`1 min'
: denotes 1 minute from now.

`1 min 5 sec'
: denotes 65 seconds from now.

`1 min 2 sec 3 hour 4 day 5 week 6 fortnight 7 month 8 year'
: denotes exactly 103 months, 123 days, and 10862 seconds from now.

If time is an integer, that specifies a relative time measured in seconds.

The argument repeat specifies how often to repeat the call. If repeat is `nil`, there are no repetitions; function is called just once, at time. If repeat is an integer, it specifies a repetition period measured in seconds.

Function: **cancel-timer** *timer*

Cancel the requested action for timer, which should be a value previously returned by `run-at-time`. This cancels the effect of that call to `run-at-time`; the arrival of the specified time will not cause anything special to happen.

Terminal Input

This section describes functions and variables for recording or manipulating terminal input. See section Emacs Display, for related functions.

Input Modes

Function: **set-input-mode** *interrupt flow meta quit-char*

This function sets the mode for reading keyboard input. If interrupt is non-null, then Emacs uses input interrupts. If it is `nil`, then it uses CBREAK mode.

If flow is non-`nil`, then Emacs uses XON/XOFF (C-q, C-s) flow control for output to terminal. This has no effect except in CBREAK mode. See section Flow Control.

The normal setting is system dependent. Some systems always use CBREAK mode regardless of what is specified.

The argument meta controls support for input character codes above 127. If meta is `t`, Emacs converts characters with the 8th bit set into Meta characters. If meta is `nil`, Emacs disregards the 8th bit; this is necessary when the terminal uses it as a parity bit. If meta is neither `t` nor `nil`, Emacs uses all 8 bits of input unchanged. This is good for terminals using European 8-bit character sets.

If quit-char is non-`nil`, it specifies the character to use for quitting. Normally this character is C-g. See section Quitting.

The `current-input-mode` function returns the input mode settings Emacs is currently using.

Function: **current-input-mode**

This function returns current mode for reading keyboard input. It returns a list, corresponding to the arguments of `set-input-mode`, of the form `(INTERRUPT FLOW META QUIT)` in which:

INTERRUPT
: is non-`nil` when Emacs is using interrupt-driven input. If `nil`, Emacs is using CBREAK mode.

FLOW
: is non-`nil` if Emacs uses XON/XOFF (C-q, C-s) flow control for output to the terminal. This value has no effect unless INTERRUPT is non-`nil`.

META
: is non-`nil` if Emacs is paying attention to the eighth bit of input characters; if nil, Emacs clears the eighth bit of every input character.

QUIT
: is the character Emacs currently uses for quitting, usually C-g.

Variable: **meta-flag**

This variable used to control whether to treat the 0200 bit in keyboard input as the Meta bit. `nil` meant no, and anything else meant yes. This variable existed in Emacs versions 18 and earlier but no longer exists in Emacs 19; use `set-input-mode` instead.

Translating Input Events

Variable: **extra-keyboard-modifiers**

This variable lets Lisp programs "press" the modifier keys on the keyboard. The value is a bit mask:

1
: The SHIFT key.

2
: The LOCK key.

4
: The CTL key.

8
: The META key.

Each time the user types a keyboard key, it is altered as if the modifier keys specified in the bit mask were held down.

When you use X windows, the program can "press" any of the modifier keys in this way. Otherwise, only the CTL and META keys can be virtually pressed.

Variable: **keyboard-translate-table**

This variable is the translate table for keyboard characters. It lets you reshuffle the keys on the keyboard

without changing any command bindings. Its value must be a string or `nil`.

If `keyboard-translate-table` is a string, then each character read from the keyboard is looked up in this string and the character in the string is used instead. If the string is of length n, character codes n and up are untranslated.

In the example below, we set `keyboard-translate-table` to a string of 128 characters. Then we fill it in to swap the characters C-s and C-\ and the characters C-q and C-^. Subsequently, typing C-\ has all the usual effects of typing C-s, and vice versa. (See section Flow Control for more information on this subject.)

```
(defun evade-flow-control ()
  "Replace C-s with C-\ and C-q with C-^."
  (interactive)
  (let ((the-table (make-string 128 0)))
    (let ((i 0))
      (while (< i 128)
        (aset the-table i i)
        (setq i (1+ i))))

    ;; Swap C-s and C-\.
    (aset the-table ?\034 ?\^s)
    (aset the-table ?\^s ?\034)
    ;; Swap C-q and C-^.
    (aset the-table ?\036 ?\^q)
    (aset the-table ?\^q ?\036)

    (setq keyboard-translate-table the-table)))
```

Note that this translation is the first thing that happens to a character after it is read from the terminal. Record-keeping features such as `recent-keys` and dribble files record the characters after translation.

Function: **keyboard-translate** *from to*

This function modifies `keyboard-translate-table` to translate character code from into character code to. It creates or enlarges the translate table if necessary.

Variable: **function-key-map**

This variable holds a keymap which describes the character sequences sent by function keys on an ordinary character terminal. This keymap uses the data structure as other keymaps, but is used differently: it specifies translations to make while reading events.

If `function-key-map` "binds" a key sequence k to a vector v, then when k appears as a subsequence *anywhere* in a key sequence, it is replaced with the events in v.

For example, VT100 terminals send ESC O P when the keypad PF1 key is pressed. Therefore, we want Emacs to translate that sequence of events into the single event `pf1`. We accomplish this by "binding"

ESC O P to `[pf1]` in `function-key-map`, when using a VT100.

Thus, typing C-c PF1 sends the character sequence C-c ESC O P; later the function `read-key-sequence` translates this back into C-c PF1, which it returns as the vector `[?\C-c pf1]`.

Entries in `function-key-map` are ignored if they conflict with bindings made in the minor mode, local, or global keymaps. The intent is that the character sequences that function keys send should not have command bindings in their own right.

The value of `function-key-map` is usually set up automatically according to the terminal's Terminfo or Termcap entry, but sometimes those need help from terminal-specific Lisp files. Emacs comes with a number of terminal-specific files for many common terminals; their main purpose is to make entries in `function-key-map` beyond those that can be deduced from Termcap and Terminfo. See section Terminal-Specific Initialization.

Emacs versions 18 and earlier used totally different means of detecting the character sequences that represent function keys.

Variable: **key-translation-map**

This variable is another keymap used just like `function-key-map` to translate input events into other events. It differs from `function-key-map` in two ways:

- `key-translation-map` goes to work after `function-key-map` is finished; it receives the results of translation by `function-key-map`.
- `key-translation-map` overrides actual key bindings.

The intent of `key-translation-map` is for users to map one character set to another, including ordinary characters normally bound to `self-insert-command`.

Recording Input

Function: **recent-keys**

This function returns a vector containing the last 100 input events from the keyboard or mouse. All input events are included, whether or not they were used as parts of key sequences. Thus, you always get the last 100 inputs, not counting keyboard macros. (Events from keyboard macros are excluded because they are less interesting for debugging; it should be enough to see the events which invoked the macros.)

Command: **open-dribble-file** *filename*

This function opens a dribble file named filename. When a dribble file is open, each input event from the keyboard or mouse (but not those from keyboard macros) are written in that file. A non-character event is expressed using its printed representation surrounded by `<...>'.

You close the dribble file by calling this function with an argument of `nil`. The function always returns `nil`.

This function is normally used to record the input necessary to trigger an Emacs bug, for the sake of a

bug report.

```
(open-dribble-file "~/dribble")
     => nil
```

See also the `open-termscript` function (see section Terminal Output).

Terminal Output

The terminal output functions send output to the terminal or keep track of output sent to the terminal. The variable `baud-rate` tells you what Emacs thinks is the output speed of the terminal.

Variable: **baud-rate**

This variable's value is the output speed of the terminal, as far as Emacs knows. Setting this variable does not change the speed of actual data transmission, but the value is used for calculations such as padding. It also affects decisions about whether to scroll part of the screen or repaint--even when using a window system, (We designed it this way despite the fact that a window system has no true "output speed", to give you a way to tune these decisions.)

The value is measured in baud.

If you are running across a network, and different parts of the network work at different baud rates, the value returned by Emacs may be different from the value used by your local terminal. Some network protocols communicate the local terminal speed to the remote machine, so that Emacs and other programs can get the proper value, but others do not. If Emacs has the wrong value, it makes decisions that are less than optimal. To fix the problem, set `baud-rate`.

Function: **baud-rate**

This function returns the value of the variable `baud-rate`. In Emacs versions 18 and earlier, this was the only way to find out the terminal speed.

Function: **send-string-to-terminal** *string*

This function sends string to the terminal without alteration. Control characters in string have terminal-dependent effects.

One use of this function is to define function keys on terminals that have downloadable function key definitions. For example, this is how on certain terminals to define function key 4 to move forward four characters (by transmitting the characters C-u C-f to the computer):

```
(send-string-to-terminal "\eF4\^U\^F")
     => nil
```

Command: **open-termscript** *filename*

This function is used to open a termscript file that will record all the characters sent by Emacs to the terminal. It returns `nil`. Termscript files are useful for investigating problems where Emacs garbles the

screen, problems which are due to incorrect Termcap entries or to undesirable settings of terminal options more often than actual Emacs bugs. Once you are certain which characters were actually output, you can determine reliably whether they correspond to the Termcap specifications in use.

See also `open-dribble-file` in section Terminal Input.

```
(open-termscript "../junk/termscript")
     => nil
```

Flow Control

This section attempts to answer the question "Why does Emacs choose to use flow-control characters in its command character set?" For a second view on this issue, read the comments on flow control in the `` `emacs/INSTALL' `` file from the distribution; for help with Termcap entries and DEC terminal concentrators, see `` `emacs/etc/TERMS' ``.

At one time, most terminals did not need flow control, and none used `C-s` and C-q for flow control. Therefore, the choice of C-s and C-q as command characters was unobjectionable. Emacs, for economy of keystrokes and portability, used nearly all the ASCII control characters, with mnemonic meanings when possible; thus, C-s for search and C-q for quote.

Later, some terminals were introduced which required these characters for flow control. They were not very good terminals for full-screen editing, so Emacs maintainers did not pay attention. In later years, flow control with C-s and C-q became widespread among terminals, but by this time it was usually an option. And the majority of users, who can turn flow control off, were unwilling to switch to less mnemonic key bindings for the sake of flow control.

So which usage is "right", Emacs's or that of some terminal and concentrator manufacturers? This is a rhetorical (or religious) question; it has no simple answer.

One reason why we are reluctant to cater to the problems caused by C-s and C-q is that they are gratuitous. There are other techniques (albeit less common in practice) for flow control that preserve transparency of the character stream. Note also that their use for flow control is not an official standard. Interestingly, on the model 33 teletype with a paper tape punch (which is very old), C-s and C-q were sent by the computer to turn the punch on and off!

GNU Emacs version 19 provides a convenient way of enabling flow control if you want it: call the function `enable-flow-control`.

Function: **enable-flow-control**

This function enables use of C-s and C-q for output flow control, and provides the characters C-\ and C-^ as aliases for them using `keyboard-translate-table` (see section Translating Input Events).

You can use the function `enable-flow-control-on` in your `` `.emacs' `` file to enable flow control automatically on certain terminal types.

Function: **enable-flow-control-on** *&rest termtypes*

This function enables flow control, and the aliases C-\ and C-^, if the terminal type is one of termtyp
For example:

```
(enable-flow-control-on "vt200" "vt300" "vt101" "vt131")
```

Here is how `enable-flow-control` does its job:

1. It sets CBREAK mode for terminal input, and tells the kernel to handle flow control, with `(set-input-mode nil t)`.
2. It sets up `keyboard-translate-table` to translate C-\ and C-^ into C-s and C-q were typed. Except at its very lowest level, Emacs never knows that the characters typed were anything but C-s and C-q, so you can in effect type them as C-\ and C-^ even when they are input for other commands. For example:

```
(setq keyboard-translate-table (make-string 128 0))
(let ((i 0))
  ;; Map most characters into themselves.
  (while (< i 128)
    (aset keyboard-translate-table i i)
    (setq i (1+ i))))
  ;; Map C-\ to C-s.
  (aset the-table ?\034 ?\^s)
  ;; Map C-^ to C-q.
  (aset the-table ?\036 ?\^q)))
```

If the terminal is the source of the flow control characters, then once you enable kernel flow control handling, you probably can make do with less padding than normal for that terminal. You can reduce the amount of padding by customizing the Termcap entry. You can also reduce it by setting `baud-rate` to a smaller value so that Emacs uses a smaller speed when calculating the padding needed. See section Terminal Output.

Batch Mode

The command line option `-batch' causes Emacs to run noninteractively. In this mode, Emacs does not read commands from the terminal, it does not alter the terminal modes, and it does not expect to be outputting to an erasable screen. The idea is that you specify Lisp programs to run; when they are finished, Emacs should exit. The way to specify the programs to run is with `-l file', which loads the library named file, and `-f function', which calls function with no arguments.

Any Lisp program output that would normally go to the echo area, either using `message` or using `prin1`, etc., with `t` as the stream, goes instead to Emacs's standard output descriptor when in batch mode. Thus, Emacs behaves much like a noninteractive application program. (The echo area output that Emacs itself normally generates, such as command echoing, is suppressed entirely.)

Variable: **noninteractive**

This variable is non-`nil` when Emacs is running in batch mode.

Go to the previous, next section.

Go to the previous, next section.

Emacs Display

This chapter describes a number of features related to the display that Emacs presents to the user.

Refreshing the Screen

The function `redraw-frame` redisplays the entire contents of a given frame. See section Frames.

Function: **redraw-frame** *frame*

This function clears and redisplays frame frame.

Even more powerful is `redraw-display`.

Command: **redraw-display**

This function clears and redisplays all visible frames.

Normally, suspending and resuming Emacs also refreshes the screen. Some terminal emulators record separate contents for display-oriented programs such as Emacs and for ordinary sequential display. If you are using such a terminal, you might want to inhibit the redisplay on resumption. See section Suspending Emacs.

Variable: **no-redraw-on-reenter**

This variable controls whether Emacs redraws the entire screen after it has been suspended and resumed. Non-`nil` means yes, `nil` means no.

Processing user input takes absolute priority over redisplay. If you call these functions when input is available, they do nothing immediately, but a full redisplay does happen eventually--after all the input has been processed.

Screen Size

The screen size functions report or tell Emacs the height or width of the terminal. When you are using multiple frames, they apply to the selected frame (see section Frames).

Function: **screen-height**

This function returns the number of lines on the screen that are available for display.

```
(screen-height)
     => 50
```

Function: **screen-width**

This function returns the number of columns on the screen that are available for display.

```
(screen-width)
     => 80
```

Function: **set-screen-height** *lines &optional not-actual-size*

This function declares that the terminal can display lines lines. The sizes of existing windows are altered proportionally to fit.

If not-actual-size is non-`nil`, then Emacs displays lines lines of output, but does not change its value for the actual height of the screen. (Knowing the correct actual size may be necessary for correct cursor positioning.) Using a smaller height than the terminal actually implements may be useful to reproduce behavior observed on a smaller screen, or if the terminal malfunctions when using its whole screen.

If lines is different from what it was previously, then the entire screen is cleared and redisplayed using the new size.

This function returns `nil`.

Function: **set-screen-width** *columns &optional not-actual-size*

This function declares that the terminal can display columns columns. The details are as in `set-screen-height`.

Truncation

When a line of text extends beyond the right edge of a window, the line can either be truncated or continued on the next line. When a line is truncated, this is shown with a `$' in the rightmost column of the window. When a line is continued or "wrapped" onto the next line, this is shown with a `\' on the rightmost column of the window. The additional screen lines used to display a long text line are called continuation lines. (Note that wrapped lines are not filled; filling has nothing to do with continuation and truncation. See section Filling.)

User Option: **truncate-lines**

This buffer-local variable controls how Emacs displays lines that extend beyond the right edge of the window. If it is non-`nil`, then Emacs does not display continuation lines; rather each line of text occupies exactly one screen line, and a dollar sign appears at the edge of any line that extends to or beyond the edge of the window. The default is `nil`.

If the variable `truncate-partial-width-windows` is non-`nil`, then truncation is used for windows that are not the full width of the screen, regardless of the value of `truncate-lines`.

Variable: **default-truncate-lines**

This variable is the default value for `truncate-lines` in buffers that do not have local values for it.

User Option: **truncate-partial-width-windows**

This variable determines how lines that are too wide to fit on the screen are displayed in side-by-side windows (see section Splitting Windows). If it is non-`nil`, then wide lines are truncated (with a `$' at the end of the line); otherwise they wrap to the next screen line (with a `\' at the end of the line).

You can override the images that indicate continuation or truncation with the display table; see section Display Tables.

The Echo Area

The echo area is used for displaying messages made with the `message` primitive, and for echoing keystrokes. It is not the same as the minibuffer, despite the fact that the minibuffer appears (when active) in the same place on the screen as the echo area. The GNU Emacs Manual specifies the rules for resolving conflicts between the echo area and the minibuffer for use of that screen space (see section 'The Minibuffer' in The GNU Emacs Manual). Error messages appear in the echo area; see section Errors.

You can write output in the echo area by using the Lisp printing functions with `t` as the stream (see section Output Functions), or as follows:

Function: **message** *string &rest arguments*

This function prints a one-line message in the echo area. The argument string is similar to a C language `printf` control string. See `format` in section Conversion of Characters and Strings, for the details on the conversion specifications. `message` returns the constructed string.

If string is `nil`, `message` clears the echo area. If the minibuffer is active, this brings the minibuffer contents back onto the screen immediately.

```
(message
 "Minibuffer depth is %d."
 (minibuffer-depth))
=> "Minibuffer depth is 0."

---------- Echo Area ----------
Minibuffer depth is 0.
---------- Echo Area ----------
```

Variable: **cursor-in-echo-area**

This variable controls where the cursor appears when a message is displayed in the echo area. If it is non-`nil`, then the cursor appears at the end of the message. Otherwise, the cursor appears at point--not in the echo area at all.

The value is normally `nil`; Lisp programs bind it to `t` for brief periods of time.

Selective Display

Selective display is a class of minor modes in which specially marked lines do not appear on the screen, or in which highly indented lines do not appear.

The first variant, explicit selective display, is designed for use in a Lisp program. The program controls which lines are hidden by altering the text. Outline mode uses this variant. In the second variant, the choice of lines to hide is made automatically based on indentation. This variant is designed as a user-level feature.

The way you control explicit selective display is by replacing a newline (control-j) with a control-m. The text which was formerly a line following that newline is now invisible. Strictly speaking, it is temporarily no longer a line at all, since only newlines can separate lines; it is now part of the previous line.

Selective display does not directly affect editing commands. For example, C-f (`forward-char`) moves point unhesitatingly into invisible space. However, the replacement of newline characters with carriage return characters affects some editing commands. For example, `next-line` skips invisible lines, since it searches only for newlines. Modes that use selective display can also define commands that take account of the newlines, or which make parts of the text visible or invisible.

When you write a selectively displayed buffer into a file, all the control-m's are replaced by their original newlines. This means that when you next read in the file, it looks OK, with nothing invisible. The selective display effect is seen only within Emacs.

Variable: **selective-display**

This buffer-local variable enables selective display. This means that lines, or portions of lines, may be made invisible.

- If the value of `selective-display` is `t`, then any portion of a line that follows a control-m is not displayed.
- If the value of `selective-display` is a positive integer, then lines that start with more than `selective-display` columns of indentation are not displayed.

When some portion of a buffer is invisible, the vertical movement commands operate as if that portion did not exist, allowing a single `next-line` command to skip any number of invisible lines. However, character movement commands (such as `forward-char`) do not skip the invisible portion, and it is possible (if tricky) to insert or delete text in an invisible portion.

In the examples below, what is shown is the *display* of the buffer `foo`, which changes with the value of `selective-display`. The *contents* of the buffer do not change.

```
(setq selective-display nil)
     => nil

---------- Buffer: foo ----------
1 on this column
 2on this column
```

```
  3n this column
  3n this column
 2on this column
1 on this column
---------- Buffer: foo ----------

(setq selective-display 2)
     => 2

---------- Buffer: foo ----------
1 on this column
 2on this column
 2on this column
1 on this column
---------- Buffer: foo ----------
```

Variable: **selective-display-ellipses**

If this buffer-local variable is non-`nil`, then Emacs displays `...' at the end of a line that is followed by invisible text. This example is a continuation of the previous one.

```
(setq selective-display-ellipses t)
     => t

---------- Buffer: foo ----------
1 on this column
 2on this column ...
 2on this column
1 on this column
---------- Buffer: foo ----------
```

You can use a display table to substitute other text for the ellipsis (`...'). See section Display Tables.

Overlay Arrow

The overlay arrow is useful for directing the user's attention to a particular line in a buffer. For example, in the modes used for interface to debuggers, the overlay arrow indicates the line of code about to be executed.

Variable: **overlay-arrow-string**

This variable holds the string to display as an arrow, or `nil` if the arrow feature is not in use.

Variable: **overlay-arrow-position**

This variable holds a marker which indicates where to display the arrow. It should point at the beginning of a line. The arrow text is displayed at the beginning of that line, overlaying any text that would

otherwise appear. Since the arrow is usually short, and the line usually begins with indentation, norm nothing significant is overwritten.

The overlay string is displayed only in the buffer which this marker points into. Thus, only one buffer can have an overlay arrow at any given time.

Temporary Displays

Temporary displays are used by commands to put output into a buffer and then present it to the user for perusal rather than for editing. Many of the help commands use this feature.

Special Form: **with-output-to-temp-buffer** *buffer-name forms...*

This function executes forms while arranging to insert any output they print into the buffer named buffer-name. The buffer is then shown in some window for viewing, displayed but not selected.

The string buffer-name specifies the temporary buffer, which need not already exist. The argument must be a string, not a buffer. The buffer is erased initially (with no questions asked), and it is marked as unmodified after `with-output-to-temp-buffer` exits.

`with-output-to-temp-buffer` binds `standard-output` to the temporary buffer, then it evaluates the forms in forms. Output using the Lisp output functions within forms goes by default to that buffer (but screen display and messages in the echo area, although output in the general sense of the word, are not affected). See section Output Functions.

The value of the last form in forms is returned.

```
---------- Buffer: foo ----------
 This is the contents of foo.
---------- Buffer: foo ----------

(with-output-to-temp-buffer "foo"
    (print 20)
    (print standard-output))
=> #<buffer foo>

---------- Buffer: foo ----------
20

#<buffer foo>

---------- Buffer: foo ----------
```

Variable: **temp-buffer-show-function**

The value of this variable, if non-`nil`, is called as a function to display a help buffer. This variable is used by `with-output-to-temp-buffer`.

In Emacs versions 18 and earlier, this variable was called `temp-buffer-show-hook`.

Function: **momentary-string-display** *string position &optional char message*

This function momentarily displays string in the current buffer at position (which is a character offset from the beginning of the buffer). The display remains until the next character is typed.

If the next character the user types is char, Emacs ignores it. Otherwise, that character remains buffered for subsequent use as input. Thus, typing char will simply remove the string from the display, while typing (say) C-f will remove the string from the display and later (presumably) move point forward. The argument char is a space by default.

The return value of `momentary-string-display` is not meaningful.

If message is non-`nil`, it is displayed in the echo area while string is displayed in the buffer. If it is `nil`, then instructions to type char are displayed there, e.g., `Type RET to continue editing'.

In this example, point is initially located at the beginning of the second line:

```
---------- Buffer: foo ----------
This is the contents of foo.
-!-Second line.
---------- Buffer: foo ----------

(momentary-string-display
   "**** Important Message! ****" (point) ?\r
   "Type RET when done reading")
=> t

---------- Buffer: foo ----------
This is the contents of foo.
**** Important Message! ****Second line.
---------- Buffer: foo ----------

---------- Echo Area ----------
Type RET when done reading
---------- Echo Area ----------
```

This function works by actually changing the text in the buffer. As a result, if you later undo in this buffer, you will see the message come and go.

Overlays

You can use overlays to alter the appearance of a buffer's text on the screen. An overlay is an object which belongs to a particular buffer, and has a specified beginning and end. It also has properties which you can examine and set; these affect the display of the text within the overlay.

Overlay Properties

Overlay properties are like text properties in some respects, but the differences are more important than the similarities. Text properties are considered a part of the text; overlays are specifically considered not to be part of the text. Thus, copying text between various buffers and strings preserves text properties, but does not try to preserve overlays. Changing a buffer's text properties marks the buffer as modified, while moving an overlay or changing its properties does not.

`face`

This property controls the font and color of text. See section Faces, for more information. This feature is temporary; in the future, we may replace it with other ways of specifying how to display text.

`mouse-face`

This property is used instead of `face` when the mouse is within the range of the overlay. This feature is not yet implemented, and may be temporary. It is documented here because we are likely to implement it this way at least for a while.

`priority`

This property's value (which should be a nonnegative number) determines the priority of the overlay. The priority matters when two or more overlays cover the same character and both specify a face for display; the one whose `priority` value is larger takes priority over the other, and its face attributes override the face attributes of the lower priority overlay.

Currently, all overlays take priority over text properties. Please avoid using negative priority values, as we have not yet decided just what they should mean.

`window`

If the `window` property is non-`nil`, then the overlay applies only on that window.

`before-string`

This property's value is a string to add to the display at the beginning of the overlay. The string does not appear in the buffer in any sense--only on the screen. This is not yet implemented, but will be.

`after-string`

This property's value is a string to add to the display at the end of the overlay. The string does not appear in the buffer in any sense--only on the screen. This is not yet implemented, but will be.

These are the functions for reading and writing the properties of an overlay.

Function: **overlay-get** *overlay prop*

This function returns the value of property prop recorded in overlay. If overlay does not record any value for that property, then the value is `nil`.

Function: **overlay-put** *overlay prop value*

This function set the value of property prop recorded in overlay to value. It returns value.

Managing Overlays

Function: **make-overlay** *start end &optional buffer*

This function creates and returns an overlay which belongs to buffer and ranges from start to end. Both start and end must specify buffer positions; they may be integers or markers. If buffer is omitted, the overlay is created in the current buffer.

The return value is the overlay itself.

Function: **overlay-start** *overlay*

This function returns the position at which overlay starts.

Function: **overlay-end** *overlay*

This function returns the position at which overlay ends.

Function: **overlay-buffer** *overlay*

This function returns the buffer that overlay belongs to.

Function: **delete-overlay** *overlay*

This function deletes overlay. The overlay continues to exist as a Lisp object, but ceases to be part of the buffer it belonged to, and ceases to have any effect on display.

Function: **move-overlay** *overlay start end &optional buffer*

This function moves overlay to buffer, and places its bounds at start and end. Both arguments start and end must specify buffer positions; they may be integers or markers. If buffer is omitted, the overlay stays in the same buffer.

The return value is overlay.

This is the only valid way to change the endpoints of an overlay. Do not try modifying the markers in the overlay by hand, as that fails to update other vital data structures and can cause some overlays to be "lost".

Function: **overlays-at** *pos*

This function returns a list of all the overlays that contain position pos in the current buffer. The list is in no particular order. An overlay contains position pos if it begins at or before pos, and ends after pos.

Function: **next-overlay-change** *pos*

This function returns the buffer position of the next beginning or end of an overlay, after pos.

Faces

A face is a named collection of graphical attributes: font, foreground color, background color and optional underlining. Faces control the display of text on the screen.

Each face has its own face id number which distinguishes faces at low levels within Emacs. However, for most purposes, you can refer to faces in Lisp programs by their names.

Each face name is meaningful for all frames, and by default it has the same meaning in all frames. But you can arrange to give a particular face name a special meaning in one frame if you wish.

The face named `default` is used for ordinary text. The face named `modeline` is used for displaying the mode line and menu bars. The face named `region` is used for highlighting the region (in Transient Mark mode only).

Merging Faces for Display

Here are all the ways to specify which face to use for display of text:

- With defaults. Each frame has a default face, whose id number is zero, which is used for all text that doesn't somehow specify another face.
- With text properties. A character may have a `face` property; if so, it's displayed with that face. If the character has a `mouse-face` property, that is used instead of the `face` property when the mouse is "near enough" to the character. See section Special Properties.
- With overlays. An overlay may have `face` and `mouse-face` properties too; they apply to all the text covered by the overlay.
- With special glyphs. Each glyph can specify a particular face id number. See section Glyphs.

If these various sources together specify more than one face for a particular character, Emacs merges the attributes of the various faces specified. The attributes of the faces of special glyphs come first; then come attributes of faces from overlays, followed by those from text properties, and last the default face.

When multiple overlays cover one character, an overlay with higher priority overrides those with lower priority. See section Overlays.

If an attribute such as the font or a color is not specified in any of the above ways, the frame's own font or color is used.

Functions for Working with Faces

The attributes a face can specify include the font, the foreground color, the background color, and underlining. The face can also leave these unspecified by giving the value `nil` for them.

Here are the primitives for creating and changing faces.

Function: **make-face** *name*

This function defines a new face named name, initially with all attributes `nil`. It does nothing if there already a face named name.

Function: **face-list**

This function returns a list of all defined face names.

Function: **copy-face** *old-face new-name &optional frame*

This function defines a new face named new which is a copy of the existing face named old. If there is already a face named new, then it alters the face to have the same attributes as old.

If the optional argument frame is given, this function applies only to that frame. Otherwise it applies to each frame individually.

You can modify the attributes of an existing face with the following functions. If you specify frame, they affect just that frame; otherwise, they affect all frames as well as the defaults that apply to new frames.

Function: **set-face-foreground** *face color &optional frame*

Function: **set-face-background** *face color &optional frame*

These functions set the foreground (respectively, background) color of face face to color. The argument color color should be a string, the name of a color.

Function: **set-face-font** *face font &optional frame*

This function sets the font of face face. The argument font should be a string.

Function: **set-face-underline-p** *face underline-p &optional frame*

This function sets the underline attribute of face face.

Function: **invert-face** *face &optional frame*

Swap the foreground and background colors of face face. If the face doesn't specify both foreground and background, then its foreground and background are set to the default background and foreground.

These functions examine the attributes of a face. If you don't specify frame, they refer to the default data for new frames.

Function: **face-foreground** *face &optional frame*

Function: **face-background** *face &optional frame*

These functions return the foreground (respectively, background) color of face face. The argument color color should be a string, the name of a color.

Function: **face-font** *face &optional frame*

This function returns the name of the font of face face.

Function: **face-underline-p** *face &optional frame*

This function returns the underline attribute of face face.

Function: **face-id-number** *face*

This function returns the id number of face face.

Function: **face-equal** *face1 face2 &optional frame*

This returns `t` if the faces face1 and face2 have the same attributes for display.

Function: **face-differs-from-default-p** *face &optional frame*

This returns `t` if the face face displays differently from the default face. A face is considered to be "the same" as the normal face if each attribute is either the same as that of the default face or `nil` (meaning to inherit from the default).

Variable: **region-face**

This variable's value specifies the face id to use to display characters in the region when it is active (in Transient Mark mode only). The face thus specified takes precedence over all faces that come from text properties and overlays, for characters in the region. See section The Mark, for more information about Transient Mark mode.

Normally, the value is the id number of the face named `region`.

Blinking

This section describes the mechanism by which Emacs shows a matching open parenthesis when the user inserts a close parenthesis.

Variable: **blink-paren-function**

The value of this variable should be a function (of no arguments) to be called whenever a char with close parenthesis syntax is inserted. The value of `blink-paren-function` may be `nil`, in which case nothing is done.

> **Please note:** this variable was named `blink-paren-hook` in older Emacs versions, but since it is not called with the standard convention for hooks, it was renamed to `blink-paren-function` in version 19.

Variable: **blink-matching-paren**

If this variable is `nil`, then `blink-matching-open` does nothing.

Variable: **blink-matching-paren-distance**

This variable specifies the maximum distance to scan for a matching parenthesis before giving up.

Function: **blink-matching-open**

This function is the default value of `blink-paren-function`. It assumes that point follows a character with close parenthesis syntax and moves the cursor momentarily to the matching opening

character. If that character is not already on the screen, then its context is shown by displaying it in the echo area. To avoid long delays, this function does not search farther than `blink-matching-paren-distance` characters.

Here is an example of calling this function explicitly.

```
(defun interactive-blink-matching-open ()
  "Indicate momentarily the start of sexp before point."
  (interactive)
  (let ((blink-matching-paren-distance
         (buffer-size))
        (blink-matching-paren t))
    (blink-matching-open)))
```

Inverse Video

User Option: **inverse-video**

This variable controls whether Emacs uses inverse video for all text on the screen. Non-`nil` means yes, `nil` means no. The default is `nil`.

User Option: **mode-line-inverse-video**

This variable controls the use of inverse video for mode lines. If it is non-`nil`, then mode lines are displayed in inverse video (under X, this uses the face named `modeline`, which you can set as you wish). Otherwise, mode lines are displayed normally, just like text. The default is `t`.

Usual Display Conventions

The usual display conventions define how to display each character code. You can override these conventions by setting up a display table (see section Display Tables). Here are the usual display conventions:

- Character codes 32 through 126 map to glyph codes 32 through 126. Normally this means they display as themselves.
- Character code 9 is a horizontal tab. It displays as whitespace up to a position determined by `tab-width`.
- Character code 10 is a newline.
- All other codes in the range 0 through 31, and code 127, display in one of two ways according to the value of `ctl-arrow`. If it is is non-`nil`, these codes map to sequences of two glyphs, where the first glyph is the ASCII code for `^'. Otherwise, these codes map just like the codes in the range 128 to 255.
- Character codes 128 through 255 map to sequences of four glyphs, where the first glyph is the ASCII code for `\', and the others are digit characters representing the code in octal.

The usual display conventions apply even when there is a display table, for any character whose entry in the active display table is `nil`. Thus, when you set up a display table, you need only specify the the characters for which you want unusual behavior.

These variables affect the way certain characters are displayed on the screen. Since they change the number of columns the characters occupy, they also affect the indentation functions.

User Option: **ctl-arrow**

This buffer-local variable controls how control characters are displayed. If it is non-`nil`, they are displayed as a caret followed by the character: `^A'. If it is `nil`, they are displayed as a backslash followed by three octal digits: `\001'.

Variable: **default-ctl-arrow**

The value of this variable is the default value for `ctl-arrow` in buffers that do not override it. This is the same as executing the following expression:

```
(default-value 'ctl-arrow)
```

See section The Default Value of a Buffer-Local Variable.

User Option: **tab-width**

The value of this variable is the spacing between tab stops used for displaying tab characters in Emacs buffers. The default is 8. Note that this feature is completely independent from the user-settable tab stops used by the command `tab-to-tab-stop`. See section Adjustable "Tab Stops".

Display Tables

You can use the display table feature to control how all 256 possible character codes display on the screen. This is useful for displaying European languages that have letters not in the ASCII character set.

The display table maps each character code into a sequence of glyphs, each glyph being an image that takes up one character position on the screen. You can also define how to display each glyph on your terminal, using the glyph table.

Display Table Format

A display table is actually an array of 261 elements.

Function: **make-display-table**

This creates and returns a display table. The table initially has `nil` in all elements.

The first 256 elements correspond to character codes; the nth element says how to display the character code n. The value should be `nil` or a vector of glyph values (see section Glyphs). If an element is `nil`, it says to display that character according to the usual display conventions (see section Usual Display

Conventions).

The remaining five elements of a display table serve special purposes, and `nil` means use the default stated below.

256
: The glyph for the end of a truncated screen line (the default for this is `$'). See section Glyphs.

257
: The glyph for the end of a continued line (the default is `\').

258
: The glyph for indicating a character displayed as an octal character code (the default is `\').

259
: The glyph for indicating a control character (the default is `^').

260
: A vector of glyphs for indicating the presence of invisible lines (the default is `...'). See section Selective Display.

For example, here is how to construct a display table that mimics the effect of setting `ctl-arrow` to a non-`nil` value:

```
(setq disptab (make-display-table))
(let ((i 0))
  (while (< i 32)
    (or (= i ?\t) (= i ?\n)
        (aset disptab i (vector ?^ (+ i 64))))
    (setq i (1+ i)))
  (aset disptab 127 (vector ?^ ??)))
```

Active Display Table

Each window can specify a display table, and so can each buffer. When a buffer b is displayed in window w, display uses the display table for window w if it has one; otherwise, the display table for buffer b if it has one; otherwise, the standard display table if any. The display table chosen is called the active display table.

Function: **window-display-table** *window*

This function returns window's display table, or `nil` if window does not have an assigned display table.

Function: **set-window-display-table** *window table*

This function sets the display table of window to table. The argument table should be either a display table or `nil`.

Variable: **buffer-display-table**

This variable is automatically local in all buffers; its value in a particular buffer is the display table f that buffer, or `nil` if the buffer does not have any assigned display table.

Variable: **standard-display-table**

This variable's value is the default display table, used when neither the current buffer nor the window displaying it has an assigned display table. This variable is `nil` by default.

If neither the selected window nor the current buffer has a display table, and if the variable `standard-display-table` is `nil`, then Emacs uses the usual display conventions. See section Usual Display Conventions.

Glyphs

A glyph is a generalization of a character; it stands for an image that takes up a single character position on the screen. Glyphs are represented in Lisp as integers, just as characters are.

The meaning of each integer, as a glyph, is defined by the glyph table, which is the value of the variable `glyph-table`.

Variable: **glyph-table**

The value of this variable is the current glyph table. It should be a vector; the gth element defines glyph code g. If the value is `nil` instead of a vector, then all glyphs are simple (see below).

Here are the possible types of elements in the glyph table:

integer

Define this glyph code as an alias for code integer. This is used with X Windows to specify a face code.

string

Send the characters in string to the terminal to output this glyph. This alternative is available on character terminals, but not under X.

`nil`

This glyph is simple. On an ordinary terminal, the glyph code mod 256 is the character to output. With X, the glyph code mod 256 is character to output, and the glyph code divided by 256 specifies the face id number to use while outputting it. See section Faces.

If a glyph code is greater than or equal to the length of the glyph table, that code is automatically simple.

ISO Latin 1

If you have a terminal that can handle the entire ISO Latin 1 character set, you can arrange to use that character set as follows:

```
(require 'disp-table)
;; Set char codes 160--255 to display as themselves.
```

```
;; (Codes 128--159 are the additional control characters.)
(standard-display-8bit 160 255)
```

If you are editing buffers written in the ISO Latin 1 character set and your terminal doesn't handle anything but ASCII, you can load the file `iso-ascii' to set up a display table which makes the other ISO characters display as sequences of ASCII characters. For example, the character "o with umlaut" displays as `{"o}'.

Some European countries have terminals that don't support ISO Latin 1 but do support the special characters for that country's language. You can define a display table to work one language using such terminals. For an example, see `lisp/iso-swed.el', which handles certain Swedish terminals.

You can load the appropriate display table for your terminal automatically by writing a terminal-specific Lisp file for the terminal type.

Beeping

You can make Emacs ring a bell (or blink the screen) to attract the user's attention. Be conservative about how often you do this; frequent bells can become irritating. Also be careful not to use beeping alone when signaling an error is appropriate. (See section Errors.)

Function: **ding** *&optional dont-terminate*

This function beeps, or flashes the screen (see `visible-bell` below). It also terminates any keyboard macro currently executing unless dont-terminate is non-`nil`.

Function: **beep** *&optional dont-terminate*

This is a synonym for `ding`.

Variable: **visible-bell**

This variable determines whether Emacs should flash the screen to represent a bell. Non-`nil` means yes, `nil` means no. This is effective only if the Termcap entry for the terminal in use has the visible bell flag (`vb') set.

Window Systems

Emacs works with several window systems, most notably the X Window Syste,. Note that both Emacs and X use the term "window", but use it differently. An Emacs frame is a single window as far as X is concerned; the individual Emacs windows are not known to X at all.

Variable: **window-system**

This variable tells Lisp programs what window system Emacs is running under. Its value should be a symbol such as `x` (if Emacs is running under X) or `nil` (if Emacs is running on an ordinary terminal).

Variable: **window-system-version**

This variable distinguishes between different versions of the X Window System. Its value is 10 or 11 when using X; `nil` otherwise.

Variable: **window-setup-hook**

This variable is a normal hook which Emacs runs after loading your `` `.emacs' `` file and the default initialization file (if any), after loading terminal-specific Lisp code, and after running the hook `term-setup-hook`.

This hook is used for internal purposes: setting up communication with the window system, and creating the initial window. Users should not interfere with it.

Go to the previous, next section.

Go to the previous, next section.

Customizing the Calendar and Diary

There are many customizations that you can use to make the calendar and diary suit your personal tastes.

Customizing the Calendar

If you set the variable `view-diary-entries-initially` to `t`, calling up the calendar automatically displays the diary entries for the current date as well. The diary dates appear only if the current date is visible. If you add both of the following lines to your `.emacs' file:

```
(setq view-diary-entries-initially t)
(calendar)
```

they display both the calendar and diary windows whenever you start Emacs.

Similarly, if you set the variable `view-calendar-holidays-initially` to `t`, entering the calendar automatically displays a list of holidays for the current three month period. The holiday list appears in a separate window.

You can set the variable `mark-diary-entries-in-calendar` to `t` in order to place a plus sign (`+') beside any dates with diary entries. Whenever the calendar window is displayed or redisplayed, the diary entries are automatically marked for holidays.

Similarly, setting the variable `mark-holidays-in-calendar` to `t` places an asterisk (`*') after all holiday dates visible in the calendar window.

There are many customizations that you can make with the hooks provided. For example, the variable `calendar-load-hook`, whose default value is `nil`, is a normal hook run when the calendar package is first loaded (before actually starting to display the calendar).

The variable `initial-calendar-window-hook`, whose default value is `nil`, is a normal hook run the first time the calendar window is displayed. The function is invoked only when you first enter Calendar mode, not when you redisplay an existing Calendar window. But if you leave the calendar with the q command and reenter it, the hook runs again.

The variable `today-visible-calendar-hook`, whose default value is `nil`, is a normal hook run after the calendar buffer has been prepared with the calendar when the current date is visible in the window. One use of this hook is to replace today's date with asterisks; a function `calendar-star-date` is included for this purpose. In your `.emacs' file, put:

```
(setq today-visible-calendar-hook 'calendar-star-date)
```

Another standard hook function adds asterisks around the current date. Here's how to use it:

```
(setq today-visible-calendar-hook 'calendar-mark-today)
```

A corresponding variable, `today-invisible-calendar-hook`, whose default value is `nil`, is a normal hook run after the calendar buffer text has been prepared, if the current date is *not* visible in the window.

Customizing the Holidays

Emacs knows about holidays defined by entries on one of several lists. You can customize theses lists of holidays to your own needs, adding holidays or deleting lists of holidays. The lists of holidays that Emacs uses are for general holidays (`general-holidays`), local holidays (`local-holidays`), Christian holidays (`christian-holidays`), Hebrew (Jewish) holidays (`hebrew-holidays`), Islamic (Moslem) holidays (`islamic-holidays`), and other holidays (`other-holidays`).

The general holidays are, by default, holidays common throughout the United States. To eliminate these holidays, set `general-holidays` to `nil`.

There are no default local holidays (but sites may supply some). You can set the variable `local-holidays` to any list of holidays, as described below.

By default, Emacs does not consider all the holidays of these religions, only those commonly found in secular calendars. For a more extensive collection of religious holidays, you can set any (or all) of the variables `all-christian-calendar-holidays`, `all-hebrew-calendar-holidays`, or `all-islamic-calendar-holidays` to `t`. If you want to eliminate the religious holidays, set any or all of the corresponding variables `christian-holidays`, `hebrew-holidays`, and `islamic-holidays` to `nil`.

You can set the variable `other-holidays` to any list of holidays. This list, normally empty, is intended for your use.

Each of the lists (`general-holidays`), (`local-holidays`), (`christian-holidays`), (`hebrew-holidays`), (`islamic-holidays`),and (`other-holidays`) is a list of holiday forms, each holiday form describing a holiday (or sometimes a list of holidays). Holiday forms may have the following formats:

`(fixed month day string)`

A fixed date on the Gregorian calendar. month and day are numbers, string is the name of the holiday.

`(float month dayname k string)`

The kth dayname in month on the Gregorian calendar (dayname=0 for Sunday, and so on); negative k means count back from the end of the month. string is the name of the holiday.

`(hebrew month day string)`

A fixed date on the Hebrew calendar. month and day are numbers, string is the name of the holiday.

`(islamic month day string)`

A fixed date on the Islamic calendar. month and day are numbers, string is the name of the holiday.

`(julian month day string)`

A fixed date on the Julian calendar. month and day are numbers, string is the name of the holiday.

`(sexp sexp string)`

sexp is a Lisp expression that should use the variable `year` to compute the date of a holiday, or `nil` if the holiday doesn't happen this year. The value represents the date as a list of the form `(month day year)`. string is the name of the holiday.

`(if boolean holiday-form &optional holiday-form)`

A choice between two holidays based on the value of boolean.

`(function &optional args)`

Dates requiring special computation; args, if any, are passed in a list to the function `calendar-holiday-function-function`.

For example, suppose you want to add Bastille Day, celebrated in France on July 14. You can do this by adding the following line to your `.emacs' file:

```
(setq other-holidays '((fixed 7 14 "Bastille Day")))
```

The holiday form `(fixed 7 14 "Bastille Day")` specifies the fourteenth day of the seventh month (July).

Many holidays occur on a specific day of the week, at a specific time of month. Here is a holiday form describing Hurricane Supplication Day, celebrated in the Virgin Islands on the fourth Monday in August:

```
(float 8 1 4 "Hurricane Supplication Day")
```

Here the 8 specifies August, the 1 specifies Monday (Sunday is 0, Tuesday is 2, and so on), and the 4 specifies the fourth occurrence in the month (1 specifies the first occurrence, 2 the second occurrence, -1 the last occurrence, -2 the second-to-last occurrence, and so on).

You can specify holidays that occur on fixed days of the Hebrew, Islamic, and Julian calendars too. For example,

```
(setq other-holidays
      '((hebrew 10 2 "Last day of Hanukkah")
        (islamic 3 12 "Mohammed's Birthday")
        (julian 4 2 "Jefferson's Birthday")))
```

adds the last day of Hanukkah (since the Hebrew months are numbered with 1 starting from Nisan), the Islamic feast celebrating Mohammed's birthday (since the Islamic months are numbered from 1 starting with Muharram), and Thomas Jefferson's birthday, which is 2 April 1743 on the Julian calendar.

To include a holiday conditionally, use either the `if' or the `sexp' form. For example, American presidential elections occur on the first Tuesday after the first Monday in November of years divisible by 4:

```
(sexp (if (= 0 (% year 4))
          (calendar-gregorian-from-absolute
            (1+ (calendar-dayname-on-or-before
                  1 (+ 6 (calendar-absolute-from-gregorian
                           (list 11 1 year))))))
      "US Presidential Election"))
```

or

```
(if (= 0 (% displayed-year 4))
    (fixed 11
           (extract-calendar-day
             (calendar-gregorian-from-absolute
               (1+ (calendar-dayname-on-or-before
                     1 (+ 6 (calendar-absolute-from-gregorian
                              (list 11 1 displayed-year)))))))
           "US Presidential Election"))
```

Some holidays just don't fit into any of these forms because special calculations are involved in their determination. In such cases you must write a Lisp function to do the calculation. The function should return a (possibly empty) list of the relevant Gregorian dates among the range visible in the calendar window, with descriptive strings, like this:

```
(((6 27 1991) "Lunar Eclipse") ((7 11 1991) "Solar Eclipse") ... )
```

Date Display Format

You can customize the manner of displaying dates in the diary, in mode lines, and in messages by setting `calendar-date-display-form`. This variable is a list of expressions that can involve the variables `month`, `day`, and `year`, all numbers in string form, and `monthname` and `dayname`, both alphabetic strings. In the American style, the default value of this list is as follows:

```
((if dayname (concat dayname ", ")) monthname " " day ", " year)
```

while in the European style this value is the default:

```
((if dayname (concat dayname ", ")) day " " monthname " " year)
```

The ISO standard date representation is this:

```
(year "-" month "-" day)
```

This specifies a typical American format:

```
(month "/" day "/" (substring year -2))
```

Time Display Format

In the calendar, diary, and related buffers, Emacs displays times of day in the conventional American style with the hours from 1 through 12, minutes, and either `am' or `pm'. If you prefer the "military" (European) style of writing times--in which the hours go from 00 to 23--you can alter the variable `calendar-time-display-form`. This variable is a list of expressions that can involve the variables `12-hours`, `24-hours`, and `minutes`, all numbers in string form, and `am-pm` and `time-zone`, both alphabetic strings. The default definition of `calendar-time-display-form` is as follows:

```
(12-hours ":" minutes am-pm (if time-zone " (") time-zone (if time-zone ")"))
```

Setting `calendar-time-display-form` to

```
(24-hours ":" minutes (if time-zone " (") time-zone (if time-zone ")"))
```

gives military-style times like `21:07 (UT)' if time zone names are defined, and times like `21:07' if they are not.

Daylight Savings Time

Emacs understands the difference between standard time and daylight savings time--the times given for sunrise, sunset, solstices, equinoxes, and the phases of the moon take that into account. The default starting and stopping dates for daylight savings time are the present-day American rules of the first Sunday in April until the last Sunday in October, but you can specify whatever rules you want by setting `calendar-daylight-savings-starts` and `calendar-daylight-savings-ends`. Their values should be Lisp expressions that refer to the variable `year`, and evaluate to the Gregorian date on which daylight savings time starts or (respectively) ends, in the form of a list `(month day year)`.

Emacs uses these expressions to determine the starting date of daylight savings time for the holiday list and for correcting times of day in the solar and lunar calculations.

The default value of `calendar-daylight-savings-starts` is this,

```
(calendar-nth-named-day 1 0 4 year)
```

which computes the first 0th day (Sunday) of the fourth month (April) in the year specified by `year`. If daylight savings time were changed to start on October 1, you would set `calendar-daylight-savings-starts` to

```
(list 10 1 year)
```

For a more complex example, suppose daylight savings time begins on the first of Nisan on the Hebrew calendar. You would set `calendar-daylight-savings-starts` to

```
(calendar-gregorian-from-absolute
  (calendar-absolute-from-hebrew
    (list 1 1 (+ year 3760))))
```

because Nisan is the first month in the Hebrew calendar and the Hebrew year differs from the Gregorian year by 3760 at Nisan.

If there is no daylight savings time at your location, or if you want all times in standard time, set `calendar-daylight-savings-starts` and `calendar-daylight-savings-ends` to `nil`.

Customizing the Diary

Ordinarily, the mode line of the diary buffer window indicates any holidays that fall on the date of the diary entries. The process of checking for holidays can take several seconds, so including holiday information delays the display of the diary buffer noticeably. If you'd prefer to have a faster display of the diary buffer but without the holiday information, set the variable `holidays-in-diary-buffer` to `nil`.

The variable `number-of-diary-entries` controls the number of days of diary entries to be displayed at one time. It affects the initial display when `view-diary-entries-initially` is `t`, as well as the command M-x diary. For example, the default value is 1, which says to display only the current day's diary entries. If the value is 2, both the current day's and the next day's entries are displayed. The value can also be a vector of seven elements: if the value is `[0 2 2 2 2 4 1]` then no diary entries appear on Sunday, the current date's and the next day's diary entries appear Monday through Thursday, Friday through Monday's entries appear on Friday, while on Saturday only that day's entries appear.

The variable `print-diary-entries-hook` is a normal hook run after preparation of a temporary buffer containing just the diary entries currently visible in the diary buffer. (The other, irrelevant diary entries are rea absent from the temporary buffer; in the diary buffer, they are merely hidden.) The default value of this hook does the printing with the command `lpr-buffer`. If you want to use a different command to do the printing, just change the value of this hook. Other uses might include, for example, rearranging the lines into order by day and time.

You can customize the form of dates in your diary file, if neither the standard American nor European styles suits your needs, by setting the variable `diary-date-forms`. This variable is a list of forms of dates recognized in the diary file. Each form is a list of regular expressions (see section Regular Expressions) and the variables `month`, `day`, `year`, `monthname`, and `dayname`. The variable `monthname` matches the name of the month, capitalized or not, or its three-letter abbreviation, followed by a period or not; it matches `*'. Similarly, `dayname` matches the name of the day, capitalized or not, or its three-letter abbreviation, followed by a period or not. The variables `month`, `day`, and `year` match those numerical values, preceded by arbitrarily many zeros; they also match `*'. The default value of `diary-date-forms` in the American style is

```
((month "/" day "[^/0-9]")
 (month "/" day "/" year "[^0-9]")
 (monthname " *" day "[^,0-9]")
 (monthname " *" day ", *" year "[^0-9]")
 (dayname "\\W"))
```

Emacs matches of the diary entries with the date forms is done with the standard syntax table from Fundamental mode (see section Syntax Tables), but with the `*' changed so that it is a word constituent.

The forms on the list must be *mutually exclusive* and must not match any portion of the diary entry itself, just the date. If, to be mutually exclusive, the pattern must match a portion of the diary entry itself, the first element of the form *must* be `backup`. This causes the date recognizer to back up to the beginning of the current word of the diary entry. Even if you use `backup`, the form must absolutely not match more than a portion of the first word of the diary entry. The default value of `diary-date-forms` in the European style is this list:

```
((day "/" month "[^/0-9]")
 (day "/" month "/" year "[^0-9]")
 (backup day " *" monthname "\\W+\\<[^*0-9]")
 (day " *" monthname " *" year "[^0-9]")
 (dayname "\\W"))
```

Notice the use of `backup` in the middle form because part of the diary entry must be matched to distinguish this form from the following one.

Hebrew- and Islamic-Date Diary Entries

Your diary file can have entries based on Hebrew or Islamic dates, as well as entries based on our usual Gregorian calendar. However, because the processing of such entries is time-consuming and most people don't need them, you must customize the processing of your diary file to specify that you want such entries recognized. If you want Hebrew-date diary entries, for example, you must include these lines in your `.emacs' file:

```
(setq nongregorian-diary-listing-hook 'list-hebrew-diary-entries)
(setq nongregorian-diary-marking-hook 'mark-hebrew-diary-entries)
```

If you want Islamic-date entries, include these lines in your `.emacs' file:

```
(setq nongregorian-diary-listing-hook 'list-islamic-diary-entries)
(setq nongregorian-diary-marking-hook 'mark-islamic-diary-entries)
```

If you want both Hebrew- and Islamic-date entries, include these lines:

```
(setq nongregorian-diary-listing-hook
      '(list-hebrew-diary-entries list-islamic-diary-entries))
(setq nongregorian-diary-marking-hook
      '(mark-hebrew-diary-entries mark-islamic-diary-entries))
```

Hebrew- and Islamic-date diary entries have the same formats as Gregorian-date diary entries, except that the date must be preceded with an `H' for Hebrew dates and an `I' for Islamic dates. Moreover, because the Hebrew and Islamic month names are not uniquely specified by the first three letters, you may not abbreviate them. For example, a diary entry for the Hebrew date Heshvan 25 could look like

```
HHeshvan 25 Happy Hebrew birthday!
```

and would appear in the diary for any date that corresponds to Heshvan 25 on the Hebrew calendar. Similarly, an Islamic-date diary entry might be

```
IDhu al-Qada 25 Happy Islamic birthday!
```

and would appear in the diary for any date that corresponds to Dhu al-Qada 25 on the Islamic calendar.

As with Gregorian-date diary entries, Hebrew- and Islamic-date entries are nonmarking if they are preceded with an ampersand (`&').

There are commands to help you in making Hebrew- and Islamic-date entries to your diary:

i h d

: Add a diary entry for the Hebrew date corresponding to the selected date (`insert-hebrew-diary-entry`).

i h m

: Add a diary entry for the day of the Hebrew month corresponding to the selected date (`insert-monthly-hebrew-diary-entry`).

i h y

: Add a diary entry for the day of the Hebrew year corresponding to the selected date (`insert-yearly-hebrew-diary-entry`).

i i d

: Add a diary entry for the Islamic date corresponding to the selected date (`insert-islamic-diary-entry`).

i i m

: Add a diary entry for the day of the Islamic month corresponding to the selected date (`insert-monthly-islamic-diary-entry`).

i i y

: Add a diary entry for the day of the Islamic year corresponding to the selected date (`insert-yearly-islamic-diary-entry`).

These commands work exactly like the corresponding commands for ordinary diary entries: Move point to a d in the calendar window and the above commands insert the Hebrew or Islamic date (corresponding to the date indicated by point) at the end of your diary file and you can then type the diary entry. If you want the diary entry to be nonmarking, give a numeric argument to the command.

Fancy Diary Display

Diary display works by preparing the diary buffer and then running the hook `diary-display-hook`. The default value of this hook hides the irrelevant diary entries and then displays the buffer (`simple-diary-display`). However, if you specify the hook as follows,

```
(add-hook 'diary-display-hook 'fancy-diary-display)
```

then fancy mode displays diary entries and holidays by copying them into a special buffer that exists only for display. Copying provides an opportunity to change the displayed text to make it prettier--for example, to sort the entries by the dates they apply to.

As with simple diary display, you can print a hard copy of the buffer with `print-diary-entries`. To print a hard copy of a day-by-day diary for a week by positioning point on Sunday of that week, type 7 d and then do M-x print-diary-entries. As usual, the inclusion of the holidays slows down the display slightly; you can speed things up by setting the variable `holidays-in-diary-buffer` to `nil`.

Ordinarily, the fancy diary buffer does not show days for which there are no diary entries, even if that day is a holiday. If you want such days to be shown in the fancy diary buffer, set the variable `diary-list-include-blanks` to `t`.

If you use the fancy diary display, you can use the normal hook `list-diary-entries-hook` to sort each day's diary entries by their time of day. Add this line to your `` `.emacs' `` file:

```
(add-hook 'list-diary-entries-hook 'sort-diary-entries)
```

For each day, this sorts diary entries that begin with a recognizable time of day according to their times. Diary entries without times come first within each day.

Included Diary Files

If you use the fancy diary display, you can have diary entries from other files included with your own by an "include" mechanism. This facility makes possible the sharing of common diary files among groups of users. Lines in the diary file of this form:

```
#include "filename"
```

includes the diary entries from the file filename in the fancy diary buffer (because the ordinary diary buffer is just the buffer associated with your diary file, you cannot use the include mechanism unless you use the fancy diary buffer). The include mechanism is recursive, by the way, so that included files can include other files, and so on; you must be careful not to have a cycle of inclusions, of course. To enable the include facility, add lines as follows to your `` `.emacs' `` file:

```
(add-hook 'list-diary-entries-hook 'include-other-diary-files)
```

```
(add-hook 'mark-diary-entries-hook 'mark-included-diary-files)
```

Sexp Entries and the Fancy Diary Display

Sexp diary entries allow you to do more than just have complicated conditions under which a diary entry applies. If you use the fancy diary display, sexp entries can generate the text of the entry depending on the date itself. For example, an anniversary diary entry can insert the number of years since the anniversary date into the text of the diary entry. Thus the `%d' in this dairy entry:

```
%%(diary-anniversary 10 31 1948) Arthur's birthday (%d years old)
```

gets replaced by the age, so on October 31, 1990 the entry appears in the fancy diary buffer like this:

```
Arthur's birthday (42 years old)
```

If the diary file instead contains this entry:

```
%%(diary-anniversary 10 31 1948) Arthur's %d%s birthday
```

the entry in the fancy diary buffer for October 31, 1990 appears like this:

```
Arthur's 42nd birthday
```

Similarly, cyclic diary entries can interpolate the number of repetitions that have occurred:

```
%%(diary-cyclic 50 1 1 1990) Renew medication (%d%s time)
```

looks like this:

```
Renew medication (5th time)
```

in the fancy diary display on September 8, 1990.

The generality of sexp diary entries lets you specify any diary entry that you can describe algorithmically. Suppose you get paid on the 21st of the month if it is a weekday, and to the Friday before if the 21st is on a weekend. The diary entry

```
&%%(let ((dayname (calendar-day-of-week date))
         (day (car (cdr date))))
      (or (and (= day 21) (memq dayname '(1 2 3 4 5)))
          (and (memq day '(19 20)) (= dayname 5)))
        ) Pay check deposited
```

applies to just those dates. This example illustrates how the sexp can depend on the variable `date`; this variable is a list (month day year) that gives the Gregorian date for which the diary entries are being found. If the value of the expression is `t`, the entry applies to that date. If the expression evaluates to `nil`, the entry does *not* apply to that date.

The following sexp diary entries take advantage of the ability (in the fancy diary display) to concoct diary entries based on the date:

`%%(diary-sunrise-sunset)`
: Make a diary entry for the local times of today's sunrise and sunset.

`%%(diary-phases-of-moon)`
: Make a diary entry for the phases (quarters) of the moon.

`%%(diary-day-of-year)`
: Make a diary entry with today's day number in the current year and the number of days remaining in the current year.

`%%(diary-iso-date)`
: Make a diary entry with today's equivalent ISO commercial date.

`%%(diary-julian-date)`
: Make a diary entry with today's equivalent date on the Julian calendar.

`%%(diary-astro-day-number)`
: Make a diary entry with today's equivalent astronomical (Julian) day number.

`%%(diary-hebrew-date)`
: Make a diary entry with today's equivalent date on the Hebrew calendar.

`%%(diary-islamic-date)`
: Make a diary entry with today's equivalent date on the Islamic calendar.

`%%(diary-french-date)`
: Make a diary entry with today's equivalent date on the French Revolutionary calendar.

`%%(diary-mayan-date)`
: Make a diary entry with today's equivalent date on the Mayan calendar.

Thus including the diary entry

```
&%%(diary-hebrew-date)
```

causes every day's diary display to contain the equivalent date on the Hebrew calendar, if you are using the fancy diary display. (With simple diary display, the line `&%%(diary-hebrew-date)' appears in the diary for any date, but does nothing particularly useful.)

There are a number of other available sexp diary entries that are important to those who follow the Hebrew calendar:

`%%(diary-rosh-hodesh)`
: Make a diary entry that tells the occurrence and ritual announcement of each new Hebrew month.

`%%(diary-parasha)`
: Make a Saturday diary entry that tells the weekly synagogue scripture reading.

`%%(diary-sabbath-candles)`
: Make a Friday diary entry that tells the *local time* of Sabbath candle lighting.

`%%(diary-omer)`
: Make a diary entry that gives the omer count, when appropriate.

`%%(diary-yahrzeit month day year) name`
: Make a diary entry marking the anniversary of a date of death. The date is the *Gregorian* (civil) date of death. The diary entry appears on the proper Hebrew calendar anniversary and on the day before. (In the

European style, the order of the parameters is changed to day, month, year.)

Customizing Appointment Reminders

You can specify exactly how Emacs reminds you of an appointment and how far in advance it begins doing so. Here are the variables that you can set:

`appt-message-warning-time`
: The time in minutes before an appointment that the reminder begins. The default is 10 minutes.

`appt-audible`
: If this is `t` (the default), Emacs rings the terminal bell for appointment reminders.

`appt-visible`
: If this is `t` (the default), Emacs displays the appointment message in echo area.

`appt-display-mode-line`
: If this is `t` (the default), Emacs displays the number of minutes to the appointment on the mode line.

`appt-msg-window`
: If this is `t` (the default), Emacs displays the appointment message in another window.

`appt-display-duration`
: The number of seconds an appointment message is displayed. The default is 5 seconds.

Go to the previous, next section.

Go to the previous, next section.

Tips and Standards

This chapter describes no additional features of Emacs Lisp. Instead it gives advice on making effective use of the features described in the previous chapters.

Writing Clean Lisp Programs

Here are some tips for avoiding common errors in writing Lisp code intended for widespread use:

- Since all global variables share the same name space, and all functions share another name space, you should choose a short word to distinguish your program from other Lisp programs. Then take care to begin the names of all global variables, constants, and functions with the chosen prefix. This helps avoid name conflicts.

  This recommendation applies even to names for traditional Lisp primitives that are not primitives in Emacs Lisp--even to `cadr`. Believe it or not, there is more than one plausible way to define `cadr`. Play it safe; append your name prefix to produce a name like `foo-cadr` or `mylib-cadr` instead.

  If one prefix is insufficient, your package may use two or three alternative common prefixes, so long as they make sense.

  Separate the prefix from the rest of the symbol name with a hyphen, `-'. This will be consistent with Emacs itself and with most Emacs Lisp programs.
- It is often useful to put a call to `provide` in each separate library program, at least if there is more than one entry point to the program.
- If one file foo uses a macro defined in another file bar, foo should contain `(require 'bar)` before the first use of the macro. (And bar should contain `(provide 'bar)`, to make the `require` work.) This will cause bar to be loaded when you byte-compile foo. Otherwise, you risk compiling foo without the necessary macro loaded, and that would produce compiled code that won't work right. See section Macros and Byte Compilation.
- If you define a major mode, make sure to run a hook variable using `run-hooks`, just as the existing major modes do. See section Hooks.
- Please do not define C-c letter as a key in your major modes. These sequences are reserved for users; they are the **only** sequences reserved for users, so we cannot do without them.

  Instead, define sequences consisting of C-c followed by a non-letter. These sequences are reserved for major modes.

  Changing all the major modes in Emacs 18 so they would follow this convention was a lot of work. Abandoning this convention would waste that work and inconvenience the users.
- It is a bad idea to define aliases for the Emacs primitives. Use the standard names instead.

- Redefining an Emacs primitive is an even worse idea. It may do the right thing for a particular program, but there is no telling what other programs might break as a result.
- If a file does replace any of the functions or library programs of standard Emacs, prominent comments at the beginning of the file should say which functions are replaced, and how the behavior of the replacements differs from that of the originals.
- If a file requires certain standard library programs to be loaded beforehand, then the comments at the beginning of the file should say so.
- Please keep the names of your Emacs Lisp source files to 13 characters or less. This way, if the files are compiled, the compiled files' names will be 14 characters or less, which is short enough to fit on all kinds of Unix systems.
- Don't use `next-line` or `previous-line` in programs; nearly always, `forward-line` is more convenient as well as more predictable and robust. See section Motion by Text Lines.
- Don't use functions that set the mark in your Lisp code (unless you are writing a command to set the mark). The mark is a user-level feature, so it is incorrect to change the mark except to supply a value for the user's benefit. See section The Mark.

  In particular, don't use these functions:
  - `beginning-of-buffer`, `end-of-buffer`
  - `replace-string`, `replace-regexp`

  If you just want to move point, or replace a certain string, without any of the other features intended for interactive users, you can replace these functions with one or two lines of simple Lisp code.
- The recommended way to print a message in the echo area is with the `message` function, not `princ`. See section The Echo Area.
- When you encounter an error condition, call the function `error` (or `signal`). The function `error` does not return. See section How to Signal an Error.

  Do not use `message`, `throw`, `sleep-for`, or `beep` to report errors.
- Avoid using recursive edits. Instead, do what the Rmail w command does: use a new local keymap that contains one command defined to switch back to the old local keymap. Or do what the `edit-options` command does: switch to another buffer and let the user switch back at will. See section Recursive Editing.
- In some other systems there is a convention of choosing variable names that begin and end with `*'. We don't use that convention in Emacs Lisp, so please don't use it in your library. (In fact, in Emacs names of this form are conventionally used for program-generated buffers.) The users will find Emacs more coherent if all libraries use the same conventions.
- Indent each function with C-M-q (`indent-sexp`) using the default indentation parameters.
- Don't make a habit of putting close-parentheses on lines by themselves; Lisp programmers find this disconcerting. Once in a while, when there is a sequence of many consecutive close-parentheses, it may make sense to split them in one or two significant places.
- Please put a copyright notice on the file if you give copies to anyone. Use the same lines that

appear at the top of the Lisp files in Emacs itself. If you have not signed papers to assign the copyright to the Foundation, then place your name in the copyright notice in place of the Foundation's name.

Tips for Making Compiled Code Fast

Here are ways of improving the execution speed of byte-compiled lisp programs.

- Use the `profile' library to profile your program. See the file `profile.el' for instructions.
- Use iteration rather than recursion whenever possible. Function calls are slow in Emacs Lisp even when a compiled function is calling another compiled function.
- Using the primitive list-searching functions `memq`, `assq` or `assoc` is even faster than explicit iteration. It may be worth rearranging a data structure so that one of these primitive search functions can be used.
- Certain built-in functions are handled specially by the byte compiler avoiding the need for an ordinary function call. It is a good idea to use these functions rather than alternatives. To see whether a function is handled specially by the compiler, examine its `byte-compile` property. If the property is non-`nil`, then the function is handled specially.

  For example, the following input will show you that `aref` is compiled specially (see section Functions that Operate on Arrays) while `elt` is not (see section Sequences):

```
(get 'aref 'byte-compile)
     => byte-compile-two-args

(get 'elt 'byte-compile)
     => nil
```

- Make small functions inline, so that calls to them in compiled code run faster. See section Inline Functions.

Tips for Documentation Strings

Here are some tips for the writing of documentation strings.

- Every command, function or variable intended for users to know about should have a documentation string.
- An internal subroutine of a Lisp program need not have a documentation string, and you can save space by using a comment instead.
- The first line of the documentation string should consist of one or two complete sentences which stand on their own as a summary. In particular, start the line with a capital letter and end with a period.

  The documentation string can have additional lines which expand on the details of how to use the

function or variable. The additional lines should be made up of complete sentences also, but th may be filled if that looks good.

- Do not start or end a documentation string with whitespace.
- Format the documentation string so that it fits in an Emacs window on an 80 column screen. It is a good idea for most lines to be no wider than 60 characters. The first line can be wider if necessary to fit the information that ought to be there.

  However, rather than simply filling the entire documentation string, you can make it much more readable by choosing line breaks with care. Use blank lines between topics if the documentation string is long.
- **Do not** indent subsequent lines of a documentation string so that the text is lined up in the source code with the text of the first line. This looks nice in the source code, but looks bizarre when users view the documentation. Remember that the indentation before the starting double-quote is not part of the string!
- A variable's documentation string should start with `*' if the variable is one that users would want to set interactively often. If the value is a long list, or a function, or if the variable would only be set in init files, then don't start the documentation string with `*'. See section Defining Global Variables.
- The documentation string for a variable that is a yes-or-no flag should start with words such as "Non-nil means...", to make it clear both that the variable only has two meaningfully distinct values and which value means "yes".
- When a function's documentation string mentions the value of an argument of the function, use the argument name in capital letters as if it were a name for that value. Thus, the documentation string of the function `/` refers to its second argument as `DIVISOR'.

  Also use all caps for meta-syntactic variables, such as when you show the decomposition of a list or vector into subunits, some of which may be variable.
- When a documentation string refers to a Lisp symbol, write it as it would be printed (which usually means in lower case), with single-quotes around it. For example: ``lambda''. There are two exceptions: write `t` and `nil` without single-quotes.
- Don't write key sequences directly in documentation strings. Instead, use the `\\[...]' construct to stand for them. For example, instead of writing `C-f', write `\\[forward-char]'. When the documentation string is printed, Emacs will substitute whatever key is currently bound to `forward-char`. This will usually be `C-f', but if the user has moved key bindings, it will be the correct key for that user. See section Substituting Key Bindings in Documentation.
- In documentation strings for a major mode, you will want to refer to the key bindings of that mode's local map, rather than global ones. Therefore, use the construct `\\<...>' once in the documentation string to specify which key map to use. Do this before the first use of `\\[...]'. The text inside the `\\<...>' should be the name of the variable containing the local keymap for the major mode.

  It is not practical to use `\\[...]' very many times, because display of the documentation string will become slow. So use this to describe the most important commands in your major mode, and then use `\\{...}' to display the rest of the mode's keymap.

- Don't use the term "Elisp", since that is or was a trademark. Use the term "Emacs Lisp".

Tips on Writing Comments

We recommend these conventions for where to put comments and how to indent them:

`;'

Comments that start with a single semicolon, `;', should all be aligned to the same column on the right of the source code. Such comments usually explain how the code on the same line does its job. In Lisp mode and related modes, the M-; (`indent-for-comment`) command automatically inserts such a `;' in the right place, or aligns such a comment if it is already inserted.

(The following examples are taken from the Emacs sources.)

```
(setq base-version-list                  ; there was a base
      (assoc (substring fn 0 start-vn)   ; version to which
             file-version-assoc-list))   ; this looks like
                                         ; a subversion
```

`;;'

Comments that start with two semicolons, `;;', should be aligned to the same level of indentation as the code. Such comments are used to describe the purpose of the following lines or the state of the program at that point. For example:

```
(prog1 (setq auto-fill-function
             ...
             ...
  ;; update mode-line
  (force-mode-line-update)))
```

These comments are also written before a function definition to explain what the function does and how to call it properly.

`;;;'

Comments that start with three semicolons, `;;;', should start at the left margin. Such comments are not used within function definitions, but are used to make more general comments. For example:

```
;;; This Lisp code is run in Emacs
;;; when it is to operate asa server
;;; for other processes.
```

`;;;;'

Comments that start with four semicolons, `;;;;', should be aligned to the left margin and are used for headings of major sections of a program. For example:

```
;;;; The kill ring
```

The indentation commands of the Lisp modes in Emacs, such as M-; (`indent-for-comment`) and TAB (`lisp-indent-line`) automatically indent comments according to these conventions, depending on the the number of semicolons. See section 'Manipulating Comments' in The GNU Emacs Manual.

If you wish to "comment out" a number of lines of code, use triple semicolons at the beginnings of the lines.

Any character may be included in a comment, but it is advisable to precede a character with syntactic significance in Lisp (such as `\' or unpaired `(' or `)') with a `\', to prevent it from confusing the Emacs commands for editing Lisp.

Conventional Headers for Emacs Libraries

Emacs 19 has conventions for using special comments in Lisp libraries to divide them into sections and give information such as who wrote them. This section explains these conventions. First, an example:

```
;;; lisp-mnt.el -- minor mode for Emacs Lisp maintainers

;; Copyright (C) 1992 Free Software Foundation, Inc.

;; Author: Eric S. Raymond <esr@snark.thyrsus.com>
;; Maintainer: Eric S. Raymond <esr@snark.thyrsus.com>
;; Created: 14 Jul 1992
;; Version: 1.2
;; Keywords: docs

;; This file is part of GNU Emacs.
copying conditions...
```

The very first line should have this format:

```
;;; filename -- description
```

The description should be complete in one line.

After the copyright notice come several header comment lines, each beginning with `;;; header-name:'. Here is a table of the conventional possibilities for header-name:

`Author'

This line states the name and net address of at least the principal author of the library.

If there are multiple authors, you can list them on continuation lines led by `;;<TAB>`, like this:

```
;; Author: Ashwin Ram <Ram-Ashwin@cs.yale.edu>
;;      Dave Sill <de5@ornl.gov>
;;      Dave Brennan <brennan@hal.com>
```

```
;;      Eric Raymond <esr@snark.thyrsus.com>
```

`Maintainer'

This line should contain a single name/address as in the Author line, or an address only, or the string "FSF". If there is no maintainer line, the person(s) in the Author field are presumed to be the maintainers. The example above is mildly bogus because the maintainer line is redundant.

The idea behind the `Author' and `Maintainer' lines is to make possible a Lisp function to "send mail to the maintainer" without having to mine the name out by hand.

Be sure to surround the network address with `<...>' if you include the person's full name as well as the network address.

`Created'

This optional line gives the original creation date of the file. For historical interest only.

`Version'

If you wish to record version numbers for the individual Lisp program, put them in this line.

`Adapted-By'

In this header line, place the name of the person who adapted the library for installation (to make it fit the style conventions, for example.

`Keywords'

This line lists keywords for the `finder-by-keyword` help command. This field is important; it's how people will find your package when they're looking for things by topic area.

Just about every Lisp library ought to have the `Author' and `Keywords' header comment lines. Use the others if they are appropriate. You can also put in header lines with other header names--they have no standard meanings, so they can't do any harm.

We use additional stylized comments to subdivide the contents of the library file. Here is a table of them:

`;;; Commentary:'

This begins introductory comments that explain how the library works. It should come right after the copying permissions.

`;;; Change log:'

This begins change log information stored in the library file (if you store the change history there). For most of the Lisp files distributed with Emacs, the change history is kept in the file `` `ChangeLog' `` and not in the source file at all; these files do not have a `;;; Change log:' line.

`;;; Code:'

This begins the actual code of the program.

`;;; filename ends here'

This is the footer line; it appears at the very end of the file. Its purpose is to enable people to detect truncated versions of the file from the lack of a footer line.

Go to the previous, next section.

GNU Emacs Internals

This chapter describes how the runnable Emacs executable is dumped with the preloaded Lisp libraries in it, how storage is allocated, and some internal aspects of GNU Emacs that may be of interest to C programmers.

Building Emacs

The first step in building Emacs is to compile the C sources. This produces a program called `temacs', also called a bare impure Emacs. It contains the Emacs Lisp interpreter and I/O routines, but not the editing commands.

Then, to create a working Emacs editor, issue the `temacs -l loadup' command. This directs `temacs' to evaluate the Lisp files specified in the file `loadup.el'. These files set up the normal Emacs editing environment, resulting in an Emacs which is still impure but no longer bare.

It takes a long time to load the standard Lisp files. Luckily, you don't have to do this each time you run Emacs; `temacs' can dump out an executable program called `emacs' which has these files preloaded. `emacs' starts more quickly because it does not need to load the files. This is the program that is normally installed.

To create `emacs', use the command `temacs -batch -l loadup dump'. The purpose of `-batch' here is to prevent `temacs' from trying to initialize any of its data on the terminal; this ensures that the tables of terminal information are empty in the dumped Emacs.

When the `emacs' executable is started, it automatically loads the user's `.emacs' file, or the default initialization file `default.el' if the user has none. (See section Starting Up Emacs.) With the `.emacs' file, you can produce a version of Emacs that suits you and is not the same as the version other people use. With `default.el', you can customize Emacs for all the users at your site who don't choose to customize it for themselves. (For further reflection: why is this different from the case of the barber who shaves every man who doesn't shave himself?)

On some systems, dumping does not work. Then, you must start Emacs with the `temacs -l loadup' command each time you use it. This takes a long time, but since you need to start Emacs once a day at most--and once a week or less frequently if you never log out--the extra time is not too severe a problem.

Before `emacs' is dumped, the documentation strings for primitive and preloaded functions (and variables) need to be found in the file where they are stored. This is done by calling `Snarf-documentation` (see section Access to Documentation Strings). These strings were moved out of `emacs' to make it smaller. See section Documentation Basics.

Function: **dump-emacs** *to-file from-file*

This function dumps the current state of Emacs into an executable file to-file. It takes symbols from from-file (this is normally the executable file `temacs').

If you use this function in an Emacs that was already dumped, you must set `command-line-processed`

to `nil` first for good results. See section Command Line Arguments.

Command: **emacs-version**

This function returns a string describing the version of Emacs that is running. It is useful to include this string in bug reports.

```
(emacs-version)
  => "GNU Emacs 18.36.1 of Fri Feb 27 1987 on slug
     (berkeley-unix)"
```

Called interactively, the function prints the same information in the echo area.

Variable: **emacs-build-time**

The value of this variable is the time at which Emacs was built at the local site.

```
emacs-build-time
     => "Fri Feb 27 14:55:57 1987"
```

Variable: **emacs-version**

The value of this variable is the version of Emacs being run. It is a string, e.g. `"18.36.1"`.

Pure Storage

There are two types of storage in GNU Emacs Lisp for user-created Lisp objects: normal storage and pure storage. Normal storage is where all the new data which is created during an Emacs session is kept; see the following section for information on normal storage. Pure storage is used for certain data in the preloaded standard Lisp files: data that should never change during actual use of Emacs.

Pure storage is allocated only while `` `temacs' `` is loading the standard preloaded Lisp libraries. In the file `` `emacs' ``, it is marked as read-only (on operating systems which permit this), so that the memory space can be shared by all the Emacs jobs running on the machine at once. Pure storage is not expandable; a fixed amount is allocated when Emacs is compiled, and if that is not sufficient for the preloaded libraries, `` `temacs' `` crashes. If that happens, you will have to increase the compilation parameter `PURESIZE` in the file `` `config.h' ``. This normally won't happen unless you try to preload additional libraries or add features to the standard ones.

Function: **purecopy** *object*

This function makes a copy of object in pure storage and returns it. It copies strings by simply making a new string with the same characters in pure storage. It recursively copies the contents of vectors and cons cells. It does not make copies of symbols, or any other objects, but just returns them unchanged. It signals an error if asked to copy markers.

This function is used only while Emacs is being built and dumped; it is called only in the file `` `emacs/lisp/loaddefs.el' ``.

Variable: **pure-bytes-used**

The value of this variable is the number of bytes of pure storage allocated so far. Typically, in a dumped Emacs, this number is very close to the total amount of pure storage available--if it were not, we would preallocate less.

Variable: **purify-flag**

This variable determines whether `defun` should make a copy of the function definition in pure storage. If it is non-`nil`, then the function definition is copied into pure storage.

This flag is `t` while loading all of the basic functions for building Emacs initially (allowing those functions to be sharable and non-collectible). It is set to `nil` when Emacs is saved out as `` `emacs' ``. The flag is set and reset in the C sources.

You should not change this flag in a running Emacs.

Garbage Collection

When a program creates a list or the user defines a new function (such as by loading a library), then that data is placed in normal storage. If normal storage runs low, then Emacs asks the operating system to allocate more memory in blocks of 1k bytes. Each block is used for one type of Lisp object, so symbols, cons cells, markers, etc. are segregated in distinct blocks in memory. (Vectors, buffers and certain other editing types, which are fairly large, are allocated in individual blocks, one per object, while strings are packed into blocks of 8k bytes.)

It is quite common to use some storage for a while, then release it by, for example, killing a buffer or deleting the last pointer to an object. Emacs provides a garbage collector to reclaim this abandoned storage. (This name is traditional, but "garbage recycler" might be a more intuitive metaphor for this facility.)

The garbage collector operates by scanning all the objects that have been allocated and marking those that are still accessible to Lisp programs. To begin with, all the symbols, their values and associated function definitions, and any data presently on the stack, are accessible. Any objects which can be reached indirectly through other accessible objects are also accessible.

When this is finished, all inaccessible objects are garbage. No matter what the Lisp program or the user does, it is impossible to refer to them, since there is no longer a way to reach them. Their space might as well be reused, since no one will notice. That is what the garbage collector arranges to do.

Unused cons cells are chained together onto a free list for future allocation; likewise for symbols and markers. The accessible strings are compacted so they are contiguous in memory; then the rest of the space formerly occupied by strings is made available to the string creation functions. Vectors, buffers, windows and other large objects are individually allocated and freed using `malloc`.

> **Common Lisp note:** unlike other Lisps, GNU Emacs Lisp does not call the garbage collector when the free list is empty. Instead, it simply requests the operating system to allocate more storage, and processing continues until `gc-cons-threshold` bytes have been used.
>
> This means that you can make sure that the garbage collector will not run during a certain portion of a Lisp program by calling the garbage collector explicitly just before it (provided that portion of the program does not use so much space as to force a second garbage collection).

Command: **garbage-collect**

This command runs a garbage collection, and returns information on the amount of space in use. (Garbage collection can also occur spontaneously if you use more than `gc-cons-threshold` bytes of Lisp data since the previous garbage collection.)

`garbage-collect` returns a list containing the following information:

```
((used-conses . free-conses)
 (used-syms . free-syms)
 (used-markers . free-markers)
 used-string-chars
 used-vector-slots
 (used-floats . free-floats))

(garbage-collect)
     => ((3435 . 2332) (1688 . 0) (57 . 417) 24510 3839 (4 . 1))
```

Here is a table explaining each element:

used-conses
: The number of cons cells in use.

free-conses
: The number of cons cells for which space has been obtained from the operating system, but that are not currently being used.

used-syms
: The number of symbols in use.

free-syms
: The number of symbols for which space has been obtained from the operating system, but that are not currently being used.

used-markers
: The number of markers in use.

free-markers
: The number of markers for which space has been obtained from the operating system, but that are not currently being used.

used-string-chars
: The total size of all strings, in characters.

used-vector-slots
: The total number of elements of existing vectors.

used-floats
: The number of floats in use.

free-floats
: The number of floats for which space has been obtained from the operating system, but that are not currently being used.

User Option: **gc-cons-threshold**

The value of this variable is the number of bytes of storage that must be allocated for Lisp objects after c garbage collection in order to request another garbage collection. A cons cell counts as eight bytes, a string as one byte per character plus a few bytes of overhead, and so on. (Space allocated to the contents of buffers does not count.) Note that the new garbage collection does not happen immediately when the threshold is exhausted, but only the next time the Lisp evaluator is called.

The initial threshold value is 100,000. If you specify a larger value, garbage collection will happen less often. This reduces the amount of time spent garbage collecting, but increases total memory use. You may want to do this when running a program which creates lots of Lisp data.

You can make collections more frequent by specifying a smaller value, down to 10,000. A value less than 10,000 will remain in effect only until the subsequent garbage collection, at which time `garbage-collect` will set the threshold back to 10,000.

Function: **memory-limit**

This function returns the address of the last byte Emacs has allocated, divided by 1024. We divide the value by 1024 to make sure it fits in a Lisp integer.

You can use this to get a general idea of how your actions affect the memory usage.

Writing Emacs Primitives

Lisp primitives are Lisp functions implemented in C. The details of interfacing the C function so that Lisp can call it are handled by a few C macros. The only way to really understand how to write new C code is to read the source, but we can explain some things here.

An example of a special form is the definition of `or`, from `` `eval.c' ``. (An ordinary function would have the same general appearance.)

```
DEFUN ("or", For, Sor, 0, UNEVALLED, 0,
  "Eval args until one of them yields non-NIL, then return that value.\n\
The remaining args are not evalled at all.\n\
If all args return NIL, return NIL.")
  (args)
     Lisp_Object args;
{
  register Lisp_Object val;
  Lisp_Object args_left;
  struct gcpro gcpro1;

  if (NULL(args))
    return Qnil;

  args_left = args;
  GCPRO1 (args_left);

  do
```

```
    {
      val = Feval (Fcar (args_left));
      if (!NULL (val))
        break;
      args_left = Fcdr (args_left);
    }
  while (!NULL(args_left));

  UNGCPRO;
  return val;
}
```

Let's start with a precise explanation of the arguments to the `DEFUN` macro. Here are the general names for them:

```
DEFUN (lname, fname, sname, min, max, interactive, doc)
```

lname

This is the name of the Lisp symbol to define with this function; in the example above, it is `or`.

fname

This is the C function name for this function. This is the name that is used in C code for calling the function. The name is, by convention, `F' prepended to the Lisp name, with all dashes (`-') in the Lisp name changed to underscores. Thus, to call this function from C code, call `For`. Remember that the arguments must be of type `Lisp_Object`; various macros and functions for creating values of type `Lisp_Object` are declared in the file `` `lisp.h' ``.

sname

This is a C variable name to use for a structure that holds the data for the subr object that represents the function in Lisp. This structure conveys the Lisp symbol name to the initialization routine that will create the symbol and store the subr object as its definition. By convention, this name is always fname with `F' replaced with `S'.

min

This is the minimum number of arguments that the function requires. For `or`, no arguments are required.

max

This is the maximum number of arguments that the function accepts. Alternatively, it can be `UNEVALLED`, indicating a special form that receives unevaluated arguments. A function with the equivalent of an `&rest` argument would have `MANY` in this position. Both `UNEVALLED` and `MANY` are macros. This argument must be one of these macros or a number at least as large as min. It may not be greater than six.

interactive

This is an interactive specification, a string such as might be used as the argument of `interactive` in a Lisp function. In the case of `or`, it is 0 (a null pointer), indicating that `or` cannot be called interactively. A value of `""` indicates an interactive function taking no arguments.

doc

This is the documentation string. It is written just like a documentation string for a function defined in

Lisp, except you must write `\n\' at the end of each line. In particular, the first line should be a sin sentence.

After the call to the `DEFUN` macro, you must write the list of argument names that every C function must have, followed by ordinary C declarations for them. Normally, all the arguments must be declared as `Lisp_Object`. If the function has no upper limit on the number of arguments in Lisp, then in C it receives two arguments: the number of Lisp arguments, and the address of a block containing their values. These have types `int` and `Lisp_Object *`.

Within the function `For` itself, note the use of the macros `GCPRO1` and `UNGCPRO`. `GCPRO1` is used to "protect" a variable from garbage collection--to inform the garbage collector that it must look in that variable and regard its contents as an accessible object. This is necessary whenever you call `Feval` or anything that can directly or indirectly call `Feval`. At such a time, any Lisp object that you intend to refer to again must be protected somehow. `UNGCPRO` cancels the protection of the variables that are protected in the current function. It is necessary to do this explicitly.

For most data types, it suffices to know that one pointer to the object is protected; as long as the object is not recycled, all pointers to it remain valid. This is not so for strings, because the garbage collector can move them. When a string is moved, any pointers to it that the garbage collector does not know about will not be properly relocated. Therefore, all pointers to strings must be protected across any point where garbage collection may be possible.

The macro `GCPRO1` protects just one local variable. If you want to protect two, use `GCPRO2` instead; repeating `GCPRO1` will not work. There are also `GCPRO3` and `GCPRO4`.

In addition to using these macros, you must declare the local variables such as `gcpro1` which they implicitly use. If you protect two variables, with `GCPRO2`, you must declare `gcpro1` and `gcpro2`, as it uses them both. Alas, we can't explain all the tricky details here.

Defining the C function is not enough; you must also create the Lisp symbol for the primitive and store a suitable subr object in its function cell. This is done by adding code to an initialization routine. The code looks like this:

```
defsubr (&subr-structure-name);
```

subr-structure-name is the name you used as the third argument to `DEFUN`.

If you are adding a primitive to a file that already has Lisp primitives defined in it, find the function (near the end of the file) named `syms_of_something`, and add that function call to it. If the file doesn't have this function, or if you create a new file, add to it a `syms_of_filename` (e.g., `syms_of_myfile`). Then find the spot in `` `emacs.c' `` where all of these functions are called, and add a call to `syms_of_filename` there.

This function `syms_of_filename` is also the place to define any C variables which are to be visible as Lisp variables. `DEFVAR_LISP` is used to make a C variable of type `Lisp_Object` visible in Lisp. `DEFVAR_INT` is used to make a C variable of type `int` visible in Lisp with a value that is an integer.

Here is another function, with more complicated arguments. This comes from the code for the X Window System, and it demonstrates the use of macros and functions to manipulate Lisp objects.

```
DEFUN ("coordinates-in-window-p", Fcoordinates_in_window_p,
  Scoordinates_in_window_p, 2, 2,
  "xSpecify coordinate pair: \nXExpression which evals to window: ",
  "Return non-nil if POSITIONS is in WINDOW.\n\
  \(POSITIONS is a list, (SCREEN-X SCREEN-Y)\)\n\
  Returned value is list of positions expressed\n\
  relative to window upper left corner.")
  (coordinate, window)
     register Lisp_Object coordinate, window;
{
  register Lisp_Object xcoord, ycoord;

  if (!CONSP (coordinate)) wrong_type_argument (Qlistp, coordinate);
  CHECK_WINDOW (window, 2);
  xcoord = Fcar (coordinate);
  ycoord = Fcar (Fcdr (coordinate));
  CHECK_NUMBER (xcoord, 0);
  CHECK_NUMBER (ycoord, 1);
  if ((XINT (xcoord) < XINT (XWINDOW (window)->left))
      || (XINT (xcoord) >= (XINT (XWINDOW (window)->left)
                            + XINT (XWINDOW (window)->width))))
    {
      return Qnil;
    }
  XFASTINT (xcoord) -= XFASTINT (XWINDOW (window)->left);
  if (XINT (ycoord) == (screen_height - 1))
    return Qnil;
  if ((XINT (ycoord) < XINT (XWINDOW (window)->top))
      || (XINT (ycoord) >= (XINT (XWINDOW (window)->top)
                            + XINT (XWINDOW (window)->height)) - 1))
    {
      return Qnil;
    }
  XFASTINT (ycoord) -= XFASTINT (XWINDOW (window)->top);
  return (Fcons (xcoord, Fcons (ycoord, Qnil)));
}
```

Note that you cannot directly call functions defined in Lisp as, for example, the primitive function `Fcons` is called above. You must create the appropriate Lisp form, protect everything from garbage collection, and `Feval` the form, as was done in `For` above.

`` `eval.c' `` is a very good file to look through for examples; `` `lisp.h' `` contains the definitions for some important macros and functions.

Object Internals

GNU Emacs Lisp manipulates many different types of data. The actual data are stored in a heap and the only access that programs have to it is through pointers. Pointers are thirty-two bits wide in most implementations. Depending on the operating system and type of machine for which you compile Emacs, twenty-four to twenty-six bits are used to address the object, and the remaining six to eight bits are used for a tag that identifies the object's type.

Because all access to data is through tagged pointers, it is always possible to determine the type of any object. This allows variables to be untyped, and the values assigned to them to be changed without regard to type. Function arguments also can be of any type; if you want a function to accept only a certain type of argument, you must check the type explicitly using a suitable predicate (see section Type Predicates).

Buffer Internals

Buffers contain fields not directly accessible by the Lisp programmer. We describe them here, naming them by the names used in the C code. Many are accessible indirectly in Lisp programs via Lisp primitives.

`name`
: The buffer name is a string which names the buffer. It is guaranteed to be unique. See section Buffer Names.

`save_modified`
: This field contains the time when the buffer was last saved, as an integer. See section Buffer Modification.

`modtime`
: This field contains the modification time of the visited file. It is set when the file is written or read. Every time the buffer is written to the file, this field is compared to the modification time of the file. See section Buffer Modification.

`auto_save_modified`
: This field contains the time when the buffer was last auto-saved.

`last_window_start`
: This field contains the `window-start` position in the buffer as of the last time the buffer was displayed in a window.

`undodata`
: This field points to the buffer's undo stack. See section Undo.

`syntax_table_v`
: This field contains the syntax table for the buffer. See section Syntax Tables.

`downcase_table`
: This field contains the conversion table for converting text to lower case. See section The Case Table.

`upcase_table`
: This field contains the conversion table for converting text to upper case. See section The Case Table.

`case_canon_table`

This field contains the conversion table for canonicalizing text for case-folding search. See section The Case Table.

`case_eqv_table`

This field contains the equivalence table for case-folding search. See section The Case Table.

`display_table`

This field contains the buffer's display table, or `nil` if it doesn't have one. See section Display Tables.

`markers`

This field contains the chain of all markers that point into the buffer. At each deletion or motion of the buffer gap, all of these markers must be checked and perhaps updated. See section Markers.

`backed_up`

This field is a flag which tells whether a backup file has been made for the visited file of this buffer.

`mark`

This field contains the mark for the buffer. The mark is a marker, hence it is also included on the list `markers`. See section The Mark.

`local_var_alist`

This field contains the association list containing all of the variables local in this buffer, and their values. The function `buffer-local-variables` returns a copy of this list. See section Buffer-Local Variables.

`mode_line_format`

This field contains a Lisp object which controls how to display the mode line for this buffer. See section Mode Line Format.

Window Internals

Windows have the following accessible fields:

`frame`

The frame that this window is on.

`mini_p`

Non-`nil` if this window is a minibuffer window.

`height`

The height of the window, measured in lines.

`width`

The width of the window, measured in columns.

`buffer`

The buffer which the window is displaying. This may change often during the life of the window.

`dedicated`

Non-`nil` if this window is dedicated to its buffer.

`start`

The position in the buffer which is the first character to be displayed in the window.

`pointm`

This is the value of point in the current buffer when this window is selected; when it is not selected, it retains its previous value.

`left`

This is the left-hand edge of the window, measured in columns. (The leftmost column on the screen is column 0.)

`top`

This is the top edge of the window, measured in lines. (The top line on the screen is line 0.)

`next`

This is the window that is the next in the chain of siblings.

`prev`

This is the window that is the previous in the chain of siblings.

`force_start`

This is a flag which, if non-`nil`, says that the window has been scrolled explicitly by the Lisp program. At the next redisplay, if point is off the screen, instead of scrolling the window to show the text around point, point will be moved to a location that is on the screen.

`hscroll`

This is the number of columns that the display in the window is scrolled horizontally to the left. Normally, this is 0.

`use_time`

This is the last time that the window was selected. The function `get-lru-window` uses this field.

`display_table`

The window's display table, or `nil` if none is specified for it.

Process Internals

The fields of a process are:

`name`

A string, the name of the process.

`command`

A list containing the command arguments that were used to start this process.

`filter`

A function used to accept output from the process instead of a buffer, or `nil`.

`sentinel`

A function called whenever the process receives a signal, or `nil`.

`buffer`

The associated buffer of the process.

`pid`

An integer, the Unix process ID.

`childp`

A flag, non-`nil` if this is really a child process. It is `nil` for a network connection.

`flags`

A symbol indicating the state of the process. Possible values include `run`, `stop`, `closed`, etc.

`reason`

An integer, the Unix signal number that the process received that caused the process to terminate or stop. If the process has exited, then this is the exit code it specified.

`mark`

A marker indicating the position of end of last output from this process inserted into the buffer. This is usually the end of the buffer.

`kill_without_query`

A flag, non-`nil` meaning this process should not cause confirmation to be needed if Emacs is killed.

Go to the previous, next section.

Go to the previous, next section.

Standard Errors

Here is the complete list of the error symbols in standard Emacs, grouped by concept. The list includes each symbol's message (on the `error-message` property of the symbol), and a cross reference to a description of how the error can occur.

Each error symbol has an `error-conditions` property which is a list of symbols. Normally, this list includes the error symbol itself, and the symbol `error`. Occasionally it includes additional symbols, which are intermediate classifications, narrower than `error` but broader than a single error symbol. For example, all the errors in accessing files have the condition `file-error`.

As a special exception, the error symbol `quit` does not have the condition `error`, because quitting is not considered an error.

See section Errors, for an explanation of how errors are generated and handled.

`symbol`
: string; reference.

`error`
: `"error"`
See section Errors.

`quit`
: `"Quit"`
See section Quitting.

`args-out-of-range`
: `"Args out of range"`
See section Sequences, Arrays, and Vectors.

`arith-error`
: `"Arithmetic error"`
See `/` and `%` in section Numbers.

`beginning-of-buffer`
: `"Beginning of buffer"`
See section Motion.

`buffer-read-only`
: `"Buffer is read-only"`
See section Read-Only Buffers.

`end-of-buffer`
: `"End of buffer"`
See section Motion.

`end-of-file`

> `"End of file during parsing"`
> This is not a `file-error`.
> See section Input Functions.

`file-error`

> This error, and its subcategories, do not have error-strings, because the error message is constructed from the data items alone when the error condition `file-error` is present.
> See section Files.

`file-locked`

> This is a `file-error`.
> See section File Locks.

`file-already-exists`

> This is a `file-error`.
> See section Writing to Files.

`file-supersession`

> This is a `file-error`.
> See section Buffer Modification.

`invalid-function`

> `"Invalid function"`
> See section Classification of List Forms.

`invalid-read-syntax`

> `"Invalid read syntax"`
> See section Input Functions.

`invalid-regexp`

> `"Invalid regexp"`
> See section Regular Expressions.

`no-catch`

> `"No catch for tag"`
> See section Explicit Nonlocal Exits: `catch` and `throw`.

`search-failed`

> `"Search failed"`
> See section Searching and Matching.

`setting-constant`

> `"Attempt to set a constant symbol"`
> The values of the symbols `nil` and `t` may not be changed.
> See section Variables that Never Change.

`void-function`

> `"Symbol's function definition is void"`

See section Accessing Function Cell Contents.

`void-variable`

`"Symbol's value as variable is void"`
See section Accessing Variable Values.

`wrong-number-of-arguments`

`"Wrong number of arguments"`
See section Classification of List Forms.

`wrong-type-argument`

`"Wrong type argument"`
See section Type Predicates.

Buffer-Local Variables

The table below shows all of the variables that are automatically local (when set) in each buffer in Emacs Version 18 with the common packages loaded.

`abbrev-mode`

see section Abbrevs And Abbrev Expansion

`auto-fill-function`

see section Auto Filling

`buffer-auto-save-file-name`

see section Auto-Saving

`buffer-backed-up`

see section Backup Files

`buffer-display-table`

see section Display Tables

`buffer-file-name`

see section Buffer File Name

`buffer-file-number`

see section Buffer File Name

`buffer-file-truename`

see section Buffer File Name

`buffer-offer-save`

see section Saving Buffers

`buffer-read-only`

see section Read-Only Buffers

`buffer-saved-size`

see section Point

`buffer-undo-list`

see section Undo

`case-fold-search`

see section Searching and Case

`ctl-arrow`

see section Usual Display Conventions

`default-directory`

see section Operating System Environment

`fill-column`

see section Auto Filling

`left-margin`

Standard Keymaps

The following symbols are used as the names for various keymaps. Some of these exist when Emacs is first started, others are only loaded when their respective mode is used. This is not an exhaustive list.

Almost all of these maps are used as local maps. Indeed, of the modes that presently exist, only Vip mode and Terminal mode ever change the global keymap.

`Buffer-menu-mode-map`
: A full keymap used by Buffer Menu mode.

`c-mode-map`
: A sparse keymap used in C mode as a local map.

`command-history-map`
: A full keymap used by Command History mode.

`ctl-x-4-map`
: A sparse keymap for subcommands of the prefix C-x 4.

`ctl-x-map`
: A full keymap for C-x commands.

`debugger-mode-map`
: A full keymap used by Debugger mode.

`dired-mode-map`
: A full keymap for `dired-mode` buffers.

`doctor-mode-map`
: A sparse keymap used by Doctor mode.

`edit-abbrevs-map`
: A sparse keymap used in `edit-abbrevs`.

`edit-tab-stops-map`
: A sparse keymap used in `edit-tab-stops`.

`electric-buffer-menu-mode-map`
: A full keymap used by Electric Buffer Menu mode.

`electric-history-map`
: A full keymap used by Electric Command History mode.

`emacs-lisp-mode-map`
: A sparse keymap used in Emacs Lisp mode.

`function-keymap`
: The keymap for the definitions of keypad and function keys.

If there are none, then it contains an empty sparse keymap.

`fundamental-mode-map`

The local keymap for Fundamental mode.
It is empty and should not be changed.

`Helper-help-map`

A full keymap used by the help utility package.
It has the same keymap in its value cell and in its function cell.

`Info-edit-map`

A sparse keymap used by the e command of Info.

`Info-mode-map`

A sparse keymap containing Info commands.

`isearch-mode-map`

A keymap that defines the characters you can type within incremental search.

`lisp-interaction-mode-map`

A sparse keymap used in Lisp mode.

`lisp-mode-map`

A sparse keymap used in Lisp mode.

`mode-specific-map`

The keymap for characters following C-c. Note, this is in the global map. This map is not actually mode specific: its name was chosen to be informative for the user in C-h b (`display-bindings`), where it describes the main use of the C-c prefix key.

`occur-mode-map`

A local keymap used in Occur mode.

`query-replace-map`

A local keymap used for responses in `query-replace` and related commands; also for `y-or-n-p` and `map-y-or-n-p`. The functions that use this map do not support prefix keys; they look up one event at a time.

`text-mode-map`

A sparse keymap used by Text mode.

`view-mode-map`

A full keymap used by View mode.

Go to the previous, next section.

Go to the previous section.

Standard Hooks

The following is a list of hook variables which let you provide functions to be called from within Emacs on suitable occasions.

Most of these variables have names ending with `-hook' are normal hooks, that are run with `run-hooks`. The value of such a hook is a list of functions. The recommended way to put a new function on such a hook is to call `add-hook`. See section Hooks, for more information about using hooks.

The variables whose names end in `-function' have single functions as their values. Usually there is a specific reason why the variable is not a normal hook, such as, the need to pass an argument to the function. (In older Emacs versions, some of these variables had names ending in `-hook' even though they were not normal hooks.)

The variables whose names end in `-hooks' have lists of functions as their values, but these functions are called in a special way (they are passed arguments, or else their values are used).

`activate-mark-hook`
`after-change-function`
`after-init-hook`

GNU Emacs Manual

Twelfth Edition, Updated for Emacs Version 19.34

Twelfth Edition
Updated for Emacs Version 19.34,
August 1996

ISBN 1-882114-05-1

Published by the Free Software Foundation
59 Temple Place, Suite 330
Boston, MA 02111-1307 USA

Cover art by Etienne Suvasa.

Preface

This manual documents the use and simple customization of the Emacs editor. The reader is not expected to be a programmer; simple customizations do not require programming skill. But the user who is not interested in customizing can ignore the scattered customization hints.

This is primarily a reference manual, but can also be used as a primer. For complete beginners, it is a good idea to start with the on-line, learn-by-doing tutorial, before reading the manual. To run the tutorial, start Emacs and type C-h t. This way you can learn Emacs by using Emacs on a specially designed file which describes commands, tells you when to try them, and then explains the results you see.

On first reading, just skim chapters one and two, which describe the notational conventions of the manual and the general appearance of the Emacs display screen. Note which questions are answered in these

chapters, so you can refer back later. After reading chapter four you should practice the commands th
The next few chapters describe fundamental techniques and concepts that are used constantly. You n
to understand them thoroughly, experimenting with them if necessary.

Chapters 14 through 18 describe intermediate-level features that are useful for all kinds of editing. Chapter 19 and following chapters describe features that you may or may not want to use; read those chapters when you need them

Read the Trouble chapter if Emacs does not seem to be working properly. It explains how to cope with some common problems (see section Dealing with Emacs Trouble), as well as when and how to report Emacs bugs (see section Reporting Bugs). To find the documentation on a particular command, look in the index. Keys (character commands) and command names have separate indexes. There is also a glossary, with a cross reference for each term.

This manual is available as a printed book and also as an Info file. The Info file is for on-line perusal with the Info program, which will be the principle way of viewing documentation on-line in the GNU system. Both the Info file and the Info program itself are distributed along with GNU Emacs. The Info file and the printed book contain substantially the same text and are generated from the same source files, which are also distributed along with GNU Emacs.

GNU Emacs is a member of the Emacs editor family. There are many Emacs editors, all sharing common principles of organization. For information on the underlying philosophy of Emacs and the lessons learned from its development, write for a copy of AI memo 519a, "Emacs, the Extensible, Customizable Self-Documenting Display Editor", to Publications Department, Artificial Intelligence Lab, 545 Tech Square, Cambridge, MA 02139, USA. At last report they charge $2.25 per copy. Another useful publication is LCS TM-165, "A Cookbook for an Emacs", by Craig Finseth, available from Publications Department, Laboratory for Computer Science, 545 Tech Square, Cambridge, MA 02139, USA. The price today is $3.

This edition of the manual is intended for use with GNU Emacs installed on GNU and Unix systems. GNU Emacs can also be used on VMS, MS-DOS (aka. MS-DOG), Windows NT, and Windows 95 systems. Those systems use different file name syntax; in addition, VMS and MS-DOS do not support all GNU Emacs features. We don't try to describe VMS usage in this manual. See section MS-DOS Issues, for information about using Emacs on MS-DOS.

Go to the next section.

Go to the previous, next section.

Distribution

GNU Emacs is free software; this means that everyone is free to use it and free to redistribute it on certain conditions. GNU Emacs is not in the public domain; it is copyrighted and there are restrictions on its distribution, but these restrictions are designed to permit everything that a good cooperating citizen would want to do. What is not allowed is to try to prevent others from further sharing any version of GNU Emacs that they might get from you. The precise conditions are found in the GNU General Public License that comes with Emacs and also appears following this section.

One way to get a copy of GNU Emacs is from someone else who has it. You need not ask for our permission to do so, or tell any one else; just copy it. If you have access to the Internet, you can get the latest distribution version of GNU Emacs by anonymous FTP; see the file `etc/FTP' in the Emacs distribution for more information.

You may also receive GNU Emacs when you buy a computer. Computer manufacturers are free to distribute copies on the same terms that apply to everyone else. These terms require them to give you the full sources, including whatever changes they may have made, and to permit you to redistribute the GNU Emacs received from them under the usual terms of the General Public License. In other words, the program must be free for you when you get it, not just free for the manufacturer.

You can also order copies of GNU Emacs from the Free Software Foundation, on various magnetic media or on CD-ROM. This is a convenient and reliable way to get a copy; it is also a good way to help fund our work. (The Foundation has always received most of its funds in this way.) An order form is included at the end of manuals printed by the Foundation. It is also included in the file `etc/ORDERS' in the Emacs distribution. For further information, write to

```
Free Software Foundation
59 Temple Place, Suite 330
Boston, MA  02111-1307 USA
USA
```

The income from distribution fees goes to support the foundation's purpose: the development of new free software, and improvements to our existing programs including GNU Emacs.

If you find GNU Emacs useful, please **send a donation** to the Free Software Foundation to support our work. Donations to the Free Software Foundation are tax deductible. If you use GNU Emacs at your workplace, suggest that the company make a donation. If company policy is unsympathetic to the idea of donating to charity, you might instead suggest ordering a CD-ROM from the Foundation occasionally, or subscribing to periodic updates.

Contributors to GNU Emacs include Per Abrahamsen, Jay K. Adams, Joe Arceneaux, Boaz Ben-Zvi, Jim Blandy, Frank Bresz, Kevin Broadey, Vincent Broman, David M. Brown, Hans Chalupsky, Bob Chassell, James Clark, Mike Clarkson, Doug Cutting, Michael DeCorte, Gary Delp, Matthieu Devin, Scott Draves, Viktor Dukhovni, Rolf Ebert, Torbj@"orn Einarsson, Hans Henrik Eriksen, Michael Ernst,

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free

use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.

2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

   You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

3. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:

   1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
   2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
   3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

These requirements apply to the modified work as a whole. If identifiable sections of that wor not derived from the Program, and can be reasonably considered independent and separate wo in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for noncommercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

    The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

    If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.

5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so

long as such parties remain in full compliance.

6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on it.
7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

   If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

   It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

   This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.
9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number

of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.

11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the

"copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and an idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or
modify it under the terms of the GNU General Public License
as published by the Free Software Foundation; either version 2
of the License, or (at your option) any later version.

This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details
type `show w'.  This is free software, and you are welcome
to redistribute it under certain conditions; type `show c'
for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright
interest in the program `Gnomovision'
(which makes passes at compilers) written
by James Hacker.

signature of Ty Coon, 1 April 1989
Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License

instead of this License.

Introduction

You are reading about GNU Emacs, the GNU incarnation of the advanced, self-documenting, customizable, extensible real-time display editor Emacs. (The `G' in `GNU' is not silent.)

We say that Emacs is a display editor because normally the text being edited is visible on the screen and is updated automatically as you type your commands. See section The Organization of the Screen.

We call it a real-time editor because the display is updated very frequently, usually after each character or pair of characters you type. This minimizes the amount of information you must keep in your head as you edit. See section Basic Editing Commands.

We call Emacs advanced because it provides facilities that go beyond simple insertion and deletion: controlling subprocesses; automatic indentation of programs; viewing two or more files at once; editing formatted text; and dealing in terms of characters, words, lines, sentences, paragraphs, and pages, as well as expressions and comments in several different programming languages.

Self-documenting means that at any time you can type a special character, Control-h, to find out what your options are. You can also use it to find out what any command does, or to find all the commands that pertain to a topic. See section Help.

Customizable means that you can change the definitions of Emacs commands in little ways. For example, if you use a programming language in which comments start with `<**' and end with `**>', you can tell the Emacs comment manipulation commands to use those strings (see section Manipulating Comments). Another sort of customization is rearrangement of the command set. For example, if you prefer the four basic cursor motion commands (up, down, left and right) on keys in a diamond pattern on the keyboard, you can rebind the keys that way. See section Customization.

Extensible means that you can go beyond simple customization and write entirely new commands, programs in the Lisp language to be run by Emacs's own Lisp interpreter. Emacs is an "on-line extensible" system, which means that it is divided into many functions that call each other, any of which can be redefined in the middle of an editing session. Almost any part of Emacs can be replaced without making a separate copy of all of Emacs. Most of the editing commands of Emacs are written in Lisp already; the few exceptions could have been written in Lisp but are written in C for efficiency. Although only a programmer can write an extension, anybody can use it afterward.

When run under the X Window System, Emacs provides its own menus and convenient bindings to mouse buttons. But Emacs can provide many of the benefits of a window system on a text-only terminal. For instance, you can look at or edit several files at once, move text between them, and edit files at the same time as you run shell commands.

Go to the previous, next section.

Go to the previous, next section.

The Organization of the Screen

On a text-only terminal, the Emacs display occupies the whole screen. On the X Window System, Emacs creates its own X windows to use. We use the term frame to mean an entire text-only screen or an entire X window used by Emacs. Emacs uses both kinds of frames in the same way to display your editing. Emacs normally starts out with just one frame, but you can create additional frames if you wish. See section Frames and X Windows.

When you start Emacs, the entire frame except for the last line is devoted to the text you are editing. This area is called window. The last line is a special echo area or minibuffer window where prompts appear and where you can enter responses. You can subdivide the large text window horizontally or vertically into multiple text windows, each of which can be used for a different file (see section Multiple Windows). In this manual, the word "window" always refers to the subdivisions of a frame within Emacs.

The window that the cursor is in is the selected window, in which editing takes place. Most Emacs commands implicitly apply to the text in the selected window (though mouse commands generally operate on whatever window you click them in, whether selected or not). The other windows display text for reference only, unless/until you select them. If you use multiple frames under the X Window System, then giving the input focus to a particular frame selects a window in that frame.

Each window's last line is a mode line which describes what is going on in that window. It appears in inverse video if the terminal supports that, and contains text that starts like `-----Emacs: something'. Its purpose is to indicate what buffer is being displayed above it in the window; what major and minor modes are in use; and whether the buffer contains unsaved changes.

Point

Within Emacs, the terminal's cursor shows the location at which editing commands will take effect. This location is called point. Many Emacs commands move point through the text, so that you can edit at different places in it. You can also place point by clicking mouse button 1.

While the cursor appears to point at a character, you should think of point as between two characters; it points before the character that appears under the cursor. For example, if your text looks like `frob' with the cursor over the `b', then point is between the `o' and the `b'. If you insert the character `!' at that position, the result is `fro!b', with point between the `!' and the `b'. Thus, the cursor remains over the `b', as before.

Sometimes people speak of "the cursor" when they mean "point", or speak of commands that move point as "cursor motion" commands.

Terminals have only one cursor, and when output is in progress it must appear where the typing is being done. This does not mean that point is moving. It is only that Emacs has no way to show you the location

of point except when the terminal is idle.

If you are editing several files in Emacs, each in its own buffer, each buffer has its own point location. A buffer that is not currently displayed remembers where point is in case you display it again later.

When there are multiple windows in a frame, each window has its own point location. The cursor shows the location of point in the selected window. This also is how you can tell which window is selected. If the same buffer appears in more than one window, each window has its own position for point in that buffer.

When there are multiple frames, each frame can display one cursor. The cursor in the selected frame is solid; the cursor in other frames is a hollow box, and appears in the window that would be selected if you give the input focus to that frame.

The term `point' comes from the character `.', which was the command in TECO (the language in which the original Emacs was written) for accessing the value now called `point'.

The Echo Area

The line at the bottom of the frame (below the mode line) is the echo area. It is used to display small amounts of text for several purposes.

Echoing means displaying the characters that you type. Outside Emacs, the operating system normally echoes all your input. Emacs handles echoing differently.

Single-character commands do not echo in Emacs, and multi-character commands echo only if you pause while typing them. As soon as you pause for more than a second in the middle of a command, Emacs echoes all the characters of the command so far. This is to prompt you for the rest of the command. Once echoing has started, the rest of the command echoes immediately as you type it. This behavior is designed to give confident users fast response, while giving hesitant users maximum feedback. You can change this behavior by setting a variable (see section Variables Controlling Display).

If a command cannot be executed, it may print an error message in the echo area. Error messages are accompanied by a beep or by flashing the screen. Also, any input you have typed ahead is thrown away when an error happens.

Some commands print informative messages in the echo area. These messages look much like error messages, but they are not announced with a beep and do not throw away input. Sometimes the message tells you what the command has done, when this is not obvious from looking at the text being edited. Sometimes the sole purpose of a command is to print a message giving you specific information--for example, C-x = prints a message describing the character position of point in the text and its current column in the window. Commands that take a long time often display messages ending in `...' while they are working, and add `done' at the end when they are finished.

Echo area informative messages are saved in an editor buffer named `*Messages*'. (We have not explained buffers yet; see section Using Multiple Buffers, for more information about them.) If you miss a message that appears briefly on the screen, you can switch to the `*Messages*' buffer to see it again. Successive progress messages are often collapsed into one.

The size of `*Messages*' is limited to a certain number of lines. The variable `message-log-max` specifies how many lines. Once the buffer has that many lines, each line added at the end deletes one line from the beginning. See section Variables, for how to set variables such as `message-log-max`.

The echo area is also used to display the minibuffer, a window that is used for reading arguments to commands, such as the name of a file to be edited. When the minibuffer is in use, the echo area begins with a prompt string that usually ends with a colon; also, the cursor appears in that line because it is the selected window. You can always get out of the minibuffer by typing C-g. See section The Minibuffer.

The Mode Line

Each text window's last line is a mode line which describes what is going on in that window. When there is only one text window, the mode line appears right above the echo area. The mode line is in inverse video if the terminal supports that, it starts and ends with dashes, and it contains text like `Emacs: something'.

A few special editing modes, such as Dired and Rmail, display something else in place of `Emacs: something'. The rest of the mode line still has the usual meaning.

Normally, the mode line looks like this:

```
--ch-Emacs: buf      (major minor)--line--pos------
```

This gives information about the buffer being displayed in the window: the buffer's name, what major and minor modes are in use, whether the buffer's text has been changed, and how far down the buffer you are currently looking.

ch contains two stars `**' if the text in the buffer has been edited (the buffer is "modified"), or `--' if the buffer has not been edited. For a read-only buffer, it is `%*' if the buffer is modified, and `%%' otherwise.

buf is the name of the window's buffer. In most cases this is the same as the name of a file you are editing. See section Using Multiple Buffers.

The buffer displayed in the selected window (the window that the cursor is in) is also Emacs's selected buffer, the one that editing takes place in. When we speak of what some command does to "the buffer", we are talking about the currently selected buffer.

line is `L' followed by the current line number of point. This is present when Line Number mode is enabled (which it normally is). You can optionally display the current column number too, by turning on Column Number mode (which is not enabled by default because it is somewhat slower). See section Optional Mode Line Features.

pos tells you whether there is additional text above the top of the window, or below the bottom. If your buffer is small and it is all visible in the window, pos is `All'. Otherwise, it is `Top' if you are looking at the beginning of the buffer, `Bot' if you are looking at the end of the buffer, or `nn%', where nn is the percentage of the buffer above the top of the window.

major is the name of the major mode in effect in the buffer. At any time, each buffer is in one and only one of the possible major modes. The major modes available include Fundamental mode (the least specialized), Text mode, Lisp mode, C mode, Texinfo mode, and many others. See section Major Modes, for details of how the modes differ and how to select one.

Some major modes display additional information after the major mode name. For example, Rmail buffers display the current message number and the total number of messages. Compilation buffers and Shell buffers display the status of the subprocess.

minor is a list of some of the minor modes that are turned on at the moment in the window's chosen buffer. For example, `Fill' means that Auto Fill mode is on. `Abbrev' means that Word Abbrev mode is on. `Ovwrt' means that Overwrite mode is on. See section Minor Modes, for more information. `Narrow' means that the buffer being displayed has editing restricted to only a portion of its text. This is not really a minor mode, but is like one. See section Narrowing. `Def' means that a keyboard macro is being defined. See section Keyboard Macros.

In addition, if Emacs is currently inside a recursive editing level, square brackets (`[...]') appear around the parentheses that surround the modes. If Emacs is in one recursive editing level within another, double square brackets appear, and so on. Since recursive editing levels affect Emacs globally, not just one buffer, the square brackets appear in every window's mode line or not in any of them. See section Recursive Editing Levels.

See section Optional Mode Line Features, for features that add other handy information to the mode line, such as the current line number of point, the current time, and whether new mail for you has arrived.

Go to the previous, next section.

Go to the previous, next section.

Characters, Keys and Commands

This chapter explains the character sets used by Emacs for input commands and for the contents of files, and also explains the concepts of keys and commands which are fundamental for understanding how Emacs interprets your keyboard and mouse input.

Kinds of User Input

GNU Emacs uses an extension of the ASCII character set for keyboard input; it also accepts non-character input events including function keys and mouse button actions.

ASCII consists of 128 character codes. Some of these codes are assigned graphic symbols such as `a' and `='; the rest are control characters, such as Control-a (usually written C-a for short). C-a gets its name from the fact that you type it by holding down the CTRL key while pressing a.

Some control characters have special names, and special keys you can type them with: for example, RET, TAB, LFD, DEL and ESC. The space character is usually referred to below as SPC, even though strictly speaking it is a graphic character whose graphic happens to be blank.

On ASCII terminals, there are only 32 possible control characters. These are the control variants of letters and `@[]\^_'. In addition, the shift key is meaningless with control characters: C-a and C-A are the same character, and Emacs cannot distinguish them.

But the Emacs character set has room for control variants of all characters, and for distinguishing between C-a and C-A. X Windows makes it possible to enter all these characters. For example, C-- (that's Control-Minus) and C-5 are meaningful Emacs commands under X.

Another Emacs character set extension is that characters have additional modifier bits. Only one modifier bit is commonly used; it is called Meta. Every character has a Meta variant; examples include Meta-a (normally written M-a, for short), M-A (not the same character as M-a, but those two characters normally have the same meaning in Emacs), M-RET, and M-C-a. For reasons of tradition, we usually write C-M-a rather than M-C-a; logically speaking, the order in which the modifier keys CTRL and META are mentioned does not matter.

Some terminals have a META key, and allow you to type Meta characters by holding this key down. Thus, Meta-a is typed by holding down META and pressing a. The META key works much like the SHIFT key. Such a key is not always labeled META, however, as this function is often a special option for a key with some other primary purpose.

If there is no META key, you can still type Meta characters using two-character sequences starting with ESC. Thus, to enter M-a, you could type ESC a. To enter C-M-a, you would type ESC C-a. ESC is allowed on terminals with META keys, too, in case you have formed a habit of using it. X Windows provides several other modifier keys that can be applied to any input character. These are called SUPER, HYPER and ALT. We write `s-', `H-' and `A-' to say that a character uses these modifiers. Thus, s-H-C-x

is short for Super-Hyper-Control-x. Not all X terminals actually provide keys for these modifier flags; fact, many terminals have a key labeled ALT which is really a META key. The standard key bindings Emacs do not include any characters with these modifiers. But you can assign them meanings of your own by customizing Emacs.

Keyboard input includes keyboard keys that are not characters at all: for example function keys and arrow keys. Mouse buttons are also outside the gamut of characters. You can modify these events with the modifier keys CONTROL, META, SUPER, HYPER and ALT like keyboard characters.

Input characters and non-character inputs are collectively called input events. See section 'Input Events' in The Emacs Lisp Manual, for more information. If you are not doing Lisp programming, but simply want to redefine the meaning of some characters or non-character events, see section Customization.

ASCII terminals cannot really send anything to the computer except ASCII characters. These terminals use a sequence of characters to represent each function key. But that is invisible to the Emacs user, because the keyboard input routines recognize these special sequences and convert them to function key events before any other part of Emacs gets to see them.

Keys

A key sequence (key, for short) is a sequence of input events that are meaningful as a unit--as "a single command." Some Emacs command sequences are just one character or one event; for example, just C-f is enough to move forward one character. But Emacs also has commands that take two or more events to invoke.

If a sequence of events is enough to invoke a command, it is a complete key. Examples of complete keys include C-a, X, RET, NEXT (a function key), DOWN (an arrow key), C-x C-f and C-x 4 C-f. If it isn't long enough to be complete, we call it a prefix key. The above examples show that C-x and C-x 4 are prefix keys. Every key sequence is either a complete key or a prefix key.

Most single characters constitute complete keys in the standard Emacs command bindings. A few of them are prefix keys. A prefix key combines with the following input event to make a longer key sequence, which may itself be complete or a prefix. For example, C-x is a prefix key, so C-x and the next input event combine to make a two-character key sequence. Most of these key sequences are complete keys, including C-x C-f and C-x b. A few, such as C-x 4 and C-x r, are themselves prefix keys that lead to three-character key sequences. There's no limit to the length of a key sequence, but in practice people rarely use sequences longer than four events.

By contrast, you can't add more events onto a complete key. For example, the two-character sequence C-f C-k is not a key, because the C-f is a complete key in itself. It's impossible to give C-f C-k an independent meaning as a command. C-f C-k is two key sequences, not one.

All told, the prefix keys in Emacs are C-c, C-h, C-x, C-x C-a, C-x n, C-x r, C-x v, C-x 4, C-x 5, C-x 6, and ESC. But this is not cast in concrete; it is just a matter of Emacs's standard key bindings. If you customize Emacs, you can make new prefix keys, or eliminate these. See section Customizing Key Bindings.

If you do make or eliminate prefix keys, that changes the set of possible key sequences. For example, if you redefine C-f as a prefix, C-f C-k automatically becomes a key (complete, unless you define it to be a prefix). Conversely, if you remove the prefix definition of C-x 4, then C-x 4 f (or C-x 4 anything) is no longer a key.

Typing the help character (C-h or F1) after a prefix character displays a list of the commands starting with that prefix. There are a few prefix characters for which C-h does not work--for historical reasons, they have other meanings for C-h which are not easy to change. But F1 should work for all prefix characters.

Keys and Commands

This manual is full of passages that tell you what particular keys do. But Emacs does not assign meanings to keys directly. Instead, Emacs assigns meanings to named commands, and then gives keys their meanings by binding them to commands.

Every command has a name chosen by a programmer. The name is usually made of a few English words separated by dashes; for example, `next-line` or `forward-word`. A command also has a function definition which is a Lisp program; this is what makes the command do what it does. In Emacs Lisp, a command is actually a special kind of Lisp function; one which specifies how to read arguments for it and call it interactively. For more information on commands and functions, see section 'What Is a Function' in The Emacs Lisp Reference Manual. (The definition we use in this manual is simplified slightly.)

The bindings between keys and commands are recorded in various tables called keymaps. See section Keymaps.

When we say that "C-n moves down vertically one line" we are glossing over a distinction that is irrelevant in ordinary use but is vital in understanding how to customize Emacs. It is the command `next-line` that is programmed to move down vertically. C-n has this effect *because* it is bound to that command. If you rebind C-n to the command `forward-word` then C-n will move forward by words instead. Rebinding keys is a common method of customization.

In the rest of this manual, we usually ignore this subtlety to keep things simple. To give the information needed for customization, we state the name of the command which really does the work in parentheses after mentioning the key that runs it. For example, we will say that "The command C-n (`next-line`) moves point vertically down," meaning that `next-line` is a command that moves vertically down and C-n is a key that is standardly bound to it.

While we are on the subject of information for customization only, it's a good time to tell you about variables. Often the description of a command will say, "To change this, set the variable `mumble-foo`." A variable is a name used to remember a value. Most of the variables documented in this manual exist just to facilitate customization: some command or other part of Emacs examines the variable and behaves differently according to the value that you set. Until you are interested in customizing, you can ignore the information about variables. When you are ready to be interested, read the basic information on variables, and then the information on individual variables will make sense. See section Variables.

Character Set for Text

Emacs buffers use an 8-bit character set, because bytes have 8 bits. ASCII graphic characters in Emacs buffers are displayed with their graphics. The newline character (which has the same character code as LFD) is displayed by starting a new line. The tab character is displayed by moving to the next tab stop column (normally every 8 columns). Other control characters are displayed as a caret (`^') followed by the non-control version of the character; thus, C-a is displayed as `^A'. Non-ASCII characters 128 and up are displayed with octal escape sequences; thus, character code 243 (octal) is displayed as `\243'.

You can customize the display of these character codes (or ASCII characters) by creating a display table. See section 'Display Tables' in The Emacs Lisp Reference Manual. This is useful for editing files that use 8-bit European character sets. See section European Character Set Display.

Go to the previous, next section.

Go to the previous, next section.

Entering and Exiting Emacs

The usual way to invoke Emacs is with the shell command `emacs'. Emacs clears the screen and then displays an initial help message and copyright notice. Some operating systems discard all type-ahead when Emacs starts up; they give Emacs no way to prevent this. Therefore, it is advisable to wait until Emacs clears the screen before typing your first editing command.

If you run Emacs from a shell window under the X Window System, run it in the background with `emacs&'. This way, Emacs does not tie up the shell window, so you can use that to run other shell commands while Emacs operates its own X windows. You can begin typing Emacs commands as soon as you direct your keyboard input to the Emacs frame.

When Emacs starts up, it makes a buffer named `*scratch*'. That's the buffer you start out in. The `*scratch*' buffer uses Lisp Interaction mode; you can use it to type Lisp expressions and evaluate them, or you can ignore that capability and simply doodle. (You can specify a different major mode for this buffer by setting the variable `initial-major-mode` in your init file. See section The Init File, `~/.emacs'.)

It is possible to specify files to be visited, Lisp files to be loaded, and functions to be called, by giving Emacs arguments in the shell command line. See section Command Line Arguments. But we don't recommend doing this. The feature exists mainly for compatibility with other editors.

Many other editors are designed to be started afresh each time you want to edit. You edit one file and then exit the editor. The next time you want to edit either another file or the same one, you must run the editor again. With these editors, it makes sense to use a command line argument to say which file to edit.

But starting a new Emacs each time you want to edit a different file does not make sense. For one thing, this would be annoyingly slow. For another, this would fail to take advantage of Emacs's ability to visit more than one file in a single editing session. And it would lose the other accumulated context, such as registers, undo history, and the mark ring.

The recommended way to use GNU Emacs is to start it only once, just after you log in, and do all your editing in the same Emacs session. Each time you want to edit a different file, you visit it with the existing Emacs, which eventually comes to have many files in it ready for editing. Usually you do not kill the Emacs until you are about to log out. See section File Handling, for more information on visiting more than one file.

Exiting Emacs

There are two commands for exiting Emacs because there are two kinds of exiting: suspending Emacs and killing Emacs.

Suspending means stopping Emacs temporarily and returning control to its parent process (usually a

shell), allowing you to resume editing later in the same Emacs job, with the same buffers, same kill r same undo history, and so on. This is the usual way to exit.

Killing Emacs means destroying the Emacs job. You can run Emacs again later, but you will get a fresh Emacs; there is no way to resume the same editing session after it has been killed.

C-z

Suspend Emacs (`suspend-emacs`) or iconify a frame (`iconify-or-deiconify-frame`).

C-x C-c

Kill Emacs (`save-buffers-kill-emacs`).

To suspend Emacs, type C-z (`suspend-emacs`). This takes you back to the shell from which you invoked Emacs. You can resume Emacs with the shell command `%emacs' in most common shells.

On systems that do not support suspending programs, C-z starts an inferior shell that communicates directly with the terminal. Emacs waits until you exit the subshell. (The way to do that is probably with C-d or `exit', but it depends on which shell you use.) The only way on these systems to get back to the shell from which Emacs was run (to log out, for example) is to kill Emacs.

Suspending also fails if you run Emacs under a shell that doesn't support suspending programs, even if the system itself does support it. In such a case, you can set the variable `cannot-suspend` to a non-`nil` value to force C-z to start an inferior shell. (One might also describe Emacs's parent shell as "inferior" for failing to support job control properly, but that is a matter of taste.)

When Emacs communicates directly with an X server and creates its own dedicated X windows, C-z has a different meaning. Suspending an applications that uses its own X windows is not meaningful or useful. Instead, C-z runs the command `iconify-or-deiconify-frame`, which temporarily closes up the selected Emacs frame (see section Frames and X Windows). The way to get back to a shell window is with the window manager.

To kill Emacs, type C-x C-c (`save-buffers-kill-emacs`). A two-character key is used for this to make it harder to type. This command first offers to save any modified file-visiting buffers. If you do not save them all, it asks for reconfirmation with yes before killing Emacs, since any changes not saved will be lost forever. Also, if any subprocesses are still running, C-x C-c asks for confirmation about them, since killing Emacs will kill the subprocesses immediately.

There is no way to restart an Emacs session once you have killed it. You can, however, arrange for Emacs to record certain session information, such as which files are visited, when you kill it, so that the next time you restart Emacs it will try to visit the same files and so on. See section Saving Emacs Sessions.

The operating system usually listens for certain special characters whose meaning is to kill or suspend the program you are running. **This operating system feature is turned off while you are in Emacs.** The meanings of C-z and C-x C-c as keys in Emacs were inspired by the use of C-z and C-c on several operating systems as the characters for stopping or killing a program, but that is their only relationship with the operating system. You can customize these keys to run any commands of your choice (see section Keymaps).

TOC

Go to the previous, next section.

Go to the previous, next section.

Basic Editing Commands

We now give the basics of how to enter text, make corrections, and save the text in a file. If this material is new to you, you might learn it more easily by running the Emacs learn-by-doing tutorial. To use the tutorial, run Emacs and type Control-h t (`help-with-tutorial`).

To clear the screen and redisplay, type C-l (`recenter`).

Inserting Text

To insert printing characters into the text you are editing, just type them. This inserts the characters you type into the buffer at the cursor (that is, at point; see section Point). The cursor moves forward, and any text after the cursor moves forward too. If the text in the buffer is `FOOBAR', with the cursor before the `B', then if you type XX, you get `FOOXXBAR', with the cursor still before the `B'.

To delete text you have just inserted, use DEL. DEL deletes the character *before* the cursor (not the one that the cursor is on top of or under; that is the character after the cursor). The cursor and all characters after it move backwards. Therefore, if you type a printing character and then type DEL, they cancel out.

To end a line and start typing a new one, type RET. This inserts a newline character in the buffer. If point is in the middle of a line, RET splits the line. Typing DEL when the cursor is at the beginning of a line deletes the preceding newline, thus joining the line with the preceding line.

Emacs can split lines automatically when they become too long, if you turn on a special minor mode called Auto Fill mode. See section Filling Text, for how to use Auto Fill mode.

If you prefer to have text characters replace (overwrite) existing text rather than shove it to the right, you can enable Overwrite mode, a minor mode. See section Minor Modes.

Direct insertion works for printing characters and SPC, but other characters act as editing commands and do not insert themselves. If you need to insert a control character or a character whose code is above 200 octal, you must quote it by typing the character Control-q (`quoted-insert`) first. (This character's name is normally written C-q for short.) There are two ways to use C-q:

- C-q followed by any non-graphic character (even C-g) inserts that character.
- C-q followed by three octal digits inserts the character with the specified character code.

A numeric argument to C-q specifies how many copies of the quoted character should be inserted (see section Numeric Arguments).

Customization information: DEL in most modes runs the command `delete-backward-char`; RET runs the command `newline`, and self-inserting printing characters run the command `self-insert`, which inserts whatever character was typed to invoke it. Some major modes rebind DEL to other commands.

Changing the Location of Point

To do more than insert characters, you have to know how to move point (see section Point). The simplest way to do this is with arrow keys, or by clicking the left mouse button where you want to move to.

There are also control and meta characters for cursor motion. Some are equivalent to the arrow keys (these date to the days before terminals had arrow keys, and are usable on terminals which don't have them). Others do more sophisticated things.

C-a

Move to the beginning of the line (`beginning-of-line`).

C-e

Move to the end of the line (`end-of-line`).

C-f

Move forward one character (`forward-char`).

C-b

Move backward one character (`backward-char`).

M-f

Move forward one word (`forward-word`).

M-b

Move backward one word (`backward-word`).

C-n

Move down one line, vertically (`next-line`). This command attempts to keep the horizontal position unchanged, so if you start in the middle of one line, you end in the middle of the next. When on the last line of text, C-n creates a new line and moves onto it.

C-p

Move up one line, vertically (`previous-line`).

M-r

Move point to left margin, vertically centered in the window (`move-to-window-line`). Text does not move on the screen.

A numeric argument says which screen line to place point on. It counts screen lines down from the top of the window (zero for the top line). A negative argument counts lines from the bottom (-1 for the bottom line).

M-<

Move to the top of the buffer (`beginning-of-buffer`). With numeric argument n, move to n/10 of the way from the top. See section Numeric Arguments, for more information on numeric arguments.

M->

Move to the end of the buffer (`end-of-buffer`).

M-x goto-char

Read a number n and move point to character number n. Position 1 is the beginning of the buffer.

M-x goto-line

Read a number n and move point to line number n. Line 1 is the beginning of the buffer.

C-x C-n

Use the current column of point as the semipermanent goal column for C-n and C-p (`set-goal-column`). Henceforth, those commands always move to this column in each line moved into, or as close as possible given the contents of the line. This goal column remains in effect until canceled.

C-u C-x C-n

Cancel the goal column. Henceforth, C-n and C-p once again try to stick to a fixed horizontal position, as usual.

If you set the variable `track-eol` to a non-`nil` value, then C-n and C-p when at the end of the starting line move to the end of another line. Normally, `track-eol` is `nil`. See section Variables, for how to set variables such as `track-eol`.

Normally, C-n on the last line of a buffer appends a newline to it. If the variable `next-line-add-newlines` is `nil`, then C-n gets an error instead (like C-p on the first line).

Erasing Text

DEL
: Delete the character before point (`delete-backward-char`).

C-d
: Delete the character after point (`delete-char`).

C-k
: Kill to the end of the line (`kill-line`).

M-d
: Kill forward to the end of the next word (`kill-word`).

M-DEL
: Kill back to the beginning of the previous word (`backward-kill-word`).

You already know about the DEL key which deletes the character before point (that is, before the cursor). Another key, Control-d (C-d for short), deletes the character after point (that is, the character that the cursor is on). This shifts the rest of the text on the line to the left. If you type C-d at the end of a line, it joins together that line and the next line.

To erase a larger amount of text, use the C-k key, which kills a line at a time. If you type C-k at the beginning or middle of a line, it kills all the text up to the end of the line. If you type C-k at the end of a line, it joins that line and the next line.

See section Deletion and Killing, for more flexible ways of killing text.

Undoing Changes

You can undo all the recent changes in the buffer text, up to a certain point. Each buffer records changes individually, and the undo command always applies to the current buffer. Usually each editing command makes a separate entry in the undo records, but some commands such as `query-replace` make many entries, and very simple commands such as self-inserting characters are often grouped to make undoing less tedious.

C-x u
: Undo one batch of changes--usually, one command worth (`undo`).

C-_
: The same.

The command C-x u or C-_ is how you undo. The first time you give this command, it undoes the last change. Point moves back to where it was before the command that made the change.

Consecutive repetitions of C-_ or C-x u undo earlier and earlier changes, back to the limit of the undo information available. If all recorded changes have already been undone, the undo command prints an error message and does

nothing.

Any command other than an undo command breaks the sequence of undo commands. Starting from that moment, the previous undo commands become ordinary changes that you can undo. Thus, to redo changes you have undone, type C-f or any other command that will harmlessly break the sequence of undoing, then type more undo commands.

If you notice that a buffer has been modified accidentally, the easiest way to recover is to type C-_ repeatedly until the stars disappear from the front of the mode line. At this time, all the modifications you made have been canceled. Whenever an undo command makes the stars disappear from the mode line, it means that the buffer contents are the same as they were when the file was last read in or saved.

If you do not remember whether you changed the buffer deliberately, type C-_ once. When you see the last change you made undone, you will see whether it was an intentional change. If it was an accident, leave it undone. If it was deliberate, redo the change as described above.

Not all buffers record undo information. Buffers whose names start with spaces don't; these buffers are used internally by Emacs and its extensions to hold text that users don't normally look at or edit.

You cannot undo mere cursor motion; only changes in the buffer contents save undo information. However, some cursor motion commands set the mark, so if you use these commands from time to time, you can move back to the neighborhoods you have moved through by popping the mark ring (see section The Mark Ring).

When the undo information for a buffer becomes too large, Emacs discards the oldest undo information from time to time (during garbage collection). You can specify how much undo information to keep by setting two variables: `undo-limit` and `undo-strong-limit`. Their values are expressed in units of bytes of space.

The variable `undo-limit` sets a soft limit: Emacs keeps undo data for enough commands to reach this size, and perhaps exceed it, but does not keep data for any earlier commands beyond that. Its default value is 20000. The variable `undo-strong-limit` sets a stricter limit: the command which pushes the size past this amount is itself forgotten. Its default value is 30000.

Regardless of the values of those variables, the most recent change is never discarded, so there is no danger that garbage collection occurring right after an unintentional large change might prevent you from undoing it.

The reason the `undo` command has two keys, C-x u and C-_, set up to run it is that it is worthy of a single-character key, but on some keyboards it is not obvious how to type C-_. C-x u is an alternative you can type straightforwardly on any terminal.

Files

The commands described above are sufficient for creating and altering text in an Emacs buffer; the more advanced Emacs commands just make things easier. But to keep any text permanently you must put it in a file. Files are named units of text which are stored by the operating system for you to retrieve later by name. To look at or use the contents of a file in any way, including editing the file with Emacs, you must specify the file name.

Consider a file named `` `/usr/rms/foo.c' ``. In Emacs, to begin editing this file, type

```
C-x C-f /usr/rms/foo.c RET
```

Here the file name is given as an argument to the command C-x C-f (`find-file`). That command uses the minibuffer to read the argument, and you type RET to terminate the argument (see section The Minibuffer).

Emacs obeys the command by visiting the file: creating a buffer, copying the contents of the file into the buffer, and then displaying the buffer for you to edit. If you alter the text, you can save the new text in the file by typing C-x C-s

(`save-buffer`). This makes the changes permanent by copying the altered buffer contents back into the file `/usr/rms/foo.c'. Until you save, the changes exist only inside Emacs, and the file `foo.c' is unaltered.

To create a file, just visit the file with C-x C-f as if it already existed. This creates an empty buffer in which you can insert the text you want to put in the file. The file is actually created when you save this buffer with C-x C-s.

Of course, there is a lot more to learn about using files. See section File Handling.

Help

If you forget what a key does, you can find out with the Help character, which is C-h (or F1, which is an alias for C-h). Type C-h k followed by the key you want to know about; for example, C-h k C-n tells you all about what C-n does. C-h is a prefix key; C-h k is just one of its subcommands (the command `describe-key`). The other subcommands of C-h provide different kinds of help. Type C-h twice to get a description of all the help facilities. See section Help.

Blank Lines

Here are special commands and techniques for putting in and taking out blank lines.

C-o
: Insert one or more blank lines after the cursor (`open-line`).

C-x C-o
: Delete all but one of many consecutive blank lines (`delete-blank-lines`).

When you want to insert a new line of text before an existing line, you can do it by typing the new line of text, followed by RET. However, it may be easier to see what you are doing if you first make a blank line and then insert the desired text into it. This is easy to do using the key C-o (`open-line`), which inserts a newline after point but leaves point in front of the newline. After C-o, type the text for the new line. C-o F O O has the same effect as F O O RET, except for the final location of point.

You can make several blank lines by typing C-o several times, or by giving it a numeric argument to tell it how many blank lines to make. See section Numeric Arguments, for how. If you have a fill prefix, then C-o command inserts the fill prefix on the new line, when you use it at the beginning of a line. See section The Fill Prefix.

The easy way to get rid of extra blank lines is with the command C-x C-o (`delete-blank-lines`). C-x C-o in a run of several blank lines deletes all but one of them. C-x C-o on a solitary blank line deletes that blank line. When point is on a nonblank line, C-x C-o deletes any blank lines following that nonblank line.

Continuation Lines

If you add too many characters to one line without breaking it with RET, the line will grow to occupy two (or more) lines on the screen, with a `\' at the extreme right margin of all but the last of them. The `\' says that the following screen line is not really a distinct line in the text, but just the continuation of a line too long to fit the screen. Continuation is also called line wrapping.

Sometimes it is nice to have Emacs insert newlines automatically when a line gets too long. Continuation on the screen does not do that. Use Auto Fill mode (see section Filling Text) if that's what you want.

As an alternative to continuation, Emacs can display long lines by truncation. This means that all the characters that

do not fit in the width of the screen or window do not appear at all. They remain in the buffer, temporarily invis
`$' is used in the last column instead of `\' to inform you that truncation is in effect.

Truncation instead of continuation happens whenever horizontal scrolling is in use, and optionally in all side-by-side windows (see section Multiple Windows). You can enable truncation for a particular buffer by setting the variable `truncate-lines` to non-`nil` in that buffer. (See section Variables.) Altering the value of `truncate-lines` makes it local to the current buffer; until that time, the default value is in effect. The default is initially `nil`. See section Local Variables.

See section Variables Controlling Display, for additional variables that affect how text is displayed.

Cursor Position Information

Here are commands to get information about the size and position of parts of the buffer, and to count lines.

M-x what-page
: Print page number of point, and line number within page.

M-x what-line
: Print line number of point in the buffer.

M-x line-number-mode
: Toggle automatic display of current line number.

M-=
: Print number of lines in the current region (`count-lines-region`). See section The Mark and the Region, for information about the region.

C-x =
: Print character code of character after point, character position of point, and column of point (`what-cursor-position`).

There are two commands for working with line numbers. M-x what-line computes the current line number and displays it in the echo area. To go to a given line by number, use M-x goto-line; it prompts you for the number. These line numbers count from one at the beginning of the buffer.

You can also see the current line number in the mode line; See section The Mode Line. If you narrow the buffer, then the line number in the mode line is relative to the accessible portion (see section Narrowing). By contrast, `what-line` shows both the line number relative to the narrowed region and the line number relative to the whole buffer.

By contrast, M-x what-page counts pages from the beginning of the file, and counts lines within the page, printing both numbers. See section Pages.

While on this subject, we might as well mention M-= (`count-lines-region`), which prints the number of lines in the region (see section The Mark and the Region). See section Pages, for the command C-x l which counts the lines in the current page.

The command C-x = (`what-cursor-position`) can be used to find out the column that the cursor is in, and other miscellaneous information about point. It prints a line in the echo area that looks like this:

```
Char: c (0143, 99, 0x63)  point=21044 of 26883(78%)  column 53
```

(In fact, this is the output produced when point is before the `column' in the example.)

The two values after `Char:' describe the character that follows point, first by showing it and second by giving its octal character code.

`point=' is followed by the position of point expressed as a character count. The front of the buffer counts as position 1, one character later as 2, and so on. The next, larger number is the total number of characters in the buffer. Afterward in parentheses comes the position expressed as a percentage of the total size.

`column' is followed by the horizontal position of point, in columns from the left edge of the window.

If the buffer has been narrowed, making some of the text at the beginning and the end temporarily inaccessible, C-x = prints additional text describing the currently accessible range. For example, it might display this:

```
Char: C (0103, 67, 0x43)  point=22015 of 26889(82%) <21660 - 22099>  column 0
```

where the two extra numbers give the smallest and largest character position that point is allowed to assume. The characters between those two positions are the accessible ones. See section Narrowing.

If point is at the end of the buffer (or the end of the accessible part), C-x = omits any description of the character after point. The output might look like this:

```
point=26957 of 26956(100%)  column 0
```

Numeric Arguments

In mathematics and computer usage, the word argument means "data provided to a function or operation." You can give any Emacs command a numeric argument (also called a prefix argument). Some commands interpret the argument as a repetition count. For example, C-f with an argument of ten moves forward ten characters instead of one. With these commands, no argument is equivalent to an argument of one. Negative arguments tell most such commands to move or act in the opposite direction.

If your terminal keyboard has a META key, the easiest way to specify a numeric argument is to type digits and/or a minus sign while holding down the the META key. For example,

```
M-5 C-n
```

would move down five lines. The characters Meta-1, Meta-2, and so on, as well as Meta--, do this because they are keys bound to commands (`digit-argument` and `negative-argument`) that are defined to contribute to an argument for the next command. Digits and - modified with Control, or Control and Meta, also specify numeric arguments.

Another way of specifying an argument is to use the C-u (`universal-argument`) command followed by the digits of the argument. With C-u, you can type the argument digits without holding down modifier keys; C-u works on all terminals. To type a negative argument, type a minus sign after C-u. Just a minus sign without digits normally means -1.

C-u followed by a character which is neither a digit nor a minus sign has the special meaning of "multiply by four". It multiplies the argument for the next command by four. C-u twice multiplies it by sixteen. Thus, C-u C-u C-f moves forward sixteen characters. This is a good way to move forward "fast", since it moves about 1/5 of a line in the usual size screen. Other useful combinations are C-u C-n, C-u C-u C-n (move down a good fraction of a screen), C-u C-u C-o (make "a lot" of blank lines), and C-u C-k (kill four lines).

Some commands care only about whether there is an argument, and not about its value. For example, the command

TOC

M-q (`fill-paragraph`) with no argument fills text; with an argument, it justifies the text as well. (See secti
Filling Text, for more information on M-q.) Plain C-u is a handy way of providing an argument for such comm

Some commands use the value of the argument as a repeat count, but do something peculiar when there is no argument. For example, the command C-k (`kill-line`) with argument n kills n lines, including their terminating newlines. But C-k with no argument is special: it kills the text up to the next newline, or, if point is right at the end of the line, it kills the newline itself. Thus, two C-k commands with no arguments can kill a nonblank line, just like C-k with an argument of one. (See section Deletion and Killing, for more information on C-k.)

A few commands treat a plain C-u differently from an ordinary argument. A few others may treat an argument of just a minus sign differently from an argument of -1. These unusual cases are described when they come up; they are always for reasons of convenience of use of the individual command.

You can use a numeric argument to insert multiple copies of a character. This is straightforward unless the character is a digit; for example, C-u 6 4 a inserts 64 copies of the character `a'. But this does not work for inserting digits; C-u 6 4 1 specifies an argument of 641, rather than inserting anything. To separate the digit to insert from the argument, type another C-u; for example, C-u 6 4 C-u 1 does insert 64 copies of the character `1'.

We use the term "prefix argument" as well as "numeric argument" to emphasize that you type the argument before the command, and to distinguish these arguments from minibuffer arguments that come after the command.

Go to the previous, next section.

Go to the previous, next section.

The Minibuffer

The minibuffer is the facility used by Emacs commands to read arguments more complicated than a single number. Minibuffer arguments can be file names, buffer names, Lisp function names, Emacs command names, Lisp expressions, and many other things, depending on the command reading the argument. You can use the usual Emacs editing commands in the minibuffer to edit the argument text.

When the minibuffer is in use, it appears in the echo area, and the terminal's cursor moves there. The beginning of the minibuffer line displays a prompt which says what kind of input you should supply and how it will be used. Often this prompt is derived from the name of the command that the argument is for. The prompt normally ends with a colon.

Sometimes a default argument appears in parentheses after the colon; it too is part of the prompt. The default will be used as the argument value if you enter an empty argument (e.g., just type RET). For example, commands that read buffer names always show a default, which is the name of the buffer that will be used if you type just RET.

The simplest way to enter a minibuffer argument is to type the text you want, terminated by RET which exits the minibuffer. You can cancel the command that wants the argument, and get out of the minibuffer, by typing C-g.

Since the minibuffer uses the screen space of the echo area, it can conflict with other ways Emacs customarily uses the echo area. Here is how Emacs handles such conflicts:

- If a command gets an error while you are in the minibuffer, this does not cancel the minibuffer. However, the echo area is needed for the error message and therefore the minibuffer itself is hidden for a while. It comes back after a few seconds, or as soon as you type anything.
- If in the minibuffer you use a command whose purpose is to print a message in the echo area, such as C-x =, the message is printed normally, and the minibuffer is hidden for a while. It comes back after a few seconds, or as soon as you type anything.
- Echoing of keystrokes does not take place while the minibuffer is in use.

Minibuffers for File Names

Sometimes the minibuffer starts out with text in it. For example, when you are supposed to give a file name, the minibuffer starts out containing the default directory, which ends with a slash. This is to inform you which directory the file will be found in if you do not specify a directory.

For example, the minibuffer might start out with these contents:

```
Find File: /u2/emacs/src/
```

where `Find File: ' is the prompt. Typing buffer.c specifies the file `/u2/emacs/src/buffer.c'.

To find files in nearby directories, use ..; thus, if you type ../lisp/simple.el, you will get the file name `/u2/emacs/lisp/simple.el'. Alternatively, you can kill with M-DEL the directory names you don't want (see section Words).

If you don't want any of the default, you can kill it with C-a C-k. But you don't need to kill the default; you can simply ignore it. Insert an absolute file name, one starting with a slash or a tilde, after the default directory. For example, to specify the file `/etc/termcap', just insert that name, giving these minibuffer contents:

```
Find File: /u2/emacs/src//etc/termcap
```

Two slashes in a row are not normally meaningful in a file name, but they are allowed in GNU Emacs. They mean, "ignore everything before the second slash in the pair." Thus, `/u2/emacs/src/' is ignored in the example above, and you get the file `/etc/termcap'.

If you set `insert-default-directory` to `nil`, the default directory is not inserted in the minibuffer. This way, the minibuffer starts out empty. But the name you type, if relative, is still interpreted with respect to the same default directory.

Editing in the Minibuffer

The minibuffer is an Emacs buffer (albeit a peculiar one), and the usual Emacs commands are available for editing the text of an argument you are entering.

Since RET in the minibuffer is defined to exit the minibuffer, you can't use it to insert a newline in the minibuffer. To do that, type C-o or C-q LFD. (Recall that a newline is really the LFD character.)

The minibuffer has its own window which always has space on the screen but acts as if it were not there when the minibuffer is not in use. When the minibuffer is in use, its window is just like the others; you can switch to another window with C-x o, edit text in other windows and perhaps even visit more files, before returning to the minibuffer to submit the argument. You can kill text in another window, return to the minibuffer window, and then yank the text to use it in the argument. See section Multiple Windows.

There are some restrictions on the use of the minibuffer window, however. You cannot switch buffers in it--the minibuffer and its window are permanently attached. Also, you cannot split or kill the minibuffer window. But you can make it taller in the normal fashion with C-x ^. If you enable Resize-Minibuffer mode, then the minibuffer window expands vertically as necessary to hold the text that you put in the minibuffer. Use M-x resize-minibuffer-mode to enable or disable this minor mode (see section Minor Modes).

If while in the minibuffer you issue a command that displays help text of any sort in another window, you can use the C-M-v command while in the minibuffer to scroll the help text. This lasts until you exit the minibuffer. This feature is especially useful if a completing minibuffer gives you a list of possible completions. See section Using Other Windows.

Emacs normally disallows most commands that use the minibuffer while the minibuffer is selected. This rule is to prevent recursive minibuffers from confusing novice users. If you want to be able to use such

commands in the minibuffer, set the variable `enable-recursive-minibuffers` to a non-`nil` value.

Completion

For certain kinds of arguments, you can use completion to enter the argument value. Completion means that you type part of the argument, then Emacs visibly fills in the rest, or as much as can be determined from the part you have typed.

When completion is available, certain keys---TAB, RET, and SPC---are rebound to complete the text present in the minibuffer into a longer string that it stands for, by matching it against a set of completion alternatives provided by the command reading the argument. ? is defined to display a list of possible completions of what you have inserted.

For example, when M-x uses the minibuffer to read the name of a command, it provides a list of all available Emacs command names to complete against. The completion keys match the text in the minibuffer against all the command names, find any additional name characters implied by the ones already present in the minibuffer, and add those characters to the ones you have given. This is what makes it possible to type M-x ins SPC b RET instead of M-x insert-buffer RET (for example).

Case is normally significant in completion, because it is significant in most of the names that you can complete (buffer names, file names and command names). Thus, `fo' does not complete to `Foo'. Completion does ignore case distinctions for certain arguments in which case does not matter.

Completion Example

A concrete example may help here. If you type M-x au TAB, the TAB looks for alternatives (in this case, command names) that start with `au'. There are only two: `auto-fill-mode` and `auto-save-mode`. These are the same as far as `auto-`, so the `au' in the minibuffer changes to `auto-'.

If you type TAB again immediately, there are multiple possibilities for the very next character--it could be `s' or `f'---so no more characters are added; instead, TAB displays a list of all possible completions in another window.

If you go on to type f TAB, this TAB sees `auto-f'. The only command name starting this way is `auto-fill-mode`, so completion fills in the rest of that. You now have `auto-fill-mode' in the minibuffer after typing just au TAB f TAB. Note that TAB has this effect because in the minibuffer it is bound to the command `minibuffer-complete` when completion is available.

Completion Commands

Here is a list of the completion commands defined in the minibuffer when completion is available.

TAB

Complete the text in the minibuffer as much as possible (`minibuffer-complete`).

SPC

Complete the minibuffer text, but don't go beyond one word (`minibuffer-complete-wo`

RET

Submit the text in the minibuffer as the argument, possibly completing first as described below (`minibuffer-complete-and-exit`).

?

Print a list of all possible completions of the text in the minibuffer (`minibuffer-list-completions`).

SPC completes much like TAB, but never goes beyond the next hyphen or space. If you have `auto-f' in the minibuffer and type SPC, it finds that the completion is `auto-fill-mode', but it stops completing after `fill-'. This gives `auto-fill-'. Another SPC at this point completes all the way to `auto-fill-mode'. SPC in the minibuffer when completion is available runs the command `minibuffer-complete-word`.

Here are some commands you can use to choose a completion from a window that displays a list of completions:

Mouse-2

Clicking mouse button 2 on a completion in the list of possible completions chooses that completion (`mouse-choose-completion`). You normally use this command while point is in the minibuffer; but you must click in the list of completions, not in the minibuffer itself.

PRIOR

M-v

Typing PRIOR or PAGE-UP, or M-v, while in the minibuffer, selects the window showing the completion list buffer (`switch-to-completions`). This paves the way for using the commands below. (Selecting that window in the usual ways has the same effect, but this way is more convenient.)

RET

Typing RET *in the completion list buffer* chooses the completion that point is in or next to (`choose-completion`). To use this command, you must first switch windows to the window that shows the list of completions.

RIGHT

Typing the right-arrow key RIGHT *in the completion list buffer* moves point to the following completion (`next-completion`).

LEFT

Typing the left-arrow key LEFT *in the completion list buffer* moves point toward the beginning of the buffer, to the previous completion (`previous-completion`).

Strict Completion

There are three different ways that RET can work in completing minibuffers, depending on how the argument will be used.

- Strict completion is used when it is meaningless to give any argument except one of the known alternatives. For example, when C-x k reads the name of a buffer to kill, it is meaningless to give

anything but the name of an existing buffer. In strict completion, RET refuses to exit if the text in the minibuffer does not complete to an exact match.

- Cautious completion is similar to strict completion, except that RET exits only if the text was an exact match already, not needing completion. If the text is not an exact match, RET does not exit, but it does complete the text. If it completes to an exact match, a second RET will exit.

  Cautious completion is used for reading file names for files that must already exist.

- Permissive completion is used when any string whatever is meaningful, and the list of completion alternatives is just a guide. For example, when C-x C-f reads the name of a file to visit, any file name is allowed, in case you want to create a file. In permissive completion, RET takes the text in the minibuffer exactly as given, without completing it.

The completion commands display a list of all possible completions in a window whenever there is more than one possibility for the very next character. Also, typing ? explicitly requests such a list. If the list of completions is long, you can scroll it with C-M-v (see section Using Other Windows).

Completion Options

When completion is done on file names, certain file names are usually ignored. The variable `completion-ignored-extensions` contains a list of strings; a file whose name ends in any of those strings is ignored as a possible completion. The standard value of this variable has several elements including `".o"`, `".elc"`, `".dvi"` and `"~"`. The effect is that, for example, `foo' can complete to `foo.c' even though `foo.o' exists as well. However, if *all* the possible completions end in "ignored" strings, then they are not ignored. Ignored extensions do not apply to lists of completions--those always mention all possible completions.

Normally, a completion command that finds the next character is undetermined automatically displays a list of all possible completions. If the variable `completion-auto-help` is set to `nil`, this does not happen, and you must type ? to display the possible completions.

The `complete` library implements a more powerful kind of completion that can complete multiple words at a time. For example, it can complete the command name abbreviation `p-b` into `print-buffer`, because no other command starts with two words whose initials are `p' and `b'. To use this library, put `(load "complete")` in your `` `~/.emacs' `` file (see section The Init File, `` `~/.emacs' ``).

Icomplete mode presents a constantly-updated display that tells you what completions are available for the text you've entered so far. The command to enable or disable this minor mode is M-x icomplete-mode.

Minibuffer History

Every argument that you enter with the minibuffer is saved on a minibuffer history list so that you can use it again later in another argument. Special commands load the text of an earlier argument in the minibuffer. They discard the old minibuffer contents, so you can think of them as moving through the history of previous arguments.

M-p

Move to the next earlier argument string saved in the minibuffer history (`previous-history-element`).

M-n

Move to the next later argument string saved in the minibuffer history (`next-history-element`).

M-r regexp RET

Move to an earlier saved argument in the minibuffer history that has a match for regexp (`previous-matching-history-element`).

M-s regexp RET

Move to a later saved argument in the minibuffer history that has a match for regexp (`next-matching-history-element`).

The simplest way to reuse the saved arguments in the history list is to move through the history list one element at a time. While in the minibuffer, type M-p (`previous-history-element`) to "move to" the next earlier minibuffer input, and use M-n (`next-history-element`) to "move to" the next later input.

The previous input that you fetch from the history entirely replaces the contents of the minibuffer. To use it as the argument, exit the minibuffer as usual with RET. You can also edit the text before you reuse it; this does not change the history element that you "moved" to, but your new argument does go at the end of the history list in its own right.

There are also commands to search forward or backward through the history. As of this writing, they search for history elements that match a regular expression that you specify with the minibuffer. M-r (`previous-matching-history-element`) searches older elements in the history, while M-s (`next-matching-history-element`) searches newer elements. By special dispensation, these commands can use the minibuffer to read their arguments even though you are already in the minibuffer when you issue them.

All uses of the minibuffer record your input on a history list, but there are separate history lists for different kinds of arguments. For example, there is a list for file names, used by all the commands that read file names. There is a list for arguments of commands like `query-replace`. There are several very specific history lists, including one for command names read by M-x and one for compilation commands read by `compile`. Finally, there is one "miscellaneous" history list that most minibuffer arguments use.

Repeating Minibuffer Commands

Every command that uses the minibuffer at least once is recorded on a special history list, together with the values of its arguments, so that you can repeat the entire command. In particular, every use of M-x is recorded there, since M-x uses the minibuffer to read the command name.

C-x ESC ESC

Re-execute a recent minibuffer command (`repeat-complex-command`).

M-x list-command-history

> Display the entire command history, showing all the commands C-x ESC ESC can repeat, most recent first.

C-x ESC ESC is used to re-execute a recent minibuffer-using command. With no argument, it repeats the last such command. A numeric argument specifies which command to repeat; one means the last one, and larger numbers specify earlier ones.

C-x ESC ESC works by turning the previous command into a Lisp expression and then entering a minibuffer initialized with the text for that expression. If you type just RET, the command is repeated as before. You can also change the command by editing the Lisp expression. Whatever expression you finally submit is what will be executed. The repeated command is added to the front of the command history unless it is identical to the most recently executed command already there.

Even if you don't understand Lisp syntax, it will probably be obvious which command is displayed for repetition. If you do not change the text, it will repeat exactly as before.

Once inside the minibuffer for C-x ESC ESC, you can use the minibuffer history commands (M-p, M-n, M-r, M-s; see section Minibuffer History) to move through the history list of saved entire commands. After finding the desired previous command, you can edit its expression as usual and then resubmit it by typing RET as usual.

The list of previous minibuffer-using commands is stored as a Lisp list in the variable `command-history`. Each element is a Lisp expression which describes one command and its arguments. Lisp programs can reexecute a command by calling `eval` with the `command-history` element.

Running Commands by Name

The Emacs commands that are used often or that must be quick to type are bound to keys--short sequences of characters--for convenient use. Other Emacs commands that do not need to be brief are not bound to keys; to run them, you must refer to them by name.

A command name is, by convention, made up of one or more words, separated by hyphens; for example, `auto-fill-mode` or `manual-entry`. The use of English words makes the command name easier to remember than a key made up of obscure characters, even though it is more characters to type.

The way to run a command by name is to start with M-x, type the command name, and finish it with RET. M-x uses the minibuffer to read the command name. RET exits the minibuffer and runs the command. The string `M-x' appears at the beginning of the minibuffer as a prompt to remind you to enter the name of a command to be run. See section The Minibuffer, for full information on the features of the minibuffer.

You can use completion to enter the command name. For example, the command `forward-char` can be invoked by name by typing

```
M-x forward-char RET
```

or

```
M-x forw TAB c RET
```

Note that `forward-char` is the same command that you invoke with the key C-f. You can run any Emacs command by name using M-x, whether or not any keys are bound to it. If you use M-x to run a command which also has a key binding, it displays a message to tell you about the key binding, before running the command. (You can turn off this notification feature by setting the variable `suggest-key-bindings` to `nil`.)

If you type C-g while the command name is being read, you cancel the M-x command and get out of the minibuffer, ending up at top level.

To pass a numeric argument to the command you are invoking with M-x, specify the numeric argument before the M-x. M-x passes the argument along to the command it runs. The argument value appears in the prompt while the command name is being read.

If the command you type has a key binding of its own, Emacs mentions this in the echo area before it runs the command. For example, if you type M-x forward-word, the message says that you can run the same command more easily by typing M-f. You can turn off these messages by setting `suggest-key-bindings` to `nil`. If `suggest-key-bindings` is a number, it says how long to show the message before proceeding with the command.

Normally, when describing a command that is run by name, we omit the RET that is needed to terminate

TOC

the name. Thus we might speak of M-x auto-fill-mode rather than M-x auto-fill-mode RET. We men the RET only when there is a need to emphasize its presence, such as when we show the command together with following arguments.

M-x works by running the command `execute-extended-command`, which is responsible for reading the name of another command and invoking it.

Go to the previous, next section.

Go to the previous, next section.

Help

Emacs provides extensive help features accessible through a single character, C-h. C-h is a prefix key that is used only for documentation-printing commands. The characters that you can type after C-h are called help options. One help option is C-h; that is how you ask for help about using C-h. To cancel, type C-g. The function key F1 is equivalent to C-h.

C-h C-h (`help-for-help`) displays a list of the possible help options, each with a brief description. Before you type a help option, you can use SPC or DEL to scroll through the list.

C-h or F1 means "help" in various other contexts as well. For example, in `query-replace`, it describes the options available. After a prefix key, it displays a list of the alternatives that can follow the prefix key. (A few prefix keys don't support this because they define other meanings for C-h.)

Most help buffers use a special major mode, Help mode, which lets you scroll conveniently with SPC and DEL.

Here is a summary of the defined help commands.

C-h a regexp RET

: Display list of commands whose names match regexp (`apropos-command`).

C-h b

: Display a table of all key bindings in effect now, in this order: minor mode bindings, major mode bindings, and global bindings (`describe-bindings`).

C-h c key

: Print the name of the command that key runs (`describe-key-briefly`). Here c stands for `character'. For more extensive information on key, use C-h k.

C-h f function RET

: Display documentation on the Lisp function named function (`describe-function`). Since commands are Lisp functions, a command name may be used.

C-h i

: Run Info, the program for browsing documentation files (`info`). The complete Emacs manual is available on-line in Info.

C-h k key

: Display name and documentation of the command that key runs (`describe-key`).

C-h l

: Display a description of the last 100 characters you typed (`view-lossage`).

C-h m

: Display documentation of the current major mode (`describe-mode`).

C-h n

Display documentation of Emacs changes, most recent first (`view-emacs-news`).

C-h p

Find packages by topic keyword (`finder-by-keyword`).

C-h s

Display current contents of the syntax table, plus an explanation of what they mean (`describe-syntax`). See section The Syntax Table.

C-h t

Enter the Emacs interactive tutorial (`help-with-tutorial`).

C-h v var RET

Display the documentation of the Lisp variable var (`describe-variable`).

C-h w command RET

Print which keys run the command named command (`where-is`).

C-h C-f function RET

Enter Info and go to the node documenting the Emacs function function (`Info-goto-emacs-command-node`).

C-h C-k key

Enter Info and go to the node where the key sequence key is documented (`Info-goto-emacs-key-command-node`).

C-h C-c

Display the copying conditions for GNU Emacs.

C-h C-d

Display information about getting new versions of GNU Emacs.

C-h C-p

Display information about the GNU Project.

Documentation for a Key

The most basic C-h options are C-h c (`describe-key-briefly`) and C-h k (`describe-key`). C-h c key prints in the echo area the name of the command that key is bound to. For example, C-h c C-f prints `forward-char'. Since command names are chosen to describe what the commands do, this is a good way to get a very brief description of what key does.

C-h k key is similar but gives more information: it displays the documentation string of the command as well as its name. This is too big for the echo area, so a window is used for the display.

C-h c and C-h k work for any sort of key sequences, including function keys and mouse events.

Help by Command or Variable Name

C-h f (`describe-function`) reads the name of a Lisp function using the minibuffer, then displays that function's documentation string in a window. Since commands are Lisp functions, you can use this to get the documentation of a command that you know by name. For example,

```
C-h f auto-fill-mode RET
```

displays the documentation of `auto-fill-mode`. This is the only way to get the documentation of a command that is not bound to any key (one which you would normally run using M-x).

C-h f is also useful for Lisp functions that you are planning to use in a Lisp program. For example, if you have just written the expression `(make-vector len)` and want to check that you are using `make-vector` properly, type C-h f make-vector RET. Because C-h f allows all function names, not just command names, you may find that some of your favorite abbreviations that work in M-x don't work in C-h f. An abbreviation may be unique among command names yet fail to be unique when other function names are allowed.

The function name for C-h f to describe has a default which is used if you type RET leaving the minibuffer empty. The default is the function called by the innermost Lisp expression in the buffer around point, *provided* that is a valid, defined Lisp function name. For example, if point is located following the text `(make-vector (car x)', the innermost list containing point is the one that starts with `(make-vector', so the default is to describe the function `make-vector`.

C-h f is often useful just to verify that you have the right spelling for the function name. If C-h f mentions a name from the buffer as the default, that name must be defined as a Lisp function. If that is all you want to know, just type C-g to cancel the C-h f command, then go on editing.

C-h w command RET tells you what keys are bound to command. It prints a list of the keys in the echo area. If it says the command is not on any key, you must use M-x to run it. C-h w runs the command `where-is`.

C-h v (`describe-variable`) is like C-h f but describes Lisp variables instead of Lisp functions. Its default is the Lisp symbol around or before point, but only if that is the name of a known Lisp variable. See section Variables.

Apropos

A more sophisticated sort of question to ask is, "What are the commands for working with files?" To ask this question, type C-h a file RET, which displays a list of all command names that contain `file', including `copy-file`, `find-file`, and so on. With each command name appears a brief description of how to use the command, and what keys you can currently invoke it with. For example, it would say that you can invoke `find-file` by typing C-x C-f. The a in C-h a stands for `Apropos'; C-h a runs the command `apropos-command`. This command does not check user variables by default; specify a numeric argument if you want it to check them.

Because C-h a looks only for functions whose names contain the string which you specify, you must ingenuity in choosing the string. If you are looking for commands for killing backwards and C-h a kill-backwards RET doesn't reveal any, don't give up. Try just kill, or just backwards, or just back. Be persistent. Also note that you can use a regular expression as the argument, for more flexibility (see section Syntax of Regular Expressions).

Here is a set of arguments to give to C-h a that covers many classes of Emacs commands, since there are strong conventions for naming the standard Emacs commands. By giving you a feel for the naming conventions, this set should also serve to aid you in developing a technique for picking `apropos` strings.

> char, line, word, sentence, paragraph, region, page, sexp, list, defun, rect, buffer, frame, window, face, file, dir, register, mode, beginning, end, forward, backward, next, previous, up, down, search, goto, kill, delete, mark, insert, yank, fill, indent, case, change, set, what, list, find, view, describe, default.

To list all Lisp symbols that contain a match for a regexp, not just the ones that are defined as commands, use the command M-x apropos instead of C-h a. This command does not check key bindings by default; specify a numeric argument if you want it to check them.

The `apropos-documentation` command is like `apropos` except that it searches documentation strings as well as symbol names for matches for the specified regular expression.

The `apropos-value` command is like `apropos` except that it searches symbols' values for matches for the specified regular expression. This command does not check function definitions or property lists by default; specify a numeric argument if you want it to check them.

If you want more information about a function definition, variable or symbol property listed in the Apropos buffer, you can click on it with Mouse-2 or move there and type RET.

Keyword Search for Lisp Libraries

The C-h p command lets you search the standard Emacs Lisp libraries by topic keywords. Here is a partial list of keywords you can use:

`abbrev'

> Abbreviation handling, typing shortcuts, macros.

`bib'

> Support for the bibliography processor `bib`.

`c'

> C and C++ language support.

`calendar'

> Calendar and time management support.

`comm'

> Communications, networking, remote access to files.

`data'
: Support for editing files of data.

`docs'
: Support for Emacs documentation.

`emulations'
: Emulations of other editors.

`extensions'
: Emacs Lisp language extensions.

`faces'
: Support for using faces (fonts and colors; see section Using Multiple Typefaces).

`frames'
: Support for Emacs frames and window systems.

`games'
: Games, jokes and amusements.

`hardware'
: Support for interfacing with exotic hardware.

`help'
: Support for on-line help systems.

`hypermedia'
: Support for links within text, or other media types.

`i18n'
: Internationalization and alternate character-set support.

`internal'
: Code for Emacs internals, build process, defaults.

`languages'
: Specialized modes for editing programming languages.

`lisp'
: Support for using Lisp (including Emacs Lisp).

`local'
: Libraries local to your site.

`maint'
: Maintenance aids for the Emacs development group.

`mail'
: Modes for electronic-mail handling.

`matching'
: Searching and matching.

`news'
: Support for netnews reading and posting.

`non-text'
: Support for editing files that are not ordinary text.

`oop'
: Support for object-oriented programming.

`outlines'
: Hierarchical outlining.

`processes'
: Process, subshell, compilation, and job control support.

`terminals'
: Support for terminal types.

`tex'
: Support for the TeX formatter.

`tools'
: Programming tools.

`unix'
: Front-ends/assistants for, or emulators of, Unix features.

`vms'
: Support code for VMS.

`wp'
: Word processing.

Other Help Commands

C-h i (`info`) runs the Info program, which is used for browsing through structured documentation files. The entire Emacs manual is available within Info. Eventually all the documentation of the GNU system will be available. Type h after entering Info to run a tutorial on using Info.

There are two special help commands for accessing Emacs documentation through Info. C-h C-f function RET enters Info and goes straight to the documentation of the Emacs function function. C-h C-k key enters Info and goes straight to the documentation of the key key. These two keys run the commands `Info-goto-emacs-command-node` and `Info-goto-emacs-key-command-node`.

If something surprising happens, and you are not sure what commands you typed, use C-h l (`view-lossage`). C-h l prints the last 100 command characters you typed in. If you see commands that you don't know, you can use C-h c to find out what they do.

Emacs has numerous major modes, each of which redefines a few keys and makes a few other changes in how editing works. C-h m (`describe-mode`) prints documentation on the current major mode, which normally describes all the commands that are changed in this mode.

C-h b (`describe-bindings`) and C-h s (`describe-syntax`) present other information about the current Emacs mode. C-h b displays a list of all the key bindings now in effect; the local bindings defined by the current minor modes first, then the local bindings defined by the current major mode, and finally the global bindings (see section Customizing Key Bindings). C-h s displays the contents of the syntax table, with explanations of each character's syntax (see section The Syntax Table).

You can get a similar list for a particular prefix key by typing C-h after the prefix key. (There are a few prefix keys for which this does not work--those that provide their own bindings for C-h. One of these is ESC, because ESC C-h is actually C-M-h, which marks a defun.)

The other C-h options display various files of useful information. C-h C-w displays the full details on the complete absence of warranty for GNU Emacs. C-h n (`view-emacs-news`) displays the file `` `emacs/etc/NEWS' ``, which contains documentation on Emacs changes arranged chronologically. C-h t (`help-with-tutorial`) displays the learn-by-doing Emacs tutorial. C-h C-c (`describe-copying`) displays the file `` `emacs/etc/COPYING' ``, which tells you the conditions you must obey in distributing copies of Emacs. C-h C-d (`describe-distribution`) displays the file `` `emacs/etc/DISTRIB' ``, which tells you how you can order a copy of the latest version of Emacs. C-h C-p (`describe-project`) displays general information about the GNU Project.

Go to the previous, next section.

The Mark and the Region

Many Emacs commands operate on an arbitrary contiguous part of the current buffer. To specify the text for such a command to operate on, you set the mark at one end of it, and move point to the other end. The text between point and the mark is called the region. Emacs highlights the region whenever there is one, if you enable Transient Mark mode (see section Transient Mark Mode).

You can move point or the mark to adjust the boundaries of the region. It doesn't matter which one is set first chronologically, or which one comes earlier in the text. Once the mark has been set, it remains where you put it until you set it again at another place. Each Emacs buffer has its own mark, so that when you return to a buffer that had been selected previously, it has the same mark it had before.

Many commands that insert text, such as C-y (`yank`) and M-x insert-buffer, position point and the mark at opposite ends of the inserted text, so that the region contains the text just inserted.

Aside from delimiting the region, the mark is also useful for remembering a spot that you may want to go back to. To make this feature more useful, each buffer remembers 16 previous locations of the mark in the mark ring.

Setting the Mark

Here are some commands for setting the mark:

C-SPC
: Set the mark where point is (`set-mark-command`).

C-@
: The same.

C-x C-x
: Interchange mark and point (`exchange-point-and-mark`).

Drag-Mouse-1
: Set point and the mark around the text you drag across.

Mouse-3
: Set the mark where point is, then move point to where you click (`mouse-save-then-kill`).

For example, suppose you wish to convert part of the buffer to all upper-case, using the C-x C-u (`upcase-region`) command which operates on the text in the region. You can first go to the beginning of the text to be capitalized, type C-SPC to put the mark there, move to the end, and then type C-x C-u. Or, you can set the mark at the end of the text, move to the beginning, and then type C-x C-u.

The most common way to set the mark is with the C-SPC command (`set-mark-command`). This sets the mark where point is. Then you can move point away, leaving the mark behind.

There are two ways to set the mark with the mouse. You can drag mouse button one across a range of text; that puts point where you release the mouse button, and sets the mark at the other end of that range. Or you can click mouse button three, which sets the mark at point (like C-SPC) and them moves point (like Mouse-1). Both of these methods copy the region into the kill ring in addition to setting the mark; that gives behavior consistent with other window-driven applications, but if you don't want to modify the kill ring, you must use keyboard commands to set the mark. See section Mouse Commands for Editing.

Ordinary terminals have only one cursor, so there is no way for Emacs to show you where the mark is located. You have to remember. The usual solution to this problem is to set the mark and then use it soon, before you forget where it is. Alternatively, you can see where the mark is with the command C-x C-x (`exchange-point-and-mark`) which puts the mark where point was and point where the mark was. The extent of the region is unchanged, but the cursor and point are now at the previous position of the mark. In Transient Mark mode, this command reactivates the mark.

C-x C-x is also useful when you are satisfied with the position of point but want to move the mark; do C-x C-x to put point at that end of the region, and then move it. A second use of C-x C-x, if necessary, puts the mark at the new position with point back at its original position.

There is no such character as C-SPC in ASCII; when you type SPC while holding down CTRL, what you get on most ordinary terminals is the character C-@. This key is actually bound to `set-mark-command`. But unless you are unlucky enough to have a terminal where typing C-SPC does not produce C-@, you might as well think of this character as C-SPC. Under X, C-SPC is actually a distinct character, but its binding is still `set-mark-command`.

Transient Mark Mode

Emacs can highlight the current region, using X Windows. But normally it does not. Why not?

Highlighting the region doesn't work well ordinarily in Emacs, because once you have set a mark, there is *always* a region (in that buffer). And highlighting the region all the time would be a nuisance.

You can turn on region highlighting by enabling Transient Mark mode. This is a more rigid mode of operation in which the region "lasts" only temporarily, so you must set up a region for each command that uses one. In Transient Mark mode, most of the time there is no region; therefore, highlighting the region when it exists is convenient.

To enable Transient Mark mode, type M-x transient-mark-mode. This command toggles the mode, so you can repeat the command to turn off the mode.

Here are the details of Transient Mark mode:

- To set the mark, type C-SPC (`set-mark-command`). This makes the mark active; as you move point, you will see the region highlighting change in extent.
- The mouse commands for specifying the mark also make it active. So do keyboard commands whose purpose is to specify a region, including M-@, C-M-@, M-h, C-M-h, C-x C-p, and C-x h.
- When the mark is active, you can execute commands that operate on the region, such as killing, indentation, or writing to a file.

- Any change to the buffer, such as inserting or deleting a character, deactivates the mark. This means any subsequent command that operates on a region will get an error and refuse to operate. You can make the region active again by typing C-x C-x.
- Commands like M-> and C-s that "leave the mark behind" in addition to some other primary purpose do not activate the new mark. You can activate the new region by executing C-x C-x (`exchange-point-and-mark`).
- C-s when the mark is active does not alter the mark.
- Quitting with C-g deactivates the mark.

Transient Mark mode is also sometimes known as "Zmacs mode" because the Zmacs editor on the MIT Lisp Machine handled the mark in a similar way.

When multiple windows show the same buffer, they can have different regions, because they can have different values of point (though they all share common one mark position). In Transient Mark mode, each window highlights its own region. The part that is highlighted in the selected window is the region that editing commands use. See section Multiple Windows.

When Transient Mark mode is not enabled, every command that sets the mark also activates it, and nothing ever deactivates it.

If the variable `mark-even-if-inactive` is non-`nil` in Transient Mark mode, then commands can use the mark and the region even when it is inactive. Region highlighting appears and disappears just as it normally does in Transient Mark mode, but the mark doesn't really go away when the highlighting disappears.

Operating on the Region

Once you have a region and the mark is active, here are some of the ways you can operate on the region:

- Kill it with C-w (see section Deletion and Killing).
- Save it in a register with C-x r s (see section Registers).
- Save it in a buffer or a file (see section Accumulating Text).
- Convert case with C-x C-l or C-x C-u (see section Case Conversion Commands).
- Indent it with C-x TAB or C-M-\ (see section Indentation).
- Fill it as text with M-x fill-region (see section Filling Text).
- Print hardcopy with M-x print-region (see section Hardcopy Output).
- Evaluate it as Lisp code with M-x eval-region (see section Evaluating Emacs-Lisp Expressions).

Most commands that operate on the text in the region have the word `region` in their names.

Commands to Mark Textual Objects

Here are the commands for placing point and the mark around a textual object such as a word, list, paragraph or page.

M-@
: Set mark after end of next word (`mark-word`). This command and the following one do not move point.

C-M-@
: Set mark after end of next Lisp expression (`mark-sexp`).

M-h
: Put region around current paragraph (`mark-paragraph`).

C-M-h
: Put region around current Lisp defun (`mark-defun`).

C-x h
: Put region around entire buffer (`mark-whole-buffer`).

C-x C-p
: Put region around current page (`mark-page`).

M-@ (`mark-word`) puts the mark at the end of the next word, while C-M-@ (`mark-sexp`) puts it at the end of the next Lisp expression. These commands handle arguments just like M-f and C-M-f.

Other commands set both point and mark, to delimit an object in the buffer. For example, M-h (`mark-paragraph`) moves point to the beginning of the paragraph that surrounds or follows point, and puts the mark at the end of that paragraph (see section Paragraphs). It prepares the region so you can indent, case-convert, or kill a whole paragraph.

C-M-h (`mark-defun`) similarly puts point before and the mark after the current or following defun (see section Defuns). C-x C-p (`mark-page`) puts point before the current page, and mark at the end (see section Pages). The mark goes after the terminating page delimiter (to include it), while point goes after the preceding page delimiter (to exclude it). A numeric argument specifies a later page (if positive) or an earlier page (if negative) instead of the current page.

Finally, C-x h (`mark-whole-buffer`) sets up the entire buffer as the region, by putting point at the beginning and the mark at the end.

In Transient Mark mode, all of these commands activate the mark.

The Mark Ring

Aside from delimiting the region, the mark is also useful for remembering a spot that you may want to go back to. To make this feature more useful, each buffer remembers 16 previous locations of the mark, in the mark ring. Commands that set the mark also push the old mark onto this ring. To return to a marked

location, use C-u C-SPC (or C-u C-@); this is the command `set-mark-command` given a numeric argument. It moves point to where the mark was, and restores the mark from the ring of former marks. Thus, repeated use of this command moves point to all of the old marks on the ring, one by one. The mark positions you move through in this way are not lost; they go to the end of the ring.

Each buffer has its own mark ring. All editing commands use the current buffer's mark ring. In particular, C-u C-SPC always stays in the same buffer.

Many commands that can move long distances, such as M-< (`beginning-of-buffer`), start by setting the mark and saving the old mark on the mark ring. This is to make it easier for you to move back later. Searches set the mark if they move point. You can tell when a command sets the mark because it displays `Mark Set' in the echo area.

If you want to move back to the same place over and over, the mark ring may not be convenient enough. If so, you can record the position in a register for later retrieval (see section Saving Positions in Registers).

The variable `mark-ring-max` specifies the maximum number of entries to keep in the mark ring. If that many entries exist and another one is pushed, the last one in the list is discarded. Repeating C-u C-SPC circulates through the positions currently in the ring.

The variable `mark-ring` holds the mark ring itself, as a list of marker objects in the order most recent first. This variable is local in every buffer.

The Global Mark Ring

In addition to the ordinary mark ring that belongs to each buffer, Emacs has a single global mark ring. It records a sequence of buffers in which you have recently set the mark, so you can go back to those buffers.

Setting the mark always makes an entry on the current buffer's mark ring. If you have switched buffers since the previous mark setting, the new mark position makes an entry on the global mark ring also. The result is that the global mark ring records a sequence of buffers that you have been in, and, for each buffer, a place where you set the mark.

The command C-x C-SPC (`pop-global-mark`) jumps to the buffer and position of the latest entry in the global ring. It also rotates the ring, so that successive uses of C-x C-SPC take you to earlier and earlier buffers.

Go to the previous, next section.

Go to the previous, next section.

Killing and Moving Text

Killing means erasing text and copying it into the kill ring, from which it can be retrieved by yanking it. Some systems use the terms "cutting" and "pasting" for these operations.

The commonest way of moving or copying text within Emacs is to kill it and later yank elsewhere it in one or more places. This is very safe because Emacs remembers several recent kills, not just the last one. It is versatile, because the many commands for killing syntactic units can also be used for moving those units. But there are other ways of copying text for special purposes.

Emacs has only one kill ring for all buffers, so you can kill text in one buffer and yank it in another buffer.

Deletion and Killing

Most commands which erase text from the buffer save it in the kill ring so that you can move or copy it to other parts of the buffer. These commands are known as kill commands. The rest of the commands that erase text do not save it in the kill ring; they are known as delete commands. (This distinction is made only for erasure of text in the buffer.) If you do a kill or delete command by mistake, you can use the C-x u (`undo`) command to undo it (see section Undoing Changes).

The delete commands include C-d (`delete-char`) and DEL (`delete-backward-char`), which delete only one character at a time, and those commands that delete only spaces or newlines. Commands that can destroy significant amounts of nontrivial data generally kill. The commands' names and individual descriptions use the words `kill' and `delete' to say which they do.

Deletion

C-d
: Delete next character (`delete-char`).

DEL
: Delete previous character (`delete-backward-char`).

M-\
: Delete spaces and tabs around point (`delete-horizontal-space`).

M-SPC
: Delete spaces and tabs around point, leaving one space (`just-one-space`).

C-x C-o
: Delete blank lines around the current line (`delete-blank-lines`).

M-^

Join two lines by deleting the intervening newline, along with any indentation following it (`delete-indentation`).

The most basic delete commands are C-d (`delete-char`) and DEL (`delete-backward-char`). C-d deletes the character after point, the one the cursor is "on top of". This doesn't move point. DEL deletes the character before the cursor, and moves point back. You can delete newlines like any other characters in the buffer; deleting a newline joins two lines. Actually, C-d and DEL aren't always delete commands; when given arguments, they kill instead, since they can erase more than one character this way.

The other delete commands are those which delete only whitespace characters: spaces, tabs and newlines. M-\ (`delete-horizontal-space`) deletes all the spaces and tab characters before and after point. M-SPC (`just-one-space`) does likewise but leaves a single space after point, regardless of the number of spaces that existed previously (even zero).

C-x C-o (`delete-blank-lines`) deletes all blank lines after the current line. If the current line is blank, it deletes all blank lines preceding the current line as well (leaving one blank line, the current line).

M-^ (`delete-indentation`) joins the current line and the previous line, by deleting a newline and all surrounding spaces, usually leaving a single space. See section Indentation.

Killing by Lines

C-k

Kill rest of line or one or more lines (`kill-line`).

The simplest kill command is C-k. If given at the beginning of a line, it kills all the text on the line, leaving it blank. When used on a blank line, it kills the whole line including its newline. To kill an entire non-blank line, go to the beginning and type C-k twice.

More generally, C-k kills from point up to the end of the line, unless it is at the end of a line. In that case it kills the newline following point, thus merging the next line into the current one. Spaces and tabs that you can't see at the end of the line are ignored when deciding which case applies, so if point appears to be at the end of the line, you can be sure C-k will kill the newline.

When C-k is given a positive argument, it kills that many lines and the newlines that follow them (however, text on the current line before point is spared). With a negative argument -n, it kills n lines preceding the current line (together with the text on the current line before point). Thus, C-u - 2 C-k at the front of a line kills the two previous lines.

C-k with an argument of zero kills the text before point on the current line.

If the variable `kill-whole-line` is non-`nil`, C-k at the very beginning of a line kills the entire line including the following newline. This variable is normally `nil`.

Other Kill Commands

C-w
: Kill region (from point to the mark) (`kill-region`).

M-d
: Kill word (`kill-word`). See section Words.

M-DEL
: Kill word backwards (`backward-kill-word`).

C-x DEL
: Kill back to beginning of sentence (`backward-kill-sentence`). See section Sentences.

M-k
: Kill to end of sentence (`kill-sentence`).

C-M-k
: Kill sexp (`kill-sexp`). See section Lists and Sexps.

M-z char
: Kill through the next occurrence of char (`zap-to-char`).

A kill command which is very general is C-w (`kill-region`), which kills everything between point and the mark. With this command, you can kill any contiguous sequence of characters, if you first set the region around them.

A convenient way of killing is combined with searching: M-z (`zap-to-char`) reads a character and kills from point up to (and including) the next occurrence of that character in the buffer. A numeric argument acts as a repeat count. A negative argument means to search backward and kill text before point.

Other syntactic units can be killed: words, with M-DEL and M-d (see section Words); sexps, with C-M-k (see section Lists and Sexps); and sentences, with C-x DEL and M-k (see section Sentences).

You can use kill commands in read-only buffers. They don't actually change the buffer, and they beep to warn you of that, but they do copy the text you tried to kill into the kill ring, so you can yank it into other buffers. Most of the kill commands move point across the text they copy in this way, so that successive kill commands build up a single kill ring entry as usual.

Yanking

Yanking means reinserting text previously killed. This is what some systems call "pasting". The usual way to move or copy text is to kill it and then yank it elsewhere one or more times.

C-y
: Yank last killed text (`yank`).

M-y

Replace text just yanked with an earlier batch of killed text (`yank-pop`).

M-w

Save region as last killed text without actually killing it (`kill-ring-save`).

C-M-w

Append next kill to last batch of killed text (`append-next-kill`).

The Kill Ring

All killed text is recorded in the kill ring, a list of blocks of text that have been killed. There is only one kill ring, shared by all buffers, so you can kill text in one buffer and yank it in another buffer. This is the usual way to move text from one file to another. (See section Accumulating Text, for some other ways.)

The command C-y (`yank`) reinserts the text of the most recent kill. It leaves the cursor at the end of the text. It sets the mark at the beginning of the text. See section The Mark and the Region.

C-u C-y leaves the cursor in front of the text, and sets the mark after it. This happens only if the argument is specified with just a C-u, precisely. Any other sort of argument, including C-u and digits, specifies an earlier kill to yank (see section Yanking Earlier Kills).

To copy a block of text, you can use M-w (`kill-ring-save`), which copies the region into the kill ring without removing it from the buffer. This is approximately equivalent to C-w followed by C-x u, except that M-w does not alter the undo history and does not temporarily change the screen.

Appending Kills

Normally, each kill command pushes a new entry onto the kill ring. However, two or more kill commands in a row combine their text into a single entry, so that a single C-y yanks all the text as a unit, just as it was before it was killed.

Thus, if you want to yank text as a unit, you need not kill all of it with one command; you can keep killing line after line, or word after word, until you have killed it all, and you can still get it all back at once.

Commands that kill forward from point add onto the end of the previous killed text. Commands that kill backward from point add text onto the beginning. This way, any sequence of mixed forward and backward kill commands puts all the killed text into one entry without rearrangement. Numeric arguments do not break the sequence of appending kills. For example, suppose the buffer contains this text:

```
This is a line -!-of sample text.
```

with point shown by -!-. If you type M-d M-DEL M-d M-DEL, killing alternately forward and backward, you end up with `a line of sample' as one entry in the kill ring, and `This is text.' in the buffer. (Note the double space, which you can clean up with M-SPC or M-q.)

Another way to kill the same text is to move back two words with M-b M-b, then kill all four words

forward with C-u M-d. This produces exactly the same results in the buffer and in the kill ring. M-f N C-u M-DEL kills the same text, all going backward; once again, the result is the same. The text in th ring entry always has the same order that it had in the buffer before you killed it.

If a kill command is separated from the last kill command by other commands (not just numeric arguments), it starts a new entry on the kill ring. But you can force it to append by first typing the command C-M-w (`append-next-kill`) right before it. The C-M-w tells the following command, if it is a kill command, to append the text it kills to the last killed text, instead of starting a new entry. With C-M-w, you can kill several separated pieces of text and accumulate them to be yanked back in one place.

A kill command following M-w does not append to the text that M-w copied into the kill ring.

Yanking Earlier Kills

To recover killed text that is no longer the most recent kill, use the M-y command (`yank-pop`). It takes the text previously yanked and replaces it with the text from an earlier kill. So, to recover the text of the next-to-the-last kill, first use C-y to yank the last kill, and then use M-y to replace it with the previous kill. M-y is allowed only after a C-y or another M-y.

You can understand M-y in terms of a "last yank" pointer which points at an entry in the kill ring. Each time you kill, the "last yank" pointer moves to the newly made entry at the front of the ring. C-y yanks the entry which the "last yank" pointer points to. M-y moves the "last yank" pointer to a different entry, and the text in the buffer changes to match. Enough M-y commands can move the pointer to any entry in the ring, so you can get any entry into the buffer. Eventually the pointer reaches the end of the ring; the next M-y moves it to the first entry again.

M-y moves the "last yank" pointer around the ring, but it does not change the order of the entries in the ring, which always runs from the most recent kill at the front to the oldest one still remembered.

M-y can take a numeric argument, which tells it how many entries to advance the "last yank" pointer by. A negative argument moves the pointer toward the front of the ring; from the front of the ring, it moves "around" to the last entry and continues forward from there.

Once the text you are looking for is brought into the buffer, you can stop doing M-y commands and it will stay there. It's just a copy of the kill ring entry, so editing it in the buffer does not change what's in the ring. As long as no new killing is done, the "last yank" pointer remains at the same place in the kill ring, so repeating C-y will yank another copy of the same previous kill.

If you know how many M-y commands it would take to find the text you want, you can yank that text in one step using C-y with a numeric argument. C-y with an argument restores the text the specified number of entries back in the kill ring. Thus, C-u 2 C-y gets the next to the last block of killed text. It is equivalent to C-y M-y. C-y with a numeric argument starts counting from the "last yank" pointer, and sets the "last yank" pointer to the entry that it yanks.

The length of the kill ring is controlled by the variable `kill-ring-max`; no more than that many blocks of killed text are saved.

The actual contents of the kill ring are stored in a variable named `kill-ring`; you can view the entire

contents of the kill ring with the command C-h v kill-ring.

Accumulating Text

Usually we copy or move text by killing it and yanking it, but there are other methods convenient for copying one block of text in many places, or for copying many scattered blocks of text into one place. To copy one block to many places, store it in a register (see section Registers). Here we describe the commands to accumulate scattered pieces of text into a buffer or into a file.

M-x append-to-buffer

Append region to contents of specified buffer.

M-x prepend-to-buffer

Prepend region to contents of specified buffer.

M-x copy-to-buffer

Copy region into specified buffer, deleting that buffer's old contents.

M-x insert-buffer

Insert contents of specified buffer into current buffer at point.

M-x append-to-file

Append region to contents of specified file, at the end.

To accumulate text into a buffer, use M-x append-to-buffer. This reads a buffer name, them inserts a copy of the region into the buffer specified. If you specify a nonexistent buffer, `append-to-buffer` creates the buffer. The text is inserted wherever point is in that buffer. If you have been using the buffer for editing, the copied text goes into the middle of the text of the buffer, wherever point happens to be in it.

Point in that buffer is left at the end of the copied text, so successive uses of `append-to-buffer` accumulate the text in the specified buffer in the same order as they were copied. Strictly speaking, `append-to-buffer` does not always append to the text already in the buffer--only if point in that buffer is at the end. However, if `append-to-buffer` is the only command you use to alter a buffer, then point is always at the end.

M-x prepend-to-buffer is just like `append-to-buffer` except that point in the other buffer is left before the copied text, so successive prependings add text in reverse order. M-x copy-to-buffer is similar except that any existing text in the other buffer is deleted, so the buffer is left containing just the text newly copied into it.

To retrieve the accumulated text from another buffer, use M-x insert-buffer; this too takes buffername as an argument. It inserts a copy of the text in buffer buffername into the selected buffer. You can alternatively select the other buffer for editing, then optionally move text from it by killing. See section Using Multiple Buffers, for background information on buffers.

Instead of accumulating text within Emacs, in a buffer, you can append text directly into a file with M-x append-to-file, which takes filename as an argument. It adds the text of the region to the end of the specified file. The file is changed immediately on disk.

You should use `append-to-file` only with files that are *not* being visited in Emacs. Using it on a file that you are editing in Emacs would change the file behind Emacs's back, which can lead to losing some of your editing.

Rectangles

The rectangle commands operate on rectangular areas of the text: all the characters between a certain pair of columns, in a certain range of lines. Commands are provided to kill rectangles, yank killed rectangles, clear them out, fill them with blanks or text, or delete them. Rectangle commands are useful with text in multicolumn formats, and for changing text into or out of such formats.

When you must specify a rectangle for a command to work on, you do it by putting the mark at one corner and point at the opposite corner. The rectangle thus specified is called the region-rectangle because you control it in about the same way the region is controlled. But remember that a given combination of point and mark values can be interpreted either as a region or as a rectangle, depending on the command that uses them.

If point and the mark are in the same column, the rectangle they delimit is empty. If they are in the same line, the rectangle is one line high. This asymmetry between lines and columns comes about because point (and likewise the mark) is between two columns, but within a line.

C-x r k

> Kill the text of the region-rectangle, saving its contents as the "last killed rectangle" (`kill-rectangle`).

C-x r d

> Delete the text of the region-rectangle (`delete-rectangle`).

C-x r y

> Yank the last killed rectangle with its upper left corner at point (`yank-rectangle`).

C-x r o

> Insert blank space to fill the space of the region-rectangle (`open-rectangle`). This pushes the previous contents of the region-rectangle rightward.

M-x clear-rectangle

> Clear the region-rectangle by replacing its contents with spaces.

M-x string-rectangle RET string RET

> Insert string on each line of the region-rectangle.

The rectangle operations fall into two classes: commands deleting and inserting rectangles, and commands for blank rectangles.

There are two ways to get rid of the text in a rectangle: you can discard the text (delete it) or save it as the "last killed" rectangle. The commands for these two ways are C-x r d (`delete-rectangle`) and C-x r k (`kill-rectangle`). In either case, the portion of each line that falls inside the rectangle's boundaries is deleted, causing following text (if any) on the line to move left into the gap.

Note that "killing" a rectangle is not killing in the usual sense; the rectangle is not stored in the kill ri but in a special place that can only record the most recent rectangle killed. This is because yanking a rectangle is so different from yanking linear text that different yank commands have to be used and yank-popping is hard to make sense of.

To yank the last killed rectangle, type C-x r y (`yank-rectangle`). Yanking a rectangle is the opposite of killing one. Point specifies where to put the rectangle's upper left corner. The rectangle's first line is inserted there, the rectangle's second line is inserted at a position one line vertically down, and so on. The number of lines affected is determined by the height of the saved rectangle.

You can convert single-column lists into double-column lists using rectangle killing and yanking; kill the second half of the list as a rectangle and then yank it beside the first line of the list. See section Two-Column Editing, for another way to edit multi-column text.

You can also copy rectangles into and out of registers with C-x r r r and C-x r i r. See section Saving Rectangles in Registers.

There are two commands for making with blank rectangles: M-x clear-rectangle to blank out existing text, and C-x r o (`open-rectangle`) to insert a blank rectangle. Clearing a rectangle is equivalent to deleting it and then inserting a blank rectangle of the same size.

The command M-x string-rectangle is similar to C-x r o, but it inserts a specified string instead of blanks. You specify the string with the minibuffer. Since the length of the string specifies how many columns to insert, the width of the region-rectangle does not matter for this command. What does matter is the position of the left edge (which specifies the column position for the insertion in each line) and the range of lines that the rectangle occupies. The previous contents of the text beyond the insertion column are pushed rightward.

Go to the previous, next section.

Go to the previous, next section.

Registers

Emacs registers are places you can save text or positions for later use. Once you save text or a rectangle in a register, you can copy it into the buffer once or many times; you can move point to a position saved in a register once or many times.

Each register has a name which is a single character. A register can store a piece of text, a rectangle, a position, a window configuration, or a file name, but only one thing at any given time. Whatever you store in a register remains there until you store something else in that register. To see what a register r contains, use M-x view-register.

M-x view-register RET r

Display a description of what register r contains.

Saving Positions in Registers

Saving a position records a place in a buffer so that you can move back there later. Moving to a saved position switches to that buffer and moves point to that place in it.

C-x r SPC r

Save position of point in register r (`point-to-register`).

C-x r j r

Jump to the position saved in register r (`jump-to-register`).

To save the current position of point in a register, choose a name r and type C-x r SPC r. The register r retains the position thus saved until you store something else in that register.

The command C-x r j r moves point to the position recorded in register r. The register is not affected; it continues to record the same position. You can jump to the saved position any number of times.

Saving Text in Registers

When you want to insert a copy of the same piece of text several times, it may be inconvenient to yank it from the kill ring, since each subsequent kill moves that entry further down the ring. An alternative is to store the text in a register and later retrieve it.

C-x r s r

Copy region into register r (`copy-to-register`).

C-x r i r

Insert text from register r (`insert-register`).

C-x r s r stores a copy of the text of the region into the register named r. Given a numeric argument, C-x r

s r deletes the text from the buffer as well.

C-x r i r inserts in the buffer the text from register r. Normally it leaves point before the text and places the mark after, but with a numeric argument (C-u) it puts point after the text and the mark before.

Saving Rectangles in Registers

A register can contain a rectangle instead of linear text. The rectangle is represented as a list of strings. See section Rectangles, for basic information on how to specify a rectangle in the buffer.

C-x r r r

> Copy the region-rectangle into register r (`copy-rectangle-to-register`). With numeric argument, delete it as well.

C-x r i r

> Insert the rectangle stored in register r (if it contains a rectangle) (`insert-register`).

The C-x r i r command inserts a text string if the register contains one, and inserts a rectangle if the register contains one.

See also the command `sort-columns`, which you can think of as sorting a rectangle. See section Sorting Text.

Saving Window Configurations in Registers

You can save the window configuration of the selected frame in a register, or even the configuration of all windows in all frames, and restore the configuration later.

C-x r w r

> Save the state of the selected frame's windows in register r (`window-configuration-to-register`).

C-x r f r

> Save the state of all frames, including all their windows, in register r (`frame-configuration-to-register`).

Use C-x r j r to restore a window or frame configuration. This is the same command used to restore a cursor position. When you restore a frame configuration, any existing frames not included in the configuration become invisible. If you wish to delete these frames instead, use C-u C-x r j r.

Keeping File Names in Registers

If you visit certain file names frequently, you can visit them more conveniently if you put their names in registers. Here's the Lisp code used to put a file name in a register:

```
(set-register ?r '(file . name))
```

For example,

```
(set-register ?z '(file . "/gd/gnu/emacs/19.0/src/ChangeLog"))
```

puts the file name shown in register `z'.

To visit the file whose name is in register r, type C-x r j r. (This is the same command used to jump to a position or restore a frame configuration.)

Bookmarks

Bookmarks are somewhat like registers in that they record positions you can jump to. Unlike registers, they have long names, and they persist automatically from one Emacs session to the next. The prototypical use of bookmarks is to record "where you were reading" in various files.

C-x r m RET
: Set the bookmark for the visited file, at point.

C-x r m bookmark RET
: Set the bookmark named bookmark at point (`bookmark-set`).

C-x r b bookmark RET
: Jump to the bookmark named bookmark (`bookmark-jump`).

C-x r l
: List all bookmarks (`list-bookmarks`).

M-x bookmark-save
: Save all the current bookmark values in the default bookmark file.

The prototypical use for bookmarks is to record one current position in each of several files. So the command C-x r m, which sets a bookmark, uses the visited file name as the default for the bookmark name. If you name each bookmark after the file it points to, then you can conveniently revisit any of those files with C-x r b, and move to the position of the bookmark at the same time.

To display a list of all your bookmarks in a separate buffer, type C-x r l (`list-bookmarks`). If you switch to that buffer, you can use it to edit your bookmark definitions or annotate the bookmarks. Type C-h m in that buffer for more information about its special editing commands.

When you kill Emacs, Emacs offers to save your bookmark values in your default bookmark file, `` `~/.emacs.bmk' ``, if you have changed any bookmark values. You can also save the bookmarks at any time with the M-x bookmark-save command. The bookmark commands load your default bookmark file automatically. This saving and loading is how bookmarks persist from one Emacs session to the next.

If you set the variable `bookmark-save-flag` to 1, then each command that sets a bookmark will also save your bookmarks; this way, you don't lose any bookmark values even if Emacs crashes. (The value, if a number, says how many bookmark modifications should go by between saving.)

Bookmark position values are saved with surrounding context, so that `bookmark-jump` can find the proper position even if the file is modified slightly. The variable `bookmark-search-size` says how

many characters of context to record, on each side of the bookmark's position.

Here are some additional commands for working with bookmarks:

M-x bookmark-load RET filename RET

Load a file named filename that contains a list of bookmark values. You can use this command, as well as `bookmark-write`, to work with other files of bookmark values in addition to your default bookmark file.

M-x bookmark-write RET filename RET

Save all the current bookmark values in the file filename.

M-x bookmark-delete RET bookmark RET

Delete the bookmark named bookmark.

M-x bookmark-insert-location RET bookmark RET

Insert in the buffer the name of the file that bookmark bookmark points to.

M-x bookmark-insert RET bookmark RET

Insert in the buffer the *contents* of the file that bookmark bookmark points to.

Go to the previous, next section.

Go to the previous, next section.

Controlling the Display

Since only part of a large buffer fits in the window, Emacs tries to show the part that is likely to be interesting. The display control commands allow you to specify which part of the text you want to see.

C-l
: Clear screen and redisplay, scrolling the selected window to center point vertically within it (`recenter`).

C-v
: Scroll forward (a windowful or a specified number of lines) (`scroll-up`).

NEXT
: Likewise, scroll forward.

M-v
: Scroll backward (`scroll-down`).

PRIOR
: Likewise, scroll backward.

arg C-l
: Scroll so point is on screen line arg (`recenter`).

C-x <
: Scroll text in current window to the left (`scroll-left`).

C-x >
: Scroll to the right (`scroll-right`).

C-x $
: Make deeply indented lines invisible (`set-selective-display`).

The names of all scroll commands are based on the direction that the text moves in the window. Thus, the command to scrolling forward is called `scroll-up`, since the text moves up.

Scrolling

If a buffer contains text that is too large to fit entirely within a window that is displaying the buffer, Emacs shows a contiguous portion of the text. The portion shown always contains point.

Scrolling means moving text up or down in the window so that different parts of the text are visible. Scrolling forward means that text moves up, and new text appears at the bottom. Scrolling backward moves text down and new text appears at the top.

Scrolling happens automatically if you move point past the bottom or top of the window. You can also explicitly request scrolling with the commands in this section.

The most basic scrolling command is C-l (`recenter`) with no argument. It clears the entire screen and redisplays all windows. In addition, it scrolls the selected window so that point is halfway down from the top of the window.

The scrolling commands C-v and M-v let you move all the text in the window up or down a few lines. C-v (`scroll-up`) with an argument shows you that many more lines at the bottom of the window, moving the text and point up together as C-l might. C-v with a negative argument shows you more lines at the top of the window. M-v (`scroll-down`) is like C-v, but moves in the opposite direction. The function keys NEXT and PRIOR are equivalent to C-v and M-v.

To read the buffer a windowful at a time, use C-v with no argument. It takes the last two lines at the bottom of the window and puts them at the top, followed by nearly a whole windowful of lines not previously visible. If point was in the text scrolled off the top, it moves to the new top of the window. M-v with no argument moves backward with overlap similarly. The number of lines of overlap across a C-v or M-v is controlled by the variable `next-screen-context-lines`; by default, it is two.

Another way to do scrolling is with C-l with a numeric argument. C-l does not clear the screen when given an argument; it only scrolls the selected window. With a positive argument n, it repositions text to put point n lines down from the top. An argument of zero puts point on the very top line. Point does not move with respect to the text; rather, the text and point move rigidly on the screen. C-l with a negative argument puts point that many lines from the bottom of the window. For example, C-u - 1 C-l puts point on the bottom line, and C-u - 5 C-l puts it five lines from the bottom. Just C-u as argument, as in C-u C-l, scrolls point to the center of the screen.

The C-M-l command (`reposition-window`) scrolls the current window heuristically in a way designed to get useful information onto the screen. For example, in a Lisp file, this command tries to get the entire current defun onto the screen if possible.

Scrolling happens automatically if point has moved out of the visible portion of the text when it is time to display. Usually the scrolling is done so as to put point vertically centered within the window. However, if the variable `scroll-step` has a nonzero value, an attempt is made to scroll the buffer by that many lines; if that is enough to bring point back into visibility, that is what is done.

Horizontal Scrolling

The text in a window can also be scrolled horizontally. This means that each line of text is shifted sideways in the window, and one or more characters at the beginning of each line are not displayed at all. When a window has been scrolled horizontally in this way, text lines are truncated rather than continued (see section Continuation Lines), with a `$' appearing in the first column when there is text truncated to the left, and in the last column when there is text truncated to the right.

The command C-x < (`scroll-left`) scrolls the selected window to the left by n columns with argument n. This moves part of the beginning of each line off the left edge of the window. With no argument, it scrolls by almost the full width of the window (two columns less, to be precise).

C-x > (`scroll-right`) scrolls similarly to the right. The window cannot be scrolled any farther to the right once it is displayed normally (with each line starting at the window's left margin); attempting to do

so has no effect. This means that you don't have to calculate the argument precisely for C-x >; any sufficiently large argument will restore normally display.

Selective Display

Emacs has the ability to hide lines indented more than a certain number of columns (you specify how many columns). You can use this to get an overview of a part of a program.

To hide lines, type C-x $ (`set-selective-display`) with a numeric argument n. Then lines with at least n columns of indentation disappear from the screen. The only indication of their presence is that three dots (`...') appear at the end of each visible line that is followed by one or more hidden ones.

The commands C-n and C-p move across the hidden lines as if they were not there.

The hidden lines are still present in the buffer, and most editing commands see them as usual, so you may find point in the middle of the hidden text. When this happens, the cursor appears at the end of the previous line, after the three dots. If point is at the end of the visible line, before the newline that ends it, the cursor appears before the three dots.

To make all lines visible again, type C-x $ with no argument.

If you set the variable `selective-display-ellipses` to `nil`, the three dots do not appear at the end of a line that precedes hidden lines. Then there is no visible indication of the hidden lines. This variable becomes local automatically when set.

European Character Set Display

Some European languages use accented letters and other special symbols. The ISO 8859 Latin-1 character set defines character codes for many European languages in the range 160 to 255.

Emacs can display those characters according to Latin-1, provided the terminal or font in use supports them. The M-x standard-display-european command toggles European character display mode. With a numeric argument, M-x standard-display-european enables European character display if and only if the argument is positive. Load the library `iso-syntax` to specify the correct syntactic properties and case conversion table for the Latin-1 character set.

If your terminal does not support display of the Latin-1 character set, Emacs can display these characters as ASCII sequences which at least give you a clear idea of what the characters are. To do this, load the library `iso-ascii`.

Some operating systems let you specify the language you are using by setting a locale. Emacs handles one common special case of this: if your locale name for character types contains the string `8859-1' or `88591', Emacs automatically enables European character display mode and its syntax.

There are three different ways you can enter Latin-1 characters:

- If your keyboard can generate character codes 128 and up, representing ISO Latin-1 characters, execute the following expression to enable Emacs to understand them:

```
(set-input-mode (car (current-input-mode))
                (nth 1 (current-input-mode))
                0)
```

- You can load the library `iso-transl` to turn the key C-x 8 into a "compose character" prefix for entry of the extra ISO Latin-1 printing characters. C-x 8 is good for insertion (in the minibuffer as well as other buffers), for searching, and in any other context where a key sequence is allowed. The ALT modifier key, if you have one, serves the same purpose as C-x 8; use ALT together with an accent character to modify the following letter.
- You can use ISO Accents mode. This minor mode is convenient if you enter non-ASCII ISO Latin-1 characters often. When this minor mode is enabled, the characters ``', `'', `'', `^', `/' and `~' modify the following letter by adding the corresponding diacritical mark to it, if possible. To enable or disable ISO Accents mode, use the command M-x iso-accents-mode. This command affects only the current buffer.

  To enter one of those six special characters while in ISO Accents mode, type the character, followed by a space. Some of those characters have a corresponding "dead key" accent character in the ISO Latin-1 character set; to enter that character, type the corresponding ASCII character twice. For example, " enters the Latin-1 character acute-accent (character code 0264).

  ISO Accents mode input is available whenever a key sequence is expected: for ordinary insertion, for searching, for the minibuffer, and for certain command arguments.

  In addition to the accented letters, you can use these special sequences in ISO Accents mode to enter certain other ISO Latin-1 characters:

  /A
  : `A' with ring.

  ~C
  : `C' with cedilla.

  ~D
  : `D' with stroke.

  /E
  : `AE' ligature.

  /a
  : `a' with ring.

  ~c
  : `c' with cedilla.

  ~d
  : `d' with stroke.

  /e
  : `ae' ligature.

  "s

German sharp `s'.

~<

Left guillemot.

~>

Right guillemot.

~!

Inverted exclamation mark.

~?

Inverted question mark.

Follow Mode

Follow mode is a minor mode which makes two windows showing the same buffer scroll as one tall "virtual window." To use Follow mode, go to a frame with just one window, split it into two side-by-side windows using C-x 3, and then type M-x follow-mode. From then on, you can edit the buffer in either of the two windows, or scroll either one; the other window follows it.

To turn off Follow mode, type M-x follow-mode a second time.

Optional Mode Line Features

The current line number of point appears in the mode line when Line Number mode is enabled. Use the command M-x line-number-mode to turn this mode on and off; normally it is on. The line number appears before the buffer percentage pos, with the letter `L' to indicate what it is. See section Minor Modes, for more information about minor modes and about how to use this command.

If the buffer is very large (larger than the value of `line-number-display-limit`), then the line number doesn't appear. Emacs doesn't compute the line number when the buffer is large, because that would be too slow. If you have narrowed the buffer (see section Narrowing), the displayed line number is relative to the accessible portion of the buffer.

You can also display the current column number by turning on Column Number mode. It displays the current column number preceded by the letter `C'. Type M-x column-number-mode to toggle this mode.

Emacs can optionally display the time and system load in all mode lines. To enable this feature, type M-x display-time. The information added to the mode line usually appears after the buffer name, before the mode names and their parentheses. It looks like this:

```
hh:mmpm l.ll
```

Here hh and mm are the hour and minute, followed always by `am' or `pm'. l.ll is the average number of running processes in the whole system recently. (Some fields may be missing if your operating system cannot support them.)

The word `Mail' appears after the load level if there is mail for you that you have not read yet.

Variables Controlling Display

This section contains information for customization only. Beginning users should skip it.

The variable `mode-line-inverse-video` controls whether the mode line is displayed in inverse video (assuming the terminal supports it); `nil` means don't do so. See section The Mode Line. If you specify the foreground color for the `modeline` face, and `mode-line-inverse-video` is non-`nil`, then the default background color for that face is the usual foreground color. See section Using Multiple Typefaces.

If the variable `inverse-video` is non-`nil`, Emacs attempts to invert all the lines of the display from what they normally are.

If the variable `visible-bell` is non-`nil`, Emacs attempts to make the whole screen blink when it would normally make an audible bell sound. This variable has no effect if your terminal does not have a way to make the screen blink.

When you reenter Emacs after suspending, Emacs normally clears the screen and redraws the entire display. On some terminals with more than one page of memory, it is possible to arrange the termcap entry so that the `ti' and `te' strings (output to the terminal when Emacs is entered and exited, respectively) switch between pages of memory so as to use one page for Emacs and another page for other output. Then you might want to set the variable `no-redraw-on-reenter` non-`nil`; this tells Emacs to assume, when resumed, that the screen page it is using still contains what Emacs last wrote there.

The variable `echo-keystrokes` controls the echoing of multi-character keys; its value is the number of seconds of pause required to cause echoing to start, or zero meaning don't echo at all. See section The Echo Area.

If the variable `ctl-arrow` is `nil`, control characters in the buffer are displayed with octal escape sequences, all except newline and tab. Altering the value of `ctl-arrow` makes it local to the current buffer; until that time, the default value is in effect. The default is initially `t`. See section 'Display Tables' in The Emacs Lisp Reference Manual.

Normally, a tab character in the buffer is displayed as whitespace which extends to the next display tab stop position, and display tab stops come at intervals equal to eight spaces. The number of spaces per tab is controlled by the variable `tab-width`, which is made local by changing it, just like `ctl-arrow`. Note that how the tab character in the buffer is displayed has nothing to do with the definition of TAB as a command. The variable `tab-width` must have an integer value between 1 and 1000, inclusive.

If the variable `truncate-lines` is non-`nil`, then each line of text gets just one screen line for display; if the text line is too long, display shows only the part that fits. If `truncate-lines` is `nil`, then long text lines display as more than one screen line, enough to show the whole text of the line. See section Continuation Lines. Altering the value of `truncate-lines` makes it local to the current buffer; until that time, the default value is in effect. The default is initially `nil`.

If the variable `truncate-partial-width-windows` is non-`nil`, it forces truncation rather than continuation in any window less than the full width of the screen or frame, regardless of the value of `truncate-lines`. For information about side-by-side windows, see section Splitting Windows. See also section 'Display' in The Emacs Lisp Reference Manual.

The variable `baud-rate` holds the the output speed of the terminal, as far as Emacs knows. Setting this variable does not change the speed of actual data transmission, but the value is used for calculations such as padding. It also affects decisions about whether to scroll part of the screen or redraw it instead--even when using a window system. (We designed it this way, despite the fact that a window system has no true "output speed", to give you a way to tune these decisions.)

Go to the previous, next section.

Go to the previous, next section.

Searching and Replacement

Like other editors, Emacs has commands for searching for occurrences of a string. The principal search command is unusual in that it is incremental; it begins to search before you have finished typing the search string. There are also nonincremental search commands more like those of other editors.

Besides the usual `replace-string` command that finds all occurrences of one string and replaces them with another, Emacs has a fancy replacement command called `query-replace` which asks interactively which occurrences to replace.

Incremental Search

An incremental search begins searching as soon as you type the first character of the search string. As you type in the search string, Emacs shows you where the string (as you have typed it so far) would be found. When you have typed enough characters to identify the place you want, you can stop. Depending on what you plan to do next, you may or may not need to terminate the search explicitly with RET.

C-s

Incremental search forward (`isearch-forward`).

C-r

Incremental search backward (`isearch-backward`).

C-s starts an incremental search. C-s reads characters from the keyboard and positions the cursor at the first occurrence of the characters that you have typed. If you type C-s and then F, the cursor moves right after the first `F'. Type an O, and see the cursor move to after the first `FO'. After another O, the cursor is after the first `FOO' after the place where you started the search. Meanwhile, the search string `FOO' has been echoed in the echo area.

If you make a mistake in typing the search string, you can cancel characters with DEL. Each DEL cancels the last character of search string. This does not happen until Emacs is ready to read another input character; first it must either find, or fail to find, the character you want to erase. If you do not want to wait for this to happen, use C-g as described below.

When you are satisfied with the place you have reached, you can type RET, which stops searching, leaving the cursor where the search brought it. Also, any command not specially meaningful in searches stops the searching and is then executed. Thus, typing C-a would exit the search and then move to the beginning of the line. RET is necessary only if the next command you want to type is a printing character, DEL, RET, or another control character that is special within searches (C-q, C-w, C-r, C-s, C-y, M-y, M-r, or M-s).

Sometimes you search for `FOO' and find it, but not the one you expected to find. There was a second `FOO' that you forgot about, before the one you were looking for. In this event, type another C-s to move to the next occurrence of the search string. This can be done any number of times. If you overshoot, you

can cancel some C-s characters with DEL.

After you exit a search, you can search for the same string again by typing just C-s C-s: the first C-s is the key that invokes incremental search, and the second C-s means "search again".

To reuse earlier search strings, use the search ring. The commands M-p and M-n move through the ring to pick a search string to reuse. These commands leave the selected search ring element in the minibuffer, where you can edit it. Type C-s or C-r to terminate editing the string and search for it.

If your string is not found at all, the echo area says `Failing I-Search'. The cursor is after the place where Emacs found as much of your string as it could. Thus, if you search for `FOOT', and there is no `FOOT', you might see the cursor after the `FOO' in `FOOL'. At this point there are several things you can do. If your string was mistyped, you can rub some of it out and correct it. If you like the place you have found, you can type RET or some other Emacs command to "accept what the search offered". Or you can type C-g, which removes from the search string the characters that could not be found (the `T' in `FOOT'), leaving those that were found (the `FOO' in `FOOT'). A second C-g at that point cancels the search entirely, returning point to where it was when the search started.

An upper-case letter in the search string makes the search case-sensitive. If you delete the upper-case character from the search string, it ceases to have this effect. See section Searching and Case.

If a search is failing and you ask to repeat it by typing another C-s, it starts again from the beginning of the buffer. Repeating a failing reverse search with C-r starts again from the end. This is called wrapping around. `Wrapped' appears in the search prompt once this has happened. If you keep on going past the original starting point of the search, it changes to `Overwrapped', which means that you are revisiting matches that you have already seen.

The C-g "quit" character does special things during searches; just what it does depends on the status of the search. If the search has found what you specified and is waiting for input, C-g cancels the entire search. The cursor moves back to where you started the search. If C-g is typed when there are characters in the search string that have not been found--because Emacs is still searching for them, or because it has failed to find them--then the search string characters which have not been found are discarded from the search string. With them gone, the search is now successful and waiting for more input, so a second C-g will cancel the entire search.

To search for a newline, type LFD (also known as C-j). To search for another control character such as control-S or carriage return, you must quote it by typing C-q first. This function of C-q is analogous to its meaning as an Emacs command: it causes the following character to be treated the way a graphic character would normally be treated in the same context. You can also specify a character by its octal code: enter C-q followed by three octal digits.

You can change to searching backwards with C-r. If a search fails because the place you started was too late in the file, you should do this. Repeated C-r keeps looking for more occurrences backwards. A C-s starts going forwards again. C-r in a search can be canceled with DEL.

If you know initially that you want to search backwards, you can use C-r instead of C-s to start the search, because C-r as a key runs a command (`isearch-backward`) to search backward.

The characters C-y and C-w can be used in incremental search to grab text from the buffer into the search

string. This makes it convenient to search for another occurrence of text at point. C-w copies the wor after point as part of the search string, advancing point over that word. Another C-s to repeat the sear will then search for a string including that word. C-y is similar to C-w but copies all the rest of the current line into the search string. Both C-y and C-w convert the text they copy to lower case if the search is current not case-sensitive; this is so the search remains case-insensitive.

The character M-y copies text from the kill ring into the search string. It uses the same text that C-y as a command would yank. See section Yanking.

When you exit the incremental search, it sets the mark to where point *was*, before the search. That is convenient for moving back there. In Transient Mark mode, incremental search sets the mark without activating it, and does so only if the mark is not already active.

To customize the special characters that incremental search understands, alter their bindings in the keymap `isearch-mode-map`. For a list of bindings, look at the documentation of `isearch-mode` with C-h f isearch-mode RET.

Slow Terminal Incremental Search

Incremental search on a slow terminal uses a modified style of display that is designed to take less time. Instead of redisplaying the buffer at each place the search gets to, it creates a new single-line window and uses that to display the line that the search has found. The single-line window comes into play as soon as point gets outside of the text that is already on the screen.

When you terminate the search, the single-line window is removed. Then Emacs redisplays the window in which the search was done, to show its new position of point.

The slow terminal style of display is used when the terminal baud rate is less than or equal to the value of the variable `search-slow-speed`, initially 1200.

The number of lines to use in slow terminal search display is controlled by the variable `search-slow-window-lines`. 1 is its normal value.

Nonincremental Search

Emacs also has conventional nonincremental search commands, which require you to type the entire search string before searching begins.

C-s RET string RET

Search for string.

C-r RET string RET

Search backward for string.

To do a nonincremental search, first type C-s RET. This enters the minibuffer to read the search string; terminate the string with RET, and then the search takes place. If the string is not found, the search command gets an error.

The way C-s RET works is that the C-s invokes incremental search, which is specially programmed t invoke nonincremental search if the argument you give it is empty. (Such an empty argument would otherwise be useless.) C-r RET also works this way.

However, nonincremental searches performed using C-s RET do not call `search-forward` right away. The first thing done is to see if the next character is C-w, which requests a word search.

Forward and backward nonincremental searches are implemented by the commands `search-forward` and `search-backward`. These commands may be bound to keys in the usual manner. The feature that you can get to them via the incremental search commands exists for historical reasons, and to avoid the need to find suitable key sequences for them.

Word Search

Word search searches for a sequence of words without regard to how the words are separated. More precisely, you type a string of many words, using single spaces to separate them, and the string can be found even if there are multiple spaces, newlines or other punctuation between the words.

Word search is useful for editing a printed document made with a text formatter. If you edit while looking at the printed, formatted version, you can't tell where the line breaks are in the source file. With word search, you can search without having to know them.

C-s RET C-w words RET

Search for words, ignoring details of punctuation.

C-r RET C-w words RET

Search backward for words, ignoring details of punctuation.

Word search is a special case of nonincremental search and is invoked with C-s RET C-w. This is followed by the search string, which must always be terminated with RET. Being nonincremental, this search does not start until the argument is terminated. It works by constructing a regular expression and searching for that; see section Regular Expression Search.

Use C-r RET C-w to do backward word search.

Forward and backward word searches are implemented by the commands `word-search-forward` and `word-search-backward`. These commands may be bound to keys in the usual manner. The feature that you can get to them via the incremental search commands exists for historical reasons, and to avoid the need to find suitable key sequences for them.

Regular Expression Search

A regular expression (regexp, for short) is a pattern that denotes a class of alternative strings to match, possibly infinitely many. In GNU Emacs, you can search for the next match for a regexp either incrementally or not.

Incremental search for a regexp is done by typing C-M-s (`isearch-forward-regexp`). This

command reads a search string incrementally just like C-s, but it treats the search string as a regexp rather than looking for an exact match against the text in the buffer. Each time you add text to the search string, you make the regexp longer, and the new regexp is searched for. To search backward in the buffer, use C-M-r (`isearch-backward-regexp`).

All of the control characters that do special things within an ordinary incremental search have the same function in incremental regexp search. Typing C-s or C-r immediately after starting the search retrieves the last incremental search regexp used; that is to say, incremental regexp and non-regexp searches have independent defaults. They also have separate search rings that you can access with M-p and M-n.

If you type SPC in incremental regexp search, it matches any sequence of whitespace characters, including newlines. If you want to match just a space, type C-q SPC.

Note that adding characters to the regexp in an incremental regexp search can make the cursor move back and start again. For example, if you have searched for `foo' and you add `\|bar', the cursor backs up in case the first `bar' precedes the first `foo'.

Nonincremental search for a regexp is done by the functions `re-search-forward` and `re-search-backward`. You can invoke these with M-x, or bind them to keys, or invoke them by way of incremental regexp search with C-M-s RET and C-M-r RET.

Syntax of Regular Expressions

Regular expressions have a syntax in which a few characters are special constructs and the rest are ordinary. An ordinary character is a simple regular expression which matches that same character and nothing else. The special characters are `$', `^', `.', `*', `+', `?', `[', `]' and `\'. Any other character appearing in a regular expression is ordinary, unless a `\' precedes it.

For example, `f' is not a special character, so it is ordinary, and therefore `f' is a regular expression that matches the string `f' and no other string. (It does *not* match the string `ff'.) Likewise, `o' is a regular expression that matches only `o'. (When case distinctions are being ignored, these regexps also match `F' and `O', but we consider this a generalization of "the same string", rather than an exception.)

Any two regular expressions a and b can be concatenated. The result is a regular expression which matches a string if a matches some amount of the beginning of that string and b matches the rest of the string.

As a simple example, we can concatenate the regular expressions `f' and `o' to get the regular expression `fo', which matches only the string `fo'. Still trivial. To do something nontrivial, you need to use one of the special characters. Here is a list of them.

. (Period)

> is a special character that matches any single character except a newline. Using concatenation, we can make regular expressions like `a.b' which matches any three-character string which begins with `a' and ends with `b'.

*

> is not a construct by itself; it is a postfix operator, which means to match the preceding regular

expression repetitively as many times as possible. Thus, `o*' matches any number of `o's (including no `o's).

`*' always applies to the *smallest* possible preceding expression. Thus, `fo*' has a repeating `o', not a repeating `fo'. It matches `f', `fo', `foo', and so on.

The matcher processes a `*' construct by matching, immediately, as many repetitions as can be found. Then it continues with the rest of the pattern. If that fails, backtracking occurs, discarding some of the matches of the `*'-modified construct in case that makes it possible to match the rest of the pattern. For example, matching `ca*ar' against the string `caaar', the `a*' first tries to match all three `a's; but the rest of the pattern is `ar' and there is only `r' left to match, so this try fails. The next alternative is for `a*' to match only two `a's. With this choice, the rest of the regexp matches successfully.

+

is a postfix character, similar to `*' except that it must match the preceding expression at least once. So, for example, `ca+r' matches the strings `car' and `caaaar' but not the string `cr', whereas `ca*r' matches all three strings.

?

is a postfix character, similar to `*' except that it can match the preceding expression either once or not at all. For example, `ca?r' matches `car' or `cr'; nothing else.

[...]

is a character set, which begins with `[' and is terminated by `]'. In the simplest case, the characters between the two brackets are what this set can match.

Thus, `[ad]' matches either one `a' or one `d', and `[ad]*' matches any string composed of just `a's and `d's (including the empty string), from which it follows that `c[ad]*r' matches `cr', `car', `cdr', `caddaar', etc.

You can also include character ranges a character set, by writing two characters with a `-' between them. Thus, `[a-z]' matches any lower-case letter. Ranges may be intermixed freely with individual characters, as in `[a-z$%.]', which matches any lower case letter or `$', `%' or period.

Note that the usual regexp special characters are not special inside a character set. A completely different set of special characters exists inside character sets: `]', `-' and `^'.

To include a `]' in a character set, you must make it the first character. For example, `[]a]' matches `]' or `a'. To include a `-', write `-' as the first or last character of the set, or put it after a range. Thus, `[]-]' matches both `]' and `-'.

To include `^', make it other than the first character in the set.

[^ ...]

`[^' begins a complemented character set, which matches any character except the ones specified. Thus, `[^a-z0-9A-Z]' matches all characters *except* letters and digits.

`^' is not special in a character set unless it is the first character. The character following the `^' is treated as if it were first (`-' and `]' are not special there).

A complemented character set can match a newline, unless newline is mentioned as one of the characters not to match. This is in contrast to the handling of regexps in programs such as `gre`.

^

is a special character that matches the empty string, but only at the beginning of a line in the text being matched. Otherwise it fails to match anything. Thus, `^foo' matches a `foo' which occurs at the beginning of a line.

$

is similar to `^' but matches only at the end of a line. Thus, `xx*$' matches a string of one `x' or more at the end of a line.

\

has two functions: it quotes the special characters (including `\'), and it introduces additional special constructs.

Because `\' quotes special characters, `\$' is a regular expression which matches only `$', and `\[' is a regular expression which matches only `[', etc.

Note: for historical compatibility, special characters are treated as ordinary ones if they are in contexts where their special meanings make no sense. For example, `*foo' treats `*' as ordinary since there is no preceding expression on which the `*' can act. It is poor practice to depend on this behavior; better to quote the special character anyway, regardless of where it appears.

For the most part, `\' followed by any character matches only that character. However, there are several exceptions: two-character sequences starting with `\' which have special meanings. The second character in the sequence is always an ordinary character on their own. Here is a table of `\' constructs.

\|

specifies an alternative. Two regular expressions a and b with `\|' in between form an expression that matches anything that either a or b matches.

Thus, `foo\|bar' matches either `foo' or `bar' but no other string.

`\|' applies to the largest possible surrounding expressions. Only a surrounding `\(... \)' grouping can limit the scope of `\|'.

Full backtracking capability exists to handle multiple uses of `\|'.

\(... \)

is a grouping construct that serves three purposes:

To enclose a set of `\|' alternatives for other operations. Thus, `\(foo\|bar\)x' matches either `foox' or `barx'.

To enclose a complicated expression for the postfix operators `*', `+' and `?' to operate on. Thus, `ba\(na\)*' matches `bananana', etc., with any (zero or more) number of `na' strings.

To mark a matched substring for future reference.

This last application is not a consequence of the idea of a parenthetical grouping; it is a separate feature which is assigned as a second meaning to the same `\(... \)' construct. In practice there is no

conflict between the two meanings. Here is an explanation of this feature:

\d

after the end of a `\( ... \)' construct, the matcher remembers the beginning and end of the text matched by that construct. Then, later on in the regular expression, you can use `\' followed by the digit d to mean "match the same text matched the dth time by the `\(... \)' construct."

The strings matching the first nine `\( ... \)' constructs appearing in a regular expression are assigned numbers 1 through 9 in order that the open-parentheses appear in the regular expression. `\1' through `\9' refer to the text previously matched by the corresponding `\(... \)' construct.

For example, `\(.*\)\1' matches any newline-free string that is composed of two identical halves. The `\(.*\)' matches the first half, which may be anything, but the `\1' that follows must match the same exact text.

If a particular `\( ... \)' construct matches more than once (which can easily happen if it is followed by `*'), only the last match is recorded.

\`

matches the empty string, provided it is at the beginning of the buffer or string being matched against.

\'

matches the empty string, provided it is at the end of the buffer or string being matched against.

\=

matches the empty string, provided it is at point.

\b

matches the empty string, provided it is at the beginning or end of a word. Thus, `\bfoo\b' matches any occurrence of `foo' as a separate word. `\bballs?\b' matches `ball' or `balls' as a separate word.

`\b' matches at the beginning or end of the buffer regardless of what text appears next to it.

\B

matches the empty string, provided it is *not* at the beginning or end of a word.

\<

matches the empty string, provided it is at the beginning of a word. `\<' matches at the beginning of the buffer only if a word-constituent character follows.

\>

matches the empty string, provided it is at the end of a word. `\>' matches at the end of the buffer only if the contents end with a word-constituent character.

\w

matches any word-constituent character. The syntax table determines which characters these are. See section The Syntax Table.

\W

matches any character that is not a word-constituent.

\sc

matches any character whose syntax is c. Here c is a character which represents a syntax code: thus, `w' for word constituent, `(' for open-parenthesis, etc. Represent a character of whitespace (which can be a newline) by either `-' or a space character.

\Sc

matches any character whose syntax is not c.

The constructs that pertain to words and syntax are controlled by the setting of the syntax table (see section The Syntax Table).

Here is a complicated regexp, used by Emacs to recognize the end of a sentence together with any whitespace that follows. It is given in Lisp syntax to enable you to distinguish the spaces from the tab characters. In Lisp syntax, the string constant begins and ends with a double-quote. `\"' stands for a double-quote as part of the regexp, `\\' for a backslash as part of the regexp, `\t' for a tab and `\n' for a newline.

```
"[.?!][]\"')]*\\($\\|\t\\|  \\)[ \t\n]*"
```

This contains four parts in succession: a character set matching period, `?', or `!'; a character set matching close-brackets, quotes, or parentheses, repeated any number of times; an alternative in backslash-parentheses that matches end-of-line, a tab, or two spaces; and a character set matching whitespace characters, repeated any number of times.

To enter the same regexp interactively, you would type TAB to enter a tab, and C-q C-j to enter a newline. You would also type single backslashes as themselves, instead of doubling them for Lisp syntax.

Searching and Case

Incremental searches in Emacs normally ignore the case of the text they are searching through, if you specify the text in lower case. Thus, if you specify searching for `foo', then `Foo' and `foo' are also considered a match. Regexps, and in particular character sets, are included: `[ab]' would match `a' or `A' or `b' or `B'.

An upper-case letter in the incremental search string makes the search case-sensitive. Thus, searching for `Foo' does not find `foo' or `FOO'. This applies to regular expression search as well as to string search. The effect ceases if you delete the upper-case letter from the search string.

If you set the variable `case-fold-search` to `nil`, then all letters must match exactly, including case. This is a per-buffer variable; altering the variable affects only the current buffer, but there is a default value which you can change as well. See section Local Variables. This variable applies to nonincremental searches also, including those performed by the replace commands (see section Replacement Commands).

Replacement Commands

Global search-and-replace operations are not needed as often in Emacs as they are in other editors(1), but they are available. In addition to the simple M-x replace-string command which is like that found in most editors, there is a M-x query-replace command which asks you, for each occurrence of the pattern, whether to replace it.

The replace commands all replace one string (or regexp) with one replacement string. It is possible to perform several replacements in parallel using the command `expand-region-abbrevs`. See section Controlling Abbrev Expansion.

Unconditional Replacement

M-x replace-string RET string RET newstring RET

Replace every occurrence of string with newstring.

M-x replace-regexp RET regexp RET newstring RET

Replace every match for regexp with newstring.

To replace every instance of `foo' after point with `bar', use the command M-x replace-string with the two arguments `foo' and `bar'. Replacement happens only in the text after point, so if you want to cover the whole buffer you must go to the beginning first. All occurrences up to the end of the buffer are replaced; to limit replacement to part of the buffer, narrow to that part of the buffer before doing the replacement (see section Narrowing).

When `replace-string` exits, it leaves point at the last occurrence replaced. It sets the mark to the prior position of point (where the `replace-string` command was issued); use C-u C-SPC to move back there.

A numeric argument restricts replacement to matches that are surrounded by word boundaries. The argument's value doesn't matter.

Regexp Replacement

The M-x replace-string command replaces exact matches for a single string. The similar command M-x replace-regexp replaces any match for a specified pattern.

In `replace-regexp`, the newstring need not be constant: it can refer to all or part of what is matched by the regexp. `\&' in newstring stands for the entire match being replaced. `\d' in newstring, where d is a digit, stands for whatever matched the dth parenthesized grouping in regexp. To include a `\' in the text to replace with, you must enter `\\'. For example,

```
M-x replace-regexp RET c[ad]+r RET \&-safe RET
```

replaces (for example) `cadr' with `cadr-safe' and `cddr' with `cddr-safe'.

```
M-x replace-regexp RET \(c[ad]+r\)-safe RET \1 RET
```

performs the inverse transformation.

Replace Commands and Case

If the arguments to a replace command are in lower case, it preserves case when it makes a replacement. Thus, the command

```
M-x replace-string RET foo RET bar RET
```

replaces a lower case `foo' with a lower case `bar', an all-caps `FOO' with `BAR', and a capitalized `Foo' with `Bar'. (These three alternatives--lower case, all caps, and capitalized, are the only ones that `replace-string` can distinguish.)

If upper case letters are used in the second argument, they remain upper case every time that argument is inserted. If upper case letters are used in the first argument, the second argument is always substituted exactly as given, with no case conversion. Likewise, if the variable `case-replace` is set to `nil`, replacement is done without case conversion. If `case-fold-search` is set to `nil`, case is significant in matching occurrences of `foo' to replace; this also inhibits case conversion of the replacement string.

Query Replace

M-% string RET newstring RET

M-x query-replace RET string RET newstring RET

Replace some occurrences of string with newstring.

M-x query-replace-regexp RET regexp RET newstring RET

Replace some matches for regexp with newstring.

If you want to change only some of the occurrences of `foo' to `bar', not all of them, then you cannot use an ordinary `replace-string`. Instead, use M-% (`query-replace`). This command finds occurrences of `foo' one by one, displays each occurrence and asks you whether to replace it. A numeric argument to `query-replace` tells it to consider only occurrences that are bounded by word-delimiter characters. This preserves case, just like `replace-string`, provided `case-replace` is non-`nil`, as it normally is.

Aside from querying, `query-replace` works just like `replace-string`, and `query-replace-regexp` works just like `replace-regexp`. The shortest way to type this command name is M-x que SPC SPC SPC RET.

The things you can type when you are shown an occurrence of string or a match for regexp are:

SPC

to replace the occurrence with newstring.

DEL

to skip to the next occurrence without replacing this one.

, (Comma)

to replace this occurrence and display the result. You are then asked for another input character to say what to do next. Since the replacement has already been made, DEL and SPC are equivalent in this situation; both move to the next occurrence.

You could type C-r at this point (see below) to alter the replaced text. You could also type C-x u to undo the replacement; this exits the `query-replace`, so if you want to do further replacement you must use C-x ESC ESC RET to restart (see section Repeating Minibuffer Commands).

RET

to exit without doing any more replacements.

. (Period)

to replace this occurrence and then exit without searching for more occurrences.

!

to replace all remaining occurrences without asking again.

^

to go back to the position of the previous occurrence (or what used to be an occurrence), in case you changed it by mistake. This works by popping the mark ring. Only one ^ in a row is meaningful, because only one previous replacement position is kept during `query-replace`.

C-r

to enter a recursive editing level, in case the occurrence needs to be edited rather than just replaced with newstring. When you are done, exit the recursive editing level with C-M-c to proceed to the next occurrence. See section Recursive Editing Levels.

C-w

to delete the occurrence, and then enter a recursive editing level as in C-r. Use the recursive edit to insert text to replace the deleted occurrence of string. When done, exit the recursive editing level with C-M-c to proceed to the next occurrence.

C-l

to redisplay the screen. Then you must type another character to specify what to do with this occurrence.

C-h

to display a message summarizing these options. Then you must type another character to specify what to do with this occurrence.

Some other characters are aliases for the ones listed above: y, n and q are equivalent to SPC, DEL and RET.

Aside from this, any other character exits the `query-replace`, and is then reread as part of a key sequence. Thus, if you type C-k, it exits the `query-replace` and then kills to end of line.

To restart a `query-replace` once it is exited, use C-x ESC ESC, which repeats the `query-replace` because it used the minibuffer to read its arguments. See section Repeating Minibuffer Commands.

See also section Transforming File Names in Dired, for Dired commands to rename, copy, or link fil by replacing regexp matches in file names.

Other Search-and-Loop Commands

Here are some other commands that find matches for a regular expression. They all operate from point to the end of the buffer.

M-x occur RET regexp RET

> Display a list showing each line in the buffer that contains a match for regexp. A numeric argument specifies the number of context lines to print before and after each matching line; the default is none. To limit the search to part of the buffer, narrow to that part (see section Narrowing).
>
> The buffer `*Occur*' containing the output serves as a menu for finding the occurrences in their original context. Click Mouse-2 on an occurrence listed in `*Occur*', or position point there and type RET; this switches to the buffer that was searched and moves point to the original of the chosen occurrence.

M-x list-matching-lines

> Synonym for M-x occur.

M-x count-matches RET regexp RET

> Print the number of matches for regexp after point.

M-x flush-lines RET regexp RET

> Delete each line that follows point and contains a match for regexp.

M-x keep-lines RET regexp RET

> Delete each line that follows point and *does not* contain a match for regexp.

Commands for Fixing Typos

In this chapter we describe the commands that are especially useful for the times when you catch a mistake in your text just after you have made it, or change your mind while composing text on the fly.
