GNU manuals (and a few others)

This (the Directory node) gives a menu of major topics.

Some of these are available in printed form. The local installation status of most of it.

A2ps

A text (and other formats) to PostScript converter, with pretty printing.

Auc-TeX

A much enhanced LaTeX mode for gnuemacs.

Automake

Create GNU Standards-compliant Makefiles from template file

Bash

Bash (Bourne Again SHell)

Bison

Bison parser generator (= GNU yacc).

Calc

An advanced calculator and mathematical tool which runs under the emacs environment.

CL

Partial Common Lisp support for Emacs Lisp.

Cpp

GNU C compiler pre-processor.

Cvs

GNU version control system

Dvips

A DVI-to-PostScript translator.

Elisp

GNU Emacs Lisp.

Emacs

The extensible self-documenting text editor.

Eplain

Expanding on plain TeX.

Forms

Forms mode is an Emacs package that lets the user edit a data structure by filling in a form.

Flex

Fast lexical analyzer generator (= GNU lex).

Gas

GNU assembler `gas'.

Gawk

Gnu version of awk.

Gcc

GNU C compiler.

G++

GNU C++. As of version 2.0 incorporated into gcc.

Gdb

The source-level C debugger.

Gdbm

GNU alternative to ndbm library

Gdiff

GNU version of diff.

Gmp

GNU C multi-precision library.

Gnumake

GNU make.

Gnus

GNU news reader.

Mh-e

Emacs interface to MH

Gzip

GNU zip - compression utilities.

Info

Documentation browsing system.

Ispell

Interactive spelling checker.

Kpathsea

The path searching library used by TeX,Metafont, dvips and xdvi.

LibG++

The GNU c++ library.

Libtool

Script to allow package developers to provide generic shared library support.

Perl

A language for easy manipulation of text, files and processes. Pages specific to Version 5.

Python

An interpreted, extensible, embeddable, interactive, object-oriented programming language. Library info only.

Readline

The GNU Readline library.

Texinfo

With one source file, make either a printed manual (through TeX) or an Info file (through texinfo).

Textutils

GNU versions of many standard UNIX text manipulation tools

Vera

V.E.R.A., a list dealing with computational acronyms.

VIP

A VI-emulation for Emacs.

Note1: most of these documents are distributed in texinfo form with the associated software. These documents are updated whenever the associated software is updated **at this site**, thus these are not necessarily the most up-to-date versions available. As such they may not be relevant at sites outside cl.cam. The texinfo documents are converted to html format using the *texi2html* tool available from those splendid people at CERN.

Note2: to overseas visitors - many other sites on the Web have similar collections to this one, it may be worth the effort looking for a collection closer to home.

Note3: These documents are not available for FTP access at this site so don't even bother to ask!

ckh@cl.cam.ac.uk

a2ps, version 4.10

General Purpose PostScript Generating Utility

Edition 4.10, 10 March 1998

Akim Demaille Miguel Santana

a2ps, version 4.10

TOC

Introduction

This document describes `a2ps` version 4.10. The latest versions may be found on the a2ps home page.

We tried to make this document informative and pleasant. It tries to be more than a plain reference guide, and intends to offer information about the concepts or tools etc. that are related to printing PostScript. This is why it is now that big: to offer you all the information you might want, **not** because using `a2ps` would be difficult.

Please, send us emailcards `:)`. Whatever the comment is, or if you just like `a2ps`, write to Miguel Santana and Akim Demaille.

Description

`a2ps` formats files for printing on a PostScript printer.

The format used is nice and compact: normally two pages on each physical page, borders surrounding pages, headers with useful information (page number, printing date, file name or supplied header), line numbering, pretty-printing, symbol substitution etc. This is very useful for making archive listings of programs.

Compared to the previous versions, `a2ps` version 4.10 provides:

1. various configuration files (see section Configuration Files)
2. some powerful meta-sequences to define the headers the way you want (see section Meta Sequences);
3. a totally open approach of fonts and encodings;
4. a rather strong support of Latin 2, 3, 4, 5 and 6 encodings, thanks to `Ogonkify` (see section

'Overview' in Ogonkify manual), written by Juliusz Chroboczek.

5. fully customizable output style: fonts, background and foreground colors, line numbering style etc. (see section Designing PostScript Prologues).
6. the ability to delegate the processing of some files to other filters (see section Your Delegations).
7. and of course, the ability to pretty-print sources written in quite a few various languages (see section Pretty Printing).

Version Numbering Scheme

`a2ps` is alive. To let you know its status, the version numbers are structured *à la* Linux.

What is to be understood in `a2ps version x.y.z.t'?

- if y is even, then this is an official release, fully tested and checked on many platforms, and widely distributed.
- if y is odd, then
  - if there is no t, then this is a distributed beta, with brand new features, and maybe some new bugs, or lacks in the documentation. It is only available on a2ps home page.
  - if there is t, then this is an alpha, only available to members of the `a2ps` mailing list, so that problems are explored and tracked down.

Reporting Bugs

We try hard to make `a2ps` portable on any Unix platform, and bug free. But sometimes there can still be bad surprises, even after having compiled and checked `a2ps` on several very different platforms.

You may encounter some of these problems yourself. In any case, please never abandon without giving us a chance. We need information from everybody so that mistakes get fixed as fast as possible.

So, if you have a problem (configuration error, compilation error, runtime error, documentation error or unclear), first check on a2ps home page and in the FAQ (see section Frequently asked questions) if the issue has not been addressed yet. If it is not the case, but it appears that the version of `a2ps` you have is old, consider upgrading.

If the problem persists, send us a mail (a2ps-bugs@inf.enst.fr) which title is `a2ps version: short-description' in which you mention the name of your machine and OS, the version of `a2ps`, every detail you have on your compiler, and as much traces as possible (the error messages you get on the screen, or the output of `make` when it fails etc.).

Be sure to get a quick answer.

a2ps Mailing List

There is a mailing list in which are discussed various topics around `a2ps`. There are also announcements about the version in alpha testing, requests for comments, new sheets, etc.

To subscribe to the list, send a mail to a2ps-request@inf.enst.fr, with `subscribe' in the body.

Please, note that the mailing list is by no means a bug reporting address: use a2ps-bugs@inf.enst.fr instead.

Helping the Development

If you like `a2ps` and if you feel like helping, there are several things you can do.

Translation

The interface of `a2ps` is under `GNU gettext` which means that all the messages can be translated, without having to look at the code of `a2ps`: you don't need to be a programmer at all. All the details are available on the a2ps translation page.

Style Sheets

Since `a2ps` is evolving and getting more powerful, the style sheets should be checked and improved. There are too many so that the authors work on them. Therefore if you feel your favorite language is not honored as it should be, improve the style sheet! (see section Pretty Printing for details.)

Encodings

`a2ps` is wide open to any 8-bit encoding. If your language is not covered today by `a2ps`, you can easily provide the support yourself. Honestly, the trickiest part is to find correct **free** fonts that support your mother tongue (see section Encoding Files, to know more).

Fonts

There are still some characters missing in Ogonkify. See the list of missing characters and the Ogonkify home page for details.

Documentation

If you feel something is missing or is unclear, send us your contributions.

Porting

Porting a program to special architectures (MS-DOS, OS/2 etc.), or building special packages (e.g., RPM) requires having an access to these architectures. If you feel like maintaining such a port, tell us.

Features

Well, if you feel like doing something else, go ahead!

User's Guide

This chapter is devoted to people who don't know `a2ps` yet: we try to give a soft and smooth introduction to the most useful features. For a reference manual, see section Invoking `a2ps`. For the definition of some words, see section Glossary, for questions you have, see section Frequently asked questions.

Purpose

`a2ps` is a program that takes a text file (i.e., human readable), and makes a PostScript file out of it.

How to print

To print a file `` `doc.txt' ``, just give it to `a2ps`: the default setting should be the one you'd like:

```
gargantua ~ $ a2ps doc.txt
[doc.txt (plain): 9 pages on 5 sheets]
[Total: 9 pages on 5 sheets] sent to the default printer
```

`a2ps` sent the file `` `doc.txt' `` to the default printer, writing two columns of text on a single face of the sheet. Indeed, by default `a2ps` uses the option `-2', standing for two virtual pages.

Basics for Printing

Say you want to print the C file `` `bar.c' ``, and its header `` `foo.h' ``, on 4 virtual pages, and save it into the file `` `foobar.ps' ``. Just hit:

```
gargantua $ a2ps foo.h bar.c -4 -o foobar.ps
[foo.h (C): 1 page on 1 sheet]
[bar.c (C): 3 pages on 1 sheets]
[Total: 4 pages on 2 sheets] saved into the file `foobar.ps'
```

The option `-4' tells `a2ps` to make four virtual pages: two rows by two columns. The option `-o' (which is the short version of `--output=foobar.ps') specifies the output file. The long options must always be separated by spaces, though short options with no arguments may be grouped.

Note too that the options may be before or after the files, it does not matter.

If you send `` `foobar.ps' `` to a printer, you'll discover that the keywords were highlighted, that the strings and comments have a different face. Indeed, `a2ps` is a pretty-printer: if it knows the (programming) language in which your file is written, it will try to make it look nice on the paper.

But too bad: `` `foo.h' `` is only one virtual page long, and `` `bar.c' `` takes three. Moreover, the comments are essential in those files. And even worse: the system's default printer is out of ink. Thanks god, precious options may help you:

```
gargantua $ a2ps -A4 foo.h bar.c --prologue=gray -P lw
[foo.h (C): 1 page on 1 sheet]
[bar.c (C): 3 pages on 1 sheet]
[Total: 4 pages on 1 sheet] sent to the printer `lw'
```

Here `-A' is used to Allow several files on the same sheet, `-P lw' means to print on the printer named `lw', and finally, the long option `--prologue' asked to use one of the alternative printing styles of `a2ps'. There are other available prologues (see option `--prologue' in section Input Options), and you can even design yours (see section Designing PostScript Prologues).

Special Printers

There are three special printers pre-defined.

The first one, `void', sends the output to the trash. Its main use is to see how many pages would have been used.

```
gargantua ~ $ a2ps -P void parsessh.c
[parsessh.c (C): 33 pages on 17 sheets]
[Total: 33 pages on 17 sheets] sent to the printer `void'
```

The second, `display' sends the output to `ghostview', so that you can check the output without printing. Of course if you don't have `ghostview', it won't work... And it is up to you to configure another displaying application (see section Your Printers).

And the last, `file' saves the output into a file named after the file you printed (e.g., saves into `foo.ps' when you print `foo.c').

Using Delegations

`a2ps' is able to decide that it is not the right tool to do what you want, in which case it delegates the task to other programs. What you should retain from this, is, *forget that there are delegations*. Indeed, the interface with the delegations has been designed so that you don't need to be aware that they exist to use them. Do as usual.

As an example, if you need to print a PostScript file, just hit:

```
gargantua ~ $ a2ps article.ps -d
[article.ps (ps, delegated to PsNup): 7 pages on 4 sheets]
[Total: 8 pages on 4 sheets] sent to the default printer
```

Using your defaults, `a2ps' delegated the task to put two virtual pages per physical page to `psnup', a powerful filter part of the famous `psutils' by Angus Duggan.

Suppose now that you want to display a Texinfo file. Then, provided you have all the programs `a2ps' needs, just hit

```
gargantua ~ $ a2ps a2ps.texi -P display
[a2ps.texi (texinfo, delegated to texi2dvi): 75 pages on 38 sheets]
[Total: 76 pages on 38 sheets] sent to the printer `display'
```

Once the documentation read, you know you want to print just the pages 10 to 20, and the cover. Just hit:

```
gargantua ~ $ a2ps a2ps.texi --pages=1,10-20 -d
[a2ps.texi (texinfo, delegated to texi2dvi): 13 pages on 7 sheets]
[Total: 14 pages on 7 sheets] sent to the default printer
```

A final word: compressed files can be treated in the very same way:

```
gargantua ~ $ a2ps a2ps.texi.gz -a1,10-20 -d
[a2ps.texi (compressed, delegated to Gzip-a2ps): 13 pages on 7 sheets]
[Total: 14 pages on 7 sheets] sent to the default printer
```

You should be aware that:

- the option `-Z' enables the delegations if they are not (see `--list=defaults' for your settings);
- the set of delegations is customizable, to know the delegations your `a2ps` knows, consult `a2ps --list=delegations'.

Checking the Defaults

If `a2ps` did not have the behavior expected, this may be because of the default settings given by your system administrator. Checking those default values is easy:

```
gargantua ~ $ a2ps --list=defaults
Configuration status of a2ps 4.10
Sheets:
  default paper         = A4
  layout per page       = 2 x 1 (landscape, rows first)
  borders               = yes
  compact mode          = yes
  inside margin         = 0
More stuff deleted here
Internals:
  verbosity level     = 2
  file command        = /usr/ucb/file -L
  temporary directory =
  library path        =
        /inf/soft/infthes/demaille/.a2ps
        /usr/local/share/a2ps/sheets
        /usr/local/share/a2ps/ps
        /usr/local/share/a2ps/encoding
        /usr/local/share/a2ps/afm
        /usr/local/share/a2ps/printers
```

```
/usr/local/share/a2ps
```

Remember that the on-line help is always available. Moreover, if your screen is small, you may *pipe* it into `more`. Just trust this:

```
a2ps --help | more
```

Important parameters

Many things are parameterizable in `a2ps`, but two things are just essential to make sure everything goes right:

The paper

Make sure that the paper `a2ps` uses is the same as your printer (See section Sheets Options, option `--medium').

The encoding

Make sure that the *encoding* `a2ps` uses is the same as the standard alphabet in your country (See section Input Options, option `--encoding').

Both values may be checked with `a2ps --list=defaults'.

Localizing

`a2ps` provides some Native Language Support, that is speaking your mother tongue. It uses three special features for non-English languages:

the tongue

i.e., the language used by the interface,

the date

i.e., the format and the words used in the language to specify a date,

the ordering

i.e., the alphabetic order that corresponds to your tongue (for instance the French letter `é' is to be considered has an `e', which is not what says its ASCII code).

To use these features, you may set your environment variable `LANG` to the standard code representing your language:

`ca`

Catalan

`cs`

Czech

`de`

German

`es`

`es`
: Spanish

`fr`
: French

`it`
: Italian

`ko`
: Korean

`nl`
: Dutch

`pl`
: Polish

`tr`
: Turkish

The problem with this approach is that a lot more than just messages and time information is affected: especially the way numbers are written changes, what may cause problems which `awk` and such.

So if you just want messages, time format and sorting order to be localized, then define:

```
set LC_MESSAGES=fr
set LC_TIME=fr
set LC_COLLATE=fr
export LC_MESSAGES
export LC_TIME
export LC_COLLATE
```

Note that the `make install' *must* have been done in order to have NLS support.

Interfacing with other programs

Here are some tips on how to use `a2ps` with other programs.

elm

Once you are in elm, hit o to enter in the options edition menu, hit p to edit the printer command, and enter `a2ps -2gEmail --strip=3 %s -d'. The option `-g' is given because there are some special escapes that `a2ps` understands, and replaces with the correct character.

pine

Jan Chrillesen suggests us how to use `a2ps` with the Pine mail-reader. Add the following to `` `.pinerc' `` (of course you can put it in `` `pine.conf' `` as well):

```
# Your printer selection
printer=a2ps -2gEmail --strip=3 -d

# Special print command if it isn't one of the standard printers
personal-print-command=a2ps -2gEmail --strip=3 -d
```

Netscape

This is actually valid for any program that generates PostScript that you want to post-process with `a2ps`.

Since the data is sent through the standard input, you need to specify that it is PostScript data (see section Style Sheet Files). And just to ensure the delegations are set, force `-Z'. Therefore, in the `Print' windows of Netscape, use the following command:

```
a2ps -ZEps -
```

Do not forget to tell Netscape whether your printer supports colors, and the type of paper it uses.

Invoking a2ps

Calling `a2ps` is fairly simple:

```
a2ps Options... Files...
```

If no Files... are given, `a2ps` prints its standard input. If `-' appears in the Files..., it designates the standard input too.

Command line options

To read the options and arguments that you give it, `a2ps` uses GNU `getopt`, hence:

- the options (short with arguments or long) must be separated by spaces.
- the order between options and files does not matter: `a2ps -4m main.c' and `a2ps main.c -4m' are identical.
- the order between options **does matter**, especially between options that influence the same parameters. For instance `a2ps -1 -l132' is not the same as `a2ps -l132 -1' (the latter being equivalent to `a2ps -1'.
- short options may be grouped together: `a2ps -4mg main.c -P printer'
- when there are no ambiguities, long options can be abbreviated, e.g., `--pro' will be understood as `--prologue',
- `--' ends the options. Anything behind `--' is considered to be a file: `a2ps -- -2' prints the file `-2' (2).

Here after a boolean is considered as true (i.e. setting the option on), if boolean is `yes', or `1'; as false if it

equals `no' or `0'; and raise an error otherwise. The corresponding short option takes no arguments, but corresponds to a positive answer.

When an argument is presented by square brackets, it means that it is optional. Optional arguments must never be separated from the short option.

Tasks Options

When these options are used, `a2ps` does not print. It executes the task and exits successfully.

Option: **-V**

Option: **--version**

print version and exit successfully.

Option: **-h**

Option: **--help**

Print a short help, and exit successfully.

Option: **--copyright**

Display Copyright and copying conditions, and exit successfully.

Option: **--guess**

Act like `file` does: display the (key of the) type of the Files.

For instance, on a `C` file, you expect it to answer `c', and upon a PostScript file, `ps'.

This can be very useful on broken systems to understand why a file is printed with a bad style sheet (see section Style Sheet Files).

Option: **--list=topic**

Display a report on `a2ps`' status with respect to topic, and exit successfully. topic can be any non-ambiguous abbreviation of:

`defaults'

`options'

Give an extensive report on `a2ps` configuration and installation.

`features'

Known media, encodings, languages, prologues, printers, macro meta sequences, delegations and user options are reported. In a word, anything that you may define.

`delegations'

Detailed list of the delegations. See section Your Delegations.

`encodings'

Detailed list of known encodings. See section Some Encodings.

`macro-meta-sequences'
: Detailed list of the macro meta sequences. See section Your Meta Sequences.

`media'
: Detailed list of known media. See section Your Media.

`prologues'
: Detailed list of PostScript prologues. See section Designing PostScript Prologues.

`printers'
: Detailed list of printers and named outputs. See section Your Printers.

`style-sheets'
: Detailed list of the known style sheets. See section Known Style Sheets.

`user-options'
: Detailed list of the user options. See section Your Shortcuts

There are also options meant for the maintainers only, presented for sake of completeness.

`texinfo-style-sheets'

`ssh-texi'
: Detailed list of known style sheets in Texinfo format. If the `sheet` verbosity is set, report version numbers, requirements and ancestors.

`html-style-sheets'

`ssh-html'
: Detailed list of the style sheets in `HTML` format.

`texinfo-encodings'

`edf-texi'
: Detailed list of encodings, in Texinfo format.

`texinfo-prologues'

`pro-texi'
: Detailed list of prologues, in Texinfo format.

Global Options

These options are related to the interface between you and `a2ps`.

Option: **-q**

Option: **--quiet**

Option: **--silent**

be really quiet

Option: **-v[level]**

Option: **--verbose[=level]**

tell what we are doing. At

- level = 0, report nothing,
- level = 1, `a2ps` just prints the total number of pages printed,
- level = 2 (default), it reports it for each file,
- above, it gives internal details.

There is also an interface made for the maintainer with finer grained selection of the verbosity level. level is a list of tokens (non ambiguous abbreviation are valid) separated by either `,' or `+'. The tokens may be:

`sheets'
: the style sheets,

`pathwalk'
`pw'
: the search for files,

`encodings'
: the encodings,

`configuration'
`options'
: reading the configurations files and the options,

`files'
: inputs and outputs,

`tools'
: launched programs or shell commands ; triggers the escape `?V' on (see section Available Meta Sequences),

`fonts'
: the font,s

`ppd'
: PPD processing,

`meta-sequences'
: the expansion of meta sequences,

`parsers'
: any parsing process (style sheets, PPD files etc.),

`all'
: all the messages.

Option: **-=shortcut**

Option: **--user-option=shortcut**

use the shortcut defined by the user. See section Your Shortcuts.

Note that contrary to the other options, this special construct must not be after the files to print. This is actually a bug. If somebody sees how to fix this, please send us a patch.

Option: **--debug**

enable debugging features. They are:

- print the overall BoundingBox in PostScript;
- down load a PostScript debugger which helps understanding why a printer may reject a file.

Option: **--macro-meta-sequence=key[:value]**

Without value, unset the macro meta sequence key. Otherwise, set it to value. See section Your Meta Sequences for more details.

Sheets Options

This options specify the general layout, how the sheet should be used.

Option: **-M** *medium*

Option: **--medium=medium**

use output medium medium. See the output of `a2ps --list=media' for the list of supported media. Typical values are `A3', `A4', `A5', `B4', `B5', `Letter', `Legal'. `A4dj', `Letterdj' are also defined for Desk Jet owners, since that printer needs bigger margins.

Option: **-r**

Option: **--landscape**

print in landscape mode

Option: **-R**

Option: **--portrait**

print in portrait mode

Option: **--columns=num**

specify the number of columns of virtual pages per physical page.

Option: **--rows=num**

specify the number of rows of virtual pages per physical page.

Option: **--major=direction**

specify whether the virtual pages should be first filled in rows (direction = `rows') or in columns (direction = `columns').

Option: **-1**

TOC

1 x 1 portrait, 80 chars/line, major rows (i.e. alias for `--columns=1 --rows=1 --portrait --chars-per-line --major=rows').

Option: **-2**

2 x 1 landscape, 80 chars/line, major rows.

Option: **-3**

3 x 1 landscape, 80 chars/line, major rows.

Option: **-4**

2 x 2 portrait, 80 chars/line, major rows.

Option: **-5**

5 x 1 landscape, 80 chars/line, major rows.

Option: **-6**

3 x 2 landscape, 80 chars/line, major rows.

Option: **-7**

7 x 1 landscape, 80 chars/line, major rows.

Option: **-8**

4 x 2 landscape, 80 chars/line, major rows.

Option: **-9**

3 x 3 portrait, 80 chars/line, major rows.

Option: **-j**

Option: **--borders=boolean**

print borders around virtual pages.

Option: **-A**

Option: **--compact=boolean**

Compact mode for a sequence of files. This option allows the printing of more than one file on the same page. Otherwise, the beginning of each file will be printed in a new sheet.

Option: **--margin[=num]**

Specify the size of the margin (num PostScript points, or 12 points without arguments) to leave in the inside (i.e. left for the front side page, and right for the back side). This is intended to ease the binding.

Pages Options

This options are related to the content of the virtual pages.

Option: **--line-numbers=number**

print the line numbers from number lines to number lines.

Option: **-C**

Alias for `--line-numbers=5'.

Option: **-f** *size[unit]*

Option: **--font-size=size[unit]**

scale font to size for body text. size is a float number, and unit can be `cm' for centimeters, `points' for PostScript points, and `in' for inches. Default unit in `inches'.

To change the fonts used, change the current prologue (see section Designing PostScript Prologues.

Option: **-l** *num*

Option: **--chars-per-line=num**

Set the number of columns per page. num is the real number of columns devoted to the body of the text, i.e., no matter whether lines are numbered or not.

Option: **-L** *num*

Option: **--lines-per-page=num**

Set the lines per virtual page for printing. The font size is automatically scaled up to fill in the whole page. This is useful for printing preformatted documents which have a fixed number of lines per page. The minimum number of lines per page is set at 40 and maximum is at 160. If a number less than 40 is supplied, scaling will be turned off.

Option: **-m**

Option: **--catman**

Understand UNIX manual **output** ie: 66 lines per page and possible bolding and underlining sequences. The understanding of bolding and underlining is there by default even if `--catman' is not specified.

If your file is actually a UNIX manual *input*, i.e., a roff file, then depending whether you left `a2ps` delegate or not, you will get a readable version of the text described, or a pretty-printed version of the describing file (see section Your Delegations).

Option: **-T** *num*

Option: **--tabsize=num**

set tabulator size to num. This option is ignored if `--interpret=no` is given.

Option: **--non-printable-format=format**

specify how non-printable chars are printed. format can be
`caret'
Use classical Unix representation: `^A', `M-^B' etc.
`space'
A space is written instead of the non-printable character.
`question-mark'
A `?' is written instead of the non-printable character.
`octal'
For instance `\001', `177' etc.
`hexa'
For instance `\x01', `\xfe' etc.
`emacs'
For instance `C-h', `M-C-c' etc.

Headings Options

These are the options through which you may define the information you want to see all around the pages.

All these options support text as an argument, which is composed of plain strings and meta sequences. See section Meta Sequences for details.

Option: **-B**

Option: **--no-header**

no page headers at all.

Option: **-b[text]**

Option: **--header[=text]**

set the page header

Option: **--center-title[=text]**

Option: **--left-title[=text]**

Option: **--right-title[=text]**

Set virtual page center, left and right titles to text.

Option: **-u[text]**

Option: **--underlay[=text]**

use text as under lay (or water mark), i.e., in a light gray, and under every page.

Option: **--left-footer[=text]**

Option: **--footer[=text]**

Option: **--right-footer[=text]**

Set sheet footers to text.

Input Options

Option: **-a[Page range]**

Option: **--pages[=Page range]**

With no argument, print all the page, otherwise select the pages to print. Page range is a list of interval, such as `-a1': print only the first page, `-a-3,4,6,10-': print the first 3 pages, page 4 and 6, and all the page after 10 (included). Giving `toc' prints the table of content whatever its page number is.

The pages referred to are the *input* pages, not the output pages, that is, in `-2', printing with `-a1' will print the first virtual page, i.e., you will get half the page filled.

Note that page selection does work with the delegations (see section Your Delegations).

Option: **-c**

Option: **--truncate-lines=boolean**

Cut lines too large to be printed inside the borders. The maximum line size depends on format and font size used and whether line numbering is enabled.

Option: **-i**

Option: **--interpret=boolean**

interpret tab, bs and ff chars

Option: **--end-of-line=type**

Specify what sequence of characters denotes the end of line. type can be:

`n`
`unix`
: `\n'.

`r`
`mac`
: `\r'.

`nr`
: `\n\r'. As far as we know, this type of end-of-line is not used.

`pc`
`rn`

`\r\n'. This is the type of end-of-line on MS-DOS.

`any`
`auto`

Any of the previous cases. This last case prevents the bad surprises with files from PC (trailing `^M').

Option: **-X** *key*

Option: **--encoding=key**

Use the input encoding identified by key. See section Some Encodings, and the result of `a2ps --list=encodings' to know what encodings are supported. Typical values are `ASCII', `latin1'... `latin6', `ison' etc.

Option: **--stdin=filename**

Give the name filename to the files read through the standard input.

Option: **-t** *name*

Option: **--title=name**

Give the name name to the document. Meta Sequences can be used (see section Meta Sequences).

This is used for instance in the name given to the document from within the PostScript code (so that GhostView and others can display a file with its real title, instead of just the PostScript file name).

It is **not** the name of the output. It is just a logical title.

Option: **--prologue=prologue**

Use prologue as the PostScript prologue for `a2ps`. prologue must be in a file named `` `prologue.pro' ``, which must be in a directory of your library path (see section Library Files). Currently the available prologues are:

`bw'

Style is plain: pure black and white, with standard fonts.

`color'

Colors are used to highlight the keywords.

`gray'

Gray foreground is used for comments and labels.

`gray2'

Black foreground is used for comments and labels.

`matrix'

The layout is the same as `bw', but alternating gray and white lines. There are two macros defining the behavior: `pro.matrix.cycle' defines the length of the cycle (number of white and gray lines). It defaults to 6. `pro.matrix.gray' defines the number of gray lines. Default is 3.

Option: **--print-anyway=boolean**

force binary printing. By default, the whole print job is stopped as soon as a binary file is detected. To detect such a file we make use of a very simple heuristic: if the first sheet of the file contains more than 40% of non-printing characters, it's a binary file.

Option: **-Z**

Option: **--delegate=boolean**

Enable delegation of some files to delegated applications. If delegating is on, then `a2ps` will *not* process the file by itself, but will call an application which handles the file in another way. If delegation is off, then `a2ps` will process *every* file itself.

Typically most people don't want to pretty-print a PostScript source file, but want to print what describes that file. Then set the delegations on.

See section Your Delegations for information on delegating, and option `--list=delegations' for the applications your `a2ps` knows.

Option: **--toc[=format]**

Generate a Table of Content, which format is a Meta Sequence (see section Meta Sequences) processed as a PreScript file (see section PreScript). If no format is given, don't generate the Table of Content.

Note that it is mostly useful to define a macro (see section Your Meta Sequences), for instance, in your `a2psrc' file:

```
MacroMetaSequence: toc.mine \
\\Keyword{Table of Content}\n\
#-1!f\
|$2# \\keyword{$-.20n} sheets $3s< to $3s> ($2s#) \
pages $3p<-$3p> $4l# lines\n||\
\\Keyword{End of toc}\n
```

and to give that macro name as argument to `--toc': `a2ps *.c --toc=#{toc.mine}'.

Note too that you can generate only the table of content using `--pages':

```
a2ps *.c --toc=#{toc.mine} -atoc
```

Pretty Printing Options

These options are related to the pretty printing features of `a2ps`.

Option: **--highlight-level=level**

Specify the level of highlighting. level can be

`none'

no highlighting

`normal'

regular highlighting

`heavy'

even more highlighting.

See the documentation of the style sheets (`--list=style-sheets') for a description of `heavy' highlighting.

Option: **-g**

Alias for `--highlight-level=heavy'.

Option: **-E** *[language]*

Option: **--pretty-print[=language]**

With no arguments, set automatic style selection on. Otherwise, set style to language. Note that setting language to `plain' turns off pretty-printing. See section Known Style Sheets, and the output of `--list=style-sheets' for the available style sheets.

If language is `key.ssh', then don't look in the library path, but use the file `key.ssh'. This is to ease debugging non installed style sheets.

Option: **--strip-level=num**

Depending on the value of num:

`0'

everything is printed;

`1'

regular comments are not printed

`2'

strong comments are not printed

`3'

no comment is printed.

This option is valuable for instance in `java` in which case strong comments are the so called documentation comments, or in `SDL` for which some graphical editors pollutes the specification with internal data as comments.

Note that the current implementation is not satisfactory: some undesired blank lines remain. This is planed to be fixed.

Output Options

These are the options to specify what you want to do out of what `a2ps` produces. Only a single destination is possible at a time, i.e., if ever there are several options `-o', `-P' or `-d', the last one is honored.

Option: **-o** *file*

Option: **--output=file**

leave output to file file. If file is `-', leave output to the standard output.

Option: **--version-control=type**

to avoid loosing a file, `a2ps` offers backup services. This is enabled when the output file already exists.

The type of backups made can be set with the `VERSION_CONTROL` environment variable, which can be overridden by this option. If `VERSION_CONTROL` is not set and this option is not given, the default backup type is `existing'. The value of the `VERSION_CONTROL` environment variable and the argument to this option are like the GNU `Emacs` `version-control' variable; they also recognize synonyms that are more descriptive. The valid values are (unique abbreviations are accepted):

`none'

`off'

Never make backups (override existing files).

`t'

`numbered'

Always make numbered backups.

`nil'

`existing'

Make numbered backups of files that already have them, simple backups of the others.

`never'

`simple'

Always make simple backups.

Option: **--suffix=suffix**

The suffix used for making simple backup files can be set with the `SIMPLE_BACKUP_SUFFIX` environment variable, which can be overridden by this option. If neither of those is given, the default is `~', as it is in `Emacs`.

Option: **-P** *name*

Option: **--printer=name**

send output to printer name. See item `Printer:' and `Unknown printer:' in section Your Printers and results of option `--list=defaults' to see the bindings between printer names and commands.

Option: **-d**

send output to the default printer. See item `DefaultPrinter:' in section Your Printers.

PostScript Options

The following options are related only to variations you want to produce onto a PostScript output.

Option: **--ppd[=key]**

With no argument, set automatic `PPD` selection, otherwise set the `PPD` to key. FIXME: what to read.

Option: **-n** *num*

Option: **--copies=num**

print num copies of each page

Option: **-s** *num*

Option: **--side=num**

number of sheet sides. num is of course 1 or 2.

Option: **-D** *key[:value]*

Option: **--setpagedevice=key[:value]**

Pass a page device definition to the generated PostScript output. If no value is given, key is removed from the definitions. Note that several `-D' can be accumulated.

For example, command

```
a2ps -DDuplex:true -DManualFeed:true report.pre
```

prints file `report.pre' in duplex (two sides) mode manually fed.

Page device operators are implementation dependent but they are standardized. See section Page Device Options for details.

Option: **-S** *key[:value]*

Option: **-S** *key[::value]*

Option: **--statusdict=key[:value]**

Option: **--statusdict=key[::value]**

Pass a statusdict definition to the generated PostScript output. `statusdict` operators and variables are implementation dependent; see the documentation of your printer for details. See section Statusdict Options for details. Several `-S' options can be accumulated.

If no value is given, key is removed from the definitions.

With a single colon, pass a call to an operator, for instance:

```
a2ps -Ssetpapertray:1 quicksort.c
```

prints file `quicksort.c' by using paper from the paper tray 1 (assuming that printer supports paper tray selection).

With two colons, define variable key to equal value. For instance:

```
a2ps -Spapertray::1 quicksort.c
```

produces

```
/papertray 1 def
```

in the PostScript.

Option: **-k**

Option: **--page-prefeed**

enable page prefeeding. It consists in positioning the sheet in the printing area while the PostScript is interpreted (instead of waiting the end of the interpretation of the page before pushing the sheet). It can lead to an significant speed up of the printing.

`a2ps` quotes the access to that feature, so that non supporting printers won't fail.

Option: **-K**

Option: **--no-page-prefeed**

disable page prefeeding.

Meta Sequences

The meta sequences (sometimes called escapes in other terminologies), are some sequences of characters that will be replaced by their values. They are very much like variables.

Use of Meta Sequences

They are used in several places in `a2ps`:

Page markers

Headers, footers, titles and the water mark (see section Headings Options), in general to print the name of file, page number etc. On a new sheet `a2ps` first draws the water mark, then the content of the first page, then the frame of the first page, (ditto with the others), and finally the sheet header and footers. This order must be taken into account for some meta sequences (e.g., `$l.', `$l^').

Named output

To specify the generic name of the file to produce, or how to access a printer (see section Your Printers).

Delegation

To specify the command associated to a delegation (see section Your Delegations).

Table of Content

To specify an index/table of content printed at the end of the job.

Variables in PostScript prologue

To allow the user to change some parameters to your prologues (see section Designing PostScript Prologues).

General Structure of the Meta Sequences

All format directives can also be given in format

escape width directive

where

escape

In general

`%'

meta sequences are related to general information (e.g., the current date, the user's name etc.),

`#'

meta sequences are related to the output (e.g., the output file name) or to the options you gave (e.g., the number of virtual pages etc.), or to special constructions (e.g., enumerations of the files, or tests etc.),

`$'

meta sequences are related to the current input file (e.g., its name, its current page number etc.),

`\'

introduces classical escaping sequences (e.g., `\n', `\f' etc.).

- width Specifies the width of the column to which the escape is printed. There are three forms for width

`+paddinginteger'

the result of the expansion is prefixed by the character padding so that the whole result is as long as integer. For instance `$+.10n' with a file name `$n'=`foo.c' gives `.....foo.c'.

If no padding is given, ` ' (white space) is used.

`-paddinginteger'

Idem as above, except that completion is done on the left: `$+.10n' gives `foo.c.....'.

`integer'

which is a short cut for `+integer'. For example, escape `$5P' will expand to something like ` 12'.

- directive See section Available Meta Sequences.

Available Meta Sequences

Supported meta-sequences are:

`\\'

character `\'

`\%'

character `%'

`\$'

character `$'

`\#'

character `#'

`#?cond|if_true|if_false|'

this may be used for conditional assignment. The separator (presented here as `|') may be any character. if_true and if_false may be defined exactly the same way as regular headers, included meta sequences and the `#?' construct.

The available tests are:

`#?1'

`#?2'

`#?3'

true if tag 1, 2 or 3 is not empty. See item `$t1' for explanation.

`#?d'

true if Duplex printing is requested (`-s2').

`#?j'

true if bordering is asked (`-j').

`#?l'

true if printing in landscape mode.

`#?o'

true if only one virtual page per page (i.e., `#v' is 1).

`#?p'

a page range has been specified (i.e., `#p' is not empty).

`#?q'

true if `a2ps` is in quiet mode.

`#?r'

true if major is rows (`--major=rows').

`#?v'

true if printing on the back side of the sheet (verso).

`#?V'

true if verbosity level includes the `tools' flag (See section Global Options option `--verbosity'.

- #!key|in|between| Used for enumerations. The separator (presented here as `|') may be any character. in and between are meta sequences.

The enumerations may be:

`#!$'

enumeration of the command line options. In this case in in never used, but is replaced by the arguments.

`#!f'

enumeration of the input files in the other they were given.

`#!F'

enumeration of the input files in the alphabetical order of their names.

`#!s'

enumeration of the files appearing in the current sheet.

For instance, the meta sequences `The files printed were: #!f|$n|, |.' evaluated with input `a2ps NEWS main.c -o foo.ps', gives `The files printed were: NEWS, main.c.'.

As an exception, `#!' meta sequences use the width as the maximum number of objects to enumerate if it is positive, e.g., `#10!f|$n|, |' lists only the ten first file names. If width is negative, then it does not enumerate the -width last objects (e.g., `#-1!f|$n|, |' lists all the files but the last).

- ${var} value of the environment variable var if defined, nothing otherwise.
- ${var:-word} if the environment variable var is defined, then its value, otherwise word.
- ${var:+word} if the environment variable var is defined, then word, otherwise nothing.
- $[num] value of the numth argument given on the command line. Note that $[0] is the name under which `a2ps` has been called.
- #{key} expansion of the macro meta sequence key if defined, nothing otherwise (see section Your Meta Sequences)
- #{key:-word} if the macro meta sequence var is defined, then its expansion, otherwise word.
- #{key:+word} if the macro meta sequence var is defined, then word, otherwise nothing.
- #. the extension corresponding to the current output language (e.g. `ps').
- %* current time in 24-hour format with seconds `hh:mm:ss'
- $* file modification time in 24-hour format with seconds `hh:mm:ss'
- $# the sequence number of the current input file
- %# the total number of files
- %a the localized equivalent for `Printed by User Name'
- %A the localized equivalent for `Printed by User Name from Host Name'
- %a{username} the localized equivalent for `Printed by username'
- %A{username@hostname} the localized equivalent for `Printed by username from hostname'.

These two are provided in the case `a2ps` would be used by the print service: since neither of the user name nor the host name can be known at the time the files reach `a2ps`, these options should be used.

- %c trailing component of the current working directory
- %C current time in `hh:mm:ss' format
- $C file modification time in `hh:mm:ss' format
- %d current working directory
- $d directory part of the current file (`.' if the directory part is empty).
- %D current date in `yy-mm-dd' format
- $D file modification date in `yy-mm-dd' format
- %D{string} format current date according to string with the `strftime(3)` function.

- $D{string} format file's last modification date according to string with the `strftime(3)` function
- %e current date in localized short format (e.g., `Jul 4, 76' in English, or `14 Juil 89' in French).
- $e file modification date in localized short format.
- %E current date in localized long format (e.g., `July 4, 76' in English, or `Samedi 14 Juillet 89' in French).
- $E file modification date in localized long format.
- $f full file name (with directory and suffix).
- \f character `\f' (`form feed`).
- #f0
- #f9 ten temporary file names. You can do anything you want with them, `a2ps` removes them at the end of the job. It is useful for the delegations (see section Your Delegations) and for the printer commands (see section Your Printers).
- %F current date in `dd.mm.yyyy' format.
- $F file modification date in `dd.mm.yyyy' format.
- #h medium height in PostScript points
- $l^ top most line number of the current page
- $l. current line number. To print the page number and the line interval in the right title, use `--right-title="$q:$l^-$l."'.
- $l# number of lines in the current file.
- %m the host name up to the first `.' character
- %M the full host name
- \n the character `\n' (`new line`).
- %n the user login name
- $n input file name without the directory part.
- %N the user's pw_gecos field up to the first `,' character (typically his/her full name).
- $N input file name without the directory, and without its suffix (e.g., on `` `foo.c' ``, it will produce `foo').
- #o name of the output, before substitution (i.e., argument of `-P', or of `-o').
- #O name of the output, after substitution. If output goes to a file, then the name of the file. If the output is a symbolic printer (see section Your Printers), the result of the evaluation. For instance, if the symbolic printer `file' is defined as `> $n.%.', then `#O' returns `foo.c.ps' when printing `` `foo.c' `` to PostScript. `#o' would have returned `file'.
- #p the range of the page to print from this page. For instance if the user asked `--pages=1-10,15', and the current page is 8, then `#p' evaluates to `1-3,8'.
- $p^ number of the first page of this file appearing on the current sheet. Note that `$p.', evaluated at the end of sheet, is also the number of the last page of this file appearing on this sheet.
- $p- interval of the page number of the current file appearing on the current sheet. It is the same as `$p^-$p.', if `$p^' and `$p.' are different, otherwise it is equal to `$p.'.
- %p. current page number

- $p. page number for this file
- %p# total number of pages printed
- $p# number of pages of the current file
- $p< number of the first page of the current file
- $p> number of the last page of the current file
- %q localized equivalent for `Page %p.'
- $q localized equivalent for `Page $p.'
- %Q localized equivalent for `Page %p./%p#'
- $Q localized equivalent for `Page $p./$p#'
- $s< number of the first sheet of the current file
- %s. current sheet number
- $s. sheet number for the current file
- $s> number of the last sheet of the current file
- %s# total number of sheets
- $s# number of sheets of the current file
- %t current time in 12-hour am/pm format
- $t file modification time in 12-hour am/pm format
- $t1
- $t2
- $t3 Content of tag 1, 2 and 3. Tags are pieces of text `a2ps` fetches in the files, according to the style. For instance, in `mail-folder` style, tag 1 is the title of the mail, and tag 2 its author.
- %T current time in 24-hour format `hh:mm'
- $T file modification time in 24-hour format `hh:mm'
- #v number of virtual sheets
- %V the version string of `a2ps`.
- #w medium width in PostScript points
- %W current date in `mm/dd/yy' format
- $W file modification date in `mm/dd/yy' format

Exit status

The following exit values are returned:

`0'
: `a2ps` terminated normally.

`1'
: an error occured.

`2'
: bad argument was given.

`3'

unknown language was given.

Library Files

To be general and to allow as much customization as possible, `a2ps` avoids to hard code its knowledge (encodings, PostScript routines, etc.), and tries to split it in various files. Hence it needs a path, i.e., a list of directories, in which it may find the files it needs.

The exact value of this library path is available by `a2ps --list=defaults'. Typically its value is:

```
gargantua ~ $ a2ps --list=defaults
Configuration status of a2ps 4.10
More stuff deleted here
Internals:
  verbosity level     = 2
  file command        = /usr/ucb/file -L
  temporary directory =
  library path        =
        /inf/soft/infthes/demaille/.a2ps
        /usr/local/share/a2ps/sheets
        /usr/local/share/a2ps/ps
        /usr/local/share/a2ps/encoding
        /usr/local/share/a2ps/afm
        /usr/local/share/a2ps/printers
        /usr/local/share/a2ps
```

You may change this default path through the configuration files (see section Your Library Path), and with the environment variable `A2PS_LIBRARY`.

If you plan to define yourself some files for `a2ps`, they should be in one of those directory.

Configuration Files

`a2ps` reads several files before the command line options. In the order, they are:

1. the system configuration file (usually `` `/usr/local/etc/a2ps.cfg' ``)
2. the user's home configuration file (`` `$HOME/.a2ps/a2psrc' ``)
3. the local file (`` `./.a2psrc' ``)

In these files, empty lines and lines starting with `#' are comments.

The other lines have all the following form:

```
Topic: Arguments
```

where Topic: is a keyword related to what you are customizing, and Arguments the customization. Arguments may be spread on several lines, provided that the last character of a line to continue is a `\'.

In the following sections, each Topic: is detailed.

Your Library Path

To define the default library path, you can use:

Configuration Setting: **LibraryPath:** *path*

Set the library path the path.

Configuration Setting: **AppendLibraryPath:** *path*

Add path at the end of the current library path.

Configuration Setting: **PrependLibraryPath:** *path*

Add path at the beginning of the current library path.

The environment variable `A2PS_LIBRARY` overrides these entries.

Note that for users configuration files, it is better not to set the library path, because the system's configuration has certainly been built to cope with your system's peculiarities. Use `AppendLibraryPath:' and `PrependLibraryPath:'.

Your Default Options

Configuration Setting: **Options:** *options+*

Give `a2ps` a list of command line options. options+ is any sequence of regular command line options (see section Command line options).

It is the correct way to define the default behavior you expect from `a2ps`. If for instance you want to use `Letter` as medium, then use:

```
Options: --medium=Letter
```

It is exactly the same as always giving `a2ps` the option `--medium=Letter' at run time.

The quoting mechanism is a bit painful: you need to quote the whole options+. For instance

```
Options: --right-title='Page $p' --center-title='Hello world'
```

is wrong. Write

```
Options: '--right-title=Page $p' '--center-title=Hello world'
```

Your Media

Configuration Setting: **Medium:** *name dimensions*

Define the medium name to have the dimensions (in PostScript points, i.e., 1/72 of inch).

There are two formats supported:

long

in which you must give both the size of the whole sheet, and the size of the printable area:

```
# A4 for Desk Jets
#       name      w       h      llx    lly    urx     ury
Medium: A4dj     595     842     24     50     571     818
```

where wxh are the dimension of the sheet, and the four other stand for lower left x and y, upper right x and y.

short

in which a surrounding margin of 24 points is used

```
# A4
#       name      w       h
Medium: A4       595     842
```

is the same as

```
# A4
#       name      w       h
Medium: A4       595     842     24     24     571     818
```

Your Printers

A general scheme is used, so that whatever the way you should address the printers on your system, the interface is still the same. Actually, the interface is so flexible, that you should understand `named destination' when we write `printer'.

Configuration Setting: **Printer:** *name [PPD-key] destination*

Specify the destination of the output when the option `-P name' is given. If PPD-key is given, declare the printer name to be described by the `PPD` file `` `PPD-key.ppd' ``.

The destination must be of one of the following forms:

`| command'

in which case the output is piped into command.

`> file'

in which case the output is saved into file.

Configuration Setting: **UnknownPrinter:** *[PPD-key] destination*

Specify the destination of the output when when the option `-P name' is given, but there is no `Printer:' entry for name.

Configuration Setting: **DefaultPrinter:** *[PPD-key] destination*

Specify the destination of the output when when the option `-d' (send to default output) is given.

Meta Sequences expansion is performed on destination (see section Meta Sequences). Recall that `#o' is evaluated to the destination name, i.e., the argument given to `-P'.

For instance

```
# My Default Printer is called dominique
DefaultPrinter: | lp -d dominique

# `a2ps foo.c -P bar' will pipe into `lp -d bar'
UnknownPrinter: | lp -d #o

# `a2ps -P foo' saves into the file `foo'
Printer: foo > foo.ps
Printer: wc | wc
Printer: lw | lp -d printer-with-a-rather-big-name

# E.g. `a2ps foo.c bar.h -P file' will save into `foo.c.ps'
Printer: file > $n.#.

# E.g. `a2ps foo.c bar.h -P home' will save into `foo.ps'
# in user's home
Printer: home > ${HOME}/$N.#.

# Here we address a printer which is not PostScript
Printer: deskj | gs -q -sDEVICE=ljet3d -sOutputFile=- - \
         | lpr -P laserwriter -h -l
```

MS-DOS users, and non-PostScript printer owners should take advantage in getting good configuration of these entries.

Your Shortcuts

You can define some kind of `Macro Options' which stands for a set of options.

Configuration Setting: **UserOption:** *shortcut options...*

Define the shortcut to be the list of options.... When `a2ps` is called with `--user-option=shortcut' (or `-=shortcut', consider the list of options....

Examples are

```
# This emulates a line printer: no features at all
```

```
# call a2ps -=lp to use it
UserOption: lp -1m --pretty-print=plain -B --borders=no

# When printing mail, I want to use the right style sheet with strong
# highlight level, and total stripping
UserOption: mail -Email -g --strip=3
```

Your PostScript magic number

`a2ps` produces full DSC compliant PostScript which is something that only PS wizards may understand(3). Adobe said

```
Thou shalt start your PostScript DSC compliant files with

%!PS-Adobe-3.0
```

The bad news is that some printers will reject this header. Then you may change this header without any worry since the PostScript produced by `a2ps` is also 100% PostScript level 1(4).

Configuration Setting: **OutputFirstLine:** *magic-number*

Specify the header of the produced PostScript file to be magic-number. Typical values include `%!PS-Adobe-2.0', or just `%!'.

Your Page Labels

In the PostScript file is dropped information on where sheets begin and end, so that post processing tools know where is the physical page 1, 2 etc. With this information can be also stored a label, i.e., a human readable text (typically the logical page numbers), which is for instance what `GhostView` shows as the list of page numbers.

`a2ps` lets you define what you want in this field.

Configuration Setting: **PageLabelFormat:** *format*

Specify the format to use to label the PostScript pages. format can use Meta Sequences (see section Meta Sequences). Two macro meta sequences are predefined for this: `#{pl.short}' and `#{pl.long}'.

Your Meta Sequences

Meta sequences are actually used so much, that it is pleasant to write sophisticated strings, that one would like not to repeat all the time. As with user short cuts, you can define macro meta sequences:

Configuration Setting: **MacroMetaSequence:** *key value*

Define the meta sequence `#{key}' to be a short cut for value. key must not have any character from `:()'.

As as example, here is a macro for `psnup`, which encloses all the option passing one would like.

Delegations are then easier to write:

```
MacroMetaSequence: psnup psnup -#v -q #?j|-d|| #?r||-c| -w#w -h#h
```

It is strongly suggested to follow a `.' (dot) separated hierarchy, starting with:

`pro'

for variables used in prologues (see section Designing PostScript Prologues). Moreover, specify the name of the prologue (e.g., `pro.matrix.gray').

`pl'

for page label formats. See section Your Page Labels the option `--page-label' in section Input Options.

`toc'

for toc formats. See the option `--toc' in section Input Options.

Your Delegations

There are some files you don't really want `a2ps` to pretty-print, typically page description files (e.g., PostScript files, `roff` files, etc.). You can let `a2ps` delegate the treatment of these files to other applications. The behavior at run time depends upon the option `--delegate' (see section Input Options).

Defining a Delegation

Configuration Setting: **Delegation:** *name in:out command*

Define the delegation name. It is to be applied upon files of type in when output type is out(5) thanks to command. Both in and out are `a2ps` type keys such as defined in `` `sheets.map' `` (see section The Entry in `` `sheets.map' ``).

command should produce the file on its standard output. Of course meta sequences substitution is performed on command (see section Meta Sequences). In particular, command should use the input file `$f'.

```
# In general, people don't want to pretty-print PostScript files.
# Pass the PostScript files to psnup
Delegation: PsNup ps:ps \
        psselect #?V||-q| -p#?p|#p|-| $f | \
        psnup -#v -q #?j|-d|| #?r||-c| -w#w -h#h
```

Advantage should be taken from the macro meta sequences, to encapsulate the peculiarities of the various programs.

```
# Passes the options to psnup.
# The files (in and out) are to be given
MacroMetaSequence: psnup psnup -#v #?V||-q| #?j|-d|| #?r||-c| -w#w -h#h
```

```
# Passes to psselect for PS page selection
MacroMetaSequence: psselect psselect #?V||-q| -p#?p|#p|-|

# In general, people don't want to pretty-print PostScript files.
# Pass the PostScript files to psnup
Delegation: PsNup ps:ps     #{psselect} $f | #{psnup}
```

Temporary file names (`#f0' to `#f9') are available for complex commands.

```
# Pass DVI files to dvips.
# A problem with dvips is that even on failure it dumps its prologue,
# hence it looks like a success (output is produced).
# To avoid that, we use an auxiliary file and a conditional call to
# psnup instead of piping.
Delegation: dvips dvi:ps    #{dvips} $f -o #f0 && #{psnup} #f0
```

Guide Line for Delegations

First of all, select carefully the applications you will use for the delegations. If a filter is known to cause problems, try to avoid it in delegations(6). As a thumb rule, you should check that the PostScript generating applications produce files that start by:

```
%!PS-Adobe-3.0
```

There are some services expected from the delegations. The delegations you may write should honor:

the input file
: available through the meta sequence `$f'.

the medium
: the dimension of the medium selected by the user are available through `#w' and `#h'.

the page layout
: the number of virtual pages is `#v'.

the page range
: the page range (in a form `1-2,4-6,10-' for instance) is available by `#p'.

the verbosity level
: please, do not make your delegations verbose by default. The silent mode should always be requested, unless `#?V' is set.

If ever you need several commands, do not use `;' to separate them, since it may prevent detection of failure. Use `&&' instead.

The slogan "*the sooner, the better*" should be applied here: in the processing chain, it is better to ask a service to the first application that supports it. An example will make it clear: when processing a `DVI` file, `dvips` knows better the page numbers than `psselect` would. So a `DVI` to PostScript delegation should ask the page selection (`#p') to `dvips`, instead of using `psselect` later in the chain.

There is a list of possible delegations, on the page `Delegations for a2ps'. If you know others, please let know.

Your Internal Details

There are settings that only meant for `a2ps` that you can tune by yourself.

Configuration Setting: **TemporaryDirectory:** *path*

Specify a directory in which the temporary files are put. Default is `` `/tmp' ``, or `` `/var/tmp' ``, or `` `$TMPDIR' `` according your environment.

Configuration Setting: **FileCommand:** *command*

The command to run to call `file(1)` on a file. If possible, make it follow the symbolic links.

Documentation Format

In various places a documentation can be given. Since some parts of this document and of web pages are extracted from documentations, some tags are needed to provide a better layout. The format is a mixture made out of Texinfo like commands, but built so that quick and easy processing can be made.

These tags are:

`code('text`)code'

Typeset text like a piece of code. This should be used for keys, variables, options etc. For instance the documentation of the `bold` prologue mentions the `bw` prologue:

```
FIXME: the doc of bold.pro, et matrix
```

`uref('link`)uref('text`)uref'

Specifies a hyper text link displayed as text.

`@example'

`@end example'

They must be alone on the line. The text between these tags is displayed in a code-like fonts. This should be used for including a piece of code. For instance, in the documentation of the `c` style sheet:

```
FIXME: c.ssh
```

`@itemize'

`@item' text

`@end itemize'

Typeset a list of items. The opening and closing tags must be alone on the line.

Map Files

Many things are defined through files. There is a general scheme to associate an object to the files to use: map files. They are typically used to:

- resolve aliases. For instance the ISO-8859-1 encoding is also called ISO Latin 1, or Latin 1 for short. The `encoding.map' file will map these three names to the same Encoding Description File.
- cope with broken files systems. For instance, the-one-you-know-I-don't-need-to-name cannot handle files named `Courier-BoldOblique.afm': it is the same as `Courier-Bold.afm'. The `fonts.map' file is here to associate a font file name to a font name.

The syntax of these files is:

- any empty line, or any line starting by a `#' is a comment.
- a line with the format

  ```
  ***                 path
  ```

  requests that the file designated by path be included at this point.
- any other line has the format

  ```
  key                 value
  ```

  meaning that when looking for key (e.g., name of a font, an encoding etc.), a2ps should use value (e.g., font file name, encoding description file name etc.).

The map files used in a2ps are:

`encoding.map'
: Resolving encodings aliases.

`fonts.map'
: Mapping font names to font file names.

`sheets.map'
: Rules to decide what style sheet to use.

Font Files

Even when a PostScript printer knows the fonts you want to use, using these fonts requires some description files.

Fonts Map File

See section Map Files, for a description of the map files. This file associates the font-key to a font name. For instance:

```
Courier                 pcrr
```

```
Courier-Bold            pcrb
Courier-BoldOblique     pcrbo
Courier-Oblique         pcrro
```

associates to font named `Courier`, the key `pcrr`. To be recognized, the font name must be exact: `courier` and `COURIER` are not admitted.

A small tool is provided with `a2ps`: `make_fonts_map.sh`. It collects the information on the font files `a2ps` can see, and generates a valid font map file, `` `fonts.map.new' ``.

Fonts Description Files

There are two kinds of data `a2ps` needs to use a font:

- the AFM file (`` `font-key.afm' ``), which describes the metrics information corresponding to font;
- in the case font is not known from the printer, the PFA or PFB file which is down loaded to the printer. These files are actually the PostScript programs which execution produces the characters to be drawn on the page, in this font.

Adding More Font Support

FIXME: A few words on how to make a2ps use more fonts. Don't forget some words on broken fonts such as those seen for Cyrillic support.

Style Sheet Files

The style sheets are defined in various files. See see section Pretty Printing for the structure of these files. As for most other features, there is main file, a road map, which defines in which condition a style sheet should be used (see section Map Files). This file is `` `sheets.map' ``.

It format is simple:

`pattern style-key'

if the current file name matches pattern, then select style style-key (i.e. file `` `style-key.ssh' ``).

`** pattern style-key'

if the result of a call to `file(1)` matches pattern, then select style style-key. Note that only the first two fields of the answer of `file(1)` are considered. E.g., in the following case

```
gargantua $ file a2ps
a2ps:   ELF 32-bit MSB executable SPARC Version 1,\
        dynamically linked, stripped
```

`ELF32-bit' will be matched against pattern.

The special style-key `binary' tells `a2ps` to consider that the file should not be printed, and will be ignored, unless option `--print-anyway' is given.

If a style name can't be found, the plain style is used.

Two things are to retain from this:

1. `a2ps` won't guess anything for a file given through the standard input.
2. if `file` is wrong on some files, `a2ps` may use bad style sheets. In this case, do try option `--guess', compare it with the output of `file`, and if the culprit is `file`, go and complain to your system administrator :-), or fix it by defining your own filename pattern matching rules.

Encodings

`a2ps` is trying to support the various usual encodings that its users use. This chapter presents what an encoding is, how the encodings support is handled within `a2ps`, and some encodings it supports.

What is an Encoding

This section is actually taken from the web pages of Alis Technologies inc.

Document encoding is the most important but also the most sensitive and explosive topic in Internet internationalization. It is an essential factor since most of the information distributed over the Internet is in text format. But the history of the Internet is such that the predominant - and in some cases the only possible - encoding is the very limited ASCII, which can represent only a handful of languages, only three of which are used to any great extent: English, Indonesian and Swahili.

All the other languages, spoken by more than 90% of the world's population, must fall back on other character sets. And there is a plethora of them, created over the years to satisfy writing constraints and constantly changing technological limitations. The ISO international character set registry contains only a small fraction; IBM's character registry is over three centimeters thick; Microsoft and Apple each have a bunch of their own, as do other software manufacturers and editors.

The problem is not that there are too few but rather too many choices, at least whenever Internet standards allow them. And the surplus is a real problem; if every Arabic user made his own choice among the three dozen or so codes available for this language, there is little likelihood that his "neighbor" would do the same and that they would thus be able to understand each other. This example is rather extreme, but it does illustrate the importance of standards in the area of internationalization. For a group of users sharing the same language to be able to communicate,

1. the code used in the shared document must always be identified (labeling)
2. they must agree on a small number of codes - only one, if possible (standards);
3. their software must recognize and process all codes (versatility)

Certain character sets stand out either because of their status as an official national or international standard, or simply because of their widespread use.

First off, there is the ISO 8859 standards series that standardize a dozen character sets that are useful for a large number of languages using the Latin, Cyrillic, Arabic, Greek and Hebrew alphabets. These standards have a limited range of application (8 bits per character, a maximum of 190 characters, no combining) but where they suffice (as they do for 10 of the 20 most widely used languages), they should be used on the Internet in preference to other codes. For all other languages, national standards should preferably be

chosen or, if none are available, a well-known and widely-used code should be the second choice.

Even when we limit ourselves to the most widely used standards, the overabundance remains considerable and this significantly complicates life for truly international software developers and users of several languages, especially when such languages can only be represented by a single code. It was to resolve this problem that both Unicode and the ISO 10646 International standard were created. Two standards? Oh no! Their designers soon realized the problem and were able to cooperate to the extent of making the character set repertoires and coding identical.

ISO 10646 (and Unicode) contain over 30,000 characters capable of representing most of the living languages within a single code. All of these characters, except for the *Han* (Chinese characters also used in Japanese and Korean), have a name. And there is still room to encode the missing languages as soon as enough of the necessary research is done. Unicode can be used to represent several languages, using different alphabets, within the same electronic document.

Encoding Files

The support of the encodings in `a2ps` is completely taken out of the code. That is to say, adding, removing or changing anything in its support for an encoding does not require programming, nor even being a programmer.

See section What is an Encoding, if you want to know more about this.

Encoding Map File

See section Map Files, for a description of the map files.

The meaningful lines of the `` `encoding.map' `` file have the form:

```
alias      key
iso-8859-1 latin1
latin1     latin1
l1         latin1
```

where

alias

specifies any name under which the encoding may be used. It influences the option `--encoding', but also the encodings dynamically required, as for instance in the `mail` style sheet (support for MIME).

When encoding is asked, the lower case version of encoding must be equal to alias.

key

specifies the prefix of the file describing the encoding (`` `key.edf' ``, section Encoding Description Files).

Encoding Description Files

The encoding description file describing the encoding key is named `key.edf'. It is subject to the same rules as any other a2ps file:

- please make the name portable: alpha-numerical, at most 8 characters,
- empty lines and lines starting by `#' are ignored.

The entries are

`Name:'

Specifies the full name of the encoding. Please, try to use the official name if there is one.

```
Name: ISO-8859-1
```

`Documentation/EndDocumentation'

Introduces the documentation on the encoding (see section Documentation Format). Typical informations expected are the other important names this encoding has, and the languages it covers.

```
Documentation
Also known as ISO Latin 1, or Latin 1.  It is a superset
of ASCII, and covers most West-European languages.
EndDocumentation
```

`Substitute:'

Introduces a font substitution. The most common fonts (e.g., Courier, Times-Roman...) do not support many encodings (for instance it does not support Latin 2). To avoid that Latin 2 users have to replace everywhere calls to Courier, a2ps allows to specify that whenever a font is called in an encoding, then another font should be used.

For instance in `latin2.edf' one can read:

```
# Fonts from Ogonkify offer full support of ISO Latin 2
Substitute: Courier               Courier-Ogonki
Substitute: Courier-Bold          Courier-Bold-Ogonki
Substitute: Courier-BoldOblique   Courier-BoldOblique-Ogonki
Substitute: Courier-Oblique       Courier-Oblique-Ogonki
```

`Default:'

Introduces the name of the font that should be used when a font (not substituted as per the previous item) is called but provides to poor a support of the encoding. The Courier equivalent is the best choice.

```
Default: Courier-Ogonki
```

`Vector:'

Introduces the PostScript encoding vector, that is a list of the 256 PostScript names of the characters. Note that only the printable characters are named in PostScript (e.g., `bell' in ASCII (^G) should not be named). The special name `.notdef' is to be used when the character is not printable.

Warning. Make sure to use real, official, PostScript names. Using names such as `c123' may be sign you use unusual names. On the other hand PostScript names such as `afii8879' are common.

Some Encodings

Most of the following information is a courtesy of Alis Technologies inc. and of Roman Czyborra's page about The ISO 8859 Alphabet Soup. See section What is an Encoding presents an instructive presentation of the encodings.

The known encodings are: Encoding: **ASCII** *(`ascii.edf')*

US-ASCII.

Encoding: **CP1250** *(`cp1250.edf')*

Microsoft's CP-1250 encoding (aka CeP).

Encoding: **HPRoman** *(`hp.edf')*

The 8 bits Roman encoding for HP.

Encoding: **IBMPC** *(`ibmpc.edf')*

Several characters may be missing, especially Greek letters and some mathematical symbols.

Encoding: **ISO-8859-1** *(`latin1.edf')*

The ISO-8859-1 character set, often simply referred to as Latin 1, can represent most Western European languages including: Albanian, Catalan, Danish, Dutch, English, Faroese, Finnish, French, Galician, German, Irish, Icelandic, Italian, Norwegian, Portuguese, Spanish and Swedish.

Encoding: **ISO-8859-10** *(`latin6.edf')*

Latin 6 (or ISO-8859-10) adds the last letters from Greenlandic and Lapp which were missing in Latin 4, and thereby covers all Scandinavia.

Support is provided thanks to Ogonkify.

Encoding: **ISO-8859-2** *(`latin2.edf')*

The Latin 2 character set supports the Slavic languages of Central Europe which use the Latin alphabet. The ISO-8859-2 set is used for the following languages: Czech, Croat, German, Hungarian, Polish, Romanian, Slovak and Slovenian.

Support is provided thanks to Ogonkify.

Encoding: **ISO-8859-3** *(`latin3.edf')*

This character set is used for Esperanto, Galician, Maltese and Turkish.

Support is provided thanks to Ogonkify.

Encoding: **ISO-8859-4** *(`latin4.edf')*

Some letters were added to the ISO-8859-4 to support languages such as Estonian, Latvian and Lithuar It is an incomplete precursor of the Latin 6 set.

Support is provided thanks to Ogonkify.

Encoding: **ISO-8859-5** *(`iso5.edf')*

The ISO-8859-5 set is used for various forms of the Cyrillic alphabet. It supports Bulgarian, Byelorussian, Macedonian, Serbian and Ukrainian.

The Cyrillic alphabet was created by St. Cyril in the 9th century from the upper case letters of the Greek alphabet. The more ancient Glagolithic (from the ancient Slav glagol, which means "word"), was created for certain dialects from the lower case Greek letters. These characters are still used by Dalmatian Catholics in their liturgical books. The kings of France were sworn in at Reims using a Gospel in Glagolithic characters attributed to St. Jerome.

Note that Russians seem to prefer the KOI8-R character set to the ISO set for computer purposes. KOI8-R is composed using the lower half (the first 128 characters) of the corresponding American ASCII character set.

Encoding: **ISO-8859-9** *(`latin5.edf')*

The ISO 8859-9 set, or Latin 5, replaces the rarely used Icelandic letters from Latin 1 with Turkish letters.

Support is provided thanks to Ogonkify.

Encoding: **KOI8** *(`koi8.edf')*

KOI-8 (+Ëë) is a subset of ISO-IR-111 that can be used in Serbia, Belarus etc.

Encoding: **Macintosh** *(`mac.edf')*

For the Macintosh encoding. The support is not sufficient, and a lot of characters may be missing at the end of the job (especially Greek letters).

Pretty Printing

The main feature of `a2ps` is its pretty-printing capabilities. Two different levels of pretty printing can be reached:

- basic (normal highlight level) in which what you print is what you wrote.
- string (heavy highlight level), in which in general, some keywords are replaced by a Symbol character which best represents them. For instance, in most languages `<=' and `>=' will be replaced by the corresponding single character from the font Symbol.

Note that the difference is up to the author of the style sheet.

Syntactic limits

`a2ps` is *not* a powerful syntactic pretty-printer: it just handles lexical structures, i.e., if in your favorite language

```
IF IF == THEN THEN THEN := ELSE ELSE ELSE := IF
```

is legal, then `a2ps` is not the tool you need. Indeed `a2ps` just looks for some keywords, or some sequences.

Known Style Sheets

Style Sheet: **68000** *(`68000.ssh')*

Style Sheet: **a2ps configuration file** *(`a2psrc.ssh')*

Style Sheet: **a2ps style sheet** *(`ssh.ssh')*

-g substitutes the LaTeX symbols.

Style Sheet: **Ada** *(`ada.ssh')*

Style Sheet: **Bourne Shell** *(`sh.ssh')*

Some classical program names, or builtin, are highlighted in the second level of pretty-printing.

Style Sheet: **C** *(`c.ssh')*

This style does not high light the function definitions. Another style which high lights them, GNUish C, is provided (gnuc.ssh). It works only if you respect some syntactic conventions.

Style Sheet: **C Shell** *(`csh.ssh')*

Written by Jim Diamond. Some classical program names, and/or builtins, are highlighted in the second level of pretty-printing.

Style Sheet: **C++** *(`cpp.ssh')*

Style Sheet: **CAML** *(`caml.ssh')*

This style should also suit other versions of ML (caml light, SML etc.)

Style Sheet: **ChangeLog** *(`chlog.ssh')*

This style covers the usual ChangeLog files.

Style Sheet: **Claire** *(`claire.ssh')*

Claire is a high-level functional and object-oriented language with advanced rule processing capabilities. It is intended to allow the programmer to express complex algorithms with fewer lines and in an elegant and readable manner.

To provide a high degree of expressivity, CLAIRE uses:

- A very rich type system including type intervals and second-order types (with dual static/dynamic typing),
- Parametric classes and methods,
- An object-oriented logic with set extensions,
- Dynamic versioning that supports easy exploration of search spaces.

To achieve its goal of readability, CLAIRE uses

- set-based programming with an intuitive syntax,
- simple-minded object-oriented programming,
- truly polymorphic and parametric functional programming,
- a powerful-yet-readable extension of DATALOG to express logical conditions,
- an entity-relation approach with explicit relations, inverses, unknown values and relational
- operations.

More information on claire can be found on claire home page.

Style Sheet: **Common Lisp** *(`clisp.ssh')*

Written by Juliusz Chroboczek.

Style Sheet: **Coq Vernacular** *(`coqv.ssh')*

This style is devoted to the Coq v 5.10 vernacular language.

Style Sheet: **Eiffel** *(`eiffel.ssh')*

Style Sheet: **Emacs Lisp** *(`elisp.ssh')*

Style Sheet: **Encapsulated PostScript** *(`eps.ssh')*

Illegal PostScript operators are highlighted as Errors.

Style Sheet: **Fortran** *(`fortran.ssh')*

Written by Denis Girou.

Style Sheet: **GNUish C** *(`gnuc.ssh')*

Declaration of functions are highlighted _only_ if you start the function name in the first column, and it is followed by an opening parenthesis. In other words, if you write

```
int main (void)
```

it won't work. Write:

```
int
main (void)
```

Style Sheet: **idl** *(`idl.ssh')*

Written by Robert S. Mallozzi. Style sheet for IDL (Interactive Data Language). http://www.rsinc.com

Style Sheet: **InstallShield 5** *(`is5rul.ssh')*

Written by Alex. InstallShield5 _TM_ RUL script.

Style Sheet: **Java** *(`java.ssh')*

Documentation comments are mapped to strong comments, and any other comment is plain comment.

Style Sheet: **LACE** *(`lace.ssh')*

This is meant for the Eiffel equivalent of the Makefiles.

Style Sheet: **Lex** *(`lex.ssh')*

In addition to the C constructs, it highlights the declaration of states, and some special `%' commands.

Style Sheet: **Mail Folder** *(`mail.ssh')*

To use from elm and others, it is better to specify -g -Email, since the file sent to printer is no longer truly a mailfolder. This style also suits to news. --strip options are also useful (they strip "useless" headers).

Whenever the changes of encoding are clear, a2ps sets itself the encoding for the parts concerned.

Tag 1 is the subject, and Tag 2 the author of the mail/news.

Note: This style sheet is _very_ difficult to write. Please don't report behavior you don't like. Just send me improvements, or write a Bison parser for mails.

Style Sheet: **Makefile** *(`make.ssh')*

Special tokens, and non terminal declarations are highlighted.

Style Sheet: **MATLAB 4** *(`matlab4.ssh')*

Written by Marco De la Cruz. Note that comments in the code should have a space after the %

Style Sheet: **Modula 2** *(`modula2.ssh')*

Written by Peter Bartke.

Style Sheet: **Modula 3** *(`modula3.ssh')*

Style Sheet: **o2c** *(`o2c.ssh')*

Style Sheet: **Oberon** *(`oberon.ssh')*

Style Sheet: **Objective C** *(`objc.ssh')*

Written by Paul Shum.

Style Sheet: **Octave** *(`octave.ssh')*

Written by C.P. Earls.

Style Sheet: **Oracle parameter file** *(`initora.ssh')*

Written by Pierre Mareschal. For init.ora parameter files.

Style Sheet: **Oracle PL/SQL** *(`plsql.ssh')*

Written by Pierre Mareschal. This style is to be checked.

Style Sheet: **Oracle SQL** *(`sql.ssh')*

Written by Pierre Mareschal. a2ps-sql Pretty Printer Version 1.0.0 beta - 18-MAR-97 For comments, support for -- /*..*/ and //. This style is to be checked.

Style Sheet: **Oracle SQL-PL/SQL-SQL*Plus** *(`oracle.ssh')*

Written by Pierre Mareschal. 18-MAR-97 For comments, support for -- /*..*/ and //. This style is to be checked.

Style Sheet: **Pascal** *(`pascal.ssh')*

The standard Pascal is covered by this style. But some extension have been added too, hence modern Pascal programs should be correctly handled. Heavy highlighting maps mathematical symbols to their typographic equivalents.

Style Sheet: **Perl** *(`perl.ssh')*

Written by Denis Girou.

Style Sheet: **Perl (Old)** *(`oldperl.ssh')*

Written by Denis Girou.

Style Sheet: **PostScript** *(`ps.ssh')*

Only some keywords are high lighted, because otherwise listings are quickly becoming a big bold spot.

Style Sheet: **PostScript Printer Description** *(`ppd.ssh')*

The support is not yet complete. Tag 1 is the printer ModelName.

Style Sheet: **PreScript** *(`pre.ssh')*

This style defines commands in the canonic syntax of a2ps. It is meant to be used either as an input language, and to highlight the table of contents etc.

It can be a good choice of destination language for people who want to produce text to print (e.g. pretty-printing, automated documentation etc.) but who definitely do not want to learn PostScript, nor to require the use of LaTeX.

Style Sheet: **PreTeX** *(`pretex.ssh')*

This style sheets provides LaTeX-like commands to format text. It is an alternative to the PreScript style sheet, in which formating commands are specified in a more a2ps related syntax.

It provides by the use of LaTeX like commands, a way to describe the pages that this program should produce.

Style Sheet: **Prolog** *(`prolog.ssh')*

Under construction.

Style Sheet: **Promela** *(`promela.ssh')*

There is no way for this program to highlight send and receive primitives.

Style Sheet: **Python** *(`python.ssh')*

Style Sheet: **Reference Card** *(`card.ssh')*

This style sheet is meant to process help messages generated by Unix applications. It highlights the options (-short or --long), and their arguments. Normal use of this style sheet is through the shell script card (part of the a2ps package), but a typical hand-driven use is:

```
program --help | a2ps -Ecard
```

Style Sheet: **Sather** *(`sather.ssh')*

Style Sheet: **Scheme** *(`scheme.ssh')*

This style sheet is looking for a maintainer and/or comments.

Style Sheet: **SDL-88** *(`sdl88.ssh')*

Written by Jean-Philippe Cottin. --strip-level=2 is very useful: it cancels the graphical information left by graphic editors. Only the pure specification is then printed.

Style Sheet: **SQL 92** *(`sql92.ssh')*

Written by Pierre Mareschal. 18-MAR-97 This style is to be checked.

Style Sheet: **Symbols** *(`symbols.ssh')*

This style sheet should be a precursor for any style sheet which uses LaTeX like symbols.

Style Sheet: **TeX** *(`tex.ssh')*

Written by Denis Girou. This is the style for (La)TeX files. It's mainly useful for people who develop (La)TeX packages. With -g, common mathematical symbols are represented graphically.

Style Sheet: **Texinfo** *(`texinfo.ssh')*

Definitely being built. With the option -g, the nodes will be printed on separated pages which title is the name of the node.

Style Sheet: **TeXScript** *(`texscript.ssh')*

TeXScript is the new name of what used to be called PreScript. New PreScript has pure a2ps names, PreTeX has pure TeX names, and TeXScript mixes both.

Style Sheet: **tk** *(`tk.ssh')*

Since everything, or almost, is a string, what is printed is not always what you would like.

Style Sheet: **Tool Command Language** *(`tcl.ssh')*

Since everything, or almost, is a string, what is printed is not always what you would like.

Style Sheet: **Unity** *(`unity.ssh')*

Written by Jean-Philippe Cottin. The graphic conversion of the symbols (option -g) is nice.

Style Sheet: **VERILOG** *(`verilog.ssh')*

Written by Edward Arthur. This style is devoted to the VERILOG hardware description language.

Style Sheet: **VHDL** *(`vhdl.ssh')*

Written by Thomas Parmelan. Non-textual operators are not highlighted. Some logical operators are printed as graphical symbols in the second level of pretty-printing.

Style Sheet: **VRML** *(`vrml.ssh')*

Written by Nadine Richard. According to Grammar Definition Version 2.0 ISO/IEC CD 14772

Style Sheet: **Yacc** *(`yacc.ssh')*

Special tokens, and non terminal declarations are highlighted.

Style Sheet: **zsh** *(`zsh.ssh')*

Type Setting Style Sheets

This section presents a few style sheets that define page description languages (compared to most other style sheet meant to pretty print source files).

Symbol

The style sheet `Symbol` introduces easy to type keywords to obtain the special characters of the PostScript font `Symbol`. The keywords are named to provide a LaTeX taste. These keywords are also the names used when designing a style sheet, hence to get the full list, see section A Bit of Syntax.

If you want to know the correspondence, it is suggested to print the style sheet file of `Symbol`:

```
a2ps -g symbol.ssh
```

PreScript

`PreScript` has been designed in conjunction with `a2ps`. Since bold sequences, special characters etc. were implemented in `a2ps`, we thought it would be good to allow direct access to those features: `PreScript` became an input language for `a2ps`, where special font treatments are specified in an `ssh` syntax (see section Style Sheets Implementation).

The main advantages for using `PreScript` are:

- it is fairly simple,
- `a2ps` is small and easy to install, hence it is available on every UNIX platform.

It can be a good candidate for generation of PostScript output (syntactic pretty-printers, generation of various reports etc.).

Syntax

Every command name begins with a backslash (`\'). If the command uses an argument, it is given between curly braces with no spaces between the command name and the argument.

The main limit on `PreScript` is that no command can be used inside another command. For instance the following line will be badly interpreted by `a2ps`:

```
\Keyword{Problems using \keyword{recursive \copyright} calls}
```

The correct way to write this in `PreScript` is

```
\Keyword{Problems using} \keyword{recursive} \copyright \Keyword{calls}.
```

Everything from an unquoted % to the end of line is ignored (comments).

PreScript Commands

These commands required arguments.

`\keyword{text}'

`\Keyword{text}'

Highlight lightly/strongly the given text. Should be used only for a couple of adjacent words.

`\comment{text}'

`\Comment{text}'

The text is given a special face. The text may be removed if option `--strip' is used.

`\label{text}'

`\Label{text}'

text should be considered as a definition, or an important point in the structure of the whole text.

`\string{text}'

Write text with string's face (e.g., in font Times).

`\error{text}'

Write text with error's face (generally a very different face, so that you see immediately).

`\symbol{text}'

text is written in the PostScript symbol font. This feature is not compatible with LaTeX. It is recommended, when possible, to use the special keywords denoting symbols, which are compatible with LaTeX (see section Symbol).

`\header{text}'

`\footer{text}'

Use text as header (footer) for the current page. If several headers or footers are defined on the same page, the last one is taken into account.

`\encoding{key}'

Change dynamically the current encoding. After this command, the text is printed using the encoding corresponding to key.

Examples

`PreScript` and `a2ps` can be used for one-the-fly formating. For instance, on the `` `passwd' `` file:

```
ypcat passwd |
 awk -F: \
   '{print "\Keyword{" $5 "} (" $1 ") \rightarrow\keyword{" $7 "}"}'\
 | a2ps -Epre -P
```

PreTeX

The aim of the PreTeX style sheet is to provide something similar to `PreScript`, but with a more LaTeX like syntax.

Special characters

`$' is ignored in `PreTeX` for compatibility with LaTeX, and `%' introduces a comment. Hence they are the only symbols which have to be quoted by a `\'. The following characters should also be quoted to produce good LaTeX files, but are accepted by `PreScript`: `_', `&', `#'.

Note that *inside a command*, like `\textbf`, the quotation mechanism does not work in `PreScript` (`\textrm{#$%}` writes `#$%') though LaTeX still requires quotation. Hence whenever special characters or symbols are introduced, they should be at the outer most level.

PreTeX Commands

These commands required arguments.

`\section{Title}'

`\subsection{Title}'

`\subsubsection{Title}.'

Used to specify the title of a section, subsection or subsubsection.

`\textbf{text}'

`\textit{text}'

`\textbi{text}'

`\textrm{text}'

write text in bold, italic, bold-italic, Times. Default font is Courier.

`\textsy{text}'

text is written in the PostScript symbol font. This feature is not compatible with LaTeX. It is recommended, when possible, to use the special keywords denoting symbols, which are compatible with LaTeX (See the style sheet `Symbol`).

`\header{text}'

`\footer{text}'

Use text as header (footer) for the current page. If several headers or footers are defined on the same page, the last one is taken into account.

`\verb+text+'

Quote text so that no special sequence will be interpreted. In `\verb+quoted string+' `+' can be any symbol in `+', `!', `|', `#', `='.

`\begin{document}'

`\end{document}'

`\begin{itemize}'

`\end{itemize}'

`\begin{enumerate}'

`\end{enumerate}'

`\begin{description}'

`\end{description}'

These commands are legal in LaTeX but have no sense in PreTeX. Hence there are simply ignored and not printed (if immediately followed by an end-of-line).

Differences with LaTeX

The following symbols, inherited from the style sheet `Symbol`, are not supported by LaTeX:

`\Alpha', `\apple', `\Beta', `\carriagereturn', `\Chi', `\Epsilon', `\Eta', `\florin', `\Iota', `\Kappa', `\Mu', `\Nu', `\Omicron', `\omicron', `\radicalex', `\register', `\Rho', `\suchthat', `\Tau', `\therefore', `\trademark', `\varUpsilon', `\Zeta'.

LaTeX is more demanding about special symbols. Most of them must be in so-called math mode, which means that the command must be inside `$' signs. For instance, though

```
If \forall x \in E, x \in F then E \subseteq F.
```

is perfectly legal in PreTeX, it should be written

```
If $\forall x \in E, x \in F$ then $E \subseteq F$.
```

for LaTeX. Since in PreTeX every `$' is discarded (unless quoted by a `\'), the second form is also admitted.

TeXScript

`TeXScript` is a replacement of the old version of `PreScript`: it combines both the `a2ps`-like and the LaTeX-like syntaxes through inheritance of both `PreScript` and `PreTeX`.

In addition it provides commands meant to ease processing of file for `a2ps` by LaTeX.

Everything between `%%TeXScript:skip' and `%%TeXScript:piks' will be ignored in `TeXScript`, so that there can be inserted command definitions for LaTeX exclusively.

The commands `\textbi' (for bold-italic) and `\textsy' (for symbol) do not exist in LaTeX. They should be defined in the preamble:

```
%%TeXScript:skip
\newcommand{\textbi}[1]{\textbf{\textit{#1}}}
\newcommand{\textsy}[1]{#1}
%%TeXScript:piks
```

There is no way in TeXScript to get an automatic numbering. There is no equivalent to the LaTeX environment `enumerate`. But every command beginning by `\text` is doubled by a command beginning by `\magic'. `a2ps` behaves the same way on both families of commands. Hence, if one specifies that arguments of those functions should be ignored in the preamble of the LaTeX document, the numbering is emulated. For instance

```
\begin{enumerate}
\magicbf{1.}\item First line
\magicbf{2.}\item Second line
\end{enumerate}
```

will be treated the same way both in TeXScript and LaTeX.

`\header' and `\footer', are not understood by LaTeX.

Faces

A face is an attribute given to a piece of text, which specifies how it should look like. Since `a2ps` is devoted to pretty-printing source files, the faces it uses are related to the syntactic entities that can be encountered in a file.

The faces `a2ps` uses are:

`Plain'

This corresponds to the text body.

`Keyword'

`Keyword_strong'

These are related to the keywords that may appear in a text.

`Comment'

`Comment_strong'

These are related to comments in the text. Remember that comments should be considered as non essential ("*Aaaeaaarg*" says the programmer); indeed, the user might suppress the comments thanks (?) to the option `--strip-level'. Hence, **never** use these faces just because you think they look better on, say, strings.

`Label'

`Label_strong'

These are used when a point of extreme importance, or a sectioning point, is met. Typically, functions declarations etc.

`String'

Used mainly for string and character literals.

`Error'

Used to underline the presence of an error. For instance in Encapsulated PostScript, some PostScript operators are forbidden: they are underlined as errors.

Actually, there is also the face `Symbol', but this one is particular: it is not legal changing its font.

Style sheets semantics

`a2ps` pretty prints a source file thanks to style sheets, one per language. In the following is described how the style sheets are defined. You may skip this section if you don't care how `a2ps` does this, and if you don't expect to implement new styles.

Name and key

Every style sheet has both a key, and a name. The name can be clean and beautiful, with any character you might want. The key is in fact the prefix part of the file name, and is alpha-numerical, lower case, and less than 8 characters long.

Anywhere `a2ps` needs to recognize a style sheet by a name, **it uses the key** (in the `` `sheets.map' `` file, with the option `-E', etc.).

As an example, C++ is implemented in a file called `` `cpp.ssh' ``, in which the name is declared to be `C++'.

The rationale is that not every system accepts any character in the file name (e.g., no `+' in MS-DOS). Moreover, it allows to make symbolic links on the ssh files (e.g., `ln -s cpp.ssh c++.ssh' let's you use `-E c++').

Comments

ssh files can include the name of its author, a version number, a documentation note and a requirement on the version of `a2ps`. For instance, if a style sheet requires `a2ps` version 4.9.6, then `a2ps` version 4.9.5 will reject it.

Alphabets

`a2ps` needs to know the beginning and the end of a word, especially keywords. Hence it needs two alphabets: the first one specifying by which letters an identifier can begin, and the second one for the rest of the word. If you prefer, a keyword starts with a character belonging to the first alphabet, and a character not pertaining to the second is a separator.

Case sensitivity

If the style is case insensitive, then matching is case insensitive (keywords, operators and sequences).

P-Rules

A P-rule (Pretty printing rule), or rule for short, is a structure which consists of two items:

lhs

left-hand side

its source string, with which the source file is compared;

rhs

right hand side

a list of faced strings which will replace the text matched in the pretty-printed output. A faced string is composed of

a string, or a reference to a part of the source string (see section 'Back-reference Operator' in Regex manual)

the face to use to print it

Just a short example: `(foo, bar, Keyword_strong)' as a rule means that every input occurrence of `foo' will be replaced by `bar', written with the `Keyword_strong` face.

If the destination string is empty, then `a2ps` will use the source string. This is different from giving the source string as a destination string if the case is different. An example will make it fairly clear.

Let `foobar` be a case insensitive style sheet including the rules `(foo, "", Keyword)' and `(bar, bar, Keyword)'. Then, on the input `FOO BAR', `a2ps` will produce `FOO bar' in `Keyword`.

`a2ps` implements two different ways to match a string. The difference comes from that some keywords are sensitive to the delimiters around them (such as `unsigned' and `int' in `C`, which are definitely not the same thing as `unsignedint'), and others not (in `C`, `!=' is "different from" both in `a != b' and `a!=b').

The first ones are called keywords in `a2ps` jargon, and the seconds are operators. Operators are matched anywhere they appear, while keywords need to have separators around them (see section Alphabets).

Let us give a more complicated example: that of the `Yacc` rules. A rule in `Yacc` is of the form:

```
a_rule : part1 part2 ;
```

Suppose you want to highlight these rules. To recognize them, you will write a regular expression specifying that:

1. it must start at the beginning of the line,
2. then there is string composed of symbols, which is what you want to highlight,
3. and a colon, which can be preceded by blank characters.

The regexp you want is: `/^[a-zA-Z0-9_]*[\t ]*:/'. But with the rule `/^[a-zA-Z0-9_]*[\t]*:/, "", Label_strong' the blanks and the colon are highlighted too. Hence you need to specify some parts in the regexp (see section 'Back-reference Operator' in Regex manual), and use a longer list of destination strings. The correct rule is

```
(/^\\([a-zA-Z0-9_]*\\)\\([\t ]*:\\)/, \1 Label_strong, \2 Plain)
```

Since it is a bit painful to read, regexps can be spread upon several lines. It is strongly suggested to break them by groups, and to document the group:

```
(/^\\([a-zA-Z0-9_]*\\)/    # \1. Name of the rule
 /\\([\t ]*:\\)/           # \2. Trailing space and colon
 \1 Label_strong, \2 Plain)
```

Sequences

A sequence is a string between two markers, along with a list of exceptions. A marker is a fixed string. Typical examples are comments, string (with usually `"' as opening and closing markers, and `\\' and `\"' as exceptions) etc. Three faces are used: one for the initial marker, one for the core of the sequence, and a last one for the final maker.

Optional entries

There are two levels of pretty-printing encoded in the style sheets. By default, `a2ps` uses the first level, called normal, unless the option `-g' is specified, in which case, heavy highlighting is invoked, i.e., optional keywords, operators and sequences are considered.

Style Sheets Implementation

A Bit of Syntax

Here are the lexical rules underlying the style sheet language:

- the separators are white space, form feed, new line, and tab.
- `#' introduces a comment, ended at the end of the line.

- special characters are the separators, plus `#', `"', `,', `(', `)', `+' and `/'. Any other character is a re character.
- the list of the structuring keywords is

  `alphabet`, `alphabets`, `are`, `case`, `documentation`, `end`, `exceptions`, `first`, `in`, `insensitive`, `is`, `keywords`, `operators`, `optional`, `second`, `sensitive`, `sequences`, `style`
- the list of the keywords designating faces is

  `Comment`, `Comment_strong`, `Encoding`, `Error`, `Index1`, `Index2`, `Index3`, `Index4`, `Invisible`, `Keyword`, `Keyword_strong`, `Label`, `Label_strong`, `Plain`, `String`, `Symbol`, `Tag1`, `Tag2`, `Tag3`, `Tag4`
- the list of keywords designating special sequences is

  `C-char`, `C-string`
- the list of keywords representing special characters is

  `---`, `\Alpha`, `\Beta`, `\Chi`, `\Delta`, `\Downarrow`, `\Epsilon`, `\Eta`, `\Gamma`, `\Im`, `\Iota`, `\Kappa`, `\Lambda`, `\Leftarrow`, `\Leftrightarrow`, `\Mu`, `\Nu`, `\Omega`, `\Omicron`, `\Phi`, `\Pi`, `\Psi`, `\Re`, `\Rho`, `\Rightarrow`, `\Sigma`, `\Tau`, `\Theta`, `\Uparrow`, `\Upsilon`, `\Xi`, `\Zeta`, `\aleph`, `\alpha`, `\angle`, `\approx`, `\beta`, `\bullet`, `\cap`, `\carriagereturn`, `\cdot`, `\chi`, `\circ`, `\clubsuit`, `\cong`, `\copyright`, `\cup`, `\delta`, `\diamondsuit`, `\div`, `\downarrow`, `\emptyset`, `\epsilon`, `\equiv`, `\eta`, `\exists`, `\florin`, `\forall`, `\gamma`, `\geq`, `\heartsuit`, `\in`, `\infty`, `\int`, `\iota`, `\kappa`, `\lambda`, `\langle`, `\lceil`, `\ldots`, `\leftarrow`, `\leftrightarrow`, `\leq`, `\lfloor`, `\mu`, `\nabla`, `\neq`, `\not`, `\not\in`, `\not\subset`, `\nu`, `\omega`, `\omicron`, `\oplus`, `\otimes`, `\partial`, `\perp`, `\phi`, `\pi`, `\pm`, `\prime`, `\prod`, `\propto`, `\psi`, `\radicalex`, `\rangle`, `\rceil`, `\register`, `\rfloor`, `\rho`, `\rightarrow`, `\sigma`, `\sim`, `\spadesuit`, `\subset`, `\subseteq`, `\suchthat`, `\sum`, `\supset`, `\supseteq`, `\surd`, `\tau`, `\theta`, `\therefore`, `\times`, `\trademark`, `\uparrow`, `\upsilon`, `\varUpsilon`, `\varcopyright`, `\vardiamondsuit`, `\varphi`, `\varpi`, `\varregister`, `\varsigma`, `\vartheta`, `\vartrademark`, `\vee`, `\wedge`, `\wp`, `\xi`, `\zeta`
- a string starts and finishes with `"', and may contain anything. Regular `C` escaping mechanism is used.
- a regular expression starts and finishes with `/', and may contain anything. Regular `C` escaping mechanism is used. Regexps can be split in several parts, *à la* C strings (i.e., `/part 1/ /part 2/').
- any sequence of regular characters which is not a keyword, is a string (consider this as a shortcut, avoiding extraneous `"').

Style Sheet Header

The definition of the name of the style sheet is:

```
style name is
```

```
  # body of the style sheet
end style
```

The following constructions are optional:

`version`

To define the version number of the style sheet

```
version is version-number
```

`written`

To define the author(s).

```
written by authors
```

Giving your email is useful for bug reports about style sheets.

```
written by "Some Body <Some.Body@some.whe.re>"
```

`requires`

To specify the version of `a2ps` it requires. `a2ps` won't accept a file which requires a higher version number than its own.

```
requires a2ps a2ps-version-number
```

`documentation`

To leave extra comments people should read.

```
documentation is
   strings
end documentation
```

strings may be a list of strings, without comas, in which case new lines are automatically inserted between each item. See section Documentation Format for details on the format.

Please, write useful comments, not `This style is devoted to C files', since the name is here for that, nor `Report errors to mail@me.somewhere', since `written by` is there for that.

```
documentation is
    "Not all the keywords are used, to avoid too much"
    "bolding. Heavy highlighting (code(-g)code), covers"
    "the whole language."
end documentation
```

Syntax of the Words

There are two things `a2ps` needs to know: what is symbol consistent, and whether the style is case insensitive.

`alphabet`

To define two different alphabets, use

```
first alphabet is string
second alphabet is string
```

If both are identical, you may use the shortcut

```
alphabets are string
```

The default alphabets are

```
first alphabet is
  "abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ_"
second alphabet is
"abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ_\
0123456789"
```

Note that it is on purpose that no characters interval are used.

`case`

```
case insensitive        # e.g., C, C++ etc.
case sensitive          # e.g., Perl, Sather, Java etc.
```

The default is `case insensitive`.

Inheriting from Other Style Sheets

It is possible to extend an existing style. The syntax is:

```
ancestors are
   ancestor_1[, ancestor_2...]
end ancestors
```

where ancestor1 etc. are style sheet keys.

For semantics, the rules are the following:

- the ancestors are read in order;
- the definition of the current style is read last;
- it is always the last item read which wins (last defined alphabets, case sensitivity, keywords, operators and sequences).

As an example, both `C++` and `Objective C` style sheets extend the `C` style sheet:

```
style "Objective C" is
#[...]
ancestors are
```

```
   c
end ancestors
#[...]
end style
```

To the biggest surprise of the author, mutually dependent style sheets do work!

Syntax for the P-Rules

See section P-Rules, for the definition of P-rule.

Because of various short cuts, there are many ways to declare a rule:

```
rules     ::= rule_1 `,' rule_2...
rule      ::= `(' lhs rhs `)'
            | lhs srhs ;
lhs       ::= string | regex ;
rhs       ::= srhs `,' ...
srhs      ::= latex-keyword | expansion face
expansion ::= string | `\'num | <nothing>;
face      ::= face-keyword | <nothing>;
```

The rules are the following:

- If the left-hand side (lhs) is a regular expression, then it is compiled with the following syntax bits:

  ```
  #define RE_SYNTAX_A2PS \
     (RE_SYNTAX_EMACS | RE_CHAR_CLASSES | RE_INTERVALS)
  ```

  See section 'Regular Expression Syntax' in Regex manual, for detailed description of the regular expressions used.
- If no expansion is specified, then the matched string is used. For instance `(/fo*/, NULL, Keyword)' applied on the source `"fooooo"' produces `"fooooo"' in `Keyword`.
- If no face is given, then
  - if the context defines the default face, then this face is used;
  - if no default face is given, `PLAIN` is used.

Declaring the keywords and the operators

Basically, keywords and operators are lists of rules. The syntax is:

```
keywords are
  rules
end keywords
```

or

```
keywords in face-keyword are
  rules
end keywords
```

in which case the default face is set to face-keyword.

As an example:

```
keywords in Keyword_strong are
  /foo*/,
  "bar" "BAR" Keyword,
  -> \rightarrow
end keywords
```

is valid.

The syntax for the operators is the same, and both constructs can be qualified with an `optional` flag, in which case they are taken into account in the heavy highlighting mode (see section Pretty Printing Options).

This is an extract of the `C` style sheet:

```
optional operators are
   -> \rightarrow,
   && \wedge,
   || \vee,
   != \neq,
   == \equiv,
   # We need to protect these, so that <= is not replaced in <<=
   <<=,
   >>=,
   <= \leq,
   >= \geq,
   ! \not
end operators
```

Note how `<<=' and `>>=' are protected (there are defined to be written as is when met in the source). This is to prevent the two last characters of `<<=' from being converted into a `less or equal' sign.

The order in which you define the elements of a category (but the sequences) does not matter. But since `a2ps` sorts them at run time, it may save time if the alphabetical `C`-order is more or less followed.

You should be aware that when declaring a keyword with a regular expression as lhs, then `a2ps` automatically makes this expression matching only if there are no character of the first alphabet both just before, and just after the string.

In term of implementation, it means that

```
keywords are
  /foo\\|bar/
```

```
end keywords
```

is exactly the same as

```
operators are
  /\\b\\(foo\\|bar\\)\\b/
end operators
```

This can cause problems if you use anchors (e.g. $, or ^) in keywords: the matcher will be broken. In this particular case, define your keywords as operators, taking care of the `\\b' by yourself.

See section 'Match-word-boundary Operator' in Regex manual, for details on `\b'.

Declaring the sequences

Sequences admit several declarations too:

```
sequences      ::= sequences are
                     sequence_1 `,' sequence_2...
                   end sequences
sequence       ::= rule in_face close_opt exceptions_opt
                 | C-string
                 | C-char
                 ;
close_opt      ::= rule
                 | closers are
                     rules
                   end closers
                 | <nothing>
                 ;
exceptions_opt ::= exceptions are
                     rules
                   end exceptions
                 | <nothing>
                 ;
```

The rules are:

- The default face is then in_face.
- If no closing rule is given, `"\n"' (i.e., end-of-line) is used.

As a first example, the definition of `C-string` is:

```
sequences are
 "\"" Plain String "\"" Plain
     exceptions are
        "\\\\", "\\\""
     end exceptions
```

```
end sequences
```

The following example comes from `ssh.ssh', the style sheet for style sheet files, in which there are two kinds of pseudo-strings: the strings (`"example"'), and the regular expressions (`/example/'). We do not want the content of the pseudo-strings in the face `String'.

```
sequences are
  # The comments
  "#" Comment,

  # The name of the style sheet
  "style " Keyword_strong (Label + Index1) " is" Keyword_strong,

  # Strings are exactly the C-strings, though we don't want to
  # have them in the "string" face
  "\"" Plain "\""
     exceptions are
        "\\\\", "\\\""
     end exceptions,

  # Regexps
  "/" Plain "/"
     exceptions are
        "\\\\", "\\\/"
     end exceptions

end sequences
```

The order between sequences does matter. For instance in Java, `/**' introduces strong comments, and `/*' comments. `/**' *must* be declared before `/*', or it will be hidden.

There are actually some sequences that could have been implemented as operators with a specific regular expression (that goes up to the closer). Nevertheless be aware of a big difference: regular expression are applied to a single line of the source file, hence, they cannot match on several lines. For instance, the `C' comments,

```
/*
 * a comment
 */
```

cannot be implemented with operators, though `C++' comments can:

```
//
// a comment
//
```

A tutorial on style sheets

In this section a simple example of style sheet is entirely covered: that of `ChangeLog' files.

`ChangeLog' files are some kind of memory of changes done to files, so that various programmers can understand what happened to the sources. This helps a lot, for instance, in guessing what recent changes may have introduced new bugs.

Example and syntax

First of all, here is a sample of a `ChangeLog' file, taken from the `misc/' directory of the original a2ps package:

```
Sun Apr 27 14:29:22 1997  Akim Demaille  <demaille@inf.enst.fr>

        * base.ps: Merged in color.ps, since now a lot is
          common [added box and underline features].

Fri Apr 25 14:05:20 1997  Akim Demaille  <demaille@inf.enst.fr>

        * color.ps: Added box and underline routines.

Mon Mar 17 20:39:11 1997  Akim Demaille  <demaille@gargantua.enst.fr>

        * base.ps: Got rid of CourierBack and reencoded_backspace_font.
          Now the C has to handle this by itself.

Sat Mar  1 19:12:22 1997  Akim Demaille  <demaille@gargantua.enst.fr>

        * *.enc: they build their own dictionaries, to ease multi
          lingual documents.
```

The syntax is really simple: A line specifying the author and the date of the changes, then a list of changes, all of them starting with an star followed by the name of the files concerned, then optionally between parentheses the functions affected, and then some comments.

Implementation

Quite naturally the style will be called ChangeLog, hence:

```
style ChangeLog is
written by "Akim Demaille <demaille@inf.enst.fr>"
version is 1.0
requires a2ps 4.9.5

documentation is
```

```
   "This is a tutorial style sheet.\n"
end documentation
  ...
end style
```

A first interesting and easy entry is that of function names, between `(' and `)':

```
sequences are
  "(" Plain Label ")" Plain
end sequences
```

A small problem that may occur is that there can be several functions mentioned separated by commas, that we don't want to highlight this way. Commas, here, are exceptions. Since regular expressions are not yet implemented in `a2ps`, there is a simple but stupid way to avoid that white spaces are all considered as part of a function name, namely defining two exceptions: one which captures a single comma, and a second, capturing a comma and its trailing space.

For the file names, the problem is a bit more delicate, since they may end with `:', or when starts the list of functions. Then, we define two sequences, each one with one of the possible closers, the exceptions being attached to the first one:

```
sequences are
  "* " Plain Label_strong ":" Plain
     exceptions are
        ", " Plain, "," Plain
     end exceptions,
  "* " Plain Label_strong " " Plain
end sequences
```

Finally, let us say that some words have a higher importance in the core of text: those about removing or adding something.

```
keywords in Keyword_strong are
  add, added, remove, removed
end keywords
```

Since they may appear in lower or upper, of mixed case, the style will be defined as case insensitive.

Finally, we end up with this style sheet file, in which an optional highlighting of the mail address of the author is done. Saving the file is last step. But do not forget that a style sheet has both a name as nice as you may want (such as `Common Lisp'), and a key on which there are strict rules: the prefix must be alpha-numerical, lower case, with no more than 8 characters. Let's chose `` `chlog.ssh' ``.

```
# This is a tutorial on a2ps' style sheets
style ChangeLog is
written by "Akim Demaille <demaille@inf.enst.fr>"
version is 1.0
requires a2ps 4.9.5
```

```
documentation is
   "Second level of high lighting covers emails."
end documentation

sequences are
  "(" Plain Label ")" Plain
     exceptions are
        ", " Plain, "," Plain
     end exceptions,
  "* " Plain Label_strong ":" Plain
     exceptions are
        ", " Plain, "," Plain
     end exceptions,
  "* " Plain Label_strong " " Plain
end sequences

keywords in Keyword_strong are
  add, added, remove, removed
end keywords

optional sequences are
   < Plain Keyword > Plain
end sequences
end style
```

The Entry in `sheets.map'

The last touch is to include the pattern rules about `ChangeLog' files (which could appear as `ChangeLog.old' etc.) in `sheets.map':

```
# ChangeLog files
ChangeLog*                chlog
```

This won't work... Well, not always. Not for instance if you print `misc/ChangeLog'. This is not a bug, but truly a feature, since sometimes one gets more information about the type of a file from its path, than from the file name.

Here, to match the preceding path that may appear, just use `*':

```
# ChangeLog files
*ChangeLog*               chlog
```

If you want to be more specific (`FooChangeLog' should not match), use:

```
# ChangeLog files
ChangeLog*                chlog
```

```
*/ChangeLog*                chlog
```

More Sophisticated Rules

The example we have presented until now uses only basic features, and does not take advantage of the regexp. In this section we should how to write more evolved pretty printing rules.

The target will be the lines like:

```
Sun Apr 27 14:29:22 1997  Akim Demaille  <demaille@inf.enst.fr>

Fri Apr 25 14:05:20 1997  Akim Demaille  <demaille@inf.enst.fr>
```

There are three fields: the date, the name, the mail. These lines all start at the beginning of line. The last field is the easier to recognize: is starts with a `<', and finishes with a `>'. Its rule is then `/<[^>]+>/'. It is now easier to specify the second: it is composed only of words, at least one, separated by blanks, and is followed by the mail: `/[[:alpha:]]+\\([\t]+[[:alpha:]]+\\)*/'. To concatenate the two, we introduce optional blanks, and we put each one into a pair of `\\('-`\\)' to make each one a recognizable part:

```
\\([[:alpha:]]+\\([ \t]+[[:alpha:]]+\\)*\\)
\\(.+\\)
\\(<[^>]+>\\)
```

Now the first part is rather easy: it starts at the beginning of the line, finishes with a digit. Once again, it is separated from the following field by blanks. Split by groups (see section 'Grouping Operators' in Regex manual), we have:

```
^
\\([^\t ].*[0-9]\\)
\\([ \t]+\\)
\\([[:alpha:]]+\\([ \t]+[[:alpha:]]+\\)*\\)
\\(.+\\)
\\(<[^>]+>\\)
```

Now the destination is composed of back references to those groups, together with a face:

```
# We want to highlight the date and the maintainer name
optional operators are
  (/^\\([^\t ].*[0-9]\\)/                          # \1. The date
   /\\([ \t]+\\)/                                  # \2. Spaces
   /\\([[:alpha:]]+\\([ \t]+[[:alpha:]]+\\)*\\)/ # \3. Name
   /\\(.+\\)/                                      # \5. space and <
   /\\(<[^>]+\\)>/                                 # \6. email
   \1 Keyword, \2 Plain, \3 Keyword_strong,
   \5 Plain, \6 Keyword, > Plain)
end operators
```

Notice the way regexps are written, to ease reading.

PostScript

This chapter is devoted to the information which is only relevant to PostScript.

Page Device Options

Page device is a PostScript level 2 feature that offers an uniform interface to control printer's output device. `a2ps` protects all page device options inside an if block so they have no effect in level 1 interpreters. Although all level 2 interpreters support page device, they do not have to support all page device options. For example some printers can print in duplex mode and some can not. Refer to the documentation of your printer for supported options.

Here are some usable page device options which can be selected with the `-D' option (`--setpagedevice'). For a complete listing, see PostScript Language Reference Manual: section 4.11 Device Setup.

`Collate boolean`
: how output is organized when printing multiple copies

`Duplex boolean`
: duplex (two side) printing

`ManualFeed boolean`
: manual feed paper tray

`OutputFaceUp boolean`
: print output `face up' or `face down'

`Tumble boolean`
: how opposite sides are positioned in duplex printing

Statusdict Options

The `statusdict` is a special storage entity in PostScript (called a dictionary), in which some variables and operators determine the behavior of the printer. This is an historic horror that existed before page device definitions were defined. They are even more printer dependent, and are provided only for the people who don't have a level printer. In any case, refer to the documentation of your printer for supported options.

Here are some statusdict definitions in which you might be interested:

`manualfeed boolean`
: Variable which determine that the manual fed paper tray will be used. Use is `-Smanualfeed::true'.

`setmanualfeed boolean`
: Idem as the previous point, but use is `-Ssetmanualfeed:true'.

`setduplexmode boolean`

If boolean, then print in Duplex mode. Use if `-Ssetduplexmode:true'.

Colors in PostScript

Nevertheless, here are some tips on how to design your PostScript styles. It is strongly recommended to use `gray.pro' or `color.pro' as a template.

There are two PostScript instructions you might want to use in your new PostScript prologue:

`setgray`
: this instruction must be preceded by a number between 0 (black) and 1 (white). It defines the gray level used.

`setrgbcolor`
: this instruction must be preceded by three numbers between 0 (0 %) and 1 (100%). Those three numbers are related to red, green and blue proportions used to designate a color.

`a2ps` uses two upper level procedures, `BG` and `FG`, but both use an argument as in `setrgbcolor`. So if you wanted a gray shade, just give three times the same ratio.

a2ps PostScript Files

`a2ps` uses several types of PostScript files. Some are standards, such as font files, and others are meant for a2ps only.

All a2ps files have two parts, one being the comments, and the other being the content, separated by the following line:

```
% code follows this line
```

Designing PostScript Prologues

It is pretty known that satisfying the various human tastes is an NEXPTIME-hard problem, so `a2ps` offers ways to customize its output through the prologue files. But since the authors feel a little small against NEXPTIME, they agreed on the fact that **you** are the one who will design the look you like.

Hence in this section, you will find what you need to know to be able to customize `a2ps` output.

Basically, `a2ps` uses faces which are associated to their "meaning" in the text. `a2ps` let's you change the way the faces look.

Definition of the faces

There are three things that define a face:

Its font
: You should never call the font by yourself, because sometimes `a2ps` may decide that another font

would be better. This is what happens for instance if a font does not support the encoding you us

Hence, never set the font by yourself, but ask `a2ps` to do it. This is done through a line:

```
%Face: face real-font-name size
```

This line tells `a2ps` that the font of face is real-font-name. It will replace this line by the correct PostScript line to call the needed font, and will do everything needed to set up the font.

The size of the text body is `bfs`.

Its background color

There are two cases:

You want a background color, then give the RGB (see section Colors in PostScript) ratio and `true` to `BG`:

```
0.8 0.8 0 true BG
```

You don't want a background color, then call `BG` with `false`:

```
false BG
```

Its foreground color

As `BG`, call `FG` with an RGB ratio:

```
0 0.5 0 FG
```

Its underlining

`UL` requires a boolean argument, depending whether you want or not the current face to be underlined.

```
true UL
```

Its boxing

Requiring a boolean, `BX` let's a face have a box drawn around.

Prologue File Format

Prologue files for `a2ps` must have `pro' as suffix. Documentation (reported with `--list-prologues') can be included in the comment part:

```
Documentation
This prologue is the same as the prologue code(pb)code, but using
the bold version of the fonts.
EndDocumentation
% code follows this line
```

See section Documentation Format for more on the format.

A step by step example

We strongly suggest our readers not to start from scratch, but to copy one of the available styles (see the result of `a2ps --list=prologues'), to drop it in one of `a2ps' directories (say `$HOME/.a2ps', and to patch it until you like it.

Here, we will start from `color.pro', trying to give it a funky look.

Say you want the keywords to be in Helvetica, drawn in a flashy pink on a light green. And strong keywords, in Times Bold Italic in brown on a soft Hawaïan sea green (you are definitely a fine art *amateur*).

Then you need to look for `k' and `K':

```
/k {
  false BG
  0 0 0.9 FG
%Face: Keyword Courier bfs
  Show
} bind def

/K {
  false BG
  0 0 0.8 FG
%Face: Keyword_strong Courier-Bold bfs
  Show
} bind def
```

and turn it into:

```
/k {
  0.2 1 0.2 true BG
  1 0.2 1 FG
%Face: Keyword Helvetica bfs
  Show
} bind def

/K {
  0.4 0.2 0 true BG
  0.5 1 1 FG
%Face: Keyword_strong Times-BoldItalic bfs
  Show
} bind def
```

Waouh! It looks great!

A bit trickier: let change the way the line numbers are printed.

First, let's look for the font definition:

```
%%BeginSetup
% The font for line numbering
/f# /Helvetica findfont bfs .6 mul scalefont def
%%EndSetup
```

Let it be in Times, twice bigger than the body font.

```
%%BeginSetup
% The font for line numbering
/f# /Times-Roman findfont bfs 2 mul scalefont def
%%EndSetup
```

How about its foreground color?

```
% Function print line number (<string> # -)
/# {
  gsave
    sx cw mul 2 div neg 0 rmoveto
    f# setfont
    0.8 0.1 0.1 FG
    c-show
  grestore
} bind def
```

Let it be blue. Now you know the process: just put `0 0 1' as `FG` arguments.

Programming with the Library

`a2ps` offers to the programmer an access to its generating routines. This section documents the API.

But since this section is empty, or almost, if I were you, I would go in contrib/sample to see how it works...

Initialization and Closing of Calls to `liba2ps`

Function: struct a2ps_job * **a2ps_job_new** *(void)*

Build a new storage unit for the library.

Function: void **a2ps_read_sys_config** *(struct a2ps_job * job)*

Set job with the default settings defined in the configuration file of the system.

Function: void **a2ps_read_config** *(struct print_job * job, char * path, char * filename)*

Set job with the default settings defined in the configuration file `` `path/filename' ``. path can be `NULL`, filename cannot.

Print Jobs

A print job should be seen as associated to a single output.

Function: void **a2ps_open_output_session** *(struct a2ps_job * job)*

Initialize job for a new print job.

Function: void **a2ps_close_output_session** *(struct print_job * job)*

Closes the current print job, and sends the output.

File Jobs

A file job should be seen as a single input.

Function: void **a2ps_new_input_session** *(struct a2ps_job * job, char * name)*

Create and open a new file job in job. name can be `NULL`, in which case its name is defaulted to that of `stdin`.

Function: void **a2ps_close_input_session** *(struct print_job * job)*

End the current input session.

Printing Functions

These are the functions to be used to send content to `liba2ps`.

Function: void **a2ps_print_char** *(struct print_job * job, unsigned char c, face_t face)*

Print the char c in face in job.

Function: void **a2ps_print_string** *(struct print_job * job, unsigned char * string, face_t face)*

Print the `C` string string in face in job.

Function: void **a2ps_print_buffer** *(struct print_job * job, unsigned char * buffer, size_t len, face_t face)*

Print the len first characters contained in buffer with face into job.

Contributions

Card

Many users of `a2ps` have asked for a reference card, presenting a summary of the options. In fact, something closely related to the output of `a2ps --help'.

The first version of this reference card was a PreScript file (see section PreScript) to be printed by `a2ps`. Very soon a much better scheme was found: using a style sheet to pretty print directly the output of `a2ps --help'! A first advantage is then that the reference cards can be printed in the tongue you choose.

A second was that this treatment could be applied to any application supporting a `--help'-like option.

Invoking `card`

```
card [options] applications
```

`card` is a shell script which tries to guess how to get your applications' help message (typically by the options `--help' or `-h'), and pretty prints it thanks to `a2ps` (or the content of the environment variable `A2PS' if it is set).

Supported options are:

Option: **-h**

Option: **--help**

print a short help message and exit successfully.

Option: **-V**

Option: **--version**

report the version and exit successfully.

Option: **-D**

Option: **--debug**

enter in debug mode.

Option: **-l** *language*

Option: **--language=language**

specify the language in which the reference card should be printed. language should be the symbol used by `LC_ALL` etc. (such as `fr', `it' etc.).

If the applications don't support internationalization, English will be used.

Option: **--command=command**

Don't try to guess the applications' way to report their help message, but rather use the call command. A typical example is

```
card --command="cc -flags"
```

Any option that is not recognized by `card` is passed to `a2ps` (see section Command line options). Be aware that these options must *not* be separated from their arguments. For instance

```
card gmake gtar --command="cc -flags" -Pdisplay
```

builds the reference card of `GNU make`, `GNU tar` (automatic detection of `--help' support), and `cc` thanks to `-flags'. Since `-P' is not supported by `card`, it is passed to `a2ps`.

Caution when Using `card`

Remember that `card` runs the programs you give it, and the commands you supplied. Hence if there is a silly programs that has a weird behavior given the option `-h' etc., beware of the result.

It is even more clear using `--command': avoid running `card --command="rm -rf *"', because the result will be exactly what you think it will be!

psmandup

I personally hate to print documents of hundreds of pages on a single sided printer. Too bad, here there are no Duplex printers. The idea is then simply first to print the odd pages, then the even in reversed order. To make sure one flips the page in the meanwhile, the second half should be printed from the manual feed tray.

Make a shell script that automates this, and you get `psmandup`

Invoking `psmandup`

```
psmandup [file]
```

produce a manual duplex version of the PostScript file (or of the standard input if no file is given, or if file is `-'). Once the first half is printed, put the sheet stack in the manual feed tray for the second half.

Supported options are:

Option: **-h**

Option: **--help**

print a short help message and exit successfully.

Option: **-V**

Option: **--version**

report the version and exit successfully.

Option: **-D**

Option: **--debug**

enter in debug mode.

Option: **-o** *file*

Option: **--output=file**

specify the file in which is saved the output.

Option: **-n**

Option: **--no-fix**

`psmandup` will fail on ill designed PostScript. Actually it is the psutils that fail. To avoid this, by default the PostScript file is sanitized by `fixps`.

When given this option, don't run `fixps`. This is meant to be used when `fixps` has already been used higher in the processing chain.

`psmandup` makes the assumptions that the printer is Level 2, and support manual feeding. The file should be reasonably sane, otherwise `psmandup` fails miserably.

Typical use is

```
psmandup file.ps | lp
```

or can be logged into `a2ps`' printer commands (see section Your Printers).

`fixps`

The shell script `fixps` tries its best to fix common problems in PostScript files that may prevent post processing. It makes heavy use of the `psutils`. It is a good idea to use `fixps` upstream in the PostScript to PostScript delegations.

Invoking `fixps`

```
fixps [file]
```

sanitize the PostScript file (or of the standard input if no file is given, or if file is `-').

Supported options are:

Option: **-h**

Option: **--help**

print a short help message and exit successfully.

Option: **-V**

Option: **--version**

report the version and exit successfully.

Option: **-D**

Option: **--debug**

enter in debug mode.

Option: **-o** *file*

Option: **--output=file**

specify the file in which is saved the output.

a2ps Emacs mode

FIXME: Document me.

Various

We collected in this chapter the things that had no place in the rest of the document.

Security issues

Note. I am not really aware of security problems. I am just making assumptions upon my poor knowledge, so if somebody sees things that should be reported here, or problem I'm not aware of, please contact us so that this note gets extended or fixed.

One should understand that any program that has not been written to be secure is never secure. It is of course the case of `a2ps`.

Do not panic, there are no reason for you to worry. Nevertheless we can yet imagine ways to obtain illegal rights thanks to some features of `a2ps`, especially virtual printers.

If `a2ps` is run by root, then the files it may create are owned by root. This can for instance happen if you install `a2ps` as one of `lp` or `lpr` filter.

Then, if one of the virtual printer creates say a shell script, it is owned by root too. With just a bit of habit, it should not be difficult then to access privileged access to the system.

In what conditions could it happen? **Only** if there are some printers defined in the system configuration file of `a2ps`, or in root's home directory `` `.a2ps/a2psrc' ``. Hence, make sure to carefully write the commands to the preconfigured printers.

As you can see, this is quite science fiction, nevertheless, you might wanted to know.

Non PostScript printers

Here are some tips we have on how to use a non PostScript printer. If somebody feels like writing a more precise documentation, he really is welcome.

From Clayton Weaver

(for a bj200ex on os2 from linux) This is a shell script called as a filter from an ":if=/usr/local/bin/filtername" entry in /etc/printcap on linux:

```
#!/bin/bash

gs -q -sDevice=bj200 -sOutputfile=- -r360 -dNOPAUSE -dSAFER -
```

The device is a gs device name, input is the ending "-" (stdin), output is stdout, -q is "no messages". Can be used with

```
lpr -Pprintername -Ffilter_path_and_name infile.ps
```

or just `lpr -Pprintcap_printername infile.ps' if the filter is specified in the printcap `:if=' entry for that "printcap_printername". Either way, lpr on linux runs it in a sub shell, so you don't want "exec" before the gs command (that kills the sub shell and leaves gs running with no way to communicate its stdout back to lpr).

You can print directly from gs, I've done it on OS/2 by specifying "lpt1" as the output device, but printing to a remote printer I need lpr and lpd to handle transmitting the job, so this way works better for me.

Regards, Clayton Weaver (Seattle)

From Pierre Juillot

To print toto.ps on my desk-jet, I hit:

```
> gsdj toto.ps
```

where `gsdj' is

```
#!/bin/sh
#                               05-06-1996
# to print a PostScript file using GhostScript on the
# desk-jet 500 (dj) or the printer specified via  the
# environment variable LPOPTS
# using GhostScript
# exec gs -q -dNOPAUSE -sPAPERSIZE=a4 -sDEVICE=djet500 \
exec gs -q -dNOPAUSE -sPAPERSIZE=a4 -sDEVICE=deskjet \
```

```
     -sOutputFile="|lp -onb -ddj -or $LPOPTS " $* quit.ps
```

These tips in a2ps

To use these examples, first see section Your Printers. The translations would be in one of your configuration files, say `$HOME/.a2ps/a2psrc':

```
Printer: lpt1 | gs -q -sDevice=bj200 -sOutputfile=- -r360 -dNOPAUSE \
        -dSAFER > lpt1
UnknownPrinter:  | gs -q -dNOPAUSE -sPAPERSIZE=a4 -sDEVICE=deskjet \
     -sOutputFile="|lp -onb -ddj -or #o" quit.ps
```

Frequently asked questions

Please, before sending us mail, make sure the problem you have is not known, and explained. Moreover, avoid using the mailing list for asking question about the options, etc. It has been built for announces and suggestions, not to contact the authors.

Why Does ...?

Error related questions.

Relocation Error

```
When I have just compiled a2ps, and I first try it, I have weird
errors such as:

gargantua ~T $ a2ps --help
ld.so.1: a2ps: fatal: relocation error: symbol not found:
       ps_comment_hook: referenced in a2ps
zsh: 7294 killed     a2ps --help
```

This is due to a mix between several versions of the `liba2ps`. To fix the problem, make sure to run `make install' in the `lib/' directory and then in the `src/' directory. Removing the previous `liba2ps.so' files may help.

Printer Errors

There are two ways that printing can fail: silently, or with an diagnostic.

First check that you did not give exotic options to an old printer (typically, avoid printing on two sides on a printer that does not support it). Avoid use of options `-D' (see section Page Device Options) and `-S' (see section Statusdict Options).

If the trouble persists, please try again but with the option `--debug' (a PostScript error handler is down-loaded), and then send us:

1. the file that gives problems
2. the error message that was printed.

Cannot Print in Duplex

If your printer is too old, then `a2ps` will not be able to send it the code it needs when `-s2' is specified. This is because your printer uses an old and not standardized interface for special features.

So you need to

1. specify that you want Duplex mode: `-s2',
2. remove at hand the standardized call to the Duplex feature: `-DDuplex',
3. add the non standard call to the Duplex features. Try `-Ssetduplexmode:true'.

Since this is painful to hit, a User Option (see section Your Shortcuts) should help.

Printing goes beyond the frame of the paper

You are currently printing with a bad medium, for instance using A4 paper within `a2ps`, while your printer uses Letter paper. See section Sheets Options, option `--medium' for more.

What I get on the printer is long and incomprehensible

You are probably printing a PostScript file or equivalent. Try to print with `-Z': `a2ps` will try to do his best to find what is the program that can help you (see section Your Delegations). In case of doubt, don't hesitate to save into a file, and check the content with GhostView, or such:

```
$ a2ps my_weird_file -Z -o mwf.ps
$ ghostview mwf.ps
```

If it is not correct, ask for help around you.

Why Not ...?

Why not having used yacc and such

There are several reasons why we decided not to use grammars to parse the files. First it would have made the design of the style sheets much more tricky, and today `a2ps` would know only 4 or 5 languages.

Second, it limits the number of persons who could build a style sheet.

Third, mixing several parsers within one program is not easy. Moreover, its would have been ten times bigger.

Fourth, we did not feel the need for such a powerful tool: handling the keywords and the sequences is just what the users expect.

Fifth, any extension of `a2ps` would have required to recompile.

And last but not least, using a parser requires that the sources are syntactic bug free, what is too strong a requirement.

Nevertheless, `PreScript` gives the possibility to have on the one hand a syntactic parser which would produce `PreScript` code, and on the other hand, `a2ps`, which would make it PostScript. This schema seems to us a good compromise. If it is still not enough for you, you can use the library (see section Programming with the Library).

How Can I ...?

How can I leave room to bind?

The option `--margin[=size]' is meant for this. See section Sheets Options.

Printing stdin

`a2ps` prints the standard input if you give no file name, or if you gave `-' as file name. It cannot automatically pretty print, nor call delegations if you don't specify the language (see section Style Sheet Files), or if you don't supply a name to the standard input (`--stdin=name') with which it could guess the language.

Change the Font

Well, yes. See section Designing PostScript Prologues, for details. Make sure that all the information `a2ps` needs is available (see section Font Files).

The Old Option -b

By the past, `a2ps` had an option `-b' with which the fonts were bold. Since now the fonts are defined by prologues (see section Designing PostScript Prologues) this option no longer makes sense. A replacement prologue is provided: `bold'. To use it, give the option `--prologue=bold'.

What next?

There are some features we would like to implement. Some are the following ones. If you feel like helping, don't hesitate to contact us.

EPSF

`a2ps` should be able to generate EPS files in a short while.

Spelling checking, syntax fixing.

When printing a human file (only English may be supported), spelling should be checked. When pretty-printing, syntax errors should be underlined.

No just kidding :). Do it yourself...

Glossary

This section settles some terms used through out this document, and provides the definitions of some terms you probably want to know about.

Adobe

Adobe is the firm who designed and owns the PostScript language. The patent that printer manufacturers must pay to Adobe is the main reason why PostScript printers are so expansive.

AFM file

AFM stands for Adobe Font Metrics. These files contain everything one needs to know about a font: the width of the characters, the available characters etc.

Charset

Code Set

Cf. Encoding.

Delegate

Another filter (application) which `a2ps` may call to process some files. This feature is especially meant for page description files (see section Your Delegations).

DSC

Document Structuring Conventions

Because PostScript is a language, any file describing a document can have an arbitrary complexity. To ease the processing of PostScript files, the document should follow some conventions. Basically there are two kinds of conventions to follow:

Page Independence

Special comments state where the pages begin and end. With these comments (and the fact that a page does start and end somewhere, which is absolutely not necessary in PostScript), very simple programs (such as `psnup`, `psselect` etc.) can post process PostScript files.

Requirements

Special features may be needed to run correctly the file. Some comments specify what services are expected from the printer (e.g., fonts, duplex printing, color etc.), and other what features are provided by the file itself (e.g., fonts, procsets etc.), so that a print manager can decide that a file cannot be printed on that printer, or that it is possible if the file is slightly modified (e.g., adding a required font not known by the printer) etc.

The DSC are edited by Adobe. A document which respects them is said to be DSC compliant.

Of course `a2ps` follows all the DSC.

- Encoding Association of human readable characters, and computers' internal numbered representatio
In other words, they are the alphabets, which are different according to your country/mother tongue. E.g.
ASCII, Latin 1, corresponding to Western Europe etc.

See section What is an Encoding to know more about encodings.

- `GhostScript` `GhostScript` is a full PostScript interpreter running under many various systems (Unixes, MS-DOS, Mac etc.). It can be used either to view PostScript files (in general thanks to a graphic interface such as `GhostView` or `gv` ...), or to translate the PostScript in another format (for instance `PCL`, `PDF`, and many formats supported by some printers such as the Desk Jets.

Thanks to `GhostScript` many people not owning a PostScript printer are still able to use the PostScript technology.

- Face A virtual style given to some text. For instance, *Keyword*, *Comment* are faces.
- Headings Everything that goes around the page and is not part of the text body. Typically the title, footer etc.
- Key Many objects used in `a2ps`, such as encodings, have both a key and a name. The word name is used for a symbol, a label, which is only meant to be nice to read by a human. For instance `ISO Latin 1' is a name. `a2ps` never uses a name, but the key.

A key is the identifier of a unique object. This is information that `a2ps` processes, hence, whenever you need to specify an object to `a2ps`, use the key, not its name. For instance `latin1' is the unique identifier of the `ISO Latin 1' encoding.

- Logical page Cf. Virtual page.
- lhs
- left hand side See P-rule.
- Medium Official name (by Adobe) given to the output physical support. In other words, it means the description of a sheet, e.g., A4, Letter etc.
- Name See Key.
- Page A single side of a sheet.
- Page Description Language A language that describes some text (which may be enriched with pointers, pictures etc.) and its layout. `HTML`, PostScript, LaTeX, `roff` and others are such languages. A file written in those languages is not made to be read as is by a human, but to be transformed (or compiled) into a readable form.
- PCL FIXME:
- PFA file PostScript Font in ASCII format. This file can be directly down loaded to provide support for another font.
- PFB file PostScript Font in Binary format. In PFA files there are long sequences of hexadecimal digits. Here these digits are represented by their value, hence compressing 2 characters in a PFA into 1 in the PFB. This is the only advantage since a PFB file cannot be directly sent to printer: it must first be decompressed (hence turned into a PFA file) before being used.
- PostScript PostScript is a page description language. It is even more powerful than that: unlike to `HTML`, or `roff`, but as TeX and LaTeX, it is truly a programming language which main purpose is to draw (on sheets). Most programs are a list of instructions that describes lines, shades of gray, or text to draw on a page.

This is the language that most printers understand.

PostScript is a trademark of Adobe Systems Incorporated.

- PPD file PostScript Printer Description file. These files report everything one needs to know about a printer: the known fonts, the patches that should be down loaded, the available memory, the trays, the way to ask it duplex printing etc.

PostScript has pretended to be a device independent page description language, and the `PPD` files are here to prove that device independence was a failure.

- ProcSet Set of (PostScript) procedures.
- Prologue PostScript being a language, a typical PostScript program (i.e. a typical PostScript file) consists of two parts. The first part is composed of resources, such as fonts, procsets, etc. and the second part of calls to these procedures. The first part is called the prologue, and the second, the script.
- P-rule FIXME:
- rhs
- right hand side See P-rule.
- Script See Prologue.
- Sheet The physical support of the printing: it may support one or two pages, depending on your printing options.
- Style sheet Set of rules used by `a2ps` to give a face to the strings of a file. In `a2ps`, each programming language which is supported is defined via one style-sheet.
- Virtual page Area on a physical page in which `a2ps` draws the content of a file. There may be several virtual pages on a physical page.

Genesis

Here are some words on `a2ps` and its history.

History

The initial version was a shell program written by Evan Kirshenbaum. It was very slow and contained many bugs.

A new version was written in `C` by Miguel Santana to improve execution speed and portability. Many new features and improvements have been added since this first version. Many contributions (changes, fixes, ideas) were done by `a2ps` users in order to improve it.

From the latest version from Miguel Santana (4.3), Emmanuel Briot implemented bold faces for keywords in `Ada`, `C` and `C++`.

From that version, Akim Demaille generalized the pretty-printing capabilities, implemented more languages support, and other features.

Contributors

Since the very beginning of `a2ps`, many people have brought help:

- Oscar Nierstrasz
- Tim Clark
- tullemans@apolloway.prl.philips.nl
- Johan Vromans
- craig.r.stevenson@att.com
- erikt@cs.umu.se
- wstahw@lso.win.tue.nl
- mai@wolfen.cc.uow.oz
- Johan Garpendahl
- John Interrante
- Chris Adamo
- Larry Barbieri
- Denis Girou
- Thomas Parmelan
- Paul Shum
- Graham Jenkins, thanks to whom `a2ps` (but also GNU `Libtool`) is ported onto Pyramid Systems.
- Didier Verna wrote `a2ps-compile-regexp` for the `a2ps-mode`.
- Jim Diamond.
- Christian Mondrup who regularly tracks down bugs appearing on DEC architectures.
- Michael Taeschner who tracked the same bug, but with another look, on Irix 6.2.
- Peter Bartke
- Joachim Backes who caught many bugs, and problems in the documentation.

Translators

Some people worked on the translation of `a2ps`:

- Daniele Ghiotti (Italian)
- Tomek Burdziak (Polish)
- Miguel A. Varo (Maintainer for Spanish and Catalan)
- Michael Wiedmann (Maintainer for German)
- Christian Kirsch (German)
- Erwin Dieterich (German)

- Juliusz Chroboczek (Polish). He is also the author of `Ogonkify` (see section 'Overview' in Ogonkify manual).
- Marcel van der Laan (Dutch)
- Lorenzo M. Catucci (Maintainer for Italian)
- Choi Jun Ho (Korean)
- Turgut Uyar (Turkish)
- Jiri Pavlovsky (Maintainer for Czech)

Thanks

Patrick Andries, from Alis Technologies inc. and Roman Czyborra (see his home page), provided us with important information on encodings. We strongly recommend that you go and read these pages: there is a lot to learn.

Juliusz Chroboczek worked a lot on the integration of the products of Ogonkify (such as Latin 2 etc. fonts) in `a2ps`. Without his help, and the time is devoted to both `a2ps` and `ogonkify`, many non west-European people would still be unable to print easily texts written in their mother tongue.

Denis Girou brought a constant and valuable support through out the genesis of pretty-printing `a2ps`. His comments on both the program and the documentation are the origin of many pleasant features (such as `--prologue').

Copying

The subroutines and source code in the `a2ps` package are "free"; this means that everyone is free to use them and free to redistribute them on a free basis. The `a2ps`-related programs are not in the public domain; they are copyrighted and there are restrictions on their distribution, but these restrictions are designed to permit everything that a good cooperating citizen would want to do. What is not allowed is to try to prevent others from further sharing any version of these programs that they might get from you.

Specifically, we want to make sure that you have the right to give away copies of the programs that relate to `a2ps`, that you receive source code or else can get it if you want it, that you can change these programs or use pieces of them in new free programs, and that you know you can do these things.

To make sure that everyone has such rights, we have to forbid you to deprive anyone else of these rights. For example, if you distribute copies of the `a2ps`-related code, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must tell them their rights.

Also, for our own protection, we must make certain that everyone finds out that there is no warranty for the programs that relate to `a2ps`. If these programs are modified by someone else and passed on, we want their recipients to know that what they have is not what we distributed, so that any problems introduced by others will not reflect on our reputation.

The precise conditions of the licenses for the programs currently being distributed that relate to `a2ps` a found in the General Public Licenses that accompany them.

a2ps, version 4.10

(2)

A classical Unix trick to make the difference between the option `-2', and the file `-2' is to type `./-2'.

(3)

Basically it means the the PostScript that `a2ps` generates is **really** modular. In other words, any kind of post-processing may be applied to the files it produced.

(4)

That is to say, there are no PostScript printers that don't understand these files.

(5)

Current `a2ps` only handles PostScript output, i.e. out=`ps'

(6)

Because hiding its use into `a2ps` just makes it even more difficult to the users to know why it failed. Let them use it at hand.

AUC TeX

A much enhanced LaTeX mode for GNU Emacs.

June 1993, for AUC TeX Version 7.3

by Kresten Krab Thorup updated for 7.3 by Per Abrahamsen

AUC TeX

TOC

Copying

(This text stolen from the TeXinfo 2.16 distribution).

The programs currently being distributed that relate to AUC TeX include lisp files for GNU Emacs, plus other separate programs (specifically `lacheck`). These programs are free; this means that everyone is free to use them and free to redistribute them on a free basis. The AUC TeX related programs are not in the public domain; they are copyrighted and there are restrictions on their distribution, but these restrictions are designed to permit everything that a good cooperating citizen would want to do. What is not allowed is to try to prevent others from further sharing any version of these programs that they might get from you.

Specifically, we want to make sure that you have the right to give away copies of the programs that relate to AUC TeX, that you receive source code or else can get it if you want it, that you can change these programs or use pieces of them in new free programs, and that you know you can do these things.

To make sure that everyone has such rights, we have to forbid you to deprive anyone else of these rights. For example, if you distribute copies of the AUC TeX related programs, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must tell them their rights.

Also, for our own protection, we must make certain that everyone finds out that there is no warranty for the programs that relate to AUC TeX. If these programs are modified by someone else and passed on, we want their recipients to know that what they have is not what we distributed, so that any problems introduced by others will not reflect on our reputation.

The precise conditions of the licenses for the programs currently being distributed that relate to AUC TeX are found in the General Public Licenses that accompany them.

Introduction

AUC TeX is a comprehensive customizable integrated environment for writing input files for LaTeX using GNU Emacs. AUC TeX lets you run TeX/LaTeX and other LaTeX-related tools, such as output filters or post processors from inside Emacs. Especially `running LaTeX' is interesting, as AUC TeX lets you browse through the errors TeX reported, while it moves the cursor directly to the reported error, and displays some documentation for that particular error. This will even work when the document is spread over several files. AUC TeX automatically indents your `LaTeX-source', not only as you write it--you can also let it indent and format an entire document. It has a special outline feature, which can greatly help you `getting the overview' of a document. Apart from these special features,

TOC

AUC TeX provides a large range of handy Emacs macros, which in several different ways can help you write yo LaTeX documents fast and without pain. Here's a short list of the major features:

- Insertion of templates for logical-structural compositions such as environments and sections.
- Hot-keys for easy access to certain often used constructs, e.g., font changes, accented letters, and mathematical symbols.
- Running application programs (such as TeX), and then parsing the output so that errors in the document may be located easily.
- Support for multi-file documents.
- Online help for (La)TeX error messages.
- Outlining--i.e., manipulating the document as a composition of nested/sequential logical constructs.
- Instant formatting and indentation of the ASCII-document in order to make it easier to read.
- `Completion' (and thereby spell-checking) of partially written control sequences.

Inserting Frequently Used Commands

The most commonly used commands/macros of AUC TeX are those which simply insert templates for often used TeX and/or LaTeX constructs, like font changes, handling of environments, etc. These features are very simple, and easy to learn, and help you avoiding stupid mistakes like mismatched braces, or `\begin{}'-`\end{}' pairs.

Insertion of Quotes Dollars, and Braces

In TeX literal double quotes `"like this"' are seldom used, instead two single quotes are used `"like this"'. To help you insert these efficiently, AUC TeX allows you to continue to press " to insert two single quotes. To get a literal double quote, press " twice.

Command: **TeX-insert-quote** *count*

(") Insert the appropriate quote marks for TeX.

Inserts the value of `tex-open-quote` (normally `"') or `tex-close-quote` (normally `"') depending on the context. With prefix argument, always inserts `"' characters.

User Option: **TeX-open-quote**

String inserted by typing " to open a quotation.

User Option: **TeX-close-quote**

String inserted by typing " to open a quotation.

If you include the style file `german' `TeX-open-quote` and `TeX-close-quote` will both be set to `"'.

In AUC TeX, dollar signs should match like they do in TeX. This has been parially implemented, we assume dollar signs always match within a paragraph. The first `$' you insert in a paragraph will do nothing special. The second `$' will match the first. This will be indicated by moving the cursor temporarily over the first dollar sign. If you enter a dollar sign that matches a double dollar sign `$$' AUC TeX will automatically insert two dollar signs. If you enter a second dollar sign that matches a single dollar sign, the single sollar sign will automatically be converted to a double dollar sign.

Command: **TeX-insert-dollar** *arg*

($) Insert dollar sign.

Show matching dollar sign if this dollar sign end the TeX math mode. Ensure double dollar signs match up correctly by inserting extra dollar signs when needed.

With optional arg, insert that many dollar signs.

To avoid unbalanced braces, it is useful to insert them pairwise. You can do this by typing C-c {.

Command: **TeX-insert-braces**

(C-c {) Make a pair of braces and position the cursor to type inside of them.

Inserting Font Specifiers

Perhaps the most used keyboard commands of AUC TeX are the short-cuts available for easy insertion of font changing macros. They all put the font change inside a TeX group, a practice that help preventing subtle errors. The most significant advantage of using these command instead of typing it in yourself, is that the braces will always match correctly.

If you give an argument (that is, type C-u) to the font command, the innermost font will be replaced, i.e. the font in the TeX group around point will be changed. The following table shows the available commands, with `-!-` indicating the position where the text will be inserted.

C-c C-f C-r
: Insert roman {\rm -!-} text.

C-c C-f C-b
: Insert **bold face** `{\bf -!-}' text.

C-c C-f C-i
: Insert *italics* `{\it -!-\/}' text.

C-c C-f C-e
: Insert *emphasized* `{\em -!-\/}' text.

C-c C-f C-s
: Insert *slanted* `{\sl -!-\/}' text.

C-c C-f C-t
: Insert `typewriter` `{\tt -!-}' text.

C-c C-f C-c
: Insert SMALL CAPS `{\sc -!-}' text.

C-c C-f C-d
: Delete the innermost font specification containing point.

Command: **TeX-font** *arg*

(C-c C-f) Insert template for font change command.

If replace is not nil, replace current font. what determines the font to use, as specified by `TeX-font-list`.

User Option: **TeX-font-list**

List of fonts used by TeX-font.

Each entry is a list with three elements. The first element is the key to activate the font. The second element is the

string to insert before point, and the third element is the string to insert after point. An optional fourth element m always replace if not nil.

Inserting chapters, sections, etc.

Insertion of sectioning macros, that is `\chapter', `\section', `\subsection', etc. and accompanying `\label"s may be eased by using C-c C-s. This command is highly customizable, the following describes the default behavior.

When invoking you will be asked for a section macro to insert. An appropriate default is automatically selected by AUC TeX, that is either: at the top of the document; the top level sectioning for that document style, and any other place: The same as the last occurring sectioning command.

Next, you will be asked for the actual name of that section, and last you will be asked for a label to be associated with that section. The label will be prefixed by the value specified in `LaTeX-section-hooks`.

Command: **LaTeX-section** *arg*

(C-c C-s) Insert a sectioning command.

Determine the type of section to be inserted, by the argument arg.

- If arg is nil or missing, use the current level.
- If arg is a list (selected by C-u), go downward one level.
- If arg is negative, go up that many levels.
- If arg is positive or zero, use absolute level:
  - 0 : part
  - 1 : chapter
  - 2 : section
  - 3 : subsection
  - 4 : subsubsection
  - 5 : paragraph
  - 6 : subparagraph

The following variables can be set to customize the function.

`LaTeX-section-hooks`

Hooks to be run when inserting a section.

`LaTeX-section-label`

Prefix to all section references.

The precise behavior of `LaTeX-section` is defined by the contents of `LaTeX-section-hooks`.

User Option: **LaTeX-section-hooks**

List of hooks to run when a new section is inserted.

The following variables are set before the hooks are run

level

Numeric section level, default set by prefix arg to `LaTeX-section`.

name

Name of the sectioning command, derived from level.

title
: The title of the section, default to an empty string.

toc
: Entry for the table of contents list, default nil.

done-mark
: Position of point afterwards, default nil meaning after the inserted text.

A number of hooks are already defined. Most likely, you will be able to get the desired functionality by choosing from these hooks.

`LaTeX-section-level-hook`
: Query the user about the name of the sectioning command. Modifies level and name.

`LaTeX-section-title-hook`
: Query the user about the title of the section. Modifies title.

`LaTeX-section-toc-hook`
: Query the user for the toc entry. Modifies toc.

`LaTeX-section-section-hook`
: Insert LaTeX section command according to name, title, and toc. If toc is nil, no toc entry is inserted. If toc or title are empty strings, done-mark will be placed at the point they should be inserted.

`LaTeX-section-label-hook`
: Insert a label after the section command. Controlled by the variable `LaTeX-section-label`.

To get a full featured `LaTeX-section` command, insert

```
(setq LaTeX-section-hooks
      '(LaTeX-section-level-hook
        LaTeX-section-title-hook
        LaTeX-section-toc-hook
        LaTeX-section-section-hook
        LaTeX-section-label-hook))
```

in your `` `.emacs' `` file.

The behavior of `LaTeX-section-label-hook` is determined by the variable `LaTeX-section-label`.

User Option: **LaTeX-section-label**

Default prefix when asking for a label.

If it is a string, it is used unchanged for all kinds of sections. If it is nil, no label is inserted. If it is a list, the list is searched for a member whose car is equal to the name of the sectioning command being inserted. The cdr is then used as the prefix. If the name is not found, or if the cdr is nil, no label is inserted.

By default, chapters have a prefix of `cha:' while sections and subsections have a prefix of `sec:'. Labels are not automatically inserted for other types of sections.

Inserting Environment Templates

A large apparatus is available that supports insertions of environments, that is `\begin{}' -- `\end{}' pairs.

AUC TeX is aware of most of the actual environments available in a specific document. This is achieved by

examining your `\documentstyle' command, and consulting a precompiled list of environments available in a large number of styles.

You insert an environment with C-c C-e, and select an environment type. Depending on the environment, AUC TeX may ask more questions about the optional parts of the selected environment type.

Command: **LaTeX-environment**

(C-c C-e) AUC TeX will prompt you for an environment to insert. At this prompt, you may press TAB or SPC to complete a partially written name, and/or to get a list of available environments. After selection of a specific environment AUC TeX may prompt you for further specifications.

As a default selection, AUC TeX will suggest the environment last inserted or, as the first choice the value of the variable `LaTeX-default-environment`.

User Option: **LaTeX-default-environment**

Default environment to insert when invoking `LaTeX-environment'.

If the document is empty, or the cursor is placed at the top of the document, AUC TeX will default to insert a `document' environment.

Most of these are described further in the following sections, and you may easily specify more, as described in `Customizing environments'.

You can close the current environment with C-c], but we suggest that you use C-c C-e to insert complete environments instead.

Command: **LaTeX-close-environment**

(C-c]) Insert an `\end' that matches the current environment.

Floats

Figures and tables (i.e., floats) may also be inserted using AUC TeX. After choosing either `figure' or `table' in the environment list described above, you will be prompted for a number of additional things.

float-to
: This field is the option of float environments that controls how they are placed in the final document. In LaTeX this is a sequence of the letters `htbp' as described in the LaTeX manual. The value will default to the value of `LaTeX-float`.

caption
: This is the caption of the float.

label
: The label of this float. The label will have a default prefix, which is controlled by the variables `LaTeX-figure-label` and `LaTeX-table-label`.

Moreover, in the case of a `figure' environment, you will be asked if you want to insert a `center' environment inside the figure.

User Option: **LaTeX-float**

Default placement for floats.

User Option: **LaTeX-figure-label**

Prefix to use for figure labels.

User Option: **LaTeX-table-label**

Prefix to use for table labels.

Itemize-like

In an itemize-like environment, nodes (i.e., `\item's) may be inserted using C-c LFD.

Command: **LaTeX-insert-item**

(C-c LFD) Close the current item, move to the next line and insert an appropriate `\item' for the current environment. That is, `itemize' and `enumerate' will have `\item ' inserted, while `description' will have `\item[]' inserted.

Tabular-like

When inserting Tabular-like environments, that is, `tabular' `array' etc., you will be prompted for a template for that environment.

Customizing environments

See section Adding Support for Environments, for how to customize the list of known environments.

Advanced Editing Features

The previous chapter described how to write the main body of the text easily and with a minimum of errors. In this chapter we will describe some features for entering more specialized sorts of text, and for indenting and navigating through the document.

Entering Mathematics

TeX is written by a mathematician, and has always contained good support for formatting mathematical text. AUC TeX supports this tradition, by offering a special minor mode for entering text with many mathematic symbols. You can enter this mode by typing C-c ~.

Command: **LaTeX-math-mode**

(C-c ~) Toggle LaTeX-math-mode. This is a minor mode rebinding the key `LaTeX-math-abbrev-prefix` to allow easy typing of mathematical symbols. ` will read a character from the keyboard, and insert the symbol as specified in `LaTeX-mathlist`. If given a prefix argument, the symbol will be surrounded by dollar signs.

You can use another prefix key (instead of `) by setting the variable LaTeX-math-abbrev-prefix.

User Option: **LaTeX-math-abbrev-prefix**

A string containing the prefix of `LaTeX-math-mode` commands; This value defaults to `.

The variable `LaTeX-mathlist` holds the actual mapping.

User Option: **LaTeX-mathlist**

A list containing key-command mappings to use in `LaTeX-math-mode`. The car of each element is the key and the

cdr is the macro name.

Completion

Emacs lisp programmers probably know the `lisp-complete-symbol` command, usually bound to M-TAB. Users of the wonderful ispell mode know and love the `ispell-complete-word` command from that package. Similarly, AUC TeX has a `TeX-complete-symbol` command, usually bound to C-c TAB. Using `LaTeX-complete-symbol` makes it easier to type and remember the names of long LaTeX macros. In order to use `TeX-complete-symbol`, you should write a backslash and the start of the macro. Typing C-c TAB will now complete as much of the macro, as it unambiguously can. For example, if you type ``\renewc" and then `C-c TAB, it will expand to ``\renewcommand". Command: **TeX-complete-symbol**

(C-c TAB) Complete TeX symbol before point.

A more direct way to insert a macro is with `TeX-insert-macro`, bound to C-c C-m. It has the advantage over completion that it knows about the argument of most standard LaTeX macros, and will prompt for them. It also knows about the type of the arguments, so it will for example give completion for the argument to `\include'. Some examples are listed below.

Command: **TeX-insert-macro**

(C-c C-m) Prompt (with completion) for the name of a TeX macro, and if AUC TeX knows the macro, prompt for each argument.

Completions work because AUC TeX can analyze TeX files, and store symbols in emacs lisp files for later retrieval. See section Automatic Customization, for more information.

Commenting

It is often necessary to comment out temporarily a region of TeX or LaTeX code. This can be done with the commands C-c ; and C-c %. C-c ; will comment out all lines in the current region, while C-c % will comment out the current paragraph. To uncomment, simply type C-u C-c ; to uncomment all lines in the region, or C-u C-c % uncomment all comment lines around point.

By default, these commands will insert or remove a single `%'. To insert more than one, give an argument. C-u 5 C-c % will add five `%' to each line, while C-u - 5 C-c % will remove up to 5 `%' from each line.

Command: **TeX-comment-region** *count*

(C-c ;) Add or remove `%' from the beginning of each line in the current region, as specified by count.

If count is nil (no prefix argument), 1 `%' will be added to each line.

If count is a list (a non-numeric prefix argument), 1 `%' will be removed from each line.

If count is positive, count `%"s will be added to each line.

If count is negative, count `%"s will be removed from each line.

Command: **TeX-comment-paragraph** *count*

(C-c %) Add or remove `%' from the beginning of each line in the current paragraph, as specified by count. When removing `%"s the paragraph is considered to consist of all preceding and succeeding lines starting with a `%', until the first non-comment line.

If count is nil (no prefix argument), 1 `%' will be added to each line.

If count is a list (a non-numeric prefix argument), 1 `%' will be removed from each line.

If count is positive, count `%"s will be added to each line.

If count is negative, count `%"s will be removed from each line.

Marking, Formatting and Indenting

AUC TeX contains very advanced handling of indentation and reformatting of the LaTeX source. If you have already tried AUC TeX with `auto-fill-mode` enabled, you may have noted that the source is automatically indented and formatted as you write it. More over, AUC TeX is able to format sections of text on demand.

It is important to realize, that AUC TeX comes with `formatting' in two fashions. Either letting TeX format the file, or letting AUC TeX make the ASCII document look better.

Indentation is done by LaTeX environments and by TeX groups, that is the body of an environment is indented by the value of `LaTeX-indent-level` (default 2). Also, items of an `itemize-like' environment are indented by the value of `LaTeX-item-indent`, default -2. This indentation makes it easier to see the structure of the document, and to catch errors such as a missing close brace. Thus, the indentation is done for precisely the same reasons that you would indent ordinary computer programs.

The following is a short sample of an itemize environment indented by AUC TeX. If more environment are nested, they are indented `accumulated' just like most programming languages usually are seen indented in nested constructs.

```
\begin{itemize}
\item Insertion of templates for logical-structural compositions such as
  environments and sections.
\item Hot-keys for easy access to certain often used constructs, e.g.,
  font changes, accented letters, and mathematical symbols.
\item Running application programs (such as \TeX), and then parsing
  the output so that errors in the document may be located
  easily.
\item Support for multi-file documents.
\item Online help for \AllTeX\ error messages.
\item Outlining\Dash i.e., manipulating the document as a composition
  of nested/sequential logical constructs.
\item Instant formatting and indentation of the \ascii-document in
  order to make it easier to read.
\item `Completion' (and thereby spell-checking) of partially written
  control sequences.
\end{itemize}
```

You can format and indent single lines, paragraphs, environments, or sections.

TAB

`LaTeX-indent-line` will indent the current line.

LFD

`reindent-then-newline-and-indent` indents the current line, and then inserts a new line (much like RET) and move the cursor to an appropriate position by the left margin.

M-q

Alias for C-c C-q C-p

C-c C-q C-p

`LaTeX-format-paragraph` will reformat or `fill' the current paragraph.

C-c C-q C-e

`LaTeX-format-environment` will reformat or `fill' the current environment. This may e.g. be the `document' environment, in which case the entire document will be formatted.

C-c C-q C-s

`LaTeX-format-section` will reformat or `fill' the current logical sectional unit.

M-g

Alias for C-c C-q C-r

C-c C-q C-r

`LaTeX-format-region` will format or `fill' the current region.

Warning: The formatting cannot handle tabular-like environments. Those will be completely messed-up if you try to format them.

User Option: **LaTeX-indent-level**

Number of spaces to add to the indentation for each `\begin' not matched by a `\end'.

User Option: **LaTeX-item-indent**

Number of spaces to add to the indentation for `\item"s in list environments.

User Option: **TeX-brace-indent-level**

Number of spaces to add to the indentation for each `{' not matched by a `}'.

Outlining the Document

Minor mode for editing outlines with selective display. Headings are lines which start with asterisks: one for major headings, two for sub-headings, etc. Lines not starting with asterisks are body lines.

Body text or sub-headings under a heading can be made temporarily invisible, or visible again. Invisible lines are attached to the end of the heading, so they move with it, if the line is killed and yanked back. A heading with text hidden under it is marked with an ellipsis (...).

C-c C-o C-n

`outline-next-visible-heading` move by visible headings

C-c C-o C-p

`outline-previous-visible-heading`

C-c C-o C-f

`outline-forward-same-level` similar but skip sub-headings

C-c C-o C-b

`outline-backward-same-level`

C-c C-o C-u

`outline-up-heading move from` sub heading to heading

C-c C-o C-t

`hide-body` make all text invisible (not headings).

C-c C-o C-a

`show-all` make everything in buffer visible.

C-c C-o C-o

`outline-minor-mode` leave outline mode.

The remaining commands are used when point is on a heading line. They apply to some of the body or sub-headings of that heading.

C-c C-o C-h

`hide-subtree` make body and sub-headings invisible.

C-c C-o C-s

`show-subtree` make body and sub-headings visible.

C-c C-o C-i

`show-children` make direct sub-headings visible. No effect on body, or sub-headings 2 or more levels down. With arg N, affects sub-headings N levels down.

C-c C-o C-c

`hide-entry` make immediately following body invisible.

C-c C-o C-e

`show-entry` make it visible.

C-c C-o C-l

`hide-leaves` make body under heading and under its sub-headings invisible. The sub-headings remain visible.

C-c C-o C-x

`show-branches` make all sub-headings at all levels visible.

User Option: **outline-prefix-char**

The prefix char (C-c C-o) used to activate the outline commands. You most likely want to set this to something shorter.

In LaTeX mode the default headings are the sectioning commands, and as top level headings `\documentstyle', `\appendix', `TeX-trailer-start', and `TeX-header-end'. You can also define extra headings at any level, by setting the variable `TeX-outline-extra'.

User Option: **TeX-outline-extra**

List of extra TeX outline levels.

Each element is a list with two entries. The first entry is the regular expression matching a header, and the second is the level of the header. See `LaTeX-section-list` for existing header levels.

You can use outlining in other modes as well, the function to do this is `outline-minor-mode`.

Command: **outline-minor-mode** *prefix*

Enters outline minor mode. With prefix: non-nil: turn outline mode on. nil: turn outline mode off.

User Option: **outline-regexp**

Regular expression matching header lines. When using outline-minor mode outside AUC TeX, this is per default set to lines beginning with one or more stars.

User Option: **outline-level-function**

Function calculating the level of a header. Outside AUC TeX, this is per default the length of the string matched by `outline-regexp`.

Formatting and Printing

The most powerful features of AUC TeX may be those allowing you to run (La)TeX and other external commands like BibTeX and `makeindex` from within Emacs, viewing and printing the results, and moreover allowing you to *debug* your documents.

Executing Commands

Formatting the document with TeX or LaTeX, viewing with a a previewer, printing the document, running BibTeX, making an index, or checking the document with `lacheck` all require running an external command.

There are two ways to run an external command, you can either run it on all of the current document with `TeX-command-master`, or on the current region with `TeX-command-region`.

Command: **TeX-command-master**

(C-c C-c) Query the user for a command, and run it on the master file associated with the current buffer. The name of the master file is controlled by the variable `TeX-master`. The available commands are controlled by the variable `TeX-command-list`.

See section Installation of AUC TeX for a discussion about `TeX-command-list` and section Multifile Documents for a discussion about `TeX-master`.

Command: **TeX-command-region**

(C-c C-r) Query the user for a command, and run it on the "region file". Some commands (typically those invoking TeX or LaTeX) will write the current region into the region file, after extracting the header and tailer from the master file. The name of the region file is controlled by the variable `TeX-region`. The name of the master file is controlled by the variable `TeX-master`. The header is all text up to the line matching the regular expression `TeX-header-end`. The trailer is all text from the line matching the regular expression `TeX-trailer-start`. The available commands are controlled by the variable `TeX-command-list`.

AUC TeX will allow one process for each document, plus one process for the region file to be active at the same time. Thus, if you are editing n different documents, you can have n plus one processes running at the same time. If the last process you started was on the region, the commands described in section Catching the errors and section Controlling the output will work on that process, otherwise they will work on the process associated with the current document.

User Option: **TeX-region**

The name of the file for temporarily storing the text when formatting the current region.

User Option: **TeX-header-end**

A regular expression matching the end of the header. By default, this is `\begin{document}' in LaTeX mode and `%**end of header' in TeX mode.

User Option: **TeX-trailer-start**

A regular expression matching the start of the trailer. By default, this is `\end{document}' in LaTeX mode and `\bye'

in TeX mode.

AUC TeX will try to guess what command you want to invoke, but by default it will assume that you want to run TeX in TeX mode and LaTeX in LaTeX mode. You can overwrite this by setting the variable `TeX-command-default`.

User Option: **TeX-command-default**

The default command to run in this buffer. Must be an entry in `TeX-command-list`.

If you want to overwrite the values of `TeX-header-end`, `TeX-trailer-start`, or `TeX-command-default`, you can do that for all files by setting them in either `TeX-mode-hook`, `plain-TeX-mode-hook`, or `LaTeX-mode-hook`. To overwrite them for a single file, define them as file variables (see section 'File Variables' in The Emacs Editor). You do this by putting special formatted text near the end of the file.

```
% Local Variables:
% TeX-header-end: "% End-Of-Header"
% TeX-trailer-start: "% Start-Of-Trailer"
% TeX-command-default: "SliTeX"
% End:
```

Catching the errors

Once you've formatted your document you may `debug' it, i.e. browse through the errors (La)TeX reported.

Command: **TeX-next-error**

(C-c `) Go to the next error reported by TeX. The view will be split in two, with the cursor placed as close as possible to the error in the top view. In the bottom view, the error message will be displayed along with some explanatory text.

Normally AUC TeX will only report real errors, but you may as well ask it to report `bad boxes' as well.

Command: **TeX-toggle-debug-bad-boxes**

(C-c C-w) Toggle whether AUC TeX should stop at bad boxes (i.e. over/under full boxes) as well as at normal errors.

As default, AUC TeX will display that special `*help*' buffer containing the error reported by TeX along with the documentation. There is however an `expert' option, which allows you to display the real TeX output.

User Option: **TeX-display-help**

When non-nil AUC TeX will automatically display a help text whenever an error is encountered using `TeX-next-error` (C-c `).

Checking for problems

Running TeX or LaTeX will only find regular errors in the document, not examples of bad style. Furthermore, description of the errors may often be confusing. The utility `lacheck` can be used to find style errors, such as forgetting to escape the space after an abbreviation or using `...' instead of `\ldots' and many other problems like that. You start `lacheck` with C-c C-c C h e c k RET. The result will be a list of errors in the `*compilation*' buffer. You can go through the errors with C-x ` (`next-error`, see section 'Compilation' in The Emacs Editor), which will move point to the location of the next error.

Controlling the output

A number of commands are available for controlling the output of an application running under AUC TeX

Command: **TeX-kill-job**

(C-c C-k) Kill currently running external application. This may be either of TeX, LaTeX, previewer BibTeX etc.

Command: **TeX-recenter-output-buffer**

(C-c C-l) Recenter the output buffer so that the bottom line is visible.

Command: **TeX-home-buffer**

(C-c ^) Go to the `master' file in the document associated with the current buffer, or if already there, to the file where the current process was started.

Multifile Documents

If you spread a document over many files (as you are likely to do if there are multiple authors, or if you have not yet discovered the power of the outline commands (see section Outlining the Document)), that can be done by having a "master" file from where you include the various files with the TeX macro `\input' or the LaTeX macro `\include'. These files may also include other files themselves. However, to format the document you must run the commands on the top level file.

When you for example ask AUC TeX to run a command on the master file, it has no way to know what the name of the master file is. If it finds the line indicating the end of the header in a master file (`TeX-header-end`), it can figure out for itself that this is a master file. Otherwise, it will ask for the name of the master file associated with the buffer. To avoid asking you again, AUC TeX will automatically insert the name of the master file as a file variable (see section 'File Variables' in The Emacs Editor). You can also insert the file variable yourself, by putting the following text at the end of your files.

```
% Local Variables:
% TeX-master: "mymaster"
% End:
```

You should always set this variable to the top level document. If you always use single file documents, or always use the same name for your top level documents, you can set this variable in your `.emacs' file.

```
(setq-default TeX-master t) ; Only use single file douments.

(setq-default TeX-master "master") ; All master files called "master".
```

User Option: **TeX-master**

The master file associated with the current buffer. If the file being edited is actually included from another file, you can tell AUC TeX the name of the master file by setting this variable. If there are multiple levels of nesting, specify the top level file.

If this variable is `nil`, AUC TeX will query you for the name.

If the variable is `t`, AUC TeX will assume the file is a master file itself.

If the variable is `'shared`, AUC TeX will query for the name, but not change the file.

It is suggested that you use the File Variables (see section 'File Variables' in The Emacs Editor) to set this variable permanently for each file.

User Option: **TeX-one-master**

Regular expression matching ordinary TeX files.

You should set this variable to match the name of all files, where automatically adding a file variable with the name of the master file is a good idea. When AUC TeX adds the name of the master file as a file variable, it does not need to ask next time you edit the file.

If you dislike AUC TeX automatically modifying your files, you can set this variable to `"<none>"'. By default, AUC TeX will modify any file with an extension of `.tex'.

AUC TeX keeps track of macros, environments, labels, and style files that are used in a given document. For this to work with multifile documents, AUC TeX has to have a place to put the information about the files in the document. This is done by having an `` `auto' `` subdirectory placed in the directory where your document is located. Each time you save a file, AUC TeX will write information about the file into the `` `auto' `` directory. When you load a file, AUC TeX will then read the information in the `` `auto' `` directory about the file you loaded, *and the master file specified by* `TeX-master`. Since the master file (perhaps indirectly) includes all other files in the document, AUC TeX will get information from all files in the document. This means that you will get from each file e.g. completion for all labels defined anywhere in the document.

You must create the `` `auto' `` directory manually for this to work. If you don't do this, the other files in the document will not know anything about each other, except for the name of the master file. See section Automatic Customization for a Directory.

Automatic Parsing of TeX files.

AUC TeX depends heavely on being able to extract information from the buffers by parsing them. Since parsing the buffer can be somewhat slow, AUC TeX will store the parsed information in an `` `auto' `` subdirectory in the directory where the TeX files are stored, see section Automatic Customization for a Directory. The information in the `` `auto' `` directory is also useful for multifile documents see section Multifile Documents, since it allows each file to access the parsed information from all the other files in the document. This is done by first reading the information from the master file, and then recursively the information from each file stored in the master file.

When you issue the first AUC TeX command on a new buffer, AUC TeX will try to read the information about the file from the `` `auto' `` directory. If this fails, for example if you have not edited the file before, it will parse the current buffer.

When you save the buffer it will be parsed again, and the information will be placed in the `` `auto' `` directory for use next time the file -- or another file in the document -- is edited.

It is possible to disable the parsing by setting the buffer local variables `TeX-parse-self` and `TeX-auto-save`.

```
(setq-default TeX-parse-self nil) ; Disable parse on load.
(setq-default TeX-auto-save nil) ; Disable parse on save.
```

This can also be done on a per file basis, by changing the file local variables.

```
% Local Variables:
```

```
% TeX-parse-self: nil
% TeX-auto-save: nil
% End:
```

Even when you have disabled the automatic parsing, you can force the generation of style information by pressing C-c C-n.

User Option: **TeX-parse-self**

Parse file after loading it if no style hook is found for it.

User Option: **TeX-auto-save**

Automatically save style information when saving the buffer.

Command: **TeX-normal-mode** *arg*

(C-c C-n) Remove all information about this buffer, and apply the style hooks again. Save buffer first including style information. With optional argument, also reload the style hooks.

Instead of disabling the parsing entirely, you can also speed it significantly up by limiting the information it will search for (and store) when parsing the buffer. You can do this by setting the default values for the buffer local variables `TeX-auto-regexp-list` and `TeX-auto-parse-length` in your `` `.emacs' `` file.

```
;; Only parse \documentstyle information.
(setq-default TeX-auto-regexp-list 'LaTeX-auto-minimal-regexp-list)
;; The documentstyle command is usually near the beginning.
(setq-default TeX-auto-parse-length 2000)
```

This example will speed the parsing up significantly, but AUC TeX will not longer be able to provide completion for labels, macros, environments, or bibitems specified in the document, not will it know what files belong to the document.

These variables can also be specified on a per file basis, by changing the file local variables.

```
% Local Variables:
% TeX-auto-regexp-list: TeX-auto-full-regexp-list
% TeX-auto-parse-length: 999999
% End:
```

User Option: **TeX-auto-regexp-list**

List of regular expresions used for parsing the current file.

User Option: **TeX-auto-parse-length**

Maximal length of TeX file that will be parsed.

The pre-specified lists of regexps are defined below. You can use these before loading AUC TeX by quoting them, as in the example above.

Constant: **LaTeX-auto-minimal-regexp-list**

Only parse documentstyle.

Constant: **LaTeX-auto-label-regexp-list**

Only parse LaTeX labels.

Constant: **LaTeX-auto-regexp-list**

Parse common LaTeX commands.

Constant: **plain-TeX-auto-regexp-list**

Parse common plain TeX commands.

Constant: **TeX-auto-full-regexp-list**

Parse all TeX and LaTeX commands that AUC TeX can use.

The Anti-American Conspiracy

AUC TeX contains some support for ease the use of various European character sets. This support is contained in two packages "Keymap Mode" in `min-key.el', which support general remapping of the keyboard, as well as converting between various character set encodings, and "Dead Key Mode" in `ltx-dead.el', which support dead keys for entering accents. Both packages depend on the "Minor Mode Keymap" support in `min-bind.el', but at least "Keymap Mode" is otherwise useful even outside AUC TeX.

If you have the necessary software, AUC TeX will also work with some Japanese versions of TeX and Emacs.

Support for the Scandinavian Languages

For some languages, it makes sense to remap the keyboard. This is true for languages that add a small set of regular letters compared to the English character set. The Scandinavian languages belong to this category. Danish, Norwegian, and Swedish each add three extra letters compared to English, all of which are equal to the other letters in the alphabet. They are **not** considered accented versions of the "regular" letters.

Since these letters have a well defined place on any Scandinavian keyboard, it makes sense to remap these keys to insert the equivalent TeX macros. This can also be done on a keyboard with international layout, just map the keys at the locations where the national letters normally are found.

In order to get the original binding of the keys, we can use a little trick. If you press one of the national keys twice, the national letter will first be inserted, and then replaced with the original binding of the key. This works since these national letters practically never occur twice in row in a Scandinavian word.

The keyboard mapping is implemented as a minor mode. To enter the minor mode for the first time, type M-x keyboard-query-mapping. It will first prompt you for a language to use. Currently only Danish, Swedish, German, and Russian are defined, so you have to chose one of those. Norway use the same character set as Denmark.

Next, it will prompt you for what encoding of the language's character set to use for the keyboard and screen. The same encodings are available for both the keyboard and screen, but they are not equally good. Choosing e.g. TeX for the keyboard encoding is not very useful. Below is a table of currently supported encodings.

`ISO 646 (DK or SE)'

> If your terminal thinks {, |, and } are letters, this is the encoding for you. You can use it for either Keyboard or Screen encoding.

`Keyboard Layout'

> If you have an international keyboard layout, use this for the keyboard encoding. If you do not have an international keyboard layout -- but wish you had -- you can use it for the Screen encoding instead.

`Digraphs'

Two letter combinations that form poor substitutes for the real national letters. It can be used as the Screen encoding, if you for example are sending electronic mail to someone on an unknown machine.

`TeX'

This is what you want to use for the Screen encoding when writing a TeX document.

`ISO 8859 Latin 1'

Only useful if you have hacked Emacs to understand 8-bit characters.

Finally, it will ask you if you want to get the original binding by pressing a key twice. For the Scandinavian languages, you want this.

Command: **keyboard-query-mapping**

(M-x keyboard-query-mapping) Query the user for what mapping to use, and use it.

After you have entered `keyboard-mode` once, you can leave and enter it with M-x keyboard-mode. It will use the same mapping as last time you called `keyboard-query-mapping`.

Command: **keyboard-query-mapping**

(M-x keyboard-mode) Toggle keyboard-mode. With prefix arg, turn keyboard-mode on iff arg is positive.

This is still inconvenient, so you may want to define a special function to turn your favorite mapping on and of, as shown in the following example.

```
(defun tex-dk-double-mode (arg)
  "DK TeX keys on international keyboard."
  (interactive "P")
  (require 'min-key)
  (if (or (and (null arg) keyboard-mode)
          (<= (prefix-numeric-value arg) 0))
      (keyboard-mode -1)
    (keyboard-set-mapping "Danish" "Keyboard Layout" "TeX" t)
    (keyboard-mode 1)))
```

To enter new character sets or new encodings, you must edit the variable `language-encodings` in the file `min-key.el'. Please send any new useful additions to me.

User Option: **language-encodings**

Language dependent mapping between different encodings.

This list determines how to map between different encodings of the character set of a language.

Each element in the list is itself a list.

The first element is the name of the language.

The second element is a short name of the language.

The third element is a list of short strings, each representing a possible encoding of the language's character set.

The fourth element is a list of long strings, each representing the same encodings of the language's character set.

The remaining elements each represent the encodings of one character. The encodings must appear in the same

sequence as they were found in the second element.

Support for Russian

See section Support for the Scandinavian Languages for a general explanation of keyboard remapping.

For Russian it not only makes sense to remap the keyboard. You have to do it, in order to get the Cyrillic character set from an ordinary QWERTY keyboard. AUC TeX will map QWERTY into the Russian keyboard layout YAWERTY, either with AMS Cyrillic encoding or the KOI8 character set encoding. The standard Russian keyboard layout JCUKEN is not implemented, contributions welcome.

The Russian character set encodings were kindly contributed by Justin R. Smith `<jsmith@king.mcs.drexel.edu>', please direct questions to him.

You can get a Cyrillic font for X11 from Serge Vakulenko `<vak@kiae.su>'. You will need an Emacs capable of displaying 8 bit characters to use it.

```

Dvorak and QWERTY

QWERTY is a well established standard for how the keys on a keyboard are placed. It is almost universally accepted, most countries use it with only minor modifications to allow for any additional letters. However, it is far from optimal. It is even said that QWERTY was purposefully designed to slow down the typist, in order to protect the early typewriters.

Modern research has shown that large speedups in typing can be obtained by designing a new keyboard radically different from the current standard. Specifically, it should be split in two, and characters should be entered by pressing several keys at once.

However, some small speedups can be obtained simply by remapping the keys using the same physical layout. The Dvorak layout is an example of this. It is usually not worth the frustration of having to master a different keyboard layout, but some people have made the effort.

With `keyboard-mode` you can use QWERTY layout on a Dvorak keyboard, or vice versa. Simply type M-x keyboard-query-mapping, select the "language" `Keyboard Layout', and specify the layout on the keyboard, and what layout you want on the screen. Answer n when it asks you about pressing the key twice to get the original binding. You can then switch between QWERTY and Dvorak with M-x keyboard-mode.

See section Support for the Scandinavian Languages for a more detailed description of these functions.

Accents on Dead Keys

In some languages, like German and Dutch, you can make variants of certain letters by giving them an accent mark. A common way to enter these combined characters on a typewriter is by first typing a "dead" key which prints the accent mark without moving the printers head, and then typing the letter. In AUC TeX we simulate this by marking certain keys as dead. When you press one of those keys, it will wait for another key to be pressed. To enter the accent by itself, press the dead key twice. Examples: ' e inserts `\'{e}'. ' ' inserts `'. ' i inserts `\'{\i}'.

To enable this feature, you must first specify what accents you are interested in. This is done by setting the variable `LaTeX-dead-keys`.

User Option: **LaTeX-dead-keys**

List of characters used as dead keys. Valid characters are `', ``', `"', `^', and `~'. By default, all the valid characters are used.

This is best done in your `.emacs' file. Then, you simply enable the dead keys with M-x LaTeX-dead-mode.

Command: **LaTeX-dead-mode**

(M-x LaTeX-dead-mode) Toggle `LaTeX-dead-mode`. With prefix arg, turn `LaTeX-dead-mode` on iff arg is positive.

This mode allows users to conveniently enter characters with accents, as found in some European languages.

The supported accents are defined by `LaTeX-dead-keys`. Modify that variable to change the list of dead keys. (You most likely want to do that).

Converting Between Encodings of a Character Set

You can convert between any of the encodings for any of the supported character sets, even the special character set called `Keyboard Layout'. However, the most useful conversion is for the Latin1 character set. You convert the current region by typing convert-character-query. It will ask you for a character set and two encodings of the character set.

Command: **convert-character-query**

(convert-character-query) Convert characters in region, query user for character set and two encodings.

This function can be useful, not only when you want to import a file written with a different character set encoding, but also when you write TeX documents normally. You can use this function to edit the TeX document using a character set that your terminal will display correctly, and then convert the file to TeX format before you format it.

Japanese TeX

To write Japanese text with AUC TeX you need to have versions of TeX and Emacs that support Japanese. There exist at least two variants of TeX for Japanese text, and AUC TeX can be used with both, as well as with the two Japanese-aware Emacses, NEMACS and MULE.

To use the Japanese TeX variants, simply enter `japanese-tex-mode`, `japanese-latex-mode`, or `japanese-slitex-mode`, and everything should work. If not, send mail to Shinji Kobayashi (`<koba@flab.fujitsu.co.jp>', who kindly donated the code for supporting Japanese in AUC TeX. None of the primary AUC TeX maintainers understand Japanese, so they can not help you.

Automatic Customization

Since AUC TeX is so highly customizable, it makes sense that it is able to customize itself. The automatic customization consists of scanning TeX files and extracting symbols, environments, and things like that.

The automatic customization is done on three different levels. The global level is the level shared by all users at your site, and consists of scanning the standard TeX style files, and any extra styles added locally for all users on the site. The private level deals with those style files you have written for your own use, and use in different documents. You may have a `~/lib/TeX/' directory where you store useful style files for your own use. The local level is for a specific directory, and deals with writing customization for the files for your normal TeX documents.

If you compare with the environment variable `TEXINPUTS`, the global level corresponds to the directories built into TeX. The private level corresponds to the directories you add yourself, except for `.', which is the local level.

By default AUC TeX will search for customization files in all the global, private, and local style directories, but you can also set the path directly. This is useful if you for example want to add another person's style hooks to your p Please note that all matching files found in `TeX-style-path` are loaded, and all hooks defined in the files will be executed.

User Option: **TeX-style-path**

List of directories to search for AUC TeX style files. Each must end with a slash.

By default, when AUC TeX searches a directory for files, it will recursively search through subdirectories.

User Option: **TeX-file-recurse**

If not nil, search TeX directories recursively.

By default, AUC TeX will ignore files name `` `.' ``, `` `..' ``, `` `SCCS' ``, `` `RCS' ``, and `` `CVS' ``.

User Option: **TeX-ignore-file**

Regular expression matching file names to ignore.

These files or directories will not be considered when searching for TeX files in a directory.

Automatic Customization for the Site

Assuming that the automatic customization at the global level was done when AUC TeX was installed, your choice is now. Will you use it? If you use it, you will benefit by having access to all the symbols and environments available for completion purposes. The drawback is slower load time when you edit a new file and perhaps too many confusing symbols when you try to do a completion.

You can disable the automatic generated global style hooks by setting the variable `TeX-auto-global` to nil.

User Option: **TeX-macro-global**

Directories containing the site's TeX style files.

User Option: **TeX-style-global**

Directory containing hand generated TeX information. Must end with a slash.

These correspond to TeX macros shared by all users of a site.

User Option: **TeX-auto-global**

Directory containing automatically generated information.

For storing automatic extracted information about the TeX macros shared by all users of a site.

Automatic Customization for a User

You should specify where you store your private TeX macros, so AUC TeX can extract their information. The extracted information will go to the directory `TeX-auto-private`

Use M-x TeX-auto-generate to extract the information.

User Option: **TeX-macro-private**

Directories where you store your personal TeX macros. Each must end with a slash.

User Option: **TeX-auto-private**

Directory containing automatically generated information. Must end with a slash.

These correspond to the personal TeX macros.

Command: **TeX-auto-generate** *TEX AUTO*

(M-x TeX-auto-generate) Generate style hook for TEX and store it in AUTO. If TEX is a directory, generate style hooks for all files in the directory.

User Option: **TeX-style-private**

Directory containing hand generated information. Must end with a slash.

These correspond to the personal TeX macros.

Automatic Customization for a Directory

AUC TeX can update the style information about a file each time you save it, and it will do this if the directory `TeX-auto-local` exist. `TeX-auto-local` is by default set to `'"auto/"', so simply creating an `` `auto' `` directory will enable automatic saving of style information.

The advantage of doing this is that macros, labels, etc. defined in any file in a multifile document will be known in all the files in the document. The disadvantage is that saving will be slower. To disable, set `TeX-auto-local` to nil.

User Option: **TeX-style-local**

Directory containing hand generated TeX information. Must end with a slash.

These correspond to TeX macros found in the current directory.

User Option: **TeX-auto-local**

Directory containing automatically generated TeX information. Must end with a slash.

These correspond to TeX macros found in the current directory.

Writing Your own Style Support

See section Automatic Customization for a discussion about automatically generated global, private, and local style files. The hand generated style files are equivalent, except that they by default are found in `` `style' `` directories instead of `` `auto' `` directories.

If you write some useful support for a public TeX style file, please send it to us.

A Simple Style File

Here is a simple example of a style file.

```
;;; book.el - Special code for book style.
```

```
(TeX-add-style-hook "book"
 (function (lambda () (setq LaTeX-largest-level
                            (LaTeX-section-level ("chapter"))))))
```

This file specifies that the largest kind of section in a LaTeX document using the book document style is chapter. The interesting thing to notice is that the style file defines an (anonymous) function, and adds it to the list of loaded style hooks by calling `TeX-add-style-hook`.

The first time the user indirectly tries to access some style specific information, such as the largest sectioning command available, the style hooks for all files directly or indirectly read by the current document is executed. The actual files will only be evaluated once, but the hooks will be called for each buffer using the style file.

Function: **TeX-add-style-hook** *style hook*

Add hook to the list of functions to run when we use the TeX file style.

Adding Support for Macros

The most common thing to define in a style hook is new symbols (TeX macros). Most likely along with a description of the arguments to the function, since the symbol itself can be defined automatically.

Here are a few examples from `` `latex.el' ``.

```
(TeX-add-style-hook "latex"
 (function
  (lambda ()
     (TeX-add-symbols
     '("arabic" TeX-argument-counter-hook)
     '("label" TeX-argument-define-label-hook)
     '("ref" TeX-argument-label-hook)
     '("newcommand" TeX-argument-define-macro-hook [ "Number of arguments" ] t)
     '("newtheorem" TeX-argument-define-environment-hook
       [ TeX-argument-environment-hook "Numbered like" ]
       t [ TeX-argument-counter-hook "Within counter" ])))))
```

Function: **TeX-add-symbols** *symbol ...*

Add each symbol to the list of known symbols.

Each argument to `TeX-add-symbols` is a list describing one symbol. The head of the list is the name if the symbol, the remaining elements describe each argument.

If there are no additional elements, the symbol will be inserted with point inside braces. Otherwise, each argument of this function should match an argument of the TeX macro. What is done depends on the argument type.

If a macro is defined multiple times, AUC TeX will chose the one with the longest definition (i.e. the one with the most arguments).

Thus, to overwrite

```
        '("tref" 1) ; one argument
```

you can specify

```
'("tref" TeX-argument-label-hook ignore) ; two arguments
```

`ignore` is a function that does not do anything, so when you insert a `tref' you will be prompted for a label and no more.

`string`
: Use the string as a prompt to prompt for the argument.

`number`
: Insert that many braces, leave point inside the first.

`nil`
: Insert empty braces.

`t`
: Insert empty braces, leave point between the braces.

`other symbols`
: Call the symbol as a function. You can define your own hook, or use one of the predefined argument hooks.

`list`
: If the car is a string, insert it as a prompt and the next element as initial input. Otherwise, call the car of the list with the remaining elements as arguments.

`vector`
: Optional argument. If it has more than one element, parse it as a list, otherwise parse the only element as above. Use square brackets instead of curly braces, and is not inserted on empty user input.

A lot of argument hooks have already been defined. The first argument to all hooks is a flag indicating if it is an optional argument. It is up to the hook to determine what to do with the remaining arguments, if any. Typically the next argument is used to overwrite the default prompt.

`TeX-argument-conditional-hook`
: Implements if EXPR THEN ELSE. If EXPR evaluates to true, parse THEN as an argument list, else parse ELSE as an argument list.

`TeX-argument-literal-hook`
: Insert its arguments into the buffer. Used for specifying extra syntax for a macro.

`TeX-argument-free-hook`
: Parse its arguments but use no braces when they are inserted.

`TeX-argument-eval-hook`
: Evaluate arguments and insert the result in the buffer.

`TeX-argument-file-hook`
: Prompt for a tex or sty filename, and use it without the extension. Run the file hooks defined for it.

`TeX-argument-label-hook`
: Prompt for a label completing with known labels.

`TeX-argument-macro-hook`
: Prompt for a TeX macro with completion.

`TeX-argument-environment-hook`
: Prompt for a LaTeX environment with completion.

`TeX-argument-cite-hook`
: Prompt for a BibTeX citation.

`TeX-argument-counter-hook`
: Prompt for a LaTeX counter.

`TeX-argument-savebox-hook`
: Prompt for a LaTeX savebox.

`TeX-argument-file-hook`
: Prompt for a filename in the current directory, and use it without the extension.

`TeX-argument-input-file-hook`
: Prompt for a filename in the current directory, and use it without the extension. Run the style hooks for the file.

`TeX-argument-define-label-hook`
: Prompt for a label completing with known labels. Add label to list of defined labels.

`TeX-argument-define-macro-hook`
: Prompt for a TeX macro with completion. Add macro to list of defined macros.

`TeX-argument-define-environment-hook`
: Prompt for a LaTeX environment with completion. Add environment to list of defined environments.

`TeX-argument-define-cite-hook`
: Prompt for a BibTeX citation.

`TeX-argument-define-counter-hook`
: Prompt for a LaTeX counter.

`TeX-argument-define-savebox-hook`
: Prompt for a LaTeX savebox.

`TeX-argument-corner-hook`
: Prompt for a LaTeX side or corner position with completion.

`TeX-argument-lr-hook`
: Prompt for a LaTeX side with completion.

`TeX-argument-tb-hook`
: Prompt for a LaTeX side with completion.

`TeX-argument-pagestyle-hook`
: Prompt for a LaTeX pagestyle with completion.

`TeX-argument-verb-hook`
: Prompt for delimiter and text.

`TeX-argument-pair-hook`
: Insert a pair of numbers, use arguments for prompt. The numbers are surrounded by parentheses and separated with a comma.

`TeX-argument-size-hook`
: Insert width and height as a pair. No arguments.

`TeX-argument-coordinate-hook`
: Insert x and y coordinates as a pair. No arguments.

If you add new hooks, you can assume that point is placed directly after the previous argument, or after the macro name if this is the first argument. Please leave point located after the argument you are inserting. If you want point to be located somewhere else after all hooks have been processed, set the value of `exit-mark`. It will point nowhere, until the argument hook sets it.

Adding Support for Environments

Adding support for environments is very much like adding support for TeX macros, except that each environment normally only takes one argument, an environment hook. The example is again a short version of `latex.el'.

```
(TeX-add-style-hook "latex"
 (function
  (lambda ()
    (LaTeX-add-environments
     '("document" LaTeX-document-hook)
     '("enumerate" LaTeX-item-hook)
     '("itemize" LaTeX-item-hook)
     '("list" LaTeX-list-hook)))))
```

The only hook that is general useful is `LaTeX-item-hook`, which is used for environments that contain items. It is completely up to the environment hook to insert the environment, but the function `LaTeX-insert-environment` may be to some help. The hook will be called with the name of the environment as its first argument, and extra arguments can be provided by adding them to a list after the hook.

If an environment is defined multiple times, AUC TeX will chose the one with the longest definition. Thus, if you have an enumerate style file, and want it to replace the standard LaTeX enumerate hook above, you could define an `enumerate.el' file as follows, and place it in the appropriate style directory.

```
(TeX-add-style-hook "latex"
 (function
  (lambda ()
    (LaTeX-add-environments
     '("enumerate" LaTeX-enumerate-hook foo)))))

(defun LaTeX-enumerate-hook (environment &optional ignore) ...)
```

The symbol `foo` will be passed to `LaTeX-enumerate-hook` as the second argument, but since we only added it to overwrite the definition in `latex.el' it is just ignored.

Function: **LaTeX-add-environments** *env ...*

Add each env to list of loaded environments.

Function: **LaTeX-insert-environment** *env [extra]*

Insert environment of type env, with optional argument extra.

Adding Other Information

You can also specify bibliographical databases and labels in the style file. This is probably of little use, since this information will usually be automatically generated from the TeX file anyway.

Function: **LaTeX-add-bibliographies** *bibliography ...*

Add each bibliography to list of loaded bibliographies.

Function: **LaTeX-add-labels** *label ...*

Add each label to the list of known labels.

Supporting Other Format Packages

You can add support for new TeX format packages. These are treated specially, in that they are loaded immediately after you enter `VirTeX-mode`, and they actually define the major mode.

Here is the file defining `slitex-mode`.

```
;;;  SLITEX.el - Special code for SliTeX mode.

(require 'tex-init)
(require 'ltx-misc)

(TeX-add-style-hook "SLITEX"
 (function
  (lambda ()
    (setq mode-name "SliTeX")
    (setq major-mode 'SliTeX-mode)
    (setq TeX-command-default TeX-command-SliTeX)
    (LaTeX-mode-initialization)
    (run-hooks 'SliTeX-mode-hook)
    (TeX-run-style-hooks "latex" "slitex"))))
```

The file should be placed in the directory `TeX-format-directory`.

User Option: **TeX-format-directory**

Directory containing information about TeX format packages. Must end with a slash.

You must also add an entry to `TeX-format-list` in order to make it known to the rest of the system.

User Option: **TeX-format-list**

List of format packages to consider when choosing a TeX mode.

A list with an entry for each format package available at the site.

Each entry is a list with three elements.

1. The name of the format package.
2. The name of the major mode.
3. A regexp typically matched in the beginning of the file.

When entering `tex-mode`, each regexp is tried in turn in order to find what major mode to enter.

Automatic Extraction of New Things

The automatic TeX information extractor works by searching for regular expressions in the TeX files, and storing the matched information. You can add support for new constructs to the parser, something that is needed when you add new commands to define symbols.

For example, in the file `` `macro.tex' `` I define the following macro.

```
\newcommand{\newmacro}[5]{%
\def#1{#3\index{#4@#5~cite{#4}}\nocite{#4}}%
\def#2{#5\index{#4@#5~cite{#4}}\nocite{#4}}%
}
```

AUC TeX will automatically figure out that `newmacro' is a macro that takes five arguments. However, it is not smart enough to automatically see that each time we use the macro, two new macros are defined. We can specify this information in a style hook file.

```
;;; macro.el - Special code for my own macro file.

;;; New Macro Definition Command

(require 'tex-auto)

(defvar TeX-newmacro-regexp
  '("\\\\newmacro{\\\\\\([a-zA-Z]+\\)}{\\\\\\([a-zA-Z]+\\)}"
    (1 2) TeX-auto-multi)
  "Matches \newmacro definitions.")

(defvar TeX-auto-multi nil
  "Temporary for parsing \newmacro definitions.")

(defun TeX-macro-cleanup ()
  "Support for \\newmacro macro."

  (mapcar (function (lambda (list)
                      (mapcar (function (lambda (symbol)
                                          (setq TeX-auto-symbol
                                                (cons symbol
                                                      TeX-auto-symbol))))
                              list)))
          TeX-auto-multi))

(setq TeX-auto-prepare-hooks (cons (function (lambda ()
                                               (setq TeX-auto-multi nil)))
                                   TeX-auto-prepare-hooks))

(setq TeX-auto-cleanup-hooks (cons 'TeX-macro-cleanup TeX-auto-cleanup-hooks))

;;; HOOK

(TeX-add-style-hook "macro"
 (function
  (lambda ()
    (TeX-auto-add-regexp TeX-newmacro-regexp)
    (TeX-add-symbols '("newmacro"
                       TeX-argument-macro-hook
                       (TeX-argument-macro-hook "Capitalized macro: \\")
                       t
```

```
                "BibTeX entry: "
                nil)))))
```

When this file is first loaded, it adds a new entry to `TeX-newmacro-regexp`, and defines a function to be called before the parsing starts, and one to be called after the parsing is done. It also declares a variable to contain the data collected during parsing. Finally, it adds a style hook which describes the `newmacro' macro, as we have seen it before.

So the general strategy is: Add new entry to `TeX-newmacro-regexp`. Declare variable to contain intermediate data during parsing. Add hook to be called before and after parsing. In this case, the hook before parsing just initialize the variable, and the hook after parsing collect the data from the variable, and add them to the list of symbols found.

Variable: **TeX-auto-regexp-list**

List of regular expressions matching TeX macro definitions.

The list has the following format ((REGEXP MATCH TABLE) ...), that is, each entry is a list with three elements.

REGEXP. Regular expression matching the macro we want to parse.

MATCH. A number or list of numbers, each representing one parenthesized subexpression matched by REGEXP.

TABLE. The symbol table to store the data. This can be a function, in which case the function is called with the argument MATCH. Use `TeX-match-buffer` to get match data. If it is not a function, it is presumed to be the name of a variable containing a list of match data. The matched data (a string if MATCH is a number, a list of strings if MATCH is a list of numbers) is put in front of the table.

Variable: **TeX-auto-prepare-hooks** *nil*

List of hooks to be called before parsing a TeX file.

Variable: **TeX-auto-cleanup-hooks** *nil*

List of hooks to be called after parsing a TeX file.

Installation of AUC TeX

Before you do anything else, make sure that you have the latest version of TeXinfo installed. It is available by ftp from `prep.ai.mit.edu'. You need at least version 2.16.

First, you should consult the file `` `tex-site.el' `` and edit it to fit your local site. Be sure to get the following two variables right, or you will not be able to complete the installation procedure:

User Option: **TeX-lisp-directory**

The directory where you want to install the AUC TeX lisp files.

User Option: **TeX-macro-global**

Directories containing the site's TeX style files.

You probably also need to change `TeX-command-list` to make sure that the commands used for starting TeX, printing, etc. work on your system.

Finally, edit `TeX-printer-list` to contain the printers available at your site.

Next, edit the file `` `Makefile' `` in the AUC TeX directory to set up paths for installation of the files. Be sure that

`bindir`
: Is set to the directory where you want the LaCheck binary to be installed.

`infodir`
: Is set to the directory where you want the AUC TeX "info" documentation to be installed.

`aucdir`
: Is set to the directory where you want the lisp files for AUC TeX to be installed. This **must** be the same directory as you specified for `TeX-lisp-directory` in `` `tex-site.el' ``. If you unpacked AUC TeX in that directory (`TeX-lisp-directory`), you should set `aucdir` to `.' in order to avoid copying the byte compiled lisp files.

  If you already have an old version of AUC TeX in that directory, you must delete it before installing the new version. Otherwise the wrong version of the files may be loaded during the byte compilation.

`mandir`
: Is set to the directory where you want to install the (unformatted) man page for LaCheck.

`elispdir`
: Is set to the directory where the lisp files from the standard Emacs distribution are found.

`CC`
: Is the compiler you want to use for compiling the LaCheck program. Is set to `gcc' by default. Change this is `cc' or whatever your system compiler is called if you do not have GCC installed.

Then type make all, and the whole thing will be `made'. If this succeeds, type make install, and it will be installed.

To extract information from your site's TeX macros, type make install-auto. This will only work if you have set `TeX-macro-global` correctly in `` `tex-site.el' ``.

Tell the users on your site to insert

```
(load-file "/path/for/auctex/tex-site.elc")
```

in their `` `.emacs' `` file in order to use AUC TeX.

Users who know the older keybindings from version 6.1 may also want to insert

```
(load "auc-tex")
```

in their `` `.emacs' ``

The History of AUC TeX

This chapter is for old users, who want to see what has been added in this version, and for the authors, who get nostalgic at times.

News in 7.3

Coordinater: Per Abrahamsen, 1993.

- More robust installation, especially for Lucid Emacs (I hope). Many people reported problems with this.
- Make `easymenu' work when byte-compiled. Many people reported this bug.
- Minimally updated the `` `README' `` file from version 6.0 (sigh). Thanks to Boris Goldowsky

`<boris@cs.rochester.edu>' for reporting this.

- Added `@finalout' to manual. Reported by Henrik Drabol `<hvd@ens004.ens.min.dk>'.
- Fixed M-q to work after an `\end{...}'. It will not work at the end of the buffer, but there are usually the local variables so it should (hopefully) not matter. Thanks to Shinji Kobayashi `<koba@flab.fujitsu.co.jp>' again.
- New variables `TeX-open-quote` and `TeX-close-quote` determine what is inserted by `TeX-insert-quote`. The `german' style file now use those variables instead of changing the keymap.
- Changes to the default settings in `tex-site.el', in particular a `Queue' command is added to display the print queue. Thanks to John Interrante `<interran@uluru.Stanford.EDU>' for code, and other members of the `auc-tex@iesd.auc.dk' mailing list for ideas.
- Make sure all outline mode commands are bound in `outline-minor-mode`.
- Added autoload for `TeX-command`. Thanks to Hanno Wirth `<wirth@igd.fhg.de>' for reporting this.
- Added support for AmSTeX and AmSLaTeX. Currently they are identical to TeX and LaTeX except for another default command.
- Added VorTeX style matching of dollar sign. The style is guaranteed to be VorTeX, since I lifted the code directly from VorTeX. Thanks to Pehong Chen `<phc@renoir.berkeley.edu>' for writing the VorTeX code. Thanks to Jak Kirman `<jak@cs.brown.edu>' for pointing out this nice VorTeX feature.
- Added information about AUC TeX mail addresses to the manual. Thanks to Dave Smith `<maa507@computing.lancaster.ac.uk>'.
- Added menu to for plain TeX. Suggested by Tim Carlson `<imsgtcar@sinc.oscs.montana.edu>'.
- Made the menus depend on `TeX-command-list`.
- Made it possible to specify `TeX-auto-regexp-list` in the local variable section of each file.
- Added variable `TeX-auto-parse-length` to specify maximal length of text that will be parsed.
- Added automatic parsing of BibTeX files and `bibitem' entries in order to get completion in `cite'. This was inspired by an add on made by Sridhar Anandakrishnan `<sak@essc.psu.edu>'.
- Added variable `TeX-byte-compile` to disable automatic byte compilation of style files when loaded. This is needed when using different Emacs versions.
- Added variable `TeX-translate-location-hook` to translate file and line information before showing an error, as requested by Thorbjoern Ravn Andersen `<ravn@imada.ou.dk>'.
- Added variable `TeX-auto-save` to allow disabling the automatic saving of style information, either per file in the file local variables, or globally by using `setq-default`. Use `TeX-normal-mode` to force style information to be saved.
- Try to create `auto' directory if it does not exists.
- Added chapter describing how to tune the TeX parsing.
- Allow (but do not encourage) a string value for `LaTeX-default-options`.
- Give `"' word syntax when german.sty is loaded. Suggested by Tim Geisler `<tmgeisle@immd8.informatik.uni-erlangen.de>'.
- Many corrections to the grammar in the manual. Thanks to Manfred Weichel `<Manfred.Weichel@sto.mchp.sni.de>'.
- Bind `TeX-home-buffer` to C-c ^ instead of C-c C-h which are reserved in Emacs 19. Suggested by Chris Moore `<Chris.Moore@src.bae.co.uk>'.

News in 7.2

Coordinater: Per Abrahamsen, 1993.

- `LaTeX-dead-mode` works again. Thanks to Patrick O'Callaghan `<poc@usb.ve>' for fixing it.
- Minor fixes to the documentation. Thanks to Shinji Kobayashi `<koba@flab.fujitsu.co.jp>'.
- Add `Compiling' to the mode line of all buffers, while there is a AUC TeX compilation process running. This is similar to the behavior of `compile` in Emacs 19.
- `TeX-normal-mode` will now save the buffer first to make sure it gets reparsed.
- Labels with underscores are now recognized. Thanks to Wolfgang Franzki `<W.Franzki@kfa-juelich.de>'
- Fix to `ghostview' printer specification. Thanks to Masayuki Kuwada `<kuwada@soliton.ee.uec.ac.jp>'.
- Recognize `abstract', `center', `titlepage', `verse', and `theindex' environments. Thanks to Masayuki Kuwada `<kuwada@soliton.ee.uec.ac.jp>'.
- Fix to `newsavebox' macro. Thanks to Shinji Kobayashi `<koba@flab.fujitsu.co.jp>' for reporting this.
- Menu support for GNU Emacs 19 and Lucid Emacs. Thanks to Alastair Burt `<burt@dfki.uni-kl.de>' for the initial Lucid Emacs version.
- C-c C-f C-d now deletes the current font. The current font is defined to be the innermost TeX group starting with a TeX macro that is terminated by a space.
- Giving C-c C-f a prefix argument will replace the current font, i.e. C-u C-c C-f C-b will change the current font to bold.

  The old functionality (putting the font around the region) has been removed. To make the region bold, type C-w C-c C-f C-b C-y instead.
- Chapter recognized as largest heading in the report style. Thanks to Shinji Kobayashi `<koba@flab.fujitsu.co.jp>' for reporting this.
- More support for Japanese style files. Thanks to Shinji Kobayashi `<koba@flab.fujitsu.co.jp>'.
- No longer put `Outline' in the mode line whenever `selective-display` is set. Thanks to Lawrence R. Dodd `<dodd@roebling.poly.edu>' for reporting this.
- Support for inserting calligraphic letters in `TeX-math-mode` with ` c LETTER. Thanks to Olaf Burkart `<burkart@zeus.informatik.rwth-aachen.de>'.
- `set-docstring` in `tex-math.el' should work better now. Thanks to Alastair Burt `<burt@dfki.uni-kl.de>' and Olaf Burkart `<burkart@zeus.informatik.rwth-aachen.de>'.
- Support for dviout preview on PC-9801. Thanks to Shinji Kobayashi `<koba@flab.fujitsu.co.jp>'.
- Inserting environment in empty buffer should work now. Thanks to Alastair Burt `<burt@dfki.uni-kl.de>'.
- Default float for figures changed from `tbp' to `htbp'.
- `LaTeX-format-environment` may work now. Thanks to Shinji Kobayashi `<koba@flab.fujitsu.co.jp>'.
- Better `LaTeX-close-environment`. Thanks to Thorbjoern Hansen `<thansen@diku.dk>'.
- Some support for Ispell 4.0.
- BibTeX in Emacs 19 need `tex-insert-quote`, make it autoload from AUC TeX instead of the standard `tex-mode`.
- `TeX-auto-generate` failed when repeated. Thanks to Peter Whaite `<peta@Thunder.McRCIM.McGill.EDU>' for reporting this.

News in 7.1

Coordinater: Per Abrahamsen, 1993.

- Allow multiple `%p' in print commands.

  Suggested by Cliff Krumvieda `<cliff@cs.cornell.edu>'.
- Improved backward compatibility in `auc-tex.el'. Thanks to Ralf Handl `<handl@cs.uni-sb.de>'.
- New style hook for `german.sty'.

  Disable smart quotes. Press C-c C-n to make it take effect.
- Allow files to have other extensions than "tex".

  But no longer allow files to have multiple dots. Sigh.
- Will no longer parse the buffer if it can use the saved state.
- New variable TeX-parse-self.

  Set it to nil if you never want to parse the buffer when you load it.
- Only offer to save files that belongs to the document.

  When you format the document with C-c C-c, AUC TeX will no longer offer to save your `RMAIL', `.newsrc', or other files that does not belong to the document. Suggested by Jim Hetrick `<hetrick@phys.uva.nl>'.
- FoilTeX support.

  Thanks to Sven Mattisson `<sven@tde.lth.se>'
- Smarter about when you need to reformat.

  Thanks to Chris Callsen `<chris@iesd.auc.dk>'.
- Japanese TeX

  Now supports Japanese TeX. Thanks to Shinji Kobayashi `<koba@keisu-s.t.u-tokyo.ac.jp>'.
- Works again under OS/2 and other case insensitive file systems.
- DEMACS support.

  Thanks to Shinji Kobayashi `<koba@keisu-s.t.u-tokyo.ac.jp>'.
- Better LaTeX-close-environment.

  Thanks to Piet van Oostrum `<piet@cs.ruu.nl>'.
- Ispell support.

  Thanks to Piet van Oostrum `<piet@cs.ruu.nl>'.
- Support for Russian letters.

  Thanks to Justin R. Smith `<jsmith@king.mcs.drexel.edu>'.
- SliTeX fixes.

  Many people.
- Fixes for spelling errors.

  Many people.

Version 7.0

Coordinator: Per Abrahamsen, 1993.

Alpha testers (in order of appearance): Piet van Oostrum `<piet@cs.ruu.nl>', Sven Mattisson `<sven@tde.lth.se>', Tim Geisler `<tmgeisle@immd8.informatik.uni-erlangen.de>', Fran E. Burstall `<F.E.Burstall@maths.bath.ac.uk>', Alastair Burt `<burt@dfki.uni-kl.de>', Sridhar Anandakrishnan `<sak@essc.psu.edu>', Kjell Gustafsson `<kjell@sccm.Stanford.EDU>', Uffe Kjaerulff `<uk@iesd.auc.dk>', Kurt Swanson `Kurt.Swanson@dna.lth.se', Mark Utting `<marku@cs.uq.oz.au>', Per Norman Oma `perno@itk.unit.no', Naji Mouawad `<nmouawad@math.uwaterloo.ca>', Bo Nygaard Bai `<bai@iesd.auc.dk>', and probably more.

- New keymap.

  The keymap has been changed in order to make it more intuitive to new users, and because the old bindings did not work well with the new buffer manipulation commands in tex-buf.el. To use the new bindings, load `tex-init.el' instead of `auc-tex.el'.

  The file `auc-tex.el' is still available and implements the old keybinding on top of the new code.

  Print out the reference card (`doc/ref-card.tex') to see the new bindings.

- Completely redesigned the buffer handling.

  No part of the interface or the customization variables remain the same, unless you use the compatibility functions in `auc-tex.el'. In that case the interactive commands remain similar in spirit, but the customization interface is still changed.

  The file `tex-buf.el' has been completely rewritten, and there are major cleanup in `tex-dbg.el', however the basic functionality remains the same in this file. The code for both `tex-buf.el' and `tex-dbg.el' should be much simpler now and easier to extent.

  `auc-tex.el' and `tex-site.el' was updated to support the new interface. I actually believe the moral equivalent to `TeX-region' to work now `:-)', at least I understand the code now.

  The two major functions are now `TeX-command-master' and `TeX-command-region'. Each function will prompt you for the command to execute. AUC TeX will make an educated guess on what command you want to run, and make that the default. The available commands are defined in the variable `TeX-command-list'.

  `TeX-command-master' will run the specified command on the buffers master file. You can have one command running for each master file. `TeX-command-region' will run the specified command on the current region, getting the header on trailer from the master file.

  You can have exactly one region command running, independent on how many master file commands that are running. Commands that operate on the active process (like `TeX-next-error') will chose the process associated with buffers master file, unless the last region process is more recent than all master file processes.

  AUC TeX now insist on knowing the master file for a buffer. If you do not specify it in the file variable section, and it is not obviously a master file itself, it will ask you. It will also add the master file name to the file variables, unless you disable this feature by setting `TeX-add-local' to nil. Furthermore, it will convert `%% Master:' lines to file variables, unless you disable it by setting `TeX-convert-master' to nil.

  Functionality removed (for now, it might appear again latter) include all other functions to start a command (e.g. `LaTeX-BibTeX'), and alternative ways to specify headers and trailers. The only place to get the header and trailer is from the master file (I can easily change that, if anyone have such needs).

- Style specific code isolated.

You can now add style specific information to AUC TeX by writing a style file somewhere in TeX-style-p

The main code is now organized around this principle.

- Automatically generate style files.

  AUC TeX can now automatically extract information from a TeX file, and will do this when you save a buffer.
- SliTeX mode.

  Just like LaTeX mode, except that the default command to format run on the buffer is `slitex'.
- `LaTeX-section` completely general.

  Rewrote `` `ltx-sec.el' ``.
  - Sectioning level, toc, and title queries can be individually turned off.
  - Label query can be turned on or off for selected sectioning levels.
  - Label prefix can be different for different sectioning levels.
  - If the title (or toc) is empty, point will be positioned there.
  - Users can add new hooks
- `TeX-insert-macro` much smarter.

  It will now prompt for the symbol with completions, and for many symbols it will also prompt for each argument. There are also completion on some of the arguments.
- Fixed center in figure environment.

  Thanks to Thomas Koenig `<ig25@rz.uni-karlsruhe.de>'.
- Changed `\M-` to `\e` in all keybindings in order to better support 8-bit input on some GNU Emacs. Thanks to Peter Dalgaard `<pd@kubism.ku.dk>'.

  Please, implementors of 8-bit input extensions to GNU Emacs. `\M-x` does *not* means x with the 8-bit set. It means pressing x while holding down the META key. Some systems (such as X11) are able to tell the different. Thus, even if you implement 256 byte keymaps, `\M-x` should still expand `meta-prefix-char` followed by an x in the keymap. This allows you to distinguish pressing x while holding down the META key from entering a literal 8-bit character.
- Made the outline commands aware of the document style.

  That is, if the document style is `article', `\section' will be one level below the `\documentstyle', while if the style is `book', `\section' will be three levels below `\documentstyle'. This will make `show-children` work better at the top level.
- The makefiles are closer to GNU coding standard.

  They now understand `prefix' and some other macros.
- Added hooks to be run after list of environments or list of completion names are updated, and also added a hook to be called after each file has been loaded. Thanks to Piet van Oostrum `<piet@cs.ruu.nl>'.
- Added `*' to lot of `(interactive)` declarations.
- The outline commands are now always accessible from LaTeX mode.
- Generalized the keyboard remapping and double modes.

  These are found in the file `` `min-key.el' ``.
- Smart Comments.

  Not really, but there are now two comment functions which use their arguments to determine what to do,

instead of four functions ignoring their arguments.

- Add outline headers.

  It is now possible to add extra outline headers, by setting the variable `TeX-outline-extra`.

- Smart quotes even smarter.

  If you press " twice, it will insert an real double quote instead of two (or four) single quotes. This is consistent with how remapping in `` `min-key.el' `` is done.

- Automatically untabify buffer when you save it.

  Hands up, everyone who have produced a `last revision' paper containing an unreadable list of data in the back, because TeX does not understands tabs.

- Call show-all when you change major mode.

  Thanks to Inge Frick's `<inge@nada.kth.se>' `` `kill-fix.el' `` enhancement, outline minor mode can now guarantee that all text is shown when you leave the minor mode, even if you leave the minor mode by changing the major mode.

- Updated documentation for 7.0.

  Also added key, variable, function, and concept indexes, as well as this history section and a new chapter on multifile documents (see section Multifile Documents).

Version 6.1

Coordinator: Per Abrahamsen, 1992.

- `TeX-region` might work now (heard that before?).

  Many people reported this one. Especially thanks to Fran Burstall `<F.E.Burstall@maths.bath.ac.uk>' and Bill Schworm `<bill@schworm.econ.ubc.ca>'.

- The specification format for the TeX command is more general.

  See the documentation for `LaTeX-command` and `plain-TeX-command`.

- The specification format for the preview commands is more general.

  See their respective documentation.

- The specification format for the print command is more general.

  See the documentation for `TeX-print-command`.

- `TeX-args` is marked as obsolete.
- The `"Emergency stop ..."' error.

  Some users of old TeX installations got might might be fixed now. Thanks to Philip Sterne `<sterne@dublin.llnl.gov>'.

- It is now possible to change the preview command.

  ... without loading TeX-site first. Thanks to Tim Bradshaw `<tim.bradshaw@edinburgh.ac.uk>'.

- New variable TeX-smart-quotes.

  Allow `` `german.sty' `` users (and others) to disable the mapping of double quote (" to `"' or `"'). Thanks to Daniel Hernandez `<danher@informatik.tu-muenchen.de>'.

- Many minor corrections to the documentation.

Thanks to Mainhard E. Mayer `<hardy@golem.ps.uci.edu>'.

- Make test for `HOSTTYPE` case insensitive.

  Thanks to Gisli Ottarsson `<gisli@liapunov.eecs.umisc.edu>'.

- `TeX-force-default-mode`

  Set to avoid AUC TeX's attempts to infer the mode of the file by itself.

Version 6.0

Coordinator: Kresten Krab Thorup, 1992.

Preliminary documentation is available in the directory `` `doc' ``. It isn't very well written, but I believe it covers most interesting points. Comments, suggestions, or even rewrites of sections are VERY WELCOME...

LaCheck has been incorporated in the package. The source code for it is available in the directory `` `lacheck' `` along with the documentation for it. Lacheck may also be used from the command line. It is bound to C-c $.

Some minor changes in:

`TeX-region`

Should work better with `Master:' option.

`LaTeX-environment`

Numerous new hooks added by Masayuki Kuwada.

`TeX-command-on-region`

Removed. C-c C-o used for `outline-minor-mode` instead.

And some additional minor fixes...

Ancient History

The origin of AUC TeX is `` `tex-mode.el' `` from Emacs 16. Lars Peter Fischer `<fischer@iesd.auc.dk>' wrote the first functions to insert font macros and Danish characters back in 1986. Per Abrahamsen `<abraham@iesd.auc.dk>' wrote the functions to insert environments and sections, to indent the text, and the outline minor mode in 1987. Kresten Krab Thorup `<krab@iesd.auc.dk>' wrote the buffer handling and debugging functions, the macro completion, and much more, including much improved indentation and text formatting functions. He also made the first public release in 1991, and was the main author and coordinator of every release up to and including 6.0.

Thanks should also go to all the people who have been a great help developing the AUC TeX system. Especially all the people on the `auc-tex' mailing list, who have been very helpful commenting and pointing out weak points and errors.

Some of the contributors are listed below. Others are mentioned in the lisp files or in the History section.

`<dduchier@csi.UOttawa.CA>'

Denys Duchier

`<ferguson@cs.rochester.edu>'

George Ferguson

`<simons@ibiza.karlsruhe.gmd.de>'

Martin Simons

`<kuwada@soliton.ee.uec.ac.jp>'
Masayuki Kuwada
`<tb06@pl118f.cc.lehigh.edu>'
Terrence Brannon
`<roseman@hustat.harvard.edu>'
Leonard Roseman

Special thanks to Leslie Lamport for supplying the source for the LaTeX error messages in the `tex-dbg.el' file.

Various Minor Modes

A number of minor modes are distributed with AUC TeX for no good reason, except that they use `min-bind.el' and they are so small that it does not matter.

Some of the minor modes have already been described elsewhere, the remaining will be described here.

Auto Indent Mode

This is a minor mode version of `indented-text-mode`. Enter and leave with M-x auto-indent-mode.

Command: **auto-indent-mode**

Toggle auto indent mode. With prefix arg, turn auto indent mode on iff arg is positive.

Auto indent mode works by invoking `indent-relative` for TAB, and using `indent-relative-maybe` as the `indent-line-function` for `auto-fill`, and LFD.

Auto Ispell Mode

In `auto-ispell-mode` SPC or RET automatically trigger `ispell-word` on previously typed word. M-TAB will make an ispell completion.

Enter and leave with M-x auto-ispell-mode.

Command: **auto-ispell-mode**

(M-x auto-ispell-mode) Toggle auto-ispell-mode. With prefix arg, turn `auto-ispell-mode` on iff arg is positive.

In `auto-ispell-mode`, inserting a space or a newline applies `ispell-word` on the previous word.

Pressing Esc-Tab activates ispell-complete-word.

Wishlist

This is a list of projects for AUC TeX. Bug reports and requests we can not fix or honor right away will be added to this list. If you have some time for emacs lisp hacking, you are encouraged to try to provide a solution to one of the following problems.

- Add completion of macro arguments to `TeX-complete-symbol`.
- Make . check for abbreviations and sentences ending with capital letters. Make , and . remove italic correction.
- Make LaCheck check for itallic correction before `.' or `,'.
- Use Emacs 19 minubuffer history to choose between previewers, and other stuff. Suggested by John Interrante `<interran@uluru.Stanford.EDU>'.
- It is often too slow to parse the file each time it is saved, especially with Emacs 19. Check if `TeX-auto-generate` is useful for doing more occasionally, like updating the `` `TAGS' `` file.
- Control TeX compilation window.

  It is not good that half of the screen is wasted for the log when TeX is processing a file. It is possible to make the log screen smaller, but the best solution would be to have a user configurable window layout that could be defined by some variables as for VM or GNUS. Or a log screen that opens only in case of an error. -- Tim Geisler `<tmgeisle@immd8.informatik.uni-erlangen.de>'
- Make features.

  A new command `TeX-update` (C-c C-u) could be used to create an up to date dvi file by repeatedly running BibTeX, MakeIndex and (La)TeX, until an error occur or we are done.

  An alternative is to have an `Update' command that ensures the `dvi' file is up to date. This could be called before printing and previewing.
- Hook naming should be accoriding to the Emacs (19) guidelines. Specifically, only the hook *variable* should be names `-hook'. The hook functions should have other names.
- The documentation of the minor modes should be separated.

  They are distributed independently of AUC TeX, and should therefore also be documented independently of AUC TeX.

- Documentation of variables that can be set in a style hook.

  We need a list of what can safely be done in an ordinary style hook. You can not set a variable that AUC TeX depends on, unless AUC TeX knows that it has to run the style hooks first.

  Here is the start of such a list.

  `LaTeX-add-environments`
  `TeX-add-symbols`
  `LaTeX-add-labels`
  `LaTeX-add-bibliographies`
  `LaTeX-largest-level`

  The rules for what can be done in a format package hook are different.
- Correct indentation for table, math, and array environments.
- Customizable indentation for verbatim-like user defined environments.
- Special indentation after an `\item'.

```
\begin{itemize}
\item blabalaskdfjlas lajf adf
      lkfjl  af jasl lkf jlsdf jlf
\item f lk jldjf lajflkas flf af
\end{itemize}
```

- Completion for citations, counters, and sboxes.

  The two latter is easy the first is useful.
- Outline should be able to hide environments.

  Probably being one level below `LaTeX-lowest-level`.
- Outline should be (better) supported in TeX mode.

  At least, support headers, trailers, as well as TeX-outline-extra.
- Outline Minor Mode should support non-regexp outlines better.

  Something like TeX-outline-extra should be standard support in `` `min-out.el' ``.
- `TeX-header-start` and `TeX-trailer-end`.

  We might want these, just for fun (and outlines)
- Plain TeX and LaTeX specific header and trailer expressions.

  We should have a way to globally specify the default value of the header and trailer regexps.
- Add support for original `TeX-mode` keybindings.

  A third initialization file (`` `tex-mode.el' ``) containing an emulator of the standard `TeX-mode` would help convince some people to change to AUC TeX.
- Make `TeX-next-error` parse ahead and store the results in a list, using markers to remember buffer positions in order to be more robust with regard to line numbers and changed files. This is what `next-error` does. (Or did, until Emacs 19).
- When `LaTeX-environment` is given an argument, change the current environment. Be smart about `\item[]' versus `\item ' and labels like `fig:' versus `tab:'.
- Check out if lightening completion from Ultra TeX is anything for us.

- TeXinfo mode.
- BibTeX mode.
- Support for AMSLaTeX style files.
- Better LaTeX letter environment.

  Make a database system for addresses in the letter environment Make the letter environment hook produce `documentstyle' too
- Add code for submitting a report, using BAW's `reporter.el'.

Credit

A big smile and thanks should go to all the folks who cheered me up, during the long hours of programming... sorry folks, but I can't help including the list below, of comments I've got...

Kresten Krab Thorup

`<monheit@psych.stanford.edu>'

I'd like to say that I'm very much enjoying using auc-tex. Thanks for the great package!

`<georgiou@rex.cs.tulane.edu>'

I really enjoy working with auc-tex.

`<toy@soho.crd.ge.com>'

Thanks for your great package. It's indispensable now! Thanks!

`<ascott@gara.une.oz.au>'

Thanks for your time and for what appears to be a great and useful package. Thanks again

`<hal@alfred.econ.lsa.umich.edu>'

Thanks for providing auc-tex.

`<simons@ibiza.karlsruhe.gmd.de>'

I really enjoy using the new emacs TeX-mode you wrote. I think you did a great job.

`<clipper@csd.uwo.ca>'

I am having fun with auc-tex already.

`<ibekhaus@athena.mit.edu>'

Thanks for your work on auc-tex, especially the math-minor mode.

`<burt@dfki.uni-kl.de>'

I like your auc-tex elisp package for writing LaTeX files - I am especially impressed by the help with error correction.

`<goncal@cnmvax.uab.es>'

Thanks so much!

`<bond@sce.carleton.ca>'

I >really< like the macro, particularly the hooks for previewing and the error parsing!

`<ascott@gara.une.oz.au>'

All in all I am pleased with your package. Thanks a lot.

GNU Automake

For version 1.4, 10 January 1999

David MacKenzie and Tom Tromey

This file documents the GNU Automake package for creating GNU Standards-compliant Makefiles from template files. This edition documents version 1.4.

This document was generated on 20 May 1999 using the texi2html translator version 1.51a.

Go to the first, previous, next, last section, table of contents.

Introduction

Automake is a tool for automatically generating `Makefile.in's from files called `Makefile.am'. Each `Makefile.am' is basically a series of `make' macro definitions (with rules being thrown in occasionally). The generated `Makefile.in's are compliant with the GNU Makefile standards.

The GNU Makefile Standards Document (see section `Makefile Conventions' in The GNU Coding Standards) is long, complicated, and subject to change. The goal of Automake is to remove the burden of Makefile maintenance from the back of the individual GNU maintainer (and put it on the back of the Automake maintainer).

The typical Automake input file is simply a series of macro definitions. Each such file is processed to create a `Makefile.in'. There should generally be one `Makefile.am' per directory of a project.

Automake does constrain a project in certain ways; for instance it assumes that the project uses Autoconf (see section `Introduction' in The Autoconf Manual), and enforces certain restrictions on the `configure.in' contents.

Automake requires `perl' in order to generate the `Makefile.in's. However, the distributions created by Automake are fully GNU standards-compliant, and do not require `perl' in order to be built.

Mail suggestions and bug reports for Automake to bug-automake@gnu.org.

General ideas

The following sections cover a few basic ideas that will help you understand how Automake works.

General Operation

Automake works by reading a `Makefile.am' and generating a `Makefile.in'. Certain macros and targets defined in the `Makefile.am' instruct Automake to generate more specialized code; for instance, a `bin_PROGRAMS' macro definition will cause targets for compiling and linking programs to be generated.

The macro definitions and targets in the `Makefile.am' are copied verbatim into the generated file. This allows you to add arbitrary code into the generated `Makefile.in'. For instance the Automake distribution includes a non-standard `cvs-dist` target, which the Automake maintainer uses to make distributions from his source control system.

Note that GNU make extensions are not recognized by Automake. Using such extensions in a `Makefile.am' will lead to errors or confusing behavior.

Automake tries to group comments with adjoining targets and macro definitions in an intelligent way.

A target defined in `Makefile.am' generally overrides any such target of a similar name that would be automatically generated by `automake`. Although this is a supported feature, it is generally best to avoid making use of it, as sometimes the generated rules are very particular.

Similarly, a macro defined in `Makefile.am' will override any definition of the macro that `automake` would ordinarily create. This feature is more often useful than the ability to override a target definition. Be warned that many of the macros generated by `automake` are considered to be for internal use only, and their names might change in future releases.

When examining a macro definition, Automake will recursively examine macros referenced in the definition. For example, if Automake is looking at the content of `foo_SOURCES` in this snippet

```
xs = a.c b.c
foo_SOURCES = c.c $(xs)
```

it would use the files `a.c', `b.c', and `c.c' as the contents of `foo_SOURCES`.

Automake also allows a form of comment which is *not* copied into the output; all lines beginning with `##' are completely ignored by Automake.

It is customary to make the first line of `Makefile.am' read:

```
## Process this file with automake to produce Makefile.in
```

Depth

`automake` supports three kinds of directory hierarchy: `flat', `shallow', and `deep'.

A **flat** package is one in which all the files are in a single directory. The `` `Makefile.am' `` for such a package by definition lacks a `SUBDIRS` macro. An example of such a package is `termutils`.

A **deep** package is one in which all the source lies in subdirectories; the top level directory contains mainly configuration information. GNU `cpio` is a good example of such a package, as is GNU `tar`. The top level `` `Makefile.am' `` for a deep package will contain a `SUBDIRS` macro, but no other macros to define objects which are built.

A **shallow** package is one in which the primary source resides in the top-level directory, while various parts (typically libraries) reside in subdirectories. Automake is one such package (as is GNU `make`, which does not currently use `automake`).

Strictness

While Automake is intended to be used by maintainers of GNU packages, it does make some effort to accommodate those who wish to use it, but do not want to use all the GNU conventions.

To this end, Automake supports three levels of **strictness**---the strictness indicating how stringently Automake should check standards conformance.

The valid strictness levels are:

`foreign'

> Automake will check for only those things which are absolutely required for proper operations. For instance, whereas GNU standards dictate the existence of a `` `NEWS' `` file, it will not be required in this mode. The name comes from the fact that Automake is intended to be used for GNU programs; these relaxed rules are not the standard mode of operation.

`gnu'

> Automake will check--as much as possible--for compliance to the GNU standards for packages. This is the default.

`gnits'

> Automake will check for compliance to the as-yet-unwritten **Gnits standards**. These are based on the GNU standards, but are even more detailed. Unless you are a Gnits standards contributor, it is recommended that you avoid this option until such time as the Gnits standard is actually published.

For more information on the precise implications of the strictness level, see section The effect of `--gnu` and `--gnits`.

The Uniform Naming Scheme

Automake macros (from here on referred to as *variables*) generally follow a **uniform naming scheme** that makes it easy to decide how programs (and other derived objects) are built, and how they are installed. This scheme also supports `configure` time determination of what should be built.

At `make` time, certain variables are used to determine which objects are to be built. These variables are called **primary variables**. For instance, the primary variable `PROGRAMS` holds a list of programs which are to be compiled and linked.

A different set of variables is used to decide where the built objects should be installed. These variables are named after the primary variables, but have a prefix indicating which standard directory should be used as the installation directory. The standard directory names are given in the GNU standards (see section `Directory Variables' in The GNU Coding Standards). Automake extends this list with `pkglibdir`, `pkgincludedir`, and `pkgdatadir`; these are the same as the non-`pkg' versions, but with `@PACKAGE@' appended. For instance, `pkglibdir` is defined as `$(datadir)/@PACKAGE@`.

For each primary, there is one additional variable named by prepending `EXTRA_' to the primary name. This variable is used to list objects which may or may not be built, depending on what `configure` decides. This variable is required because Automake must statically know the entire list of objects that may be built in order to generate a `Makefile.in' that will work in all cases.

For instance, `cpio` decides at configure time which programs are built. Some of the programs are installed in `bindir`, and some are installed in `sbindir`:

```
EXTRA_PROGRAMS = mt rmt
bin_PROGRAMS = cpio pax
sbin_PROGRAMS = @PROGRAMS@
```

Defining a primary variable without a prefix (e.g. `PROGRAMS`) is an error.

Note that the common `dir' suffix is left off when constructing the variable names; thus one writes `bin_PROGRAMS' and not `bindir_PROGRAMS'.

Not every sort of object can be installed in every directory. Automake will flag those attempts it finds in error. Automake will also diagnose obvious misspellings in directory names.

Sometimes the standard directories--even as augmented by Automake--- are not enough. In particular it is sometimes useful, for clarity, to install objects in a subdirectory of some predefined directory. To this end, Automake allows you to extend the list of possible installation directories. A given prefix (e.g. `zar') is valid if a variable of the same name with `dir' appended is defined (e.g. `zardir`).

For instance, until HTML support is part of Automake, you could use this to install raw HTML documentation:

```
htmldir = $(prefix)/html
html_DATA = automake.html
```

The special prefix `noinst' indicates that the objects in question should not be installed at all.

The special prefix `check' indicates that the objects in question should not be built until the `make check` command is run.

Possible primary names are `PROGRAMS', `LIBRARIES', `LISP', `SCRIPTS', `DATA', `HEADERS', `MANS', and `TEXINFOS'.

How derived variables are named

Sometimes a Makefile variable name is derived from some text the user supplies. For instance, program names are rewritten into Makefile macro names. Automake canonicalizes this text, so that it does not have to follow Makefile macro naming rules. All characters in the name except for letters, numbers, and the underscore are turned into underscores when making macro references. For example, if your program is named `sniff-glue`, the derived variable name would be `sniff_glue_SOURCES`, not `sniff-glue_SOURCES`.

Some example packages

A simple example, start to finish

Let's suppose you just finished writing `zardoz`, a program to make your head float from vortex to vortex. You've been using Autoconf to provide a portability framework, but your `` `Makefile.in' ``s have been ad-hoc. You want to make them bulletproof, so you turn to Automake.

The first step is to update your `` `configure.in' `` to include the commands that `automake` needs. The simplest way to do this is to add an `AM_INIT_AUTOMAKE` call just after `AC_INIT`:

```
AM_INIT_AUTOMAKE(zardoz, 1.0)
```

Since your program doesn't have any complicating factors (e.g., it doesn't use `gettext`, it doesn't want to build a shared library), you're done with this part. That was easy!

Now you must regenerate `` `configure' ``. But to do that, you'll need to tell `autoconf` how to find the new macro you've used. The easiest way to do this is to use the `aclocal` program to generate your `` `aclocal.m4' `` for you. But wait... you already have an `` `aclocal.m4' ``, because you had to write some hairy macros for your program. The `aclocal` program lets you put your own macros into `` `acinclude.m4' ``, so simply rename and then run:

```
mv aclocal.m4 acinclude.m4
aclocal
autoconf
```

Now it is time to write your `` `Makefile.am' `` for `zardoz`. Since `zardoz` is a user program, you want to install it where the rest of the user programs go. Additionally, `zardoz` has some Texinfo documentation. Your `` `configure.in' `` script uses `AC_REPLACE_FUNCS`, so you need to link against `@LIBOBJS@'. So here's what you'd write:

```
bin_PROGRAMS = zardoz
zardoz_SOURCES = main.c head.c float.c vortex9.c gun.c
zardoz_LDADD = @LIBOBJS@

info_TEXINFOS = zardoz.texi
```

Now you can run `automake --add-missing` to generate your `` `Makefile.in' `` and grab any auxiliary files you might need, and you're done!

A classic program

GNU hello is renowned for its classic simplicity and versatility. This section shows how Automake could be used with the GNU Hello package. The examples below are from the latest beta version of GNU Hello, but with all of the maintainer-only code stripped out, as well as all copyright comments.

Of course, GNU Hello is somewhat more featureful than your traditional two-liner. GNU Hello is internationalized, does option processing, and has a manual and a test suite. GNU Hello is a deep package.

Here is the `configure.in' from GNU Hello:

```
dnl Process this file with autoconf to produce a configure script.
AC_INIT(src/hello.c)
AM_INIT_AUTOMAKE(hello, 1.3.11)
AM_CONFIG_HEADER(config.h)

dnl Set of available languages.
ALL_LINGUAS="de fr es ko nl no pl pt sl sv"

dnl Checks for programs.
AC_PROG_CC
AC_ISC_POSIX

dnl Checks for libraries.

dnl Checks for header files.
AC_STDC_HEADERS
AC_HAVE_HEADERS(string.h fcntl.h sys/file.h sys/param.h)

dnl Checks for library functions.
AC_FUNC_ALLOCA

dnl Check for st_blksize in struct stat
AC_ST_BLKSIZE

dnl internationalization macros
AM_GNU_GETTEXT
AC_OUTPUT([Makefile doc/Makefile intl/Makefile po/Makefile.in \
           src/Makefile tests/Makefile tests/hello],
   [chmod +x tests/hello])
```

The `AM_' macros are provided by Automake (or the Gettext library); the rest are standard Autoconf macros.

The top-level `Makefile.am':

```
EXTRA_DIST = BUGS ChangeLog.O
SUBDIRS = doc intl po src tests
```

As you can see, all the work here is really done in subdirectories.

The `po' and `intl' directories are automatically generated using `gettextize'; they will not be discussed here.

In `doc/Makefile.am' we see:

```
info_TEXINFOS = hello.texi
hello_TEXINFOS = gpl.texi
```

This is sufficient to build, install, and distribute the GNU Hello manual.

Here is `tests/Makefile.am':

```
TESTS = hello
EXTRA_DIST = hello.in testdata
```

The script `hello' is generated by `configure', and is the only test case. `make check' will run this test.

Last we have `src/Makefile.am', where all the real work is done:

```
bin_PROGRAMS = hello
hello_SOURCES = hello.c version.c getopt.c getopt1.c getopt.h system.h
hello_LDADD = @INTLLIBS@ @ALLOCA@
localedir = $(datadir)/locale
INCLUDES = -I../intl -DLOCALEDIR=\"$(localedir)\"
```

Building etags and ctags

Here is another, trickier example. It shows how to generate two programs (`ctags' and `etags') from the same source file (`etags.c'). The difficult part is that each compilation of `etags.c' requires different `cpp' flags.

```
bin_PROGRAMS = etags ctags
ctags_SOURCES =
ctags_LDADD = ctags.o

etags.o: etags.c
        $(COMPILE) -DETAGS_REGEXPS -c etags.c

ctags.o: etags.c
        $(COMPILE) -DCTAGS -o ctags.o -c etags.c
```

Note that `ctags_SOURCES` is defined to be empty--that way no implicit value is substituted. The implicit value, however, is used to generate `etags` from `` `etags.o' ``.

`ctags_LDADD` is used to get `` `ctags.o' `` into the link line. `ctags_DEPENDENCIES` is generated by Automake.

The above rules won't work if your compiler doesn't accept both `-c' and `-o'. The simplest fix for this is to introduce a bogus dependency (to avoid problems with a parallel `make`):

```
etags.o: etags.c ctags.o
        $(COMPILE) -DETAGS_REGEXPS -c etags.c

ctags.o: etags.c
        $(COMPILE) -DCTAGS -c etags.c && mv etags.o ctags.o
```

Also, these explicit rules do not work if the de-ANSI-fication feature is used (see section Automatic de-ANSI-fication). Supporting de-ANSI-fication requires a little more work:

```
etags._o: etags._c ctags.o
        $(COMPILE) -DETAGS_REGEXPS -c etags.c

ctags._o: etags._c
        $(COMPILE) -DCTAGS -c etags.c && mv etags._o ctags.o
```

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Creating a `Makefile.in'

To create all the `Makefile.in's for a package, run the `automake` program in the top level directory, with no arguments. `automake` will automatically find each appropriate `Makefile.am' (by scanning `configure.in'; see section Scanning `configure.in') and generate the corresponding `Makefile.in'. Note that `automake` has a rather simplistic view of what constitutes a package; it assumes that a package has only one `configure.in', at the top. If your package has multiple `configure.in's, then you must run `automake` in each directory holding a `configure.in'.

You can optionally give `automake` an argument; `.am' is appended to the argument and the result is used as the name of the input file. This feature is generally only used to automatically rebuild an out-of-date `Makefile.in'. Note that `automake` must always be run from the topmost directory of a project, even if being used to regenerate the `Makefile.in' in some subdirectory. This is necessary because `automake` must scan `configure.in', and because `automake` uses the knowledge that a `Makefile.in' is in a subdirectory to change its behavior in some cases.

`automake` accepts the following options:

`-a'

`--add-missing'

> Automake requires certain common files to exist in certain situations; for instance `config.guess' is required if `configure.in' runs `AC_CANONICAL_HOST`. Automake is distributed with several of these files; this option will cause the missing ones to be automatically added to the package, whenever possible. In general if Automake tells you a file is missing, try using this option. By default Automake tries to make a symbolic link pointing to its own copy of the missing file; this can be changed with `--copy`.

`--amdir=dir'

> Look for Automake data files in directory dir instead of in the installation directory. This is typically used for debugging.

`--build-dir=dir'

> Tell Automake where the build directory is. This option is used when including dependencies into a `Makefile.in' generated by `make dist`; it should not be used otherwise.

`-c'

`--copy'

> When used with `--add-missing`, causes installed files to be copied. The default is to make a symbolic link.

`--cygnus'

> Causes the generated `Makefile.in's to follow Cygnus rules, instead of GNU or Gnits rules.

For more information, see section The effect of `--cygnus`.

`--foreign'

Set the global strictness to `foreign'. For more information, see section Strictness.

`--gnits'

Set the global strictness to `gnits'. For more information, see section The effect of `--gnu` and `--gnits`.

`--gnu'

Set the global strictness to `gnu'. For more information, see section The effect of `--gnu` and `--gnits`. This is the default strictness.

`--help'

Print a summary of the command line options and exit.

`-i'

`--include-deps'

Include all automatically generated dependency information (see section Automatic dependency tracking) in the generated `Makefile.in'. This is generally done when making a distribution; see section What Goes in a Distribution.

`--generate-deps'

Generate a file concatenating all automatically generated dependency information (see section Automatic dependency tracking) into one file, `.dep_segment'. This is generally done when making a distribution; see section What Goes in a Distribution. It is useful when maintaining a `SMakefile' or makefiles for other platforms (`Makefile.DOS', etc.) It can only be used in conjunction with `--include-deps', `--srcdir-name', and `--build-dir'. Note that if this option is given, no other processing is done.

`--no-force'

Ordinarily `automake` creates all `Makefile.in's mentioned in `configure.in'. This option causes it to only update those `Makefile.in's which are out of date with respect to one of their dependents.

`-o dir'

`--output-dir=dir'

Put the generated `Makefile.in' in the directory dir. Ordinarily each `Makefile.in' is created in the directory of the corresponding `Makefile.am'. This option is used when making distributions.

`--srcdir-name=dir'

Tell Automake the name of the source directory associated with the current build. This option is used when including dependencies into a `Makefile.in' generated by `make dist`; it should not be used otherwise.

`-v'

`--verbose'

Cause Automake to print information about which files are being read or created.

`--version'

Print the version number of Automake and exit.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Scanning `configure.in'

Automake scans the package's `configure.in' to determine certain information about the package. Some autoconf macros are required and some variables must be defined in `configure.in'. Automake will also use information from `configure.in' to further tailor its output.

Automake also supplies some Autoconf macros to make the maintenance easier. These macros can automatically be put into your `aclocal.m4' using the aclocal program.

Configuration requirements

The simplest way to meet the basic Automake requirements is to use the macro AM_INIT_AUTOMAKE (see section Autoconf macros supplied with Automake). But if you prefer, you can do the required steps by hand:

- Define the variables PACKAGE and VERSION with AC_SUBST. PACKAGE should be the name of the package as it appears when bundled for distribution. For instance, Automake defines PACKAGE to be `automake'. VERSION should be the version number of the release that is being developed. We recommend that you make `configure.in' the only place in your package where the version number is defined; this makes releases simpler. Automake doesn't do any interpretation of PACKAGE or VERSION, except in `Gnits' mode (see section The effect of --gnu and --gnits).
- Use the macro AC_ARG_PROGRAM if a program or script is installed. See section `Transforming Program Names When Installing' in The Autoconf.
- Use AC_PROG_MAKE_SET if the package is not flat. See section `Creating Output Files' in The Autoconf Manual.
- Use AM_SANITY_CHECK to make sure the build environment is sane.
- Call AC_PROG_INSTALL (see section `Particular Program Checks' in The Autoconf Manual).
- Use AM_MISSING_PROG to see whether the programs aclocal, autoconf, automake, autoheader, and makeinfo are in the build environment. Here is how this is done:

```
missing_dir=`cd $ac_aux_dir && pwd`
AM_MISSING_PROG(ACLOCAL, aclocal, $missing_dir)
AM_MISSING_PROG(AUTOCONF, autoconf, $missing_dir)
AM_MISSING_PROG(AUTOMAKE, automake, $missing_dir)
AM_MISSING_PROG(AUTOHEADER, autoheader, $missing_dir)
AM_MISSING_PROG(MAKEINFO, makeinfo, $missing_dir)
```

Here are the other macros which Automake requires but which are not run by AM_INIT_AUTOMAKE:

AC_OUTPUT

Automake uses this to determine which files to create (see section `Creating Output Files' in The Autoconf Manual). Listed files named `Makefile` are treated as `Makefile'`s. Other listed files are treated differently. Currently the only difference is that a `Makefile'` is removed by `make distclean`, while other files are removed by `make clean`.

Other things Automake recognizes

Automake will also recognize the use of certain macros and tailor the generated `Makefile.in'` appropriately. Currently recognized macros and their effects are:

AC_CONFIG_HEADER

Automake requires the use of AM_CONFIG_HEADER, which is similar to AC_CONFIG_HEADER (see section `Configuration Header Files' in The Autoconf Manual), but does some useful Automake-specific work.

AC_CONFIG_AUX_DIR

Automake will look for various helper scripts, such as `mkinstalldirs'`, in the directory named in this macro invocation. If not seen, the scripts are looked for in their `standard' locations (either the top source directory, or in the source directory corresponding to the current `Makefile.am'`, whichever is appropriate). See section `Finding `configure' Input' in The Autoconf Manual. FIXME: give complete list of things looked for in this directory

AC_PATH_XTRA

Automake will insert definitions for the variables defined by AC_PATH_XTRA into each `Makefile.in'` that builds a C program or library. See section `System Services' in The Autoconf Manual.

AC_CANONICAL_HOST

AC_CHECK_TOOL

Automake will ensure that `config.guess'` and `config.sub'` exist. Also, the `Makefile'` variables `host_alias' and `host_triplet' are introduced. See both section `Getting the Canonical System Type' in The Autoconf Manual, and section `Generic Program Checks' in The Autoconf Manual.

AC_CANONICAL_SYSTEM

This is similar to AC_CANONICAL_HOST, but also defines the `Makefile'` variables `build_alias' and `target_alias'. See section `Getting the Canonical System Type' in The Autoconf Manual.

AC_FUNC_ALLOCA

AC_FUNC_GETLOADAVG

AC_FUNC_MEMCMP

AC_STRUCT_ST_BLOCKS

AC_FUNC_FNMATCH

AM_FUNC_STRTOD

`AC_REPLACE_FUNCS`

`AC_REPLACE_GNU_GETOPT`

`AM_WITH_REGEX`

Automake will ensure that the appropriate dependencies are generated for the objects corresponding to these macros. Also, Automake will verify that the appropriate source files are part of the distribution. Note that Automake does not come with any of the C sources required to use these macros, so `automake -a` will not install the sources. See section Building a library, for more information. Also, see section `Particular Function Checks' in The Autoconf Manual.

`LIBOBJS`

Automake will detect statements which put `.o' files into `LIBOBJS`, and will treat these additional files as if they were discovered via `AC_REPLACE_FUNCS`. See section `Generic Function Checks' in The Autoconf Manual.

`AC_PROG_RANLIB`

This is required if any libraries are built in the package. See section `Particular Program Checks' in The Autoconf Manual.

`AC_PROG_CXX`

This is required if any C++ source is included. See section `Particular Program Checks' in The Autoconf Manual.

`AC_PROG_F77`

This is required if any Fortran 77 source is included. This macro is distributed with Autoconf version 2.13 and later. See section `Particular Program Checks' in The Autoconf Manual.

`AC_F77_LIBRARY_LDFLAGS`

This is required for programs and shared libraries that are a mixture of languages that include Fortran 77 (see section Mixing Fortran 77 With C and C++). See section Autoconf macros supplied with Automake.

`AM_PROG_LIBTOOL`

Automake will turn on processing for `libtool` (see section `Introduction' in The Libtool Manual).

`AC_PROG_YACC`

If a Yacc source file is seen, then you must either use this macro or define the variable `YACC' in `configure.in'. The former is preferred (see section `Particular Program Checks' in The Autoconf Manual).

`AC_DECL_YYTEXT`

This macro is required if there is Lex source in the package. See section `Particular Program Checks' in The Autoconf Manual.

`AC_PROG_LEX`

If a Lex source file is seen, then this macro must be used. See section `Particular Program Checks' in The Autoconf Manual.

`ALL_LINGUAS`

If Automake sees that this variable is set in `configure.in', it will check the `po' direc to ensure that all the named `.po' files exist, and that all the `.po' files that exist are named.

AM_C_PROTOTYPES

This is required when using automatic de-ANSI-fication; see section Automatic de-ANSI-fication.

AM_GNU_GETTEXT

This macro is required for packages which use GNU gettext (see section Gettext). It is distributed with gettext. If Automake sees this macro it ensures that the package meets some of gettext's requirements.

AM_MAINTAINER_MODE

This macro adds a `--enable-maintainer-mode' option to `configure'. If this is used, `automake' will cause `maintainer-only' rules to be turned off by default in the generated `Makefile.in's. This macro is disallowed in `Gnits' mode (see section The effect of `--gnu' and `--gnits'). This macro defines the `MAINTAINER_MODE' conditional, which you can use in your own `Makefile.am'.

AC_SUBST

AC_CHECK_TOOL

AC_CHECK_PROG

AC_CHECK_PROGS

AC_PATH_PROG

AC_PATH_PROGS

For each of these macros, the first argument is automatically defined as a variable in each generated `Makefile.in'. See section `Setting Output Variables' in The Autoconf Manual, and section `Generic Program Checks' in The Autoconf Manual.

Auto-generating aclocal.m4

Automake includes a number of Autoconf macros which can be used in your package; some of them are actually required by Automake in certain situations. These macros must be defined in your `aclocal.m4'; otherwise they will not be seen by `autoconf'.

The `aclocal' program will automatically generate `aclocal.m4' files based on the contents of `configure.in'. This provides a convenient way to get Automake-provided macros, without having to search around. Also, the `aclocal' mechanism is extensible for use by other packages.

At startup, `aclocal' scans all the `.m4' files it can find, looking for macro definitions. Then it scans `configure.in'. Any mention of one of the macros found in the first step causes that macro, and any macros it in turn requires, to be put into `aclocal.m4'.

The contents of `acinclude.m4', if it exists, are also automatically included in `aclocal.m4'. This is useful for incorporating local macros into `configure'.

`aclocal' accepts the following options:

`--acdir=dir`

Look for the macro files in dir instead of the installation directory. This is typically used for debugging.

`--help`

Print a summary of the command line options and exit.

`-I dir`

Add the directory dir to the list of directories searched for `` `.m4' `` files.

`--output=file`

Cause the output to be put into file instead of `` `aclocal.m4' ``.

`--print-ac-dir`

Prints the name of the directory which `aclocal` will search to find the `` `.m4' `` files. When this option is given, normal processing is suppressed. This option can be used by a package to determine where to install a macro file.

`--verbose`

Print the names of the files it examines.

`--version`

Print the version number of Automake and exit.

Autoconf macros supplied with Automake

`AM_CONFIG_HEADER`

Automake will generate rules to automatically regenerate the config header. If you do use this macro, you must create the file `` `stamp-h.in' `` in your source directory. It can be empty.

`AM_ENABLE_MULTILIB`

This is used when a "multilib" library is being built. A **multilib** library is one that is built multiple times, once per target flag combination. This is only useful when the library is intended to be cross-compiled. The first optional argument is the name of the `` `Makefile' `` being generated; it defaults to `Makefile'. The second option argument is used to find the top source directory; it defaults to the empty string (generally this should not be used unless you are familiar with the internals).

`AM_FUNC_STRTOD`

If the `strtod` function is not available, or does not work correctly (like the one on SunOS 5.4), add `` `strtod.o' `` to output variable `LIBOBJS`.

`AM_FUNC_ERROR_AT_LINE`

If the function `error_at_line` is not found, then add `` `error.o' `` to `LIBOBJS`.

`AM_FUNC_MKTIME`

Check for a working `mktime` function. If not found, add `` `mktime.o' `` to `LIBOBJS'.

`AM_FUNC_OBSTACK`

Check for the GNU obstacks code; if not found, add `` `obstack.o' `` to `LIBOBJS'.

`AM_C_PROTOTYPES`

Check to see if function prototypes are understood by the compiler. If so, define `PROTOTYPES' and set the output variables `U' and `ANSI2KNR' to the empty string. Otherwise, set `U' to `_' and `ANSI2KNR' to `./ansi2knr'. Automake uses these values to implement automatic de-ANSI-fication.

`AM_HEADER_TIOCGWINSZ_NEEDS_SYS_IOCTL`

If the use of `TIOCGWINSZ` requires `<sys/ioctl.h>', then define `GWINSZ_IN_SYS_IOCTL`. Otherwise `TIOCGWINSZ` can be found in `<termios.h>'.

`AM_INIT_AUTOMAKE`

Runs many macros that most `configure.in`'s need. This macro has two required arguments, the package and the version number. By default this macro `AC_DEFINE`'s `PACKAGE' and `VERSION'. This can be avoided by passing in a non-empty third argument.

`AM_PATH_LISPDIR`

Searches for the program `emacs`, and, if found, sets the output variable `lispdir` to the full path to Emacs' site-lisp directory.

`AM_PROG_CC_STDC`

If the C compiler in not in ANSI C mode by default, try to add an option to output variable `CC` to make it so. This macro tries various options that select ANSI C on some system or another. It considers the compiler to be in ANSI C mode if it handles function prototypes correctly. If you use this macro, you should check after calling it whether the C compiler has been set to accept ANSI C; if not, the shell variable `am_cv_prog_cc_stdc` is set to `no'. If you wrote your source code in ANSI C, you can make an un-ANSIfied copy of it by using the `ansi2knr` option (see section Automatic de-ANSI-fication).

`AM_PROG_LEX`

Like `AC_PROG_LEX` with `AC_DECL_YYTEXT` (see section `Particular Program Checks' in The Autoconf Manual), but uses the `missing` script on systems that do not have `lex`. `HP-UX 10' is one such system.

`AM_SANITY_CHECK`

This checks to make sure that a file created in the build directory is newer than a file in the source directory. This can fail on systems where the clock is set incorrectly. This macro is automatically run from `AM_INIT_AUTOMAKE`.

`AM_SYS_POSIX_TERMIOS`

Check to see if POSIX termios headers and functions are available on the system. If so, set the shell variable `am_cv_sys_posix_termios` to `yes'. If not, set the variable to `no'.

`AM_TYPE_PTRDIFF_T`

Define `HAVE_PTRDIFF_T' if the type `ptrdiff_t' is defined in `<stddef.h>'.

`AM_WITH_DMALLOC`

Add support for the `dmalloc` package. If the user configures with `--with-dmalloc', then define `WITH_DMALLOC` and add `-ldmalloc' to `LIBS`.

`AM_WITH_REGEX`

Adds `--with-regex' to the `configure` command line. If specified (the default), then the `reg
regular expression library is used, `regex.o' is put into `LIBOBJS', and `WITH_REGEX' i
defined.. If `--without-regex' is given, then the `rx' regular expression library is used, and `rx.o'
is put into `LIBOBJS'.

Writing your own aclocal macros

The `aclocal` program doesn't have any built-in knowledge of any macros, so it is easy to extend it with your own macros.

This is mostly used for libraries which want to supply their own Autoconf macros for use by other programs. For instance the `gettext` library supplies a macro `AM_GNU_GETTEXT` which should be used by any package using `gettext`. When the library is installed, it installs this macro so that `aclocal` will find it.

A file of macros should be a series of `AC_DEFUN`'s. The `aclocal` programs also understands `AC_REQUIRE`, so it is safe to put each macro in a separate file. See section `Prerequisite Macros' in The Autoconf Manual, and section `Macro Definitions' in The Autoconf Manual.

A macro file's name should end in `.m4'. Such files should be installed in `$(datadir)/aclocal'.

Go to the first, previous, next, last section, table of contents.

The top-level `Makefile.am'

In non-flat packages, the top level `Makefile.am' must tell Automake which subdirectories are to be built. This is done via the SUBDIRS variable.

The SUBDIRS macro holds a list of subdirectories in which building of various sorts can occur. Many targets (e.g. all) in the generated `Makefile' will run both locally and in all specified subdirectories. Note that the directories listed in SUBDIRS are not required to contain `Makefile.am's; only `Makefile's (after configuration). This allows inclusion of libraries from packages which do not use Automake (such as gettext). The directories mentioned in SUBDIRS must be direct children of the current directory. For instance, you cannot put `src/subdir' into SUBDIRS.

In a deep package, the top-level `Makefile.am' is often very short. For instance, here is the `Makefile.am' from the GNU Hello distribution:

```
EXTRA_DIST = BUGS ChangeLog.O README-alpha
SUBDIRS = doc intl po src tests
```

It is possible to override the SUBDIRS variable if, like in the case of GNU Inetutils, you want to only build a subset of the entire package. In your `Makefile.am' include:

```
SUBDIRS = @SUBDIRS@
```

Then in your `configure.in' you can specify:

```
SUBDIRS = "src doc lib po"
AC_SUBST(SUBDIRS)
```

The upshot of this is that Automake is tricked into building the package to take the subdirs, but doesn't actually bind that list until configure is run.

Although the SUBDIRS macro can contain configure substitutions (e.g. `@DIRS@'); Automake itself does not actually examine the contents of this variable.

If SUBDIRS is defined, then your `configure.in' must include AC_PROG_MAKE_SET.

The use of SUBDIRS is not restricted to just the top-level `Makefile.am'. Automake can be used to construct packages of arbitrary depth.

By default, Automake generates `Makefiles' which work depth-first (`postfix'). However, it is possible to change this ordering. You can do this by putting `.' into SUBDIRS. For instance, putting `.' first will cause a `prefix' ordering of directories.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Building Programs and Libraries

A large part of Automake's functionality is dedicated to making it easy to build programs and libraries.

Building a program

In a directory containing source that gets built into a program (as opposed to a library), the `PROGRAMS' primary is used. Programs can be installed in `bindir`, `sbindir`, `libexecdir`, `pkglibdir`, or not at all (`noinst').

For instance:

```
bin_PROGRAMS = hello
```

In this simple case, the resulting `Makefile.in' will contain code to generate a program named `hello`. The variable `hello_SOURCES` is used to specify which source files get built into an executable:

```
hello_SOURCES = hello.c version.c getopt.c getopt1.c getopt.h system.h
```

This causes each mentioned `.c' file to be compiled into the corresponding `.o'. Then all are linked to produce `hello'.

If `prog_SOURCES' is needed, but not specified, then it defaults to the single file `prog.c'.

Multiple programs can be built in a single directory. Multiple programs can share a single source file, which must be listed in each `_SOURCES' definition.

Header files listed in a `_SOURCES' definition will be included in the distribution but otherwise ignored. In case it isn't obvious, you should not include the header file generated by `configure' in an `_SOURCES' variable; this file should not be distributed. Lex (`.l') and Yacc (`.y') files can also be listed; see section Yacc and Lex support.

Automake must know all the source files that could possibly go into a program, even if not all the files are built in every circumstance. Any files which are only conditionally built should be listed in the appropriate `EXTRA_' variable. For instance, if `hello-linux.c' were conditionally included in `hello`, the `Makefile.am' would contain:

```
EXTRA_hello_SOURCES = hello-linux.c
```

Similarly, sometimes it is useful to determine the programs that are to be built at configure time. For instance, GNU `cpio` only builds `mt` and `rmt` under special circumstances.

In this case, you must notify Automake of all the programs that can possibly be built, but at the same cause the generated `Makefile.in' to use the programs specified by `configure'. This is done by having `configure' substitute values into each `_PROGRAMS' definition, while listing all optionally built programs in `EXTRA_PROGRAMS'.

If you need to link against libraries that are not found by `configure', you can use `LDADD' to do so. This variable actually can be used to add any options to the linker command line.

Sometimes, multiple programs are built in one directory but do not share the same link-time requirements. In this case, you can use the `prog_LDADD' variable (where prog is the name of the program as it appears in some `_PROGRAMS' variable, and usually written in lowercase) to override the global `LDADD'. If this variable exists for a given program, then that program is not linked using `LDADD'.

For instance, in GNU cpio, `pax', `cpio' and `mt' are linked against the library `libcpio.a'. However, `rmt' is built in the same directory, and has no such link requirement. Also, `mt' and `rmt' are only built on certain architectures. Here is what cpio's `src/Makefile.am' looks like (abridged):

```
bin_PROGRAMS = cpio pax @MT@
libexec_PROGRAMS = @RMT@
EXTRA_PROGRAMS = mt rmt

LDADD = ../lib/libcpio.a @INTLLIBS@
rmt_LDADD =

cpio_SOURCES = ...
pax_SOURCES = ...
mt_SOURCES = ...
rmt_SOURCES = ...
```

`prog_LDADD' is inappropriate for passing program-specific linker flags (except for `-l' and `-L'). So, use the `prog_LDFLAGS' variable for this purpose.

It is also occasionally useful to have a program depend on some other target which is not actually part of that program. This can be done using the `prog_DEPENDENCIES' variable. Each program depends on the contents of such a variable, but no further interpretation is done.

If `prog_DEPENDENCIES' is not supplied, it is computed by Automake. The automatically-assigned value is the contents of `prog_LDADD', with most configure substitutions, `-l', and `-L' options removed. The configure substitutions that are left in are only `@LIBOBJS@' and `@ALLOCA@'; these are left because it is known that they will not cause an invalid value for `prog_DEPENDENCIES' to be generated.

Building a library

Building a library is much like building a program. In this case, the name of the primary is `LIBRARIES'. Libraries can be installed in `libdir' or `pkglibdir'.

See section Building a Shared Library, for information on how to build shared libraries using Libtool and

the `LTLIBRARIES' primary.

Each `_LIBRARIES' variable is a list of the libraries to be built. For instance to create a library named `libcpio.a', but not install it, you would write:

```
noinst_LIBRARIES = libcpio.a
```

The sources that go into a library are determined exactly as they are for programs, via the `_SOURCES' variables. Note that the library name is canonicalized (see section How derived variables are named), so the `_SOURCES' variable corresponding to `liblob.a' is `liblob_a_SOURCES', not `liblob.a_SOURCES'.

Extra objects can be added to a library using the `library_LIBADD' variable. This should be used for objects determined by `configure'. Again from `cpio':

```
libcpio_a_LIBADD = @LIBOBJS@ @ALLOCA@
```

Special handling for LIBOBJS and ALLOCA

Automake explicitly recognizes the use of `@LIBOBJS@' and `@ALLOCA@', and uses this information, plus the list of `LIBOBJS' files derived from `configure.in' to automatically include the appropriate source files in the distribution (see section What Goes in a Distribution). These source files are also automatically handled in the dependency-tracking scheme; see See section Automatic dependency tracking.

`@LIBOBJS@' and `@ALLOCA@' are specially recognized in any `_LDADD' or `_LIBADD' variable.

Building a Shared Library

Building shared libraries is a relatively complex matter. For this reason, GNU Libtool (see section `Introduction' in The Libtool Manual) was created to help build shared libraries in a platform-independent way.

Automake uses Libtool to build libraries declared with the `LTLIBRARIES' primary. Each `_LTLIBRARIES' variable is a list of shared libraries to build. For instance, to create a library named `libgettext.a' and its corresponding shared libraries, and install them in `libdir', write:

```
lib_LTLIBRARIES = libgettext.la
```

Note that shared libraries *must* be installed, so `check_LTLIBRARIES' is not allowed. However, `noinst_LTLIBRARIES' is allowed. This feature should be used for libtool "convenience libraries".

For each library, the `library_LIBADD' variable contains the names of extra libtool objects (`.lo' files) to add to the shared library. The `library_LDFLAGS' variable contains any additional libtool flags, such as `-version-info' or `-static'.

Where an ordinary library might include `@LIBOBJS@`, a libtool library must use `@LTLIBOBJS@`. Th required because the object files that libtool operates on do not necessarily end in `.o'`. The libtool manual contains more details on this topic.

For libraries installed in some directory, Automake will automatically supply the appropriate `-rpath' option. However, for libraries determined at configure time (and thus mentioned in `EXTRA_LTLIBRARIES`), Automake does not know the eventual installation directory; for such libraries you must add the `-rpath' option to the appropriate `_LDFLAGS' variable by hand.

See section `The Libtool Manual' in The Libtool Manual, for more information.

Variables used when building a program

Occasionally it is useful to know which `Makefile'` variables Automake uses for compilations; for instance you might need to do your own compilation in some special cases.

Some variables are inherited from Autoconf; these are `CC`, `CFLAGS`, `CPPFLAGS`, `DEFS`, `LDFLAGS`, and `LIBS`.

There are some additional variables which Automake itself defines:

`INCLUDES`

A list of `-I' options. This can be set in your `Makefile.am'` if you have special directories you want to look in. Automake already provides some `-I' options automatically. In particular it generates `-I$(srcdir)' and a `-I' pointing to the directory holding `config.h'` (if you've used `AC_CONFIG_HEADER` or `AM_CONFIG_HEADER`). `INCLUDES` can actually be used for other `cpp` options besides `-I'. For instance, it is sometimes used to pass arbitrary `-D' options to the compiler.

`COMPILE`

This is the command used to actually compile a C source file. The filename is appended to form the complete command line.

`LINK`

This is the command used to actually link a C program.

Yacc and Lex support

Automake has somewhat idiosyncratic support for Yacc and Lex.

Automake assumes that the `.c'` file generated by `yacc` (or `lex`) should be named using the basename of the input file. That is, for a yacc source file `foo.y'`, Automake will cause the intermediate file to be named `foo.c'` (as opposed to `y.tab.c'`, which is more traditional).

The extension of a yacc source file is used to determine the extension of the resulting `C' or `C++' file. Files with the extension `.y' will be turned into `.c' files; likewise, `.yy' will become `.cc'; `.y++', `c++'; and `.yxx', `.cxx'.

Likewise, lex source files can be used to generate `C' or `C++'; the extensions `.l', `.ll', `.l++', and `.lx` recognized.

You should never explicitly mention the intermediate (`C' or `C++') file in any `SOURCES' variable; only list the source file.

The intermediate files generated by `yacc` (or `lex`) will be included in any distribution that is made. That way the user doesn't need to have `yacc` or `lex`.

If a `yacc` source file is seen, then your `configure.in' must define the variable `YACC'. This is most easily done by invoking the macro `AC_PROG_YACC' (see section `Particular Program Checks' in The Autoconf Manual).

Similarly, if a `lex` source file is seen, then your `configure.in' must define the variable `LEX'. You can use `AC_PROG_LEX' to do this (see section `Particular Program Checks' in The Autoconf Manual). Automake's `lex` support also requires that you use the `AC_DECL_YYTEXT' macro--automake needs to know the value of `LEX_OUTPUT_ROOT'. This is all handled for you if you use the `AM_PROG_LEX` macro (see section Autoconf macros supplied with Automake).

Automake makes it possible to include multiple `yacc` (or `lex`) source files in a single program. Automake uses a small program called `ylwrap` to run `yacc` (or `lex`) in a subdirectory. This is necessary because yacc's output filename is fixed, and a parallel make could conceivably invoke more than one instance of `yacc` simultaneously. The `ylwrap` program is distributed with Automake. It should appear in the directory specified by `AC_CONFIG_AUX_DIR' (see section `Finding `configure' Input' in The Autoconf Manual), or the current directory if that macro is not used in `configure.in'.

For `yacc`, simply managing locking is insufficient. The output of `yacc` always uses the same symbol names internally, so it isn't possible to link two `yacc` parsers into the same executable.

We recommend using the following renaming hack used in `gdb`:

```
#define yymaxdepth c_maxdepth
#define yyparse c_parse
#define yylex   c_lex
#define yyerror c_error
#define yylval  c_lval
#define yychar  c_char
#define yydebug c_debug
#define yypact  c_pact
#define yyr1    c_r1
#define yyr2    c_r2
#define yydef   c_def
#define yychk   c_chk
#define yypgo   c_pgo
#define yyact   c_act
#define yyexca  c_exca
#define yyerrflag c_errflag
#define yynerrs c_nerrs
```

```
#define yyps    c_ps
#define yypv    c_pv
#define yys     c_s
#define yy_yys  c_yys
#define yystate c_state
#define yytmp   c_tmp
#define yyv     c_v
#define yy_yyv  c_yyv
#define yyval   c_val
#define yylloc  c_lloc
#define yyreds  c_reds
#define yytoks  c_toks
#define yylhs   c_yylhs
#define yylen   c_yylen
#define yydefred c_yydefred
#define yydgoto c_yydgoto
#define yysindex c_yysindex
#define yyrindex c_yyrindex
#define yygindex c_yygindex
#define yytable  c_yytable
#define yycheck  c_yycheck
#define yyname   c_yyname
#define yyrule   c_yyrule
```

For each define, replace the `c_' prefix with whatever you like. These defines work for `bison`, `byacc`, and traditional `yacc`s. If you find a parser generator that uses a symbol not covered here, please report the new name so it can be added to the list.

C++ Support

Automake includes full support for C++.

Any package including C++ code must define the output variable `CXX' in `configure.in'; the simplest way to do this is to use the `AC_PROG_CXX` macro (see section `Particular Program Checks' in The Autoconf Manual).

A few additional variables are defined when a C++ source file is seen:

`CXX`

The name of the C++ compiler.

`CXXFLAGS`

Any flags to pass to the C++ compiler.

`CXXCOMPILE`

The command used to actually compile a C++ source file. The file name is appended to form the complete command line.

`CXXLINK`

The command used to actually link a C++ program.

Fortran 77 Support

Automake includes full support for Fortran 77.

Any package including Fortran 77 code must define the output variable `F77' in `configure.in'; the simplest way to do this is to use the `AC_PROG_F77` macro (see section `Particular Program Checks' in The Autoconf Manual). See section Fortran 77 and Autoconf.

A few additional variables are defined when a Fortran 77 source file is seen:

`F77`

The name of the Fortran 77 compiler.

`FFLAGS`

Any flags to pass to the Fortran 77 compiler.

`RFLAGS`

Any flags to pass to the Ratfor compiler.

`F77COMPILE`

The command used to actually compile a Fortran 77 source file. The file name is appended to form the complete command line.

`FLINK`

The command used to actually link a pure Fortran 77 program or shared library.

Automake can handle preprocessing Fortran 77 and Ratfor source files in addition to compiling them(1). Automake also contains some support for creating programs and shared libraries that are a mixture of Fortran 77 and other languages (see section Mixing Fortran 77 With C and C++).

These issues are covered in the following sections.

Preprocessing Fortran 77

`N.f' is made automatically from `N.F' or `N.r'. This rule runs just the preprocessor to convert a preprocessable Fortran 77 or Ratfor source file into a strict Fortran 77 source file. The precise command used is as follows:

`.F'

```
$(F77) -F $(DEFS) $(INCLUDES) $(AM_CPPFLAGS) $(CPPFLAGS)
$(AM_FFLAGS) $(FFLAGS)
```

`.r'

```
$(F77) -F $(AM_FFLAGS) $(FFLAGS) $(AM_RFLAGS) $(RFLAGS)
```

Compiling Fortran 77 Files

`N.o' is made automatically from `N.f', `N.F' or `N.r' by running the Fortran 77 compiler. The precise command used is as follows:

```
`.f'
    $(F77) -c $(AM_FFLAGS) $(FFLAGS)
`.F'
    $(F77) -c $(DEFS) $(INCLUDES) $(AM_CPPFLAGS) $(CPPFLAGS)
    $(AM_FFLAGS) $(FFLAGS)
`.r'
    $(F77) -c $(AM_FFLAGS) $(FFLAGS) $(AM_RFLAGS) $(RFLAGS)
```

Mixing Fortran 77 With C and C++

Automake currently provides *limited* support for creating programs and shared libraries that are a mixture of Fortran 77 and C and/or C++. However, there are many other issues related to mixing Fortran 77 with other languages that are *not* (currently) handled by Automake, but that are handled by other packages(2).

Automake can help in two ways:

1. Automatic selection of the linker depending on which combinations of source code.
2. Automatic selection of the appropriate linker flags (e.g. `-L' and `-l') to pass to the automatically selected linker in order to link in the appropriate Fortran 77 intrinsic and run-time libraries. These extra Fortran 77 linker flags are supplied in the output variable FLIBS by the AC_F77_LIBRARY_LDFLAGS Autoconf macro supplied with newer versions of Autoconf (Autoconf version 2.13 and later). See section `Fortran 77 Compiler Characteristics' in The Autoconf.

If Automake detects that a program or shared library (as mentioned in some _PROGRAMS or _LTLIBRARIES primary) contains source code that is a mixture of Fortran 77 and C and/or C++, then it requires that the macro AC_F77_LIBRARY_LDFLAGS be called in `configure.in', and that either $(FLIBS) or @FLIBS@ appear in the appropriate _LDADD (for programs) or _LIBADD (for shared libraries) variables. It is the responsibility of the person writing the `Makefile.am' to make sure that $(FLIBS) or @FLIBS@ appears in the appropriate _LDADD or _LIBADD variable.

For example, consider the following `Makefile.am':

```
bin_PROGRAMS = foo
foo_SOURCES  = main.cc foo.f
foo_LDADD    = libfoo.la @FLIBS@

pkglib_LTLIBRARIES = libfoo.la
libfoo_la_SOURCES  = bar.f baz.c zardoz.cc
libfoo_la_LIBADD   = $(FLIBS)
```

In this case, Automake will insist that AC_F77_LIBRARY_LDFLAGS is mentioned in

`configure.in'. Also, if @FLIBS@ hadn't been mentioned in foo_LDADD and libfoo_la_LIBADD, then Automake would have issued a warning.

How the Linker is Chosen

The following diagram demonstrates under what conditions a particular linker is chosen by Automake.

For example, if Fortran 77, C and C++ source code were to be compiled into a program, then the C++ linker will be used. In this case, if the C or Fortran 77 linkers required any special libraries that weren't included by the C++ linker, then they must be manually added to an _LDADD or _LIBADD variable by the user writing the `Makefile.am'.

source code \ Linker	C	C++	Fortran
C	x		
C++		x	
Fortran			x
C + C++		x	
C + Fortran			x
C++ + Fortran		x	
C + C++ + Fortran		x	

Fortran 77 and Autoconf

The current Automake support for Fortran 77 requires a recent enough version Autoconf that also includes support for Fortran 77. Full Fortran 77 support was added to Autoconf 2.13, so you will want to use that version of Autoconf or later.

Support for Other Languages

Automake currently only includes full support for C, C++ (see section C++ Support)and Fortran 77 (see section Fortran 77 Support). There is only rudimentary support for other languages, support for which will be improved based on user demand.

Automatic de-ANSI-fication

Although the GNU standards allow the use of ANSI C, this can have the effect of limiting portability of a package to some older compilers (notably SunOS).

Automake allows you to work around this problem on such machines by **de-ANSI-fying** each source file before the actual compilation takes place.

If the `Makefile.am' variable AUTOMAKE_OPTIONS (see section Changing Automake's Behavior) contains the option ansi2knr then code to handle de-ANSI-fication is inserted into the generated `Makefile.in'.

This causes each C source file in the directory to be treated as ANSI C. If an ANSI C compiler is available, it is used. If no ANSI C compiler is available, the ansi2knr program is used to convert the source files into K&R C, which is then compiled.

The ansi2knr program is simple-minded. It assumes the source code will be formatted in a particular way; see the ansi2knr man page for details.

Support for de-ANSI-fication requires the source files `ansi2knr.c' and `ansi2knr.1' to be in the same package as the ANSI C source; these files are distributed with Automake. Also, the package `configure.in' must call the macro AM_C_PROTOTYPES (see section Autoconf macros supplied with Automake).

Automake also handles finding the ansi2knr support files in some other directory in the current package. This is done by prepending the relative path to the appropriate directory to the ansi2knr option. For instance, suppose the package has ANSI C code in the `src' and `lib' subdirs. The files `ansi2knr.c' and `ansi2knr.1' appear in `lib'. Then this could appear in `src/Makefile.am':

```
AUTOMAKE_OPTIONS = ../lib/ansi2knr
```

If no directory prefix is given, the files are assumed to be in the current directory.

Files mentioned in `LIBOBJS` which need de-ANSI-fication will not be automatically handled. That's because `configure` will generate an object name like `` `regex.o' ``, while `make` will be looking for `` `regex_.o' `` (when de-ANSI-fying). Eventually this problem will be fixed via `autoconf` magic, but for now you must put this code into your `` `configure.in' ``, just before the `AC_OUTPUT` call:

```
# This is necessary so that .o files in LIBOBJS are also built via
# the ANSI2KNR-filtering rules.
LIBOBJS=`echo $LIBOBJS|sed 's/\.o /\$U.o /g;s/\.o$/\$U.o/'`
```

Automatic dependency tracking

As a developer it is often painful to continually update the `` `Makefile.in' `` whenever the include-file dependencies change in a project. Automake supplies a way to automatically track dependency changes, and distribute the dependencies in the generated `` `Makefile.in' ``.

Currently this support requires the use of GNU `make` and `gcc`. It might become possible in the future to supply a different dependency generating program, if there is enough demand. In the meantime, this mode is enabled by default if any C program or library is defined in the current directory, so you may get a `Must be a separator' error from non-GNU make.

When you decide to make a distribution, the `dist` target will re-run `automake` with `--include-deps' and other options. See section Creating a `` `Makefile.in' ``, and section Changing Automake's Behavior. This will cause the previously generated dependencies to be inserted into the generated `` `Makefile.in' ``, and thus into the distribution. This step also turns off inclusion of the dependency generation code, so that those who download your distribution but don't use GNU `make` and `gcc` will not get errors.

When added to the `` `Makefile.in' ``, the dependencies have all system-specific dependencies automatically removed. This can be done by listing the files in `OMIT_DEPENDENCIES'. For instance all references to system header files are removed by Automake. Sometimes it is useful to specify that a certain header file should be removed. For instance if your `` `configure.in' `` uses `AM_WITH_REGEX', then any dependency on `` `rx.h' `` or `` `regex.h' `` should be removed, because the correct one cannot be known until the user configures the package.

As it turns out, Automake is actually smart enough to handle the particular case of the regular expression header. It will also automatically omit `` `libintl.h' `` if `AM_GNU_GETTEXT' is used.

Automatic dependency tracking can be suppressed by putting `no-dependencies` in the variable `AUTOMAKE_OPTIONS`.

If you unpack a distribution made by `make dist`, and you want to turn on the dependency-tracking code again, simply re-run `automake`.

The actual dependency files are put under the build directory, in a subdirectory named `` `.deps' ``. These dependencies are machine specific. It is safe to delete them if you like; they will be automatically recreated during the next build.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Other Derived Objects

Automake can handle derived objects which are not C programs. Sometimes the support for actually building such objects must be explicitly supplied, but Automake will still automatically handle installation and distribution.

Executable Scripts

It is possible to define and install programs which are scripts. Such programs are listed using the `SCRIPTS' primary name. Automake doesn't define any dependencies for scripts; the `Makefile.am' should include the appropriate rules.

Automake does not assume that scripts are derived objects; such objects must be deleted by hand (see section What Gets Cleaned).

The automake program itself is a Perl script that is generated at configure time from `automake.in'. Here is how this is handled:

```
bin_SCRIPTS = automake
```

Since automake appears in the AC_OUTPUT macro, a target for it is automatically generated.

Script objects can be installed in bindir, sbindir, libexecdir, or pkgdatadir.

Header files

Header files are specified by the `HEADERS' family of variables. Generally header files are not installed, so the noinst_HEADERS variable will be the most used.

All header files must be listed somewhere; missing ones will not appear in the distribution. Often it is clearest to list uninstalled headers with the rest of the sources for a program. See section Building a program. Headers listed in a `_SOURCES' variable need not be listed in any `_HEADERS' variable.

Headers can be installed in includedir, oldincludedir, or pkgincludedir.

Architecture-independent data files

Automake supports the installation of miscellaneous data files using the `DATA' family of variables.

Such data can be installed in the directories datadir, sysconfdir, sharedstatedir,

`localstatedir`, or `pkgdatadir`.

By default, data files are *not* included in a distribution.

Here is how Automake installs its auxiliary data files:

```
pkgdata_DATA = clean-kr.am clean.am ...
```

Built sources

Occasionally a file which would otherwise be called `source' (e.g. a C `.h' file) is actually derived from some other file. Such files should be listed in the `BUILT_SOURCES` variable.

Built sources are also not compiled by default. You must explicitly mention them in some other `_SOURCES' variable for this to happen.

Note that, in some cases, `BUILT_SOURCES` will work in somewhat surprising ways. In order to get the built sources to work with automatic dependency tracking, the `` `Makefile' `` must depend on `$(BUILT_SOURCES)`. This can cause these sources to be rebuilt at what might seem like funny times.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Other GNU Tools

Since Automake is primarily intended to generate `Makefile.in's for use in GNU programs, it tries hard to interoperate with other GNU tools.

Emacs Lisp

Automake provides some support for Emacs Lisp. The `LISP' primary is used to hold a list of `.el' files. Possible prefixes for this primary are `lisp_' and `noinst_'. Note that if `lisp_LISP' is defined, then `configure.in' must run `AM_PATH_LISPDIR' (see section Autoconf macros supplied with Automake).

By default Automake will byte-compile all Emacs Lisp source files using the Emacs found by `AM_PATH_LISPDIR'. If you wish to avoid byte-compiling, simply define the variable `ELCFILES' to be empty. Byte-compiled Emacs Lisp files are not portable among all versions of Emacs, so it makes sense to turn this off if you expect sites to have more than one version of Emacs installed. Furthermore, many packages don't actually benefit from byte-compilation. Still, we recommend that you leave it enabled by default. It is probably better for sites with strange setups to cope for themselves than to make the installation less nice for everybody else.

Gettext

If `AM_GNU_GETTEXT' is seen in `configure.in', then Automake turns on support for GNU gettext, a message catalog system for internationalization (see section `GNU Gettext' in GNU gettext utilities).

The `gettext' support in Automake requires the addition of two subdirectories to the package, `intl' and `po'. Automake insures that these directories exist and are mentioned in `SUBDIRS'.

Furthermore, Automake checks that the definition of `ALL_LINGUAS' in `configure.in' corresponds to all the valid `.po' files, and nothing more.

Guile

Automake provides some automatic support for writing Guile modules. Automake will turn on Guile support if the `AM_INIT_GUILE_MODULE' macro is used in `configure.in'.

Right now Guile support just means that the `AM_INIT_GUILE_MODULE' macro is understood to mean:

- `AM_INIT_AUTOMAKE' is run.

- `AC_CONFIG_AUX_DIR` is run, with a path of `..'.

As the Guile module code matures, no doubt the Automake support will grow as well.

Libtool

Automake provides support for GNU Libtool (see section `Introduction' in The Libtool Manual) with the `LTLIBRARIES' primary. See section Building a Shared Library.

Java

Automake provides some minimal support for Java compilation with the `JAVA' primary.

Any `.java' files listed in a `_JAVA' variable will be compiled with `JAVAC` at build time. By default, `.class' files are not included in the distribution.

Currently Automake enforces the restriction that only one `_JAVA' primary can be used in a given `Makefile.am'. The reason for this restriction is that, in general, it isn't possible to know which `.class' files were generated from which `.java' files -- so it would be impossible to know which files to install where.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Building documentation

Currently Automake provides support for Texinfo and man pages.

Texinfo

If the current directory contains Texinfo source, you must declare it with the `TEXINFOS' primary. Generally Texinfo files are converted into info, and thus the `info_TEXINFOS` macro is most commonly used here. Note that any Texinfo source file must end in the `.texi' or `.texinfo' extension.

If the `.texi' file `@includes` `version.texi', then that file will be automatically generated. The file `version.texi' defines three Texinfo macros you can reference: `EDITION`, `VERSION`, and `UPDATED`. The first two hold the version number of your package (but are kept separate for clarity); the last is the date the primary file was last modified. The `version.texi' support requires the `mdate-sh` program; this program is supplied with Automake and automatically included when `automake` is invoked with the `--add-missing` option.

Sometimes an info file actually depends on more than one `.texi' file. For instance, in GNU Hello, `hello.texi' includes the file `gpl.texi'. You can tell Automake about these dependencies using the `texi_TEXINFOS` variable. Here is how GNU Hello does it:

```
info_TEXINFOS = hello.texi
hello_TEXINFOS = gpl.texi
```

By default, Automake requires the file `texinfo.tex' to appear in the same directory as the Texinfo source. However, if you used `AC_CONFIG_AUX_DIR` in `configure.in' (see section `Finding `configure' Input' in The Autoconf Manual), then `texinfo.tex' is looked for there. Automake supplies `texinfo.tex' if `--add-missing' is given.

If your package has Texinfo files in many directories, you can use the variable `TEXINFO_TEX` to tell Automake where to find the canonical `texinfo.tex' for your package. The value of this variable should be the relative path from the current `Makefile.am' to `texinfo.tex':

```
TEXINFO_TEX = ../doc/texinfo.tex
```

The option `no-texinfo.tex' can be used to eliminate the requirement for `texinfo.tex'. Use of the variable `TEXINFO_TEX` is preferable, however, because that allows the `dvi` target to still work.

Automake generates an `install-info` target; some people apparently use this. By default, info pages are installed by `make install'. This can be prevented via the `no-installinfo` option.

Man pages

A package can also include man pages (but see the GNU standards on this matter, section `Man Pages' in The GNU Coding Standards.) Man pages are declared using the `MANS' primary. Generally the `man_MANS` macro is used. Man pages are automatically installed in the correct subdirectory of `mandir`, based on the file extension. They are not automatically included in the distribution.

By default, man pages are installed by `make install'. However, since the GNU project does not require man pages, many maintainers do not expend effort to keep the man pages up to date. In these cases, the `no-installman` option will prevent the man pages from being installed by default. The user can still explicitly install them via `make install-man'.

Here is how the documentation is handled in GNU `cpio` (which includes both Texinfo documentation and man pages):

```
info_TEXINFOS = cpio.texi
man_MANS = cpio.1 mt.1
EXTRA_DIST = $(man_MANS)
```

Texinfo source and info pages are all considered to be source for the purposes of making a distribution.

Man pages are not currently considered to be source, because it is not uncommon for man pages to be automatically generated. For the same reason, they are not automatically included in the distribution.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

What Gets Installed

Naturally, Automake handles the details of actually installing your program once it has been built. All `PROGRAMS`, `SCRIPTS`, `LIBRARIES`, `LISP`, `DATA` and `HEADERS` are automatically installed in the appropriate places.

Automake also handles installing any specified info and man pages.

Automake generates separate `install-data` and `install-exec` targets, in case the installer is installing on multiple machines which share directory structure--these targets allow the machine-independent parts to be installed only once. The `install` target depends on both of these targets.

Automake also generates an `uninstall` target, an `installdirs` target, and an `install-strip` target.

It is possible to extend this mechanism by defining an `install-exec-local` or `install-data-local` target. If these targets exist, they will be run at `make install' time.

Variables using the standard directory prefixes `data', `info', `man', `include', `oldinclude', `pkgdata', or `pkginclude' (e.g. `data_DATA') are installed by `install-data'.

Variables using the standard directory prefixes `bin', `sbin', `libexec', `sysconf', `localstate', `lib', or `pkglib' (e.g. `bin_PROGRAMS') are installed by `install-exec'.

Any variable using a user-defined directory prefix with `exec' in the name (e.g. `myexecbin_PROGRAMS' is installed by `install-exec'. All other user-defined prefixes are installed by `install-data'.

Automake generates support for the `DESTDIR' variable in all install rules. `DESTDIR' is used during the `make install' step to relocate install objects into a staging area. Each object and path is prefixed with the value of `DESTDIR' before being copied into the install area. Here is an example of typical DESTDIR usage:

```
make DESTDIR=/tmp/staging install
```

This places install objects in a directory tree built under `/tmp/staging'. If `/gnu/bin/foo' and `/gnu/share/aclocal/foo.m4' are to be installed, the above command would install `/tmp/staging/gnu/bin/foo' and `/tmp/staging/gnu/share/aclocal/foo.m4'.

This feature is commonly used to build install images and packages. For more information, see section `Makefile Conventions' in The GNU Coding Standards.

Go to the first, previous, next, last section, table of contents.

TOC

Go to the first, previous, next, last section, table of contents.

What Gets Cleaned

The GNU Makefile Standards specify a number of different clean rules. Generally the files that can be cleaned are determined automatically by Automake. Of course, Automake also recognizes some variables that can be defined to specify additional files to clean. These variables are `MOSTLYCLEANFILES`, `CLEANFILES`, `DISTCLEANFILES`, and `MAINTAINERCLEANFILES`.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

What Goes in a Distribution

The `dist` target in the generated `Makefile.in' can be used to generate a gzip'd `tar` file for distribution. The tar file is named based on the `PACKAGE' and `VERSION' variables; more precisely it is named `package-version.tar.gz'. You can use the `make` variable `GZIP_ENV' to control how gzip is run. The default setting is `--best'.

For the most part, the files to distribute are automatically found by Automake: all source files are automatically included in a distribution, as are all `Makefile.am's and `Makefile.in's. Automake also has a built-in list of commonly used files which, if present in the current directory, are automatically included. This list is printed by `automake --help'. Also, files which are read by `configure` (i.e. the source files corresponding to the files specified in the `AC_OUTPUT` invocation) are automatically distributed.

Still, sometimes there are files which must be distributed, but which are not covered in the automatic rules. These files should be listed in the `EXTRA_DIST` variable. You can mention files from subdirectories in `EXTRA_DIST`. You can also mention a directory there; in this case the entire directory will be recursively copied into the distribution.

If you define `SUBDIRS`, Automake will recursively include the subdirectories in the distribution. If `SUBDIRS` is defined conditionally (see section Conditionals), Automake will normally include all directories that could possibly appear in `SUBDIRS` in the distribution. If you need to specify the set of directories conditionally, you can set the variable `DIST_SUBDIRS` to the exact list of subdirectories to include in the distribution.

Occasionally it is useful to be able to change the distribution before it is packaged up. If the `dist-hook` target exists, it is run after the distribution directory is filled, but before the actual tar (or shar) file is created. One way to use this is for distributing files in subdirectories for which a new `Makefile.am' is overkill:

```
dist-hook:
        mkdir $(distdir)/random
        cp -p $(srcdir)/random/a1 $(srcdir)/random/a2 $(distdir)/random
```

Automake also generates a `distcheck` target which can be help to ensure that a given distribution will actually work. `distcheck` makes a distribution, and then tries to do a `VPATH` build.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Support for test suites

Automake supports two forms of test suites.

If the variable `TESTS` is defined, its value is taken to be a list of programs to run in order to do the testing. The programs can either be derived objects or source objects; the generated rule will look both in `srcdir` and `.'. Programs needing data files should look for them in `srcdir` (which is both an environment variable and a make variable) so they work when building in a separate directory (see section `Build Directories' in The Autoconf Manual), and in particular for the `distcheck` target (see section What Goes in a Distribution).

The number of failures will be printed at the end of the run. If a given test program exits with a status of 77, then its result is ignored in the final count. This feature allows non-portable tests to be ignored in environments where they don't make sense.

The variable `TESTS_ENVIRONMENT` can be used to set environment variables for the test run; the environment variable `srcdir` is set in the rule. If all your test programs are scripts, you can also set `TESTS_ENVIRONMENT` to an invocation of the shell (e.g. `$(SHELL) -x'); this can be useful for debugging the tests.

If `dejagnu' appears in `AUTOMAKE_OPTIONS`, then a `dejagnu`-based test suite is assumed. The value of the variable `DEJATOOL` is passed as the `--tool` argument to `runtest`; it defaults to the name of the package.

The variable `RUNTESTDEFAULTFLAGS` holds the `--tool` and `--srcdir` flags that are passed to dejagnu by default; this can be overridden if necessary.

The variables `EXPECT`, `RUNTEST` and `RUNTESTFLAGS` can also be overridden to provide project-specific values. For instance, you will need to do this if you are testing a compiler toolchain, because the default values do not take into account host and target names.

In either case, the testing is done via `make check'.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Changing Automake's Behavior

Various features of Automake can be controlled by options in the `Makefile.am'. Such options are listed in a special variable named AUTOMAKE_OPTIONS. Currently understood options are:

`gnits`

`gnu`

`foreign`

`cygnus`

> Set the strictness as appropriate. The `gnits` option also implies `readme-alpha` and `check-news`.

`ansi2knr`

`path/ansi2knr`

> Turn on automatic de-ANSI-fication. See section Automatic de-ANSI-fication. If preceded by a path, the generated `Makefile.in' will look in the specified directory to find the `ansi2knr' program. Generally the path should be a relative path to another directory in the same distribution (though Automake currently does not check this).

`check-news`

> Cause `make dist` to fail unless the current version number appears in the first few lines of the `NEWS' file.

`dejagnu`

> Cause `dejagnu`-specific rules to be generated. See section Support for test suites.

`dist-shar`

> Generate a `dist-shar` target as well as the ordinary `dist` target. This new target will create a shar archive of the distribution.

`dist-zip`

> Generate a `dist-zip` target as well as the ordinary `dist` target. This new target will create a zip archive of the distribution.

`dist-tarZ`

> Generate a `dist-tarZ` target as well as the ordinary `dist` target. This new target will create a compressed tar archive of the distribution; a traditional `tar` and `compress` will be assumed. Warning: if you are actually using `GNU tar`, then the generated archive might contain nonportable constructs.

`no-dependencies`

> This is similar to using `--include-deps' on the command line, but is useful for those situations where you don't have the necessary bits to make automatic dependency tracking work See section

Automatic dependency tracking. In this case the effect is to effectively disable automatic dependency tracking.

`no-installinfo`

The generated `Makefile.in' will not cause info pages to be built or installed by default. However, `info` and `install-info` targets will still be available. This option is disallowed at `GNU' strictness and above.

`no-installman`

The generated `Makefile.in' will not cause man pages to be installed by default. However, an `install-man` target will still be available for optional installation. This option is disallowed at `GNU' strictness and above.

`no-texinfo.tex`

Don't require `texinfo.tex', even if there are texinfo files in this directory.

`readme-alpha`

If this release is an alpha release, and the file `README-alpha' exists, then it will be added to the distribution. If this option is given, version numbers are expected to follow one of two forms. The first form is `MAJOR.MINOR.ALPHA', where each element is a number; the final period and number should be left off for non-alpha releases. The second form is `MAJOR.MINORALPHA', where ALPHA is a letter; it should be omitted for non-alpha releases.

version

A version number (e.g. `0.30') can be specified. If Automake is not newer than the version specified, creation of the `Makefile.in' will be suppressed.

Unrecognized options are diagnosed by `automake`.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Miscellaneous Rules

There are a few rules and variables that didn't fit anywhere else.

Interfacing to `etags`

Automake will generate rules to generate `TAGS' files for use with GNU Emacs under some circumstances.

If any C, C++ or Fortran 77 source code or headers are present, then `tags` and `TAGS` targets will be generated for the directory.

At the topmost directory of a multi-directory package, a `tags` target file will be generated which, when run, will generate a `TAGS' file that includes by reference all `TAGS' files from subdirectories.

Also, if the variable `ETAGS_ARGS` is defined, a `tags` target will be generated. This variable is intended for use in directories which contain taggable source that `etags` does not understand.

Here is how Automake generates tags for its source, and for nodes in its Texinfo file:

```
ETAGS_ARGS = automake.in --lang=none \
 --regex='/^@node[ \t]+\([^,]+\)/\1/' automake.texi
```

If you add filenames to `ETAGS_ARGS', you will probably also want to set `TAGS_DEPENDENCIES'. The contents of this variable are added directly to the dependencies for the `tags` target.

Automake will also generate an `ID` target which will run `mkid` on the source. This is only supported on a directory-by-directory basis.

Handling new file extensions

It is sometimes useful to introduce a new implicit rule to handle a file type that Automake does not know about. If this is done, you must notify GNU Make of the new suffixes. This can be done by putting a list of new suffixes in the `SUFFIXES` variable.

For instance, currently Automake does not provide any Java support. If you wrote a macro to generate `.class' files from `.java' source files, you would also need to add these suffixes to the list:

```
SUFFIXES = .java .class
```

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Include

To include another file (perhaps for common rules), the following syntax is supported:

include ($(srcdir)|$(top_srcdir))/filename

Using files in the current directory:

```
include $(srcdir)/Makefile.extra
```

```
include Makefile.generated
```

Using a file in the top level directory:

```
include $(top_srcdir)/filename
```

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Conditionals

Automake supports a simple type of conditionals.

Before using a conditional, you must define it by using `AM_CONDITIONAL` in the `configure.in` file (see section Autoconf macros supplied with Automake). The `AM_CONDITIONAL` macro takes two arguments.

The first argument to `AM_CONDITIONAL` is the name of the conditional. This should be a simple string starting with a letter and containing only letters, digits, and underscores.

The second argument to `AM_CONDITIONAL` is a shell condition, suitable for use in a shell `if` statement. The condition is evaluated when `configure` is run.

Conditionals typically depend upon options which the user provides to the `configure` script. Here is an example of how to write a conditional which is true if the user uses the `--enable-debug' option.

```
AC_ARG_ENABLE(debug,
[  --enable-debug    Turn on debugging],
[case "${enableval}" in
  yes) debug=true ;;
  no)  debug=false ;;
  *) AC_MSG_ERROR(bad value ${enableval} for --enable-debug) ;;
esac],[debug=false])
AM_CONDITIONAL(DEBUG, test x$debug = xtrue)
```

Here is an example of how to use that conditional in `Makefile.am':

```
if DEBUG
DBG = debug
else
DBG =
endif
noinst_PROGRAMS = $(DBG)
```

This trivial example could also be handled using EXTRA_PROGRAMS (see section Building a program).

You may only test a single variable in an `if` statement. The `else` statement may be omitted. Conditionals may be nested to any depth.

Note that conditionals in Automake are not the same as conditionals in GNU Make. Automake conditionals are checked at configure time by the `configure' script, and affect the translation from

`Makefile.in' to `Makefile'. They are based on options passed to `configure' and on results that `configure' has discovered about the host system. GNU Make conditionals are checked at `make' time, and are based on variables passed to the make program or defined in the `Makefile'.

Automake conditionals will work with any make program.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

The effect of `--gnu` and `--gnits`

The `--gnu' option (or `gnu' in the `AUTOMAKE_OPTIONS' variable) causes `automake` to check the following:

- The files `INSTALL', `NEWS', `README', `COPYING', `AUTHORS', and `ChangeLog' are required at the topmost directory of the package.
- The options `no-installman' and `no-installinfo' are prohibited.

Note that this option will be extended in the future to do even more checking; it is advisable to be familiar with the precise requirements of the GNU standards. Also, `--gnu' can require certain non-standard GNU programs to exist for use by various maintainer-only targets; for instance in the future `pathchk` might be required for `make dist'.

The `--gnits' option does everything that `--gnu' does, and checks the following as well:

- `make dist' will check to make sure the `NEWS' file has been updated to the current version.
- The file `COPYING.LIB' is prohibited. The LGPL is apparently considered a failed experiment.
- `VERSION' is checked to make sure its format complies with Gnits standards.
- If `VERSION' indicates that this is an alpha release, and the file `README-alpha' appears in the topmost directory of a package, then it is included in the distribution. This is done in `--gnits' mode, and no other, because this mode is the only one where version number formats are constrained, and hence the only mode where Automake can automatically determine whether `README-alpha' should be included.
- The file `THANKS' is required.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

The effect of `--cygnus`

Cygnus Solutions has slightly different rules for how a `Makefile.in' is to be constructed. Passing `--cygnus' to `automake` will cause any generated `Makefile.in' to comply with Cygnus rules.

Here are the precise effects of `--cygnus':

- Info files are always created in the build directory, and not in the source directory.
- `texinfo.tex' is not required if a Texinfo source file is specified. The assumption is that the file will be supplied, but in a place that Automake cannot find. This assumption is an artifact of how Cygnus packages are typically bundled.
- `make dist' will look for files in the build directory as well as the source directory. This is required to support putting info files into the build directory.
- Certain tools will be searched for in the build tree as well as in the user's `PATH'. These tools are `runtest`, `expect`, `makeinfo` and `texi2dvi`.
- `--foreign` is implied.
- The options `no-installinfo' and `no-dependencies' are implied.
- The macros `AM_MAINTAINER_MODE' and `AM_CYGWIN32' are required.
- The `check` target doesn't depend on `all`.

GNU maintainers are advised to use `gnu' strictness in preference to the special Cygnus mode.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

When Automake Isn't Enough

Automake's implicit copying semantics means that many problems can be worked around by simply adding some `make` targets and rules to `` `Makefile.in' ``. Automake will ignore these additions.

There are some caveats to doing this. Although you can overload a target already used by Automake, it is often inadvisable, particularly in the topmost directory of a non-flat package. However, various useful targets have a `-local' version you can specify in your `` `Makefile.in' ``. Automake will supplement the standard target with these user-supplied targets.

The targets that support a local version are `all`, `info`, `dvi`, `check`, `install-data`, `install-exec`, `uninstall`, and the various `clean` targets (`mostlyclean`, `clean`, `distclean`, and `maintainer-clean`). Note that there are no `uninstall-exec-local` or `uninstall-data-local` targets; just use `uninstall-local`. It doesn't make sense to uninstall just data or just executables.

For instance, here is one way to install a file in `` `/etc' ``:

```
install-data-local:
        $(INSTALL_DATA) $(srcdir)/afile /etc/afile
```

Some targets also have a way to run another target, called a **hook**, after their work is done. The hook is named after the principal target, with `-hook' appended. The targets allowing hooks are `install-data`, `install-exec`, `dist`, and `distcheck`.

For instance, here is how to create a hard link to an installed program:

```
install-exec-hook:
        ln $(bindir)/program $(bindir)/proglink
```

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

Distributing `Makefile.in's

Automake places no restrictions on the distribution of the resulting `Makefile.in's. We still encourage software authors to distribute their work under terms like those of the GPL, but doing so is not required to use Automake.

Some of the files that can be automatically installed via the `--add-missing` switch do fall under the GPL; examine each file to see.

Go to the first, previous, next, last section, table of contents.

Go to the first, previous, next, last section, table of contents.

TOC

Some ideas for the future

Here are some things that might happen in the future:

- HTML support.
- The output will be cleaned up. For instance, only variables which are actually used will appear in the generated `Makefile.in'.
- There will be support for automatically recoding a distribution. The intent is to allow a maintainer to use whatever character set is most convenient locally, but for all distributions to be Unicode or ISO 10646 with the UTF-8 encoding.
- Rewrite in Guile. This won't happen in the near future, but it will eventually happen.

Go to the first, previous, next, last section, table of contents.

GNU Automake

For version 1.4, 10 January 1999

David MacKenzie and Tom Tromey

---

(1)

Much, if not most, of the information in the following sections pertaining to preprocessing Fortran 77 programs was taken almost verbatim from section `Catalogue of Rules' in The GNU Make Manual.

(2)

For example, `the cfortran package` addresses all of these inter-language issues, and runs under nearly all Fortran 77, C and C++ compilers on nearly all platforms. However, `cfortran` is not yet Free Software, but it will be in the next major release.

This document was generated on 20 May 1999 using the texi2html translator version 1.51a.

Bash Features

Bourne Shell Style Features

Bash is an acronym for Bourne Again SHell. The Bourne shell is the traditional Unix shell written by Stephen Bourne. All of the Bourne shell builtin commands are available in Bash, and the rules for evaluation and quoting are taken from the Posix 1003 specification for the `standard' Unix shell.

The shell builtin control features are briefly discussed here.

Looping Constructs

Note that wherever you see an `;' in the description of a command's syntax, it can be replaced indiscriminately with newlines.

Bash supports the following looping constructs.

`until`

The syntax of the `until` command is:

```
until test-commands; do consequent-commands; done
```

Execute consequent-commands as long as the final command in test-commands has an exit status which is not zero.

`while`

The syntax of the `while` command is:

```
while test-commands; do consequent-commands; done
```

Execute consequent-commands as long as the final command in test-commands has an exit status of zero.

`for`

The syntax of the for command is:

```
for name [in words ...]; do commands; done
```

Execute commands for each member in words, with name bound to the current member. If "`in words`" is not present, "`in "$@"`" is assumed.

Conditional Constructs

`if`

The syntax of the `if` command is:

```
if test-commands; then
  consequent-commands;
```

```
[else alternate-consequents;]
fi
```

Execute consequent-commands only if the final command in test-commands has an exit status of zero. If "`else alternate-consequents`" is present, and the final command in test-commands has a non-zero exit status, then execute alternate-consequents.

`case`

The syntax of the `case` command is:

```
case word in [pattern [| pattern]...) commands ;;]... esac
```

Selectively execute commands based upon word matching pattern. The `|' is used to separate multiple patterns.

Here is an example using `case` in a script that could be used to describe an interesting feature of an animal:

```
echo -n "Enter the name of an animal:"
read ANIMAL
echo -n "The $ANIMAL has "
case $ANIMAL in
  horse | dog | cat) echo -n "four";;
  man | kangaroo ) echo -n "two";;
  *) echo -n "an unknown number of";;
esac
echo "legs."
```

(T)C-Shell Style Features

The C-Shell `csh` was created by Bill Joy at UC Berkeley. It is generally considered to have better features for interactive use than the Bourne shell. Some of the `csh` features present in Bash include job control, history expansion, `protected' redirection, and several variables for controlling the interactive behaviour of the shell (e.g. `ignoreeof`).

For details on history expansion, @xref{Using History Interactively}.

Bash has tilde (~) expansion, similar, but not identical, to that of `csh`. The following table shows what unquoted words beginning with a tilde expand to.

`~`

The current value of `$HOME`.

`~/foo`

`$HOME`/foo

`~fred/foo`

The subdirectory `foo` of the home directory of the user named `fred`.

`~+/foo`

`$PWD`/foo

`~-`

`$OLDPWD`/foo

Here is a list of the commands and variables whose meanings were taken from `csh`.

`pushd`

```
pushd [dir | +n]
```

Save the current directory on a list and then CD to DIR. With no arguments, exchanges the top two directories.

`+n`

Brings the nth directory to the top of the list by rotating.

`dir`

Makes the current working directory be the top of the stack, and then cd's to DIR. You can see the saved directory list with the `dirs' command.

- popd

```
popd [+n]
```

Pops the directory stack, and cd's to the new top directory. The elements are numbered from 0 starting at the first directory listed with `dirs`; i.e. `popd` is equivalent to `popd 0`.

- dirs

```
dirs
```

Display the list of currently remembered directories. Directories find their way onto the list with the `pushd` command; you can get back up through the list with the `popd` command.

- history

```
history [n] [ [-w -r] [filename]]
```

Display the history list with line numbers. Lines listed with with a `*` have been modified. Argument of n says to list only the last n lines. Argument `-w` means write out the current history file. `-r` means to read it instead. If filename is given, then use that file, else if `$HISTFILE` has a value, use that, else use `` `~/.bash_history' ``.

- ignoreeof If this variable is set, it represents the number of consecutive `EOF`s Bash will read before exiting. By default, Bash will exit upon reading an `EOF` character.

Korn Shell Style Features

```
fc
```

```
fc [-e ename] [-nlr] [first] [last]
fc -s [pat=rep] [command]
```

Fix Command. In the first form, a range of commands from first to last is selected from the history list. First and/or last may be specified as a string (to locate the most recent command beginning with that string) or as a number (an index into the history list, where a negative number is used as an offset from the current command number). If last is not specified it is set to first. If first is not specified it is set to the previous command for editing and -16 for listing. If the `-l` flag is given, the commands are listed on standard output. The `-n` flag suppresses the command numbers when listing. The `-r` flag reverses the order of the listing. Otherwise, the editor given by ename is invoked on a file containing those commands. If ename is not given, the value of the following variable expansion is used: `${FCEDIT:-${EDITOR:-vi}}`. This says to use the value of the `FCEDIT` variable if set, or the value of the `EDITOR` variable if that is set, or `vi` if neither is set. When editing is complete, the edited commands are echoed and executed.

In the second form, command is re-executed after the substitution old=new is performed.

A useful alias to use with the `fc` command is `r='fc -s'`, so that typing `r cc` runs the last command beginning with `cc` and typing `r` re-executes the last command.

`typeset`

The `typeset` command is supplied for compatibility with the Korn shell; however, it has been made obsolete by the presence of the `declare` command, documented with the Bash specific features.

`type`

Bash's `type` command is a superset of the `type` found in Korn shells; See section Bash Builtin Commands for details.

Bash Specific Features

Shell Command Line Options

Along with the single character shell command-line options (See section The Set Builtin) there are several other options that you can use. These options must appear on the command line before the single character command options to be recognized.

`-norc`

Don't load ~/.bashrc init file. (Default if shell name is `sh').

`-rcfile filename`

Load filename init file (instead `~/.bashrc').

`-noprofile`

Don't load `~/.bash_profile' (nor `/etc/profile').

`-version`

Display the version number of this shell.

`-login`

Make this shell act as if it were directly invoked from login. This is equivalent to "exec - bash" but can be issued from another shell, such as csh. If you wanted to replace your current login shell with a bash login shell, you would say "exec bash -login".

`-nobraceexpansion`

Do not perform curly brace expansion (foo{a,b} -> fooa foob).

`-nolinediting`

Do not use the GNU Readline library to read interactive text lines.

The Set Builtin

This builtin is so overloaded that it deserves its own section. So here it is.

`set`

```
set [-aefhknotuvxldH] [arg ...]
-a
```

Mark variables which are modified or created for export.

`-e`

Exit immediately if a command exits with a non-zero status.

`-f`

Disable file name generation (globbing).

`-k`

All keyword arguments are placed in the environment for a command, not just those that precede the command name.

`-m`

Job control is enabled.

`-n`

Read commands but do not execute them.

`-o option-name`

Set the variable corresponding to option-name:

`allexport`

same as -a.

`braceexpand`

the shell will perform brace expansion.

`emacs`

use an emacs-style line editing interface.

`errexit`

same as -e.

`histexpand`

same as -H.

`ignoreeof`

the shell will not exit upon reading EOF.

`monitor`

same as -m.

`noclobber`

disallow redirection to existing files.

`noexec`

same as -n.

`noglob`

same as -f.

`nohash`

same as -d.

`notify`

notify of job termination immediately.

`nounset`

same as -u.

`verbose`

same as -v.

`vi`
: use a vi-style line editing interface.

`xtrace`
: same as -x.

- -t Exit after reading and executing one command.
- -u Treat unset variables as an error when substituting.
- -v Print shell input lines as they are read.
- -x Print commands and their arguments as they are executed.
- -l Save and restore the binding of the name in a `for` command.
- -d Disable the hashing of commands that are looked up for execution. Normally, commands are remembered in a hash table, and once found, do not have to be looked up again.
- -H Enable ! style history substitution. This flag is on by default.

Using `+' rather than `-' causes these flags to be turned off. The flags can also be used upon invocation of the shell. The current set of flags may be found in `$-`. The remaining args are positional parameters and are assigned, in order, to `$1`, `$2`, .. `$9`. If no args are given, all shell variables are printed.

Is This Shell Interactive?

You may wish to determine within a startup script whether Bash is running interactively or not. To do this, you examine the variable `$PS1`; it is unset in non-interactive shells, and set in interactive shells. Thus:

```
if [ "$PS1" = "" ]; then
  echo "This shell is not interactive"
else
  echo "This shell is interactive"
fi
```

You can ask an interactive Bash to not run your `` `~/.bashrc' `` file with the `-norc` flag. You can change the name of the `` `~/.bashrc' `` file to any other file name with `-rcfile filename`. You can ask Bash to not run your `` `~/.bash_profile' `` file with the `-noprofile` flag.

Controlling the Prompt

The value of the variable `$PROMPT_COMMAND` is examined just before Bash prints each toplevel prompt. If it is set and non-null, then the value is executed just as if you had typed it on the command line.

In addition, the following table describes the special characters which can appear in the `PS1` variable:

`\t`
: the time.

`\d`
: the date.

`\n`
: CRLF.

`\s`
: the name of the shell.

`\w`
: the current working directory.

`\W`
: the last element of PWD.

`\u`
: your username.

`\h`
: the hostname.

`\#`
: the command number of this command.

`\!`
: the history number of this command.

`\<octal>`
: the character code in octal.

`\\`
: a backslash.

Bash Startup Files

When and how Bash executes `` `~/.bash_profile' ``, `` `~/.bashrc' ``, and `` `~/.bash_logout' ``.

```
For Login shells:

    On logging in:
       If `/etc/profile' exists, then source it.

       If `~/.bash_profile' exists, then source it,
          else if `~/.bash_login' exists, then source it,
             else if `~/.profile' exists, then source it.

    On logging out:
       If `~/.bash_logout' exists, source it.

For non-login interactive shells:
    On starting up:
       If `~/.bashrc' exists, then source it.

For non-interactive shells:
    On starting up:
       If the environment variable ENV is non-null, source the
       file mentioned there.
```

So, typically, your `~/.bash_profile` contains the line

```
if [ -f `~/.bashrc' ]; then source `~/.bashrc'; fi
```

after (or before) any login specific initializations.

Bash Builtin Commands

`builtin`

`builtin [shell-builtin [args]]`

Run a shell builtin. This is useful when you wish to rename a shell builtin to be a function, but need the functionality of the builtin within the function itself.

`declare`

`declare [-[frxi]] name[=value]`

Declare variables and/or give them attributes. If no names are given, then display the values of variables instead. `-f` means to use function names only. `-r` says to make names readonly. `-x` says to make names export. `-i` says that the variable is to be treated as an integer; arithmetic evaluation (see `let`) will be done when the variable is assigned to. Using `+` instead of `-` turns off the attribute instead. When used in a function, makes names local, as with the `local` command.

`type`

`type [-all] [-type | -path] [name ...]`

For each name, indicate how it would be interpreted if used as a command name.

If the `-type` flag is used, `type` returns a single word which is one of "alias", "function", "builtin", "file" or "", if name is an alias, shell function, shell builtin, disk file, or unfound, respectively.

If the `-path` flag is used, `type` either returns the name of the disk file that would be exec'ed, or nothing if `-type` wouldn't return "file".

If the `-all` flag is used, returns all of the places that contain an executable named file. This includes aliases and functions, if and only if the `-path` flag is not also used.

`enable`

`enable [-n] [name ...]`

Enable and disable builtin shell commands. This allows you to use a disk command which has the same name as a shell builtin. If `-n` is used, the names become disabled. Otherwise names are enabled. For example, to use the `test` found on your path instead of the shell builtin version, you type `enable -n test`.

`help`

`help [pattern]`

Display helpful information about builtin commands. If pattern is specified, gives detailed help on all commands matching pattern, otherwise a list of the builtins is printed.

`command`

`command [command [args ...]]`

Runs command with arg ignoring shell functions. If you have a shell function called `ls`, and you wish to call the command `ls`, you can say "command ls".

`hash`

`hash [-r] [name]`

For each name, the full pathname of the command is determined and remembered. The `-r` option causes the shell to forget all remembered locations. If no arguments are given, information about remembered commands is presented.

`local`

`local name[=value]`

Create a local variable called name, and give it value. `local` can only be used within a function; it makes the variable name have a visible scope restricted to that function and its children.

`readonly`

`readonly [-f] [name ...]`

The given names are marked readonly and the values of these names may not be changed by subsequent assignment. If the -f option is given, the functions corresponding to the names are so marked. If no arguments are given, a list of all readonly names is printed.

`ulimit`

`ulimit [-acdmstfpn [limit]]`

Ulimit provides control over the resources available to processes started by the shell, on systems that allow such control. If an option is given, it is interpreted as follows:

`-a`
: all current limits are reported.

`-c`
: the maximum size of core files created.

`-d`
: the maximum size of a process's data segment.

`-m`
: the maximum resident set size.

`-s`
: the maximum stack size.

`-t`
: the maximum amount of cpu time in seconds.

`-f`
: the maximum size of files created by the shell.

`-p`
: the pipe buffer size.

`-n`
: the maximum number of open file descriptors.

If limit is given, it is the new value of the specified resource. Otherwise, the current value of the specified resource is printed. If no option is given, then `-f` is assumed. Values are in 1k increments, except for `-t`, which is in seconds, and `-p`, which is in increments of 512 bytes.

Bash Variables

`history_control`

Set to a value of "ignorespace", it means don't enter lines which begin with a SPC on the history list. Set to a value of "ignoredups", it means don't enter lines which match the last entered line. Unset, or any other value than those above mean to save all lines on the history list.

`HISTFILE`

The name of the file that the command history is saved in.

`HISTSIZE`

If set, this is the maximum number of commands to remember in the history.

`histchars`

Up to three characters which control history expansion, quick substitution, and tokenization. The first character is the history-expansion-char, that is, the character which signifies the start of a history expansion, normally `!'. The second character is the character which signifies `quick substitution' when seen as the first character on a line, normally `^'. The optional third character is the character which signifies the remainder of the line is a comment, when found as the first character of a word, usually `#'.

`hostname_completion_file`

Contains the name of a file in the same format as `` `/etc/hosts' `` that should be read when the shell needs to complete a hostname. You can change the file interactively; the next time you want to complete a hostname Bash will add the contents of the new file to the already existing database.

`MAILCHECK`

How often (in seconds) that the shell should check for mail in the file(s) specified in `MAILPATH`.

`MAILPATH`

Colon separated list of pathnames to check for mail in. You can also specify what message is printed by separating the pathname from the message with a `?'. `$_` stands for the name of the current mailfile. For example:

```
MAILPATH='/usr/spool/mail/bfox?"You have mail":~/shell-mail?"$_ has mail!"'
```

`ignoreeof`

`IGNOREEOF`

Controls the action of the shell on receipt of an `EOF` character as the sole input. If set, then the value of it is the number of `EOF` characters that can be seen in a row as sole input characters before the shell will exit. If the variable exists but does not have a numeric value (or has no value) then the default is 10. if the variable does not exist, then `EOF` signifies the end of input to the shell. This is only in effect for interactive shells.

`auto_resume`

This variable controls how the shell interacts with the user and job control. If this variable exists then single word simple commands without redirects are treated as candidates for resumption of an existing job. There is no ambiguity allowed; if you have more than one job beginning with the string that you have typed, then the most recently accessed job will be selected.

`no_exit_on_failed_exec`

If this variable exists, the shell will not exit in the case that it couldn't execute the file specified in the `exec` command.

`PROMPT_COMMAND`

If present, this contains a string which is a command to execute before the printing of each toplevel prompt.

`nolinks`

If present, says not to follow symbolic links when doing commands that change the current working direct
By default, bash follows the logical chain of directories when performing `cd` type commands.

For example, if `` `/usr/sys' `` is a link to `` `/usr/local/sys' `` then:

```
cd /usr/sys; echo $PWD -> /usr/sys
cd ..; pwd -> /usr
```

If `nolinks` exists, then:

```
cd /usr/sys; echo $PWD -> /usr/local/sys
cd ..; pwd -> /usr/local
```

Bison

The YACC-compatible Parser Generator

November 1995, Bison Version 1.25

by Charles Donnelly and Richard Stallman

Go to the next section.

Introduction

Bison is a general-purpose parser generator that converts a grammar description for an LALR(1) context-free grammar into a C program to parse that grammar. Once you are proficient with Bison, you may use it to develop a wide range of language parsers, from those used in simple desk calculators to complex programming languages.

Bison is upward compatible with Yacc: all properly-written Yacc grammars ought to work with Bison with no change. Anyone familiar with Yacc should be able to use Bison with little trouble. You need to be fluent in C programming in order to use Bison or to understand this manual.

We begin with tutorial chapters that explain the basic concepts of using Bison and show three explained examples, each building on the last. If you don't know Bison or Yacc, start by reading these chapters. Reference chapters follow which describe specific aspects of Bison in detail.

Bison was written primarily by Robert Corbett; Richard Stallman made it Yacc-compatible. Wilfred Hansen of Carnegie Mellon University added multicharacter string literals and other features.

This edition corresponds to version 1.25 of Bison.

Go to the next section.

Go to the previous, next section.

Conditions for Using Bison

As of Bison version 1.24, we have changed the distribution terms for `yyparse` to permit using Bison's output in non-free programs. Formerly, Bison parsers could be used only in programs that were free software.

The other GNU programming tools, such as the GNU C compiler, have never had such a requirement. They could always be used for non-free software. The reason Bison was different was not due to a special policy decision; it resulted from applying the usual General Public License to all of the Bison source code.

The output of the Bison utility--the Bison parser file--contains a verbatim copy of a sizable piece of Bison, which is the code for the `yyparse` function. (The actions from your grammar are inserted into this function at one point, but the rest of the function is not changed.) When we applied the GPL terms to the code for `yyparse`, the effect was to restrict the use of Bison output to free software.

We didn't change the terms because of sympathy for people who want to make software proprietary. **Software should be free.** But we concluded that limiting Bison's use to free software was doing little to encourage people to make other software free. So we decided to make the practical conditions for using Bison match the practical conditions for using the other GNU tools.

Go to the previous, next section.

GNU GENERAL PUBLIC LICENSE

Version 2, June 1991

Preamble

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION

1. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

   Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.
2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

   You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.
3. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:
   1. You must cause the modified files to carry prominent notices stating that you changed the files and the date of any change.
   2. You must cause any work that you distribute or publish, that in whole or in part contains or is derived from the Program or any part thereof, to be licensed as a whole at no charge to all third parties under the terms of this License.
   3. If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the most ordinary way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this License. (Exception: if the Program itself is interactive but does not normally print such an announcement, your work based on the Program is not required to print an announcement.)

   These requirements apply to the modified work as a whole. If identifiable sections of that work are not derived from the Program, and can be reasonably considered independent and separate works in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work

based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regard of who wrote it.

Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

4. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:
    1. Accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    2. Accompany it with a written offer, valid for at least three years, to give any third party, for a charge no more than your cost of physically performing source distribution, a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Sections 1 and 2 above on a medium customarily used for software interchange; or,
    3. Accompany it with the information you received as to the offer to distribute corresponding source code. (This alternative is allowed only for noncommercial distribution and only if you received the program in object code or executable form with such an offer, in accord with Subsection b above.)

    The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

    If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.

5. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.
6. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this License. Therefore, by modifying or distributing the

Program (or any work based on the Program), you indicate your acceptance of this License to do and all its terms and conditions for copying, distributing or modifying the Program or works based on it.

7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.
8. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

   If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

   It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

   This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.
9. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.
10. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

    Each version is given a distinguishing version number. If the Program specifies a version number of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.
11. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted

by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

12. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.
13. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

```
one line to give the program's name and a brief idea of what it does.
Copyright (C) 19yy  name of author

This program is free software; you can redistribute it and/or modify
it under the terms of the GNU General Public License as published by
the Free Software Foundation; either version 2 of the License, or
(at your option) any later version.
```

```
This program is distributed in the hope that it will be useful,
but WITHOUT ANY WARRANTY; without even the implied warranty of
MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
GNU General Public License for more details.

You should have received a copy of the GNU General Public License
along with this program; if not, write to the Free Software
Foundation, Inc., 675 Mass Ave, Cambridge, MA 02139, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
Gnomovision version 69, Copyright (C) 19yy name of author
Gnomovision comes with ABSOLUTELY NO WARRANTY; for details
type `show w'.
This is free software, and you are welcome to redistribute it
under certain conditions; type `show c' for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than `show w' and `show c'; they could even be mouse-clicks or menu items--whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
Yoyodyne, Inc., hereby disclaims all copyright interest in the program
`Gnomovision' (which makes passes at compilers) written by James Hacker.

signature of Ty Coon, 1 April 1989
Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License instead of this License.

Go to the previous, next section.

The Concepts of Bison

This chapter introduces many of the basic concepts without which the details of Bison will not make sense. If you do not already know how to use Bison or Yacc, we suggest you start by reading this chapter carefully.

Languages and Context-Free Grammars

In order for Bison to parse a language, it must be described by a context-free grammar. This means that you specify one or more syntactic groupings and give rules for constructing them from their parts. For example, in the C language, one kind of grouping is called an `expression'. One rule for making an expression might be, "An expression can be made of a minus sign and another expression". Another would be, "An expression can be an integer". As you can see, rules are often recursive, but there must be at least one rule which leads out of the recursion.

The most common formal system for presenting such rules for humans to read is Backus-Naur Form or "BNF", which was developed in order to specify the language Algol 60. Any grammar expressed in BNF is a context-free grammar. The input to Bison is essentially machine-readable BNF.

Not all context-free languages can be handled by Bison, only those that are LALR(1). In brief, this means that it must be possible to tell how to parse any portion of an input string with just a single token of look-ahead. Strictly speaking, that is a description of an LR(1) grammar, and LALR(1) involves additional restrictions that are hard to explain simply; but it is rare in actual practice to find an LR(1) grammar that fails to be LALR(1). See section Mysterious Reduce/Reduce Conflicts, for more information on this.

In the formal grammatical rules for a language, each kind of syntactic unit or grouping is named by a symbol. Those which are built by grouping smaller constructs according to grammatical rules are called nonterminal symbols; those which can't be subdivided are called terminal symbols or token types. We call a piece of input corresponding to a single terminal symbol a token, and a piece corresponding to a single nonterminal symbol a grouping.

We can use the C language as an example of what symbols, terminal and nonterminal, mean. The tokens of C are identifiers, constants (numeric and string), and the various keywords, arithmetic operators and punctuation marks. So the terminal symbols of a grammar for C include `identifier', `number', `string', plus one symbol for each keyword, operator or punctuation mark: `if', `return', `const', `static', `int', `char', `plus-sign', `open-brace', `close-brace', `comma' and many more. (These tokens can be subdivided into characters, but that is a matter of lexicography, not grammar.)

Here is a simple C function subdivided into tokens:

```
int             /* keyword `int' */
square (x)      /* identifier, open-paren, */
```

```
                /* identifier, close-paren */
    int x;      /* keyword `int', identifier, semicolon */
{               /* open-brace */
  return x * x; /* keyword `return', identifier, */
                /* asterisk, identifier, semicolon */
}               /* close-brace */
```

The syntactic groupings of C include the expression, the statement, the declaration, and the function definition. These are represented in the grammar of C by nonterminal symbols `expression', `statement', `declaration' and `function definition'. The full grammar uses dozens of additional language constructs, each with its own nonterminal symbol, in order to express the meanings of these four. The example above is a function definition; it contains one declaration, and one statement. In the statement, each `x' is an expression and so is `x * x'.

Each nonterminal symbol must have grammatical rules showing how it is made out of simpler constructs. For example, one kind of C statement is the `return` statement; this would be described with a grammar rule which reads informally as follows:

> A `statement' can be made of a `return' keyword, an `expression' and a `semicolon'.

There would be many other rules for `statement', one for each kind of statement in C.

One nonterminal symbol must be distinguished as the special one which defines a complete utterance in the language. It is called the start symbol. In a compiler, this means a complete input program. In the C language, the nonterminal symbol `sequence of definitions and declarations' plays this role.

For example, `1 + 2' is a valid C expression--a valid part of a C program--but it is not valid as an *entire* C program. In the context-free grammar of C, this follows from the fact that `expression' is not the start symbol.

The Bison parser reads a sequence of tokens as its input, and groups the tokens using the grammar rules. If the input is valid, the end result is that the entire token sequence reduces to a single grouping whose symbol is the grammar's start symbol. If we use a grammar for C, the entire input must be a `sequence of definitions and declarations'. If not, the parser reports a syntax error.

From Formal Rules to Bison Input

A formal grammar is a mathematical construct. To define the language for Bison, you must write a file expressing the grammar in Bison syntax: a Bison grammar file. See section Bison Grammar Files.

A nonterminal symbol in the formal grammar is represented in Bison input as an identifier, like an identifier in C. By convention, it should be in lower case, such as `expr`, `stmt` or `declaration`.

The Bison representation for a terminal symbol is also called a token type. Token types as well can be represented as C-like identifiers. By convention, these identifiers should be upper case to distinguish them from nonterminals: for example, `INTEGER`, `IDENTIFIER`, `IF` or `RETURN`. A terminal symbol that stands for a particular keyword in the language should be named after that keyword converted to upper case. The terminal symbol `error` is reserved for error recovery. See section Symbols, Terminal

and Nonterminal.

A terminal symbol can also be represented as a character literal, just like a C character constant. You should do this whenever a token is just a single character (parenthesis, plus-sign, etc.): use that same character in a literal as the terminal symbol for that token.

A third way to represent a terminal symbol is with a C string constant containing several characters. See section Symbols, Terminal and Nonterminal, for more information.

The grammar rules also have an expression in Bison syntax. For example, here is the Bison rule for a C `return` statement. The semicolon in quotes is a literal character token, representing part of the C syntax for the statement; the naked semicolon, and the colon, are Bison punctuation used in every rule.

```
stmt:   RETURN expr ';'
        ;
```

See section Syntax of Grammar Rules.

Semantic Values

A formal grammar selects tokens only by their classifications: for example, if a rule mentions the terminal symbol `integer constant', it means that *any* integer constant is grammatically valid in that position. The precise value of the constant is irrelevant to how to parse the input: if `x+4' is grammatical then `x+1' or `x+3989' is equally grammatical.

But the precise value is very important for what the input means once it is parsed. A compiler is useless if it fails to distinguish between 4, 1 and 3989 as constants in the program! Therefore, each token in a Bison grammar has both a token type and a semantic value. See section Defining Language Semantics, for details.

The token type is a terminal symbol defined in the grammar, such as `INTEGER`, `IDENTIFIER` or `','`. It tells everything you need to know to decide where the token may validly appear and how to group it with other tokens. The grammar rules know nothing about tokens except their types.

The semantic value has all the rest of the information about the meaning of the token, such as the value of an integer, or the name of an identifier. (A token such as `','` which is just punctuation doesn't need to have any semantic value.)

For example, an input token might be classified as token type `INTEGER` and have the semantic value 4. Another input token might have the same token type `INTEGER` but value 3989. When a grammar rule says that `INTEGER` is allowed, either of these tokens is acceptable because each is an `INTEGER`. When the parser accepts the token, it keeps track of the token's semantic value.

Each grouping can also have a semantic value as well as its nonterminal symbol. For example, in a calculator, an expression typically has a semantic value that is a number. In a compiler for a programming language, an expression typically has a semantic value that is a tree structure describing the meaning of the expression.

Semantic Actions

In order to be useful, a program must do more than parse input; it must also produce some output based on the input. In a Bison grammar, a grammar rule can have an action made up of C statements. Each time the parser recognizes a match for that rule, the action is executed. See section Actions. Most of the time, the purpose of an action is to compute the semantic value of the whole construct from the semantic values of its parts. For example, suppose we have a rule which says an expression can be the sum of two expressions. When the parser recognizes such a sum, each of the subexpressions has a semantic value which describes how it was built up. The action for this rule should create a similar sort of value for the newly recognized larger expression.

For example, here is a rule that says an expression can be the sum of two subexpressions:

```
expr: expr '+' expr   { $$ = $1 + $3; }
        ;
```

The action says how to produce the semantic value of the sum expression from the values of the two subexpressions.

Bison Output: the Parser File

When you run Bison, you give it a Bison grammar file as input. The output is a C source file that parses the language described by the grammar. This file is called a Bison parser. Keep in mind that the Bison utility and the Bison parser are two distinct programs: the Bison utility is a program whose output is the Bison parser that becomes part of your program.

The job of the Bison parser is to group tokens into groupings according to the grammar rules--for example, to build identifiers and operators into expressions. As it does this, it runs the actions for the grammar rules it uses.

The tokens come from a function called the lexical analyzer that you must supply in some fashion (such as by writing it in C). The Bison parser calls the lexical analyzer each time it wants a new token. It doesn't know what is "inside" the tokens (though their semantic values may reflect this). Typically the lexical analyzer makes the tokens by parsing characters of text, but Bison does not depend on this. See section The Lexical Analyzer Function `yylex`.

The Bison parser file is C code which defines a function named `yyparse` which implements that grammar. This function does not make a complete C program: you must supply some additional functions. One is the lexical analyzer. Another is an error-reporting function which the parser calls to report an error. In addition, a complete C program must start with a function called `main`; you have to provide this, and arrange for it to call `yyparse` or the parser will never run. See section Parser C-Language Interface.

Aside from the token type names and the symbols in the actions you write, all variable and function names used in the Bison parser file begin with `yy' or `YY'. This includes interface functions such as the

lexical analyzer function `yylex`, the error reporting function `yyerror` and the parser function `yyparse` itself. This also includes numerous identifiers used for internal purposes. Therefore, you should avoid using C identifiers starting with `yy' or `YY' in the Bison grammar file except for the ones defined in this manual.

Stages in Using Bison

The actual language-design process using Bison, from grammar specification to a working compiler or interpreter, has these parts:

1. Formally specify the grammar in a form recognized by Bison (see section Bison Grammar Files). For each grammatical rule in the language, describe the action that is to be taken when an instance of that rule is recognized. The action is described by a sequence of C statements.
2. Write a lexical analyzer to process input and pass tokens to the parser. The lexical analyzer may be written by hand in C (see section The Lexical Analyzer Function `yylex`). It could also be produced using Lex, but the use of Lex is not discussed in this manual.
3. Write a controlling function that calls the Bison-produced parser.
4. Write error-reporting routines.

To turn this source code as written into a runnable program, you must follow these steps:

1. Run Bison on the grammar to produce the parser.
2. Compile the code output by Bison, as well as any other source files.
3. Link the object files to produce the finished product.

The Overall Layout of a Bison Grammar

The input file for the Bison utility is a Bison grammar file. The general form of a Bison grammar file is as follows:

```
%{
C declarations
%}

Bison declarations

%%
Grammar rules
%%
Additional C code
```

The `%%', `%{' and `%}' are punctuation that appears in every Bison grammar file to separate the sections.

The C declarations may define types and variables used in the actions. You can also use preprocessor

commands to define macros used there, and use `#include` to include header files that do any of these things.

The Bison declarations declare the names of the terminal and nonterminal symbols, and may also describe operator precedence and the data types of semantic values of various symbols.

The grammar rules define how to construct each nonterminal symbol from its parts.

The additional C code can contain any C code you want to use. Often the definition of the lexical analyzer `yylex` goes here, plus subroutines called by the actions in the grammar rules. In a simple program, all the rest of the program can go here.

Go to the previous, next section.

Go to the previous, next section.

Examples

Now we show and explain three sample programs written using Bison: a reverse polish notation calculator, an algebraic (infix) notation calculator, and a multi-function calculator. All three have been tested under BSD Unix 4.3; each produces a usable, though limited, interactive desk-top calculator.

These examples are simple, but Bison grammars for real programming languages are written the same way.

Reverse Polish Notation Calculator

The first example is that of a simple double-precision reverse polish notation calculator (a calculator using postfix operators). This example provides a good starting point, since operator precedence is not an issue. The second example will illustrate how operator precedence is handled.

The source code for this calculator is named `` `rpcalc.y' ``. The `.y' extension is a convention used for Bison input files.

Declarations for `rpcalc`

Here are the C and Bison declarations for the reverse polish notation calculator. As in C, comments are placed between `/*...*/'.

```
/* Reverse polish notation calculator. */

%{
#define YYSTYPE double
#include <math.h>
%}

%token NUM

%% /* Grammar rules and actions follow */
```

The C declarations section (see section The C Declarations Section) contains two preprocessor directives.

The `#define` directive defines the macro `YYSTYPE`, thus specifying the C data type for semantic values of both tokens and groupings (see section Data Types of Semantic Values). The Bison parser will use whatever type `YYSTYPE` is defined as; if you don't define it, `int` is the default. Because we specify `double`, each token and each expression has an associated value, which is a floating point number.

The `#include` directive is used to declare the exponentiation function `pow`.

The second section, Bison declarations, provides information to Bison about the token types (see sec The Bison Declarations Section). Each terminal symbol that is not a single-character literal must be declared here. (Single-character literals normally don't need to be declared.) In this example, all the arithmetic operators are designated by single-character literals, so the only terminal symbol that needs to be declared is `NUM`, the token type for numeric constants.

Grammar Rules for `rpcalc`

Here are the grammar rules for the reverse polish notation calculator.

```
input:    /* empty */
        | input line
;

line:     '\n'
        | exp '\n'  { printf ("\t%.10g\n", $1); }
;

exp:      NUM             { $$ = $1;         }
        | exp exp '+'     { $$ = $1 + $2;    }
        | exp exp '-'     { $$ = $1 - $2;    }
        | exp exp '*'     { $$ = $1 * $2;    }
        | exp exp '/'     { $$ = $1 / $2;    }
      /* Exponentiation */
        | exp exp '^'     { $$ = pow ($1, $2); }
      /* Unary minus    */
        | exp 'n'         { $$ = -$1;        }
;
%%
```

The groupings of the rpcalc "language" defined here are the expression (given the name `exp`), the line of input (`line`), and the complete input transcript (`input`). Each of these nonterminal symbols has several alternate rules, joined by the `|' punctuator which is read as "or". The following sections explain what these rules mean.

The semantics of the language is determined by the actions taken when a grouping is recognized. The actions are the C code that appears inside braces. See section Actions.

You must specify these actions in C, but Bison provides the means for passing semantic values between the rules. In each action, the pseudo-variable `$$` stands for the semantic value for the grouping that the rule is going to construct. Assigning a value to `$$` is the main job of most actions. The semantic values of the components of the rule are referred to as `$1`, `$2`, and so on.

Explanation of `input`

Consider the definition of `input`:

```
input:    /* empty */
        | input line
;
```

This definition reads as follows: "A complete input is either an empty string, or a complete input followed by an input line". Notice that "complete input" is defined in terms of itself. This definition is said to be left recursive since `input` appears always as the leftmost symbol in the sequence. See section Recursive Rules.

The first alternative is empty because there are no symbols between the colon and the first `|'; this means that `input` can match an empty string of input (no tokens). We write the rules this way because it is legitimate to type Ctrl-d right after you start the calculator. It's conventional to put an empty alternative first and write the comment `/* empty */' in it.

The second alternate rule (`input line`) handles all nontrivial input. It means, "After reading any number of lines, read one more line if possible." The left recursion makes this rule into a loop. Since the first alternative matches empty input, the loop can be executed zero or more times.

The parser function `yyparse` continues to process input until a grammatical error is seen or the lexical analyzer says there are no more input tokens; we will arrange for the latter to happen at end of file.

Explanation of `line`

Now consider the definition of `line`:

```
line:     '\n'
        | exp '\n'  { printf ("\t%.10g\n", $1); }
;
```

The first alternative is a token which is a newline character; this means that rpcalc accepts a blank line (and ignores it, since there is no action). The second alternative is an expression followed by a newline. This is the alternative that makes rpcalc useful. The semantic value of the `exp` grouping is the value of `$1` because the `exp` in question is the first symbol in the alternative. The action prints this value, which is the result of the computation the user asked for.

This action is unusual because it does not assign a value to `$$`. As a consequence, the semantic value associated with the `line` is uninitialized (its value will be unpredictable). This would be a bug if that value were ever used, but we don't use it: once rpcalc has printed the value of the user's input line, that value is no longer needed.

Explanation of `expr`

The `exp` grouping has several rules, one for each kind of expression. The first rule handles the simplest expressions: those that are just numbers. The second handles an addition-expression, which looks like two expressions followed by a plus-sign. The third handles subtraction, and so on.

```
exp:      NUM
        | exp exp '+'     { $$ = $1 + $2;    }
        | exp exp '-'     { $$ = $1 - $2;    }
        ...
        ;
```

We have used `|' to join all the rules for `exp', but we could equally well have written them separately:

```
exp:      NUM ;
exp:      exp exp '+'     { $$ = $1 + $2;    } ;
exp:      exp exp '-'     { $$ = $1 - $2;    } ;
        ...
```

Most of the rules have actions that compute the value of the expression in terms of the value of its parts. For example, in the rule for addition, `$1' refers to the first component `exp' and `$2' refers to the second one. The third component, `'+'', has no meaningful associated semantic value, but if it had one you could refer to it as `$3'. When `yyparse' recognizes a sum expression using this rule, the sum of the two subexpressions' values is produced as the value of the entire expression. See section Actions.

You don't have to give an action for every rule. When a rule has no action, Bison by default copies the value of `$1' into `$$'. This is what happens in the first rule (the one that uses `NUM').

The formatting shown here is the recommended convention, but Bison does not require it. You can add or change whitespace as much as you wish. For example, this:

```
exp   : NUM | exp exp '+' {$$ = $1 + $2; } | ...
```

means the same thing as this:

```
exp:      NUM
        | exp exp '+'    { $$ = $1 + $2; }
        | ...
```

The latter, however, is much more readable.

The `rpcalc' Lexical Analyzer

The lexical analyzer's job is low-level parsing: converting characters or sequences of characters into tokens. The Bison parser gets its tokens by calling the lexical analyzer. See section The Lexical Analyzer Function `yylex'.

Only a simple lexical analyzer is needed for the RPN calculator. This lexical analyzer skips blanks and tabs, then reads in numbers as `double' and returns them as `NUM' tokens. Any other character that isn't part of a number is a separate token. Note that the token-code for such a single-character token is the character itself.

The return value of the lexical analyzer function is a numeric code which represents a token type. The

same text used in Bison rules to stand for this token type is also a C expression for the numeric code for the type. This works in two ways. If the token type is a character literal, then its numeric code is the ASCII code for that character; you can use the same character literal in the lexical analyzer to express the number. If the token type is an identifier, that identifier is defined by Bison as a C macro whose definition is the appropriate number. In this example, therefore, `NUM` becomes a macro for `yylex` to use.

The semantic value of the token (if it has one) is stored into the global variable `yylval`, which is where the Bison parser will look for it. (The C data type of `yylval` is `YYSTYPE`, which was defined at the beginning of the grammar; see section Declarations for `rpcalc`.)

A token type code of zero is returned if the end-of-file is encountered. (Bison recognizes any nonpositive value as indicating the end of the input.)

Here is the code for the lexical analyzer:

```
/* Lexical analyzer returns a double floating point
   number on the stack and the token NUM, or the ASCII
   character read if not a number.  Skips all blanks
   and tabs, returns 0 for EOF. */

#include <ctype.h>

yylex ()
{
  int c;

  /* skip white space  */
  while ((c = getchar ()) == ' ' || c == '\t')
    ;
  /* process numbers   */
  if (c == '.' || isdigit (c))
    {
      ungetc (c, stdin);
      scanf ("%lf", &yylval);
      return NUM;
    }
  /* return end-of-file  */
  if (c == EOF)
    return 0;
  /* return single chars */
  return c;
}
```

The Controlling Function

In keeping with the spirit of this example, the controlling function is kept to the bare minimum. The only requirement is that it call `yyparse` to start the process of parsing.

```
main ()
{
  yyparse ();
}
```

The Error Reporting Routine

When `yyparse` detects a syntax error, it calls the error reporting function `yyerror` to print an error message (usually but not always `"parse error"`). It is up to the programmer to supply `yyerror` (see section Parser C-Language Interface), so here is the definition we will use:

```
#include <stdio.h>

yyerror (s)  /* Called by yyparse on error */
     char *s;
{
  printf ("%s\n", s);
}
```

After `yyerror` returns, the Bison parser may recover from the error and continue parsing if the grammar contains a suitable error rule (see section Error Recovery). Otherwise, `yyparse` returns nonzero. We have not written any error rules in this example, so any invalid input will cause the calculator program to exit. This is not clean behavior for a real calculator, but it is adequate in the first example.

Running Bison to Make the Parser

Before running Bison to produce a parser, we need to decide how to arrange all the source code in one or more source files. For such a simple example, the easiest thing is to put everything in one file. The definitions of `yylex`, `yyerror` and `main` go at the end, in the "additional C code" section of the file (see section The Overall Layout of a Bison Grammar).

For a large project, you would probably have several source files, and use `make` to arrange to recompile them.

With all the source in a single file, you use the following command to convert it into a parser file:

```
bison file_name.y
```

In this example the file was called `` `rpcalc.y' `` (for "Reverse Polish CALCulator"). Bison produces a

file named `file_name.tab.c', removing the `.y' from the original file name. The file output by Bison contains the source code for `yyparse`. The additional functions in the input file (`yylex`, `yyerror` and `main`) are copied verbatim to the output.

Compiling the Parser File

Here is how to compile and run the parser file:

```
# List files in current directory.
% ls
rpcalc.tab.c  rpcalc.y

# Compile the Bison parser.
# `-lm' tells compiler to search math library for pow.
% cc rpcalc.tab.c -lm -o rpcalc

# List files again.
% ls
rpcalc  rpcalc.tab.c  rpcalc.y
```

The file `rpcalc' now contains the executable code. Here is an example session using `rpcalc`.

```
% rpcalc
4 9 +
13
3 7 + 3 4 5 *+-
-13
3 7 + 3 4 5 * + - n                  Note the unary minus, `n'
13
5 6 / 4 n +
-3.166666667
3 4 ^                                Exponentiation
81
^D                                   End-of-file indicator
%
```

Infix Notation Calculator: `calc`

We now modify rpcalc to handle infix operators instead of postfix. Infix notation involves the concept of operator precedence and the need for parentheses nested to arbitrary depth. Here is the Bison code for `calc.y', an infix desk-top calculator.

```
/* Infix notation calculator--calc */
```

```
%{
#define YYSTYPE double
#include <math.h>
%}

/* BISON Declarations */
%token NUM
%left '-' '+'
%left '*' '/'
%left NEG     /* negation--unary minus */
%right '^'    /* exponentiation        */

/* Grammar follows */
%%
input:    /* empty string */
        | input line
;

line:     '\n'
        | exp '\n'  { printf ("\t%.10g\n", $1); }
;

exp:      NUM                { $$ = $1;         }
        | exp '+' exp        { $$ = $1 + $3;    }
        | exp '-' exp        { $$ = $1 - $3;    }
        | exp '*' exp        { $$ = $1 * $3;    }
        | exp '/' exp        { $$ = $1 / $3;    }
        | '-' exp  %prec NEG { $$ = -$2;        }
        | exp '^' exp        { $$ = pow ($1, $3); }
        | '(' exp ')'        { $$ = $2;         }
;
%%
```

The functions `yylex`, `yyerror` and `main` can be the same as before.

There are two important new features shown in this code.

In the second section (Bison declarations), `%left` declares token types and says they are left-associative operators. The declarations `%left` and `%right` (right associativity) take the place of `%token` which is used to declare a token type name without associativity. (These tokens are single-character literals, which ordinarily don't need to be declared. We declare them here to specify the associativity.)

Operator precedence is determined by the line ordering of the declarations; the higher the line number of the declaration (lower on the page or screen), the higher the precedence. Hence, exponentiation has the highest precedence, unary minus (`NEG`) is next, followed by `*' and `/', and so on. See section Operator Precedence.

The other important new feature is the `%prec` in the grammar section for the unary minus operator. The `%prec` simply instructs Bison that the rule `| '-' exp' has the same precedence as `NEG`---in this case the next-to-highest. See section Context-Dependent Precedence.

Here is a sample run of `calc.y':

```
% calc
4 + 4.5 - (34/(8*3+-3))
6.880952381
-56 + 2
-54
3 ^ 2
9
```

Simple Error Recovery

Up to this point, this manual has not addressed the issue of error recovery---how to continue parsing after the parser detects a syntax error. All we have handled is error reporting with `yyerror`. Recall that by default `yyparse` returns after calling `yyerror`. This means that an erroneous input line causes the calculator program to exit. Now we show how to rectify this deficiency.

The Bison language itself includes the reserved word `error`, which may be included in the grammar rules. In the example below it has been added to one of the alternatives for `line`:

```
line:     '\n'
        | exp '\n'   { printf ("\t%.10g\n", $1); }
        | error '\n' { yyerrok;                  }
;
```

This addition to the grammar allows for simple error recovery in the event of a parse error. If an expression that cannot be evaluated is read, the error will be recognized by the third rule for `line`, and parsing will continue. (The `yyerror` function is still called upon to print its message as well.) The action executes the statement `yyerrok`, a macro defined automatically by Bison; its meaning is that error recovery is complete (see section Error Recovery). Note the difference between `yyerrok` and `yyerror`; neither one is a misprint.

This form of error recovery deals with syntax errors. There are other kinds of errors; for example, division by zero, which raises an exception signal that is normally fatal. A real calculator program must handle this signal and use `longjmp` to return to `main` and resume parsing input lines; it would also have to discard the rest of the current line of input. We won't discuss this issue further because it is not specific to Bison programs.

Multi-Function Calculator: `mfcalc`

Now that the basics of Bison have been discussed, it is time to move on to a more advanced problem. The above calculators provided only five functions, `+', `-', `*', `/' and `^'. It would be nice to have a calculator that provides other mathematical functions such as `sin`, `cos`, etc.

It is easy to add new operators to the infix calculator as long as they are only single-character literals. The lexical analyzer `yylex` passes back all non-number characters as tokens, so new grammar rules suffice for adding a new operator. But we want something more flexible: built-in functions whose syntax has this form:

```
function_name (argument)
```

At the same time, we will add memory to the calculator, by allowing you to create named variables, store values in them, and use them later. Here is a sample session with the multi-function calculator:

```
% mfcalc
pi = 3.141592653589
3.1415926536
sin(pi)
0.0000000000
alpha = beta1 = 2.3
2.3000000000
alpha
2.3000000000
ln(alpha)
0.8329091229
exp(ln(beta1))
2.3000000000
%
```

Note that multiple assignment and nested function calls are permitted.

Declarations for `mfcalc`

Here are the C and Bison declarations for the multi-function calculator.

```
%{
#include <math.h>  /* For math functions, cos(), sin(), etc. */
#include "calc.h"  /* Contains definition of `symrec'        */
%}
%union {
double     val;  /* For returning numbers.                   */
symrec  *tptr;   /* For returning symbol-table pointers      */
}
```

```
%token <val>  NUM        /* Simple double precision number   */
%token <tptr> VAR FNCT   /* Variable and Function            */
%type  <val>  exp

%right '='
%left '-' '+'
%left '*' '/'
%left NEG     /* Negation--unary minus */
%right '^'    /* Exponentiation        */

/* Grammar follows */

%%
```

The above grammar introduces only two new features of the Bison language. These features allow semantic values to have various data types (see section More Than One Value Type).

The `%union` declaration specifies the entire list of possible types; this is instead of defining `YYSTYPE`. The allowable types are now double-floats (for `exp` and `NUM`) and pointers to entries in the symbol table. See section The Collection of Value Types.

Since values can now have various types, it is necessary to associate a type with each grammar symbol whose semantic value is used. These symbols are `NUM`, `VAR`, `FNCT`, and `exp`. Their declarations are augmented with information about their data type (placed between angle brackets).

The Bison construct `%type` is used for declaring nonterminal symbols, just as `%token` is used for declaring token types. We have not used `%type` before because nonterminal symbols are normally declared implicitly by the rules that define them. But `exp` must be declared explicitly so we can specify its value type. See section Nonterminal Symbols.

Grammar Rules for `mfcalc`

Here are the grammar rules for the multi-function calculator. Most of them are copied directly from `calc`; three rules, those which mention `VAR` or `FNCT`, are new.

```
input:   /* empty */
        | input line
;

line:
          '\n'
        | exp '\n'   { printf ("\t%.10g\n", $1); }
        | error '\n' { yyerrok;                  }
;
```

```
exp:      NUM                { $$ = $1;                         }
        | VAR                { $$ = $1->value.var;              }
        | VAR '=' exp        { $$ = $3; $1->value.var = $3;     }
        | FNCT '(' exp ')'   { $$ = (*($1->value.fnctptr))($3); }
        | exp '+' exp        { $$ = $1 + $3;                    }
        | exp '-' exp        { $$ = $1 - $3;                    }
        | exp '*' exp        { $$ = $1 * $3;                    }
        | exp '/' exp        { $$ = $1 / $3;                    }
        | '-' exp  %prec NEG { $$ = -$2;                        }
        | exp '^' exp        { $$ = pow ($1, $3);               }
        | '(' exp ')'        { $$ = $2;                         }
;
/* End of grammar */
%%
```

The `mfcalc` Symbol Table

The multi-function calculator requires a symbol table to keep track of the names and meanings of variables and functions. This doesn't affect the grammar rules (except for the actions) or the Bison declarations, but it requires some additional C functions for support.

The symbol table itself consists of a linked list of records. Its definition, which is kept in the header `` `calc.h' ``, is as follows. It provides for either functions or variables to be placed in the table.

```
/* Data type for links in the chain of symbols.      */
struct symrec
{
  char *name;  /* name of symbol                     */
  int type;    /* type of symbol: either VAR or FNCT */
  union {
    double var;           /* value of a VAR         */
    double (*fnctptr)();  /* value of a FNCT        */
  } value;
  struct symrec *next;    /* link field             */
};

typedef struct symrec symrec;

/* The symbol table: a chain of `struct symrec'.     */
extern symrec *sym_table;

symrec *putsym ();
symrec *getsym ();
```

The new version of `main` includes a call to `init_table`, a function that initializes the symbol table. Here it is, and `init_table` as well:

```
#include <stdio.h>

main ()
{
  init_table ();
  yyparse ();
}

yyerror (s)  /* Called by yyparse on error */
     char *s;
{
  printf ("%s\n", s);
}

struct init
{
  char *fname;
  double (*fnct)();
};

struct init arith_fncts[]
  = {
      "sin", sin,
      "cos", cos,
      "atan", atan,
      "ln", log,
      "exp", exp,
      "sqrt", sqrt,
      0, 0
    };

/* The symbol table: a chain of `struct symrec'.  */
symrec *sym_table = (symrec *)0;

init_table ()  /* puts arithmetic functions in table. */
{
  int i;
  symrec *ptr;
  for (i = 0; arith_fncts[i].fname != 0; i++)
    {
      ptr = putsym (arith_fncts[i].fname, FNCT);
      ptr->value.fctptr = arith_fncts[i].fnct;
    }
}
```

By simply editing the initialization list and adding the necessary include files, you can add additional functions to the calculator.

Two important functions allow look-up and installation of symbols in the symbol table. The function `putsym` is passed a name and the type (VAR or FNCT) of the object to be installed. The object is linked to the front of the list, and a pointer to the object is returned. The function `getsym` is passed the name of the symbol to look up. If found, a pointer to that symbol is returned; otherwise zero is returned.

```
symrec *
putsym (sym_name,sym_type)
     char *sym_name;
     int sym_type;
{
  symrec *ptr;
  ptr = (symrec *) malloc (sizeof (symrec));
  ptr->name = (char *) malloc (strlen (sym_name) + 1);
  strcpy (ptr->name,sym_name);
  ptr->type = sym_type;
  ptr->value.var = 0; /* set value to 0 even if fctn.  */
  ptr->next = (struct symrec *)sym_table;
  sym_table = ptr;
  return ptr;
}

symrec *
getsym (sym_name)
     char *sym_name;
{
  symrec *ptr;
  for (ptr = sym_table; ptr != (symrec *) 0;
       ptr = (symrec *)ptr->next)
    if (strcmp (ptr->name,sym_name) == 0)
      return ptr;
  return 0;
}
```

The function `yylex` must now recognize variables, numeric values, and the single-character arithmetic operators. Strings of alphanumeric characters with a leading nondigit are recognized as either variables or functions depending on what the symbol table says about them.

The string is passed to `getsym` for look up in the symbol table. If the name appears in the table, a pointer to its location and its type (VAR or FNCT) is returned to `yyparse`. If it is not already in the table, then it is installed as a VAR using `putsym`. Again, a pointer and its type (which must be VAR) is returned to `yyparse`.

No change is needed in the handling of numeric values and arithmetic operators in `yylex`.

```
#include <ctype.h>
yylex ()
{
  int c;

  /* Ignore whitespace, get first nonwhite character.  */
  while ((c = getchar ()) == ' ' || c == '\t');

  if (c == EOF)
    return 0;

  /* Char starts a number => parse the number.         */
  if (c == '.' || isdigit (c))
    {
      ungetc (c, stdin);
      scanf ("%lf", &yylval.val);
      return NUM;
    }

  /* Char starts an identifier => read the name.       */
  if (isalpha (c))
    {
      symrec *s;
      static char *symbuf = 0;
      static int length = 0;
      int i;

      /* Initially make the buffer long enough
         for a 40-character symbol name.  */
      if (length == 0)
        length = 40, symbuf = (char *)malloc (length + 1);

      i = 0;
      do
        {
          /* If buffer is full, make it bigger.        */
          if (i == length)
            {
              length *= 2;
              symbuf = (char *)realloc (symbuf, length + 1);
            }
          /* Add this character to the buffer.         */
          symbuf[i++] = c;
          /* Get another character.                    */
          c = getchar ();
```

```
        }
      while (c != EOF && isalnum (c));

      ungetc (c, stdin);
      symbuf[i] = '\0';

      s = getsym (symbuf);
      if (s == 0)
        s = putsym (symbuf, VAR);
      yylval.tptr = s;
      return s->type;
    }

  /* Any other character is a token by itself.        */
  return c;
}
```

This program is both powerful and flexible. You may easily add new functions, and it is a simple job to modify this code to install predefined variables such as `pi` or `e` as well.

Exercises

1. Add some new functions from `` `math.h' `` to the initialization list.
2. Add another array that contains constants and their values. Then modify `init_table` to add these constants to the symbol table. It will be easiest to give the constants type `VAR`.
3. Make the program report an error if the user refers to an uninitialized variable in any way except to store a value in it.

Go to the previous, next section.

Go to the previous, next section.

Bison Grammar Files

Bison takes as input a context-free grammar specification and produces a C-language function that recognizes correct instances of the grammar.

The Bison grammar input file conventionally has a name ending in `.y'.

Outline of a Bison Grammar

A Bison grammar file has four main sections, shown here with the appropriate delimiters:

```
%{
C declarations
%}

Bison declarations

%%
Grammar rules
%%

Additional C code
```

Comments enclosed in `/* ... */' may appear in any of the sections.

The C Declarations Section

The C declarations section contains macro definitions and declarations of functions and variables that are used in the actions in the grammar rules. These are copied to the beginning of the parser file so that they precede the definition of `yyparse`. You can use `#include' to get the declarations from a header file. If you don't need any C declarations, you may omit the `%{' and `%}' delimiters that bracket this section.

The Bison Declarations Section

The Bison declarations section contains declarations that define terminal and nonterminal symbols, specify precedence, and so on. In some simple grammars you may not need any declarations. See section Bison Declarations.

The Grammar Rules Section

The grammar rules section contains one or more Bison grammar rules, and nothing else. See section Syntax of Grammar Rules.

There must always be at least one grammar rule, and the first `%%' (which precedes the grammar rules) may never be omitted even if it is the first thing in the file.

The Additional C Code Section

The additional C code section is copied verbatim to the end of the parser file, just as the C declarations section is copied to the beginning. This is the most convenient place to put anything that you want to have in the parser file but which need not come before the definition of `yyparse`. For example, the definitions of `yylex` and `yyerror` often go here. See section Parser C-Language Interface.

If the last section is empty, you may omit the `%%' that separates it from the grammar rules.

The Bison parser itself contains many static variables whose names start with `yy' and many macros whose names start with `YY'. It is a good idea to avoid using any such names (except those documented in this manual) in the additional C code section of the grammar file.

Symbols, Terminal and Nonterminal

Symbols in Bison grammars represent the grammatical classifications of the language.

A terminal symbol (also known as a token type) represents a class of syntactically equivalent tokens. You use the symbol in grammar rules to mean that a token in that class is allowed. The symbol is represented in the Bison parser by a numeric code, and the `yylex` function returns a token type code to indicate what kind of token has been read. You don't need to know what the code value is; you can use the symbol to stand for it.

A nonterminal symbol stands for a class of syntactically equivalent groupings. The symbol name is used in writing grammar rules. By convention, it should be all lower case.

Symbol names can contain letters, digits (not at the beginning), underscores and periods. Periods make sense only in nonterminals.

There are three ways of writing terminal symbols in the grammar:

- A named token type is written with an identifier, like an identifier in C. By convention, it should be all upper case. Each such name must be defined with a Bison declaration such as `%token`. See section Token Type Names.
- A character token type (or literal character token) is written in the grammar using the same syntax used in C for character constants; for example, `'+'` is a character token type. A character token type doesn't need to be declared unless you need to specify its semantic value data type (see section Data Types of Semantic Values), associativity, or precedence (see section Operator Precedence).

By convention, a character token type is used only to represent a token that consists of that particular character. Thus, the token type `'+'` is used to represent the character `+' as a token. Nothing enforces this convention, but if you depart from it, your program will confuse other readers.

All the usual escape sequences used in character literals in C can be used in Bison as well, but you must not use the null character as a character literal because its ASCII code, zero, is the code `yylex` returns for end-of-input (see section Calling Convention for `yylex`}).

- A literal string token is written like a C string constant; for example, `"<="` is a literal string token. A literal string token doesn't need to be declared unless you need to specify its semantic value data type (see section Data Types of Semantic Values), associativity, precedence (see section Operator Precedence).

  You can associate the literal string token with a symbolic name as an alias, using the `%token` declaration (see section Token Type Names). If you don't do that, the lexical analyzer has to retrieve the token number for the literal string token from the `yytname` table (see section Calling Convention for `yylex`).

  WARNING: literal string tokens do not work in Yacc.

  By convention, a literal string token is used only to represent a token that consists of that particular string. Thus, you should use the token type `"<="` to represent the string `<=' as a token. Bison does not enforces this convention, but if you depart from it, people who read your program will be confused.

  All the escape sequences used in string literals in C can be used in Bison as well. A literal string token must contain two or more characters; for a token containing just one character, use a character token (see above).

How you choose to write a terminal symbol has no effect on its grammatical meaning. That depends only on where it appears in rules and on when the parser function returns that symbol.

The value returned by `yylex` is always one of the terminal symbols (or 0 for end-of-input). Whichever way you write the token type in the grammar rules, you write it the same way in the definition of `yylex`. The numeric code for a character token type is simply the ASCII code for the character, so `yylex` can use the identical character constant to generate the requisite code. Each named token type becomes a C macro in the parser file, so `yylex` can use the name to stand for the code. (This is why periods don't make sense in terminal symbols.) See section Calling Convention for `yylex`.

If `yylex` is defined in a separate file, you need to arrange for the token-type macro definitions to be available there. Use the `-d' option when you run Bison, so that it will write these macro definitions into a separate header file `` `name.tab.h' `` which you can include in the other source files that need it. See section Invoking Bison.

The symbol `error` is a terminal symbol reserved for error recovery (see section Error Recovery); you shouldn't use it for any other purpose. In particular, `yylex` should never return this value.

Syntax of Grammar Rules

A Bison grammar rule has the following general form:

```
result: components...
        ;
```

where result is the nonterminal symbol that this rule describes and components are various terminal and nonterminal symbols that are put together by this rule (see section Symbols, Terminal and Nonterminal).

For example,

```
exp:      exp '+' exp
        ;
```

says that two groupings of type `exp`, with a `+' token in between, can be combined into a larger grouping of type `exp`.

Whitespace in rules is significant only to separate symbols. You can add extra whitespace as you wish.

Scattered among the components can be actions that determine the semantics of the rule. An action looks like this:

```
{C statements}
```

Usually there is only one action and it follows the components. See section Actions.

Multiple rules for the same result can be written separately or can be joined with the vertical-bar character `|' as follows:

```
result:    rule1-components...
        | rule2-components...
        ...
        ;
```

They are still considered distinct rules even when joined in this way.

If components in a rule is empty, it means that result can match the empty string. For example, here is how to define a comma-separated sequence of zero or more `exp` groupings:

```
expseq:   /* empty */
        | expseq1
        ;

expseq1:  exp
        | expseq1 ',' exp
        ;
```

It is customary to write a comment `/* empty */' in each rule with no components.

Recursive Rules

A rule is called recursive when its result nonterminal appears also on its right hand side. Nearly all Bison grammars need to use recursion, because that is the only way to define a sequence of any number of somethings. Consider this recursive definition of a comma-separated sequence of one or more expressions:

```
expseq1:  exp
        | expseq1 ',' exp
        ;
```

Since the recursive use of `expseq1` is the leftmost symbol in the right hand side, we call this left recursion. By contrast, here the same construct is defined using right recursion:

```
expseq1:  exp
        | exp ',' expseq1
        ;
```

Any kind of sequence can be defined using either left recursion or right recursion, but you should always use left recursion, because it can parse a sequence of any number of elements with bounded stack space. Right recursion uses up space on the Bison stack in proportion to the number of elements in the sequence, because all the elements must be shifted onto the stack before the rule can be applied even once. See section The Bison Parser Algorithm, for further explanation of this.

Indirect or mutual recursion occurs when the result of the rule does not appear directly on its right hand side, but does appear in rules for other nonterminals which do appear on its right hand side.

For example:

```
expr:     primary
        | primary '+' primary
        ;

primary:  constant
        | '(' expr ')'
        ;
```

defines two mutually-recursive nonterminals, since each refers to the other.

Defining Language Semantics

The grammar rules for a language determine only the syntax. The semantics are determined by the semantic values associated with various tokens and groupings, and by the actions taken when various groupings are recognized.

For example, the calculator calculates properly because the value associated with each expression is the proper number; it adds properly because the action for the grouping `x + y' is to add the numbers associated with x and y.

Data Types of Semantic Values

In a simple program it may be sufficient to use the same data type for the semantic values of all language constructs. This was true in the RPN and infix calculator examples (see section Reverse Polish Notation Calculator).

Bison's default is to use type `int` for all semantic values. To specify some other type, define `YYSTYPE` as a macro, like this:

```
#define YYSTYPE double
```

This macro definition must go in the C declarations section of the grammar file (see section Outline of a Bison Grammar).

More Than One Value Type

In most programs, you will need different data types for different kinds of tokens and groupings. For example, a numeric constant may need type `int` or `long`, while a string constant needs type `char *`, and an identifier might need a pointer to an entry in the symbol table.

To use more than one data type for semantic values in one parser, Bison requires you to do two things:

- Specify the entire collection of possible data types, with the `%union` Bison declaration (see section The Collection of Value Types).
- Choose one of those types for each symbol (terminal or nonterminal) for which semantic values are used. This is done for tokens with the `%token` Bison declaration (see section Token Type Names) and for groupings with the `%type` Bison declaration (see section Nonterminal Symbols).

Actions

An action accompanies a syntactic rule and contains C code to be executed each time an instance of that rule is recognized. The task of most actions is to compute a semantic value for the grouping built by the rule from the semantic values associated with tokens or smaller groupings.

An action consists of C statements surrounded by braces, much like a compound statement in C. It can be placed at any position in the rule; it is executed at that position. Most rules have just one action at the end

of the rule, following all the components. Actions in the middle of a rule are tricky and used only for special purposes (see section Actions in Mid-Rule).

The C code in an action can refer to the semantic values of the components matched by the rule with the construct `$n`, which stands for the value of the nth component. The semantic value for the grouping being constructed is `$$`. (Bison translates both of these constructs into array element references when it copies the actions into the parser file.)

Here is a typical example:

```
exp:    ...
        | exp '+' exp
            { $$ = $1 + $3; }
```

This rule constructs an `exp` from two smaller `exp` groupings connected by a plus-sign token. In the action, `$1` and `$3` refer to the semantic values of the two component `exp` groupings, which are the first and third symbols on the right hand side of the rule. The sum is stored into `$$` so that it becomes the semantic value of the addition-expression just recognized by the rule. If there were a useful semantic value associated with the `+' token, it could be referred to as `$2`.

If you don't specify an action for a rule, Bison supplies a default: `$$ = $1`. Thus, the value of the first symbol in the rule becomes the value of the whole rule. Of course, the default rule is valid only if the two data types match. There is no meaningful default action for an empty rule; every empty rule must have an explicit action unless the rule's value does not matter.

`$n` with n zero or negative is allowed for reference to tokens and groupings on the stack *before* those that match the current rule. This is a very risky practice, and to use it reliably you must be certain of the context in which the rule is applied. Here is a case in which you can use this reliably:

```
foo:      expr bar '+' expr  { ... }
        | expr bar '-' expr  { ... }
        ;

bar:      /* empty */
        { previous_expr = $0; }
        ;
```

As long as `bar` is used only in the fashion shown here, `$0` always refers to the `expr` which precedes `bar` in the definition of `foo`.

Data Types of Values in Actions

If you have chosen a single data type for semantic values, the `$$` and `$n` constructs always have that data type.

If you have used `%union` to specify a variety of data types, then you must declare a choice among these types for each terminal or nonterminal symbol that can have a semantic value. Then each time you use

$$ or $n, its data type is determined by which symbol it refers to in the rule. In this example,

```
exp:    ...
        | exp '+' exp
            { $$ = $1 + $3; }
```

$1 and $3 refer to instances of exp, so they all have the data type declared for the nonterminal symbol exp. If $2 were used, it would have the data type declared for the terminal symbol '+', whatever that might be.

Alternatively, you can specify the data type when you refer to the value, by inserting `<type>' after the `$' at the beginning of the reference. For example, if you have defined types as shown here:

```
%union {
  int itype;
  double dtype;
}
```

then you can write $<itype>1 to refer to the first subunit of the rule as an integer, or $<dtype>1 to refer to it as a double.

Actions in Mid-Rule

Occasionally it is useful to put an action in the middle of a rule. These actions are written just like usual end-of-rule actions, but they are executed before the parser even recognizes the following components.

A mid-rule action may refer to the components preceding it using $n, but it may not refer to subsequent components because it is run before they are parsed.

The mid-rule action itself counts as one of the components of the rule. This makes a difference when there is another action later in the same rule (and usually there is another at the end): you have to count the actions along with the symbols when working out which number n to use in $n.

The mid-rule action can also have a semantic value. The action can set its value with an assignment to $$, and actions later in the rule can refer to the value using $n. Since there is no symbol to name the action, there is no way to declare a data type for the value in advance, so you must use the `$<...>' construct to specify a data type each time you refer to this value.

There is no way to set the value of the entire rule with a mid-rule action, because assignments to $$ do not have that effect. The only way to set the value for the entire rule is with an ordinary action at the end of the rule.

Here is an example from a hypothetical compiler, handling a let statement that looks like `let (variable) statement' and serves to create a variable named variable temporarily for the duration of statement. To parse this construct, we must put variable into the symbol table while statement is parsed, then remove it afterward. Here is how it is done:

```
stmt:   LET '(' var ')'
```

```
                { $<context>$ = push_context ();
                  declare_variable ($3); }
        stmt    { $$ = $6;
                  pop_context ($<context>5); }
```

As soon as `let (variable)' has been recognized, the first action is run. It saves a copy of the current semantic context (the list of accessible variables) as its semantic value, using alternative `context` in the data-type union. Then it calls `declare_variable` to add the new variable to that list. Once the first action is finished, the embedded statement `stmt` can be parsed. Note that the mid-rule action is component number 5, so the `stmt' is component number 6.

After the embedded statement is parsed, its semantic value becomes the value of the entire `let`-statement. Then the semantic value from the earlier action is used to restore the prior list of variables. This removes the temporary `let`-variable from the list so that it won't appear to exist while the rest of the program is parsed.

Taking action before a rule is completely recognized often leads to conflicts since the parser must commit to a parse in order to execute the action. For example, the following two rules, without mid-rule actions, can coexist in a working parser because the parser can shift the open-brace token and look at what follows before deciding whether there is a declaration or not:

```
compound: '{' declarations statements '}'
        | '{' statements '}'
        ;
```

But when we add a mid-rule action as follows, the rules become nonfunctional:

```
compound: { prepare_for_local_variables (); }
          '{' declarations statements '}'
        | '{' statements '}'
        ;
```

Now the parser is forced to decide whether to run the mid-rule action when it has read no farther than the open-brace. In other words, it must commit to using one rule or the other, without sufficient information to do it correctly. (The open-brace token is what is called the look-ahead token at this time, since the parser is still deciding what to do about it. See section Look-Ahead Tokens.)

You might think that you could correct the problem by putting identical actions into the two rules, like this:

```
compound: { prepare_for_local_variables (); }
          '{' declarations statements '}'
        | { prepare_for_local_variables (); }
          '{' statements '}'
        ;
```

But this does not help, because Bison does not realize that the two actions are identical. (Bison never

tries to understand the C code in an action.)

If the grammar is such that a declaration can be distinguished from a statement by the first token (which is true in C), then one solution which does work is to put the action after the open-brace, like this:

```
compound: '{' { prepare_for_local_variables (); }
          declarations statements '}'
        | '{' statements '}'
        ;
```

Now the first token of the following declaration or statement, which would in any case tell Bison which rule to use, can still do so.

Another solution is to bury the action inside a nonterminal symbol which serves as a subroutine:

```
subroutine: /* empty */
          { prepare_for_local_variables (); }
        ;

compound: subroutine
          '{' declarations statements '}'
        | subroutine
          '{' statements '}'
        ;
```

Now Bison can execute the action in the rule for `subroutine` without deciding which rule for `compound` it will eventually use. Note that the action is now at the end of its rule. Any mid-rule action can be converted to an end-of-rule action in this way, and this is what Bison actually does to implement mid-rule actions.

Bison Declarations

The Bison declarations section of a Bison grammar defines the symbols used in formulating the grammar and the data types of semantic values. See section Symbols, Terminal and Nonterminal.

All token type names (but not single-character literal tokens such as `'+'` and `'*'`) must be declared. Nonterminal symbols must be declared if you need to specify which data type to use for the semantic value (see section More Than One Value Type).

The first rule in the file also specifies the start symbol, by default. If you want some other symbol to be the start symbol, you must declare it explicitly (see section Languages and Context-Free Grammars).

Token Type Names

The basic way to declare a token type name (terminal symbol) is as follows:

```
%token name
```

Bison will convert this into a `#define` directive in the parser, so that the function `yylex` (if it is in this file) can use the name name to stand for this token type's code.

Alternatively, you can use `%left`, `%right`, or `%nonassoc` instead of `%token`, if you wish to specify precedence. See section Operator Precedence.

You can explicitly specify the numeric code for a token type by appending an integer value in the field immediately following the token name:

```
%token NUM 300
```

It is generally best, however, to let Bison choose the numeric codes for all token types. Bison will automatically select codes that don't conflict with each other or with ASCII characters.

In the event that the stack type is a union, you must augment the `%token` or other token declaration to include the data type alternative delimited by angle-brackets (see section More Than One Value Type).

For example:

```
%union {              /* define stack type */
  double val;
  symrec *tptr;
}
%token <val> NUM      /* define token NUM and its type */
```

You can associate a literal string token with a token type name by writing the literal string at the end of a `%token` declaration which declares the name. For example:

```
%token arrow "=>"
```

For example, a grammar for the C language might specify these names with equivalent literal string tokens:

```
%token  <operator>  OR      "||"
%token  <operator>  LE 134  "<="
%left  OR  "<="
```

Once you equate the literal string and the token name, you can use them interchangeably in further declarations or the grammar rules. The `yylex` function can use the token name or the literal string to obtain the token type code number (see section Calling Convention for `yylex`).

Operator Precedence

Use the `%left`, `%right` or `%nonassoc` declaration to declare a token and specify its precedence and associativity, all at once. These are called precedence declarations. See section Operator Precedence, for general information on operator precedence.

The syntax of a precedence declaration is the same as that of `%token`: either

```
%left symbols...
```

or

```
%left <type> symbols...
```

And indeed any of these declarations serves the purposes of `%token`. But in addition, they specify the associativity and relative precedence for all the symbols:

- The associativity of an operator op determines how repeated uses of the operator nest: whether `x op y op z' is parsed by grouping x with y first or by grouping y with z first. `%left` specifies left-associativity (grouping x with y first) and `%right` specifies right-associativity (grouping y with z first). `%nonassoc` specifies no associativity, which means that `x op y op z' is considered a syntax error.
- The precedence of an operator determines how it nests with other operators. All the tokens declared in a single precedence declaration have equal precedence and nest together according to their associativity. When two tokens declared in different precedence declarations associate, the one declared later has the higher precedence and is grouped first.

The Collection of Value Types

The `%union` declaration specifies the entire collection of possible data types for semantic values. The keyword `%union` is followed by a pair of braces containing the same thing that goes inside a `union` in C.

For example:

```
%union {
  double val;
  symrec *tptr;
}
```

This says that the two alternative types are `double` and `symrec *`. They are given names `val` and `tptr`; these names are used in the `%token` and `%type` declarations to pick one of the types for a terminal or nonterminal symbol (see section Nonterminal Symbols).

Note that, unlike making a `union` declaration in C, you do not write a semicolon after the closing brace.

Nonterminal Symbols

When you use `%union` to specify multiple value types, you must declare the value type of each nonterminal symbol for which values are used. This is done with a `%type` declaration, like this:

```
%type <type> nonterminal...
```

Here nonterminal is the name of a nonterminal symbol, and type is the name given in the `%union` to the alternative that you want (see section The Collection of Value Types). You can give any number of nonterminal symbols in the same `%type` declaration, if they have the same value type. Use spaces to separate the symbol names.

You can also declare the value type of a terminal symbol. To do this, use the same `<type>` construction in a declaration for the terminal symbol. All kinds of token declarations allow `<type>`.

Suppressing Conflict Warnings

Bison normally warns if there are any conflicts in the grammar (see section Shift/Reduce Conflicts), but most real grammars have harmless shift/reduce conflicts which are resolved in a predictable way and would be difficult to eliminate. It is desirable to suppress the warning about these conflicts unless the number of conflicts changes. You can do this with the `%expect` declaration.

The declaration looks like this:

```
%expect n
```

Here n is a decimal integer. The declaration says there should be no warning if there are n shift/reduce conflicts and no reduce/reduce conflicts. The usual warning is given if there are either more or fewer conflicts, or if there are any reduce/reduce conflicts.

In general, using `%expect` involves these steps:

- Compile your grammar without `%expect`. Use the `-v' option to get a verbose list of where the conflicts occur. Bison will also print the number of conflicts.
- Check each of the conflicts to make sure that Bison's default resolution is what you really want. If not, rewrite the grammar and go back to the beginning.
- Add an `%expect` declaration, copying the number n from the number which Bison printed.

Now Bison will stop annoying you about the conflicts you have checked, but it will warn you again if changes in the grammar result in additional conflicts.

The Start-Symbol

Bison assumes by default that the start symbol for the grammar is the first nonterminal specified in the grammar specification section. The programmer may override this restriction with the `%start` declaration as follows:

```
%start symbol
```

A Pure (Reentrant) Parser

A reentrant program is one which does not alter in the course of execution; in other words, it consists entirely of pure (read-only) code. Reentrancy is important whenever asynchronous execution is possible; for example, a nonreentrant program may not be safe to call from a signal handler. In systems with multiple threads of control, a nonreentrant program must be called only within interlocks.

The Bison parser is not normally a reentrant program, because it uses statically allocated variables for communication with `yylex`. These variables include `yylval` and `yylloc`.

The Bison declaration `%pure_parser` says that you want the parser to be reentrant. It looks like this:

```
%pure_parser
```

The effect is that the two communication variables become local variables in `yyparse`, and a different calling convention is used for the lexical analyzer function `yylex`. See section Calling Conventions for Pure Parsers, for the details of this. The variable `yynerrs` also becomes local in `yyparse` (see section The Error Reporting Function `yyerror`). The convention for calling `yyparse` itself is unchanged.

Bison Declaration Summary

Here is a summary of all Bison declarations:

`%union`

> Declare the collection of data types that semantic values may have (see section The Collection of Value Types).

`%token`

> Declare a terminal symbol (token type name) with no precedence or associativity specified (see section Token Type Names).

`%right`

> Declare a terminal symbol (token type name) that is right-associative (see section Operator Precedence).

`%left`

> Declare a terminal symbol (token type name) that is left-associative (see section Operator Precedence).

`%nonassoc`

> Declare a terminal symbol (token type name) that is nonassociative (using it in a way that would be associative is a syntax error) (see section Operator Precedence).

`%type`

> Declare the type of semantic values for a nonterminal symbol (see section Nonterminal Symbols).

`%start`

Specify the grammar's start symbol (see section The Start-Symbol).

`%expect`

Declare the expected number of shift-reduce conflicts (see section Suppressing Conflict Warnings).

`%pure_parser`

Request a pure (reentrant) parser program (see section A Pure (Reentrant) Parser).

`%no_lines`

Don't generate any `#line` preprocessor commands in the parser file. Ordinarily Bison writes these commands in the parser file so that the C compiler and debuggers will associate errors and object code with your source file (the grammar file). This directive causes them to associate errors with the parser file, treating it an independent source file in its own right.

`%raw`

The output file `` `name.h' `` normally defines the tokens with Yacc-compatible token numbers. If this option is specified, the internal Bison numbers are used instead. (Yacc-compatible numbers start at 257 except for single character tokens; Bison assigns token numbers sequentially for all tokens starting at 3.)

`%token_table`

Generate an array of token names in the parser file. The name of the array is `yytname`; `yytname[i]` is the name of the token whose internal Bison token code number is i. The first three elements of `yytname` are always `"$"`, `"error"`, and `"$illegal"`; after these come the symbols defined in the grammar file.

For single-character literal tokens and literal string tokens, the name in the table includes the single-quote or double-quote characters: for example, `"'+'"` is a single-character literal and `"\"<=\""` is a literal string token. All the characters of the literal string token appear verbatim in the string found in the table; even double-quote characters are not escaped. For example, if the token consists of three characters `*"*', its string in `yytname` contains `"*"*"'. (In C, that would be written as `"\"*\"*\""`).

When you specify `%token_table`, Bison also generates macro definitions for macros `YYNTOKENS`, `YYNNTS`, and `YYNRULES`, and `YYNSTATES`:

`YYNTOKENS`

The highest token number, plus one.

`YYNNTS`

The number of non-terminal symbols.

`YYNRULES`

The number of grammar rules,

`YYNSTATES`

The number of parser states (see section Parser States).

Multiple Parsers in the Same Program

Most programs that use Bison parse only one language and therefore contain only one Bison parser. But what if you want to parse more than one language with the same program? Then you need to avoid a name conflict between different definitions of `yyparse`, `yylval`, and so on.

The easy way to do this is to use the option `-p prefix' (see section Invoking Bison). This renames the interface functions and variables of the Bison parser to start with prefix instead of `yy'. You can use this to give each parser distinct names that do not conflict.

The precise list of symbols renamed is `yyparse`, `yylex`, `yyerror`, `yynerrs`, `yylval`, `yychar` and `yydebug`. For example, if you use `-p c', the names become `cparse`, `clex`, and so on.

All the other variables and macros associated with Bison are not renamed. These others are not global; there is no conflict if the same name is used in different parsers. For example, YYSTYPE is not renamed, but defining this in different ways in different parsers causes no trouble (see section Data Types of Semantic Values).

The `-p' option works by adding macro definitions to the beginning of the parser source file, defining `yyparse` as `prefixparse`, and so on. This effectively substitutes one name for the other in the entire parser file.

Go to the previous, next section.

Go to the previous, next section.

Parser C-Language Interface

The Bison parser is actually a C function named `yyparse`. Here we describe the interface conventions of `yyparse` and the other functions that it needs to use.

Keep in mind that the parser uses many C identifiers starting with `yy' and `YY' for internal purposes. If you use such an identifier (aside from those in this manual) in an action or in additional C code in the grammar file, you are likely to run into trouble.

The Parser Function `yyparse`

You call the function `yyparse` to cause parsing to occur. This function reads tokens, executes actions, and ultimately returns when it encounters end-of-input or an unrecoverable syntax error. You can also write an action which directs `yyparse` to return immediately without reading further.

The value returned by `yyparse` is 0 if parsing was successful (return is due to end-of-input).

The value is 1 if parsing failed (return is due to a syntax error).

In an action, you can cause immediate return from `yyparse` by using these macros:

`YYACCEPT`

Return immediately with value 0 (to report success).

`YYABORT`

Return immediately with value 1 (to report failure).

The Lexical Analyzer Function `yylex`

The lexical analyzer function, `yylex`, recognizes tokens from the input stream and returns them to the parser. Bison does not create this function automatically; you must write it so that `yyparse` can call it. The function is sometimes referred to as a lexical scanner.

In simple programs, `yylex` is often defined at the end of the Bison grammar file. If `yylex` is defined in a separate source file, you need to arrange for the token-type macro definitions to be available there. To do this, use the `-d' option when you run Bison, so that it will write these macro definitions into a separate header file `name.tab.h' which you can include in the other source files that need it. See section Invoking Bison.

Calling Convention for `yylex`

The value that `yylex` returns must be the numeric code for the type of token it has just found, or 0 for end-of-input.

When a token is referred to in the grammar rules by a name, that name in the parser file becomes a C macro whose definition is the proper numeric code for that token type. So `yylex` can use the name to indicate that type. See section Symbols, Terminal and Nonterminal.

When a token is referred to in the grammar rules by a character literal, the numeric code for that character is the code for the token type. So `yylex` can simply return that character code. The null character must not be this way, because its code is zero and that is what signifies end-of-input.

Here is an example showing these things:

```
yylex ()
{
  ...
  if (c == EOF)     /* Detect end of file. */
    return 0;
  ...
  if (c == '+' || c == '-')
    return c;      /* Assume token type for `+' is '+'. */
  ...
  return INT;      /* Return the type of the token. */
  ...
}
```

This interface has been designed so that the output from the `lex` utility can be used without change as the definition of `yylex`.

If the grammar uses literal string tokens, there are two ways that `yylex` can determine the token type codes for them:

- If the grammar defines symbolic token names as aliases for the literal string tokens, `yylex` can use these symbolic names like all others. In this case, the use of the literal string tokens in the grammar file has no effect on `yylex`.
- `yylex` can find the multi-character token in the `yytname` table. The index of the token in the table is the token type's code. The name of a multi-character token is recorded in `yytname` with a double-quote, the token's characters, and another double-quote. The token's characters are not escaped in any way; they appear verbatim in the contents of the string in the table.

  Here's code for looking up a token in `yytname`, assuming that the characters of the token are stored in `token_buffer`.

  ```
  for (i = 0; i < YYNTOKENS; i++)
    {
      if (yytname[i] != 0
          && yytname[i][0] == '"'
          && strncmp (yytname[i] + 1, token_buffer, strlen (token_buffer))
          && yytname[i][strlen (token_buffer) + 1] == '"'
          && yytname[i][strlen (token_buffer) + 2] == 0)
        break;
    }
  ```

  The `yytname` table is generated only if you use the `%token_table` declaration. See section Bison Declaration Summary.

Semantic Values of Tokens

In an ordinary (nonreentrant) parser, the semantic value of the token must be stored into the global variable `yylval`. When you are using just one data type for semantic values, `yylval` has that type. Thus, if the type is `int` (the default), you might write this in `yylex`:

```
  ...
  yylval = value;  /* Put value onto Bison stack. */
  return INT;      /* Return the type of the token. */
  ...
```

When you are using multiple data types, `yylval`'s type is a union made from the `%union` declaration (see section The Collection of Value Types). So when you store a token's value, you must use the proper member of the union. If the `%union` declaration looks like this:

```
%union {
  int intval;
  double val;
  symrec *tptr;
}
```

then the code in `yylex` might look like this:

```
  ...
  yylval.intval = value; /* Put value onto Bison stack. */
  return INT;          /* Return the type of the token. */
  ...
```

Textual Positions of Tokens

If you are using the `@n'-feature (see section Special Features for Use in Actions) in actions to keep track of the textual locations of tokens and groupings, then you must provide this information in `yylex`. The function `yyparse` expects to find the textual location of a token just parsed in the global variable `yylloc`. So `yylex` must store the proper data in that variable. The value of `yylloc` is a structure and you need only initialize the members that are going to be used by the actions. The four members are called `first_line`, `first_column`, `last_line` and `last_column`. Note that the use of this feature makes the parser noticeably slower.

The data type of `yylloc` has the name `YYLTYPE`.

Calling Conventions for Pure Parsers

When you use the Bison declaration `%pure_parser` to request a pure, reentrant parser, the global communication variables `yylval` and `yylloc` cannot be used. (See section A Pure (Reentrant) Parser.) In such parsers the two global variables are replaced by pointers passed as arguments to `yylex`. You must declare them as shown here, and pass the information back by storing it through those pointers.

```
yylex (lvalp, llocp)
     YYSTYPE *lvalp;
```

```
     YYLTYPE *llocp;
{
  ...
  *lvalp = value;  /* Put value onto Bison stack.  */
  return INT;      /* Return the type of the token.  */
  ...
}
```

If the grammar file does not use the `@' constructs to refer to textual positions, then the type `YYLTYPE' will not be defined. In this case, omit the second argument; `yylex' will be called with only one argument.

If you use a reentrant parser, you can optionally pass additional parameter information to it in a reentrant way. To do so, define the macro `YYPARSE_PARAM' as a variable name. This modifies the `yyparse' function to accept one argument, of type `void *', with that name.

When you call `yyparse', pass the address of an object, casting the address to `void *'. The grammar actions can refer to the contents of the object by casting the pointer value back to its proper type and then dereferencing it. Here's an example. Write this in the parser:

```
%{
struct parser_control
{
  int nastiness;
  int randomness;
};

#define YYPARSE_PARAM parm
%}
```

Then call the parser like this:

```
struct parser_control
{
  int nastiness;
  int randomness;
};

...

{
  struct parser_control foo;
  ...  /* Store proper data in foo.  */
  value = yyparse ((void *) &foo);
  ...
}
```

In the grammar actions, use expressions like this to refer to the data:

```
((struct parser_control *) parm)->randomness
```

If you wish to pass the additional parameter data to `yylex', define the macro `YYLEX_PARAM' just like

YYPARSE_PARAM, as shown here:

```
%{
struct parser_control
{
  int nastiness;
  int randomness;
};

#define YYPARSE_PARAM parm
#define YYLEX_PARAM parm
%}
```

You should then define `yylex` to accept one additional argument--the value of `parm`. (This makes either two or three arguments in total, depending on whether an argument of type YYLTYPE is passed.) You can declare the argument as a pointer to the proper object type, or you can declare it as `void *` and access the contents as shown above.

You can use `%pure_parser' to request a reentrant parser without also using YYPARSE_PARAM. Then you should call `yyparse` with no arguments, as usual.

The Error Reporting Function `yyerror`

The Bison parser detects a parse error or syntax error whenever it reads a token which cannot satisfy any syntax rule. A action in the grammar can also explicitly proclaim an error, using the macro YYERROR (see section Special Features for Use in Actions).

The Bison parser expects to report the error by calling an error reporting function named `yyerror`, which you must supply. It is called by `yyparse` whenever a syntax error is found, and it receives one argument. For a parse error, the string is normally `"parse error"`.

If you define the macro YYERROR_VERBOSE in the Bison declarations section (see section The Bison Declarations Section), then Bison provides a more verbose and specific error message string instead of just plain `"parse error"`. It doesn't matter what definition you use for YYERROR_VERBOSE, just whether you define it.

The parser can detect one other kind of error: stack overflow. This happens when the input contains constructions that are very deeply nested. It isn't likely you will encounter this, since the Bison parser extends its stack automatically up to a very large limit. But if overflow happens, `yyparse` calls `yyerror` in the usual fashion, except that the argument string is `"parser stack overflow"`.

The following definition suffices in simple programs:

```
yyerror (s)
     char *s;
{
  fprintf (stderr, "%s\n", s);
}
```

After `yyerror` returns to `yyparse`, the latter will attempt error recovery if you have written suitable error

recovery grammar rules (see section Error Recovery). If recovery is impossible, `yyparse` will immediately return 1.

The variable `yynerrs` contains the number of syntax errors encountered so far. Normally this variable is global; but if you request a pure parser (see section A Pure (Reentrant) Parser) then it is a local variable which only the actions can access.

Special Features for Use in Actions

Here is a table of Bison constructs, variables and macros that are useful in actions.

`$$'

Acts like a variable that contains the semantic value for the grouping made by the current rule. See section Actions.

`$n'

Acts like a variable that contains the semantic value for the nth component of the current rule. See section Actions.

`$<typealt>$'

Like `$$` but specifies alternative typealt in the union specified by the `%union` declaration. See section Data Types of Values in Actions.

`$<typealt>n'

Like `$n` but specifies alternative typealt in the union specified by the `%union` declaration. See section Data Types of Values in Actions.

`YYABORT;'

Return immediately from `yyparse`, indicating failure. See section The Parser Function `yyparse`.

`YYACCEPT;'

Return immediately from `yyparse`, indicating success. See section The Parser Function `yyparse`.

`YYBACKUP (token, value);'

Unshift a token. This macro is allowed only for rules that reduce a single value, and only when there is no look-ahead token. It installs a look-ahead token with token type token and semantic value value; then it discards the value that was going to be reduced by this rule.

If the macro is used when it is not valid, such as when there is a look-ahead token already, then it reports a syntax error with a message `cannot back up' and performs ordinary error recovery.

In either case, the rest of the action is not executed.

`YYEMPTY'

Value stored in `yychar` when there is no look-ahead token.

`YYERROR;'

Cause an immediate syntax error. This statement initiates error recovery just as if the parser itself had detected an error; however, it does not call `yyerror`, and does not print any message. If you want to print an error message, call `yyerror` explicitly before the `YYERROR;' statement. See section Error Recovery.

`YYRECOVERING'

This macro stands for an expression that has the value 1 when the parser is recovering from a syntax error,

and 0 the rest of the time. See section Error Recovery.

`yychar'

Variable containing the current look-ahead token. (In a pure parser, this is actually a local variable within `yyparse`.) When there is no look-ahead token, the value `YYEMPTY` is stored in the variable. See section Look-Ahead Tokens.

`yyclearin;'

Discard the current look-ahead token. This is useful primarily in error rules. See section Error Recovery.

`yyerrok;'

Resume generating error messages immediately for subsequent syntax errors. This is useful primarily in error rules. See section Error Recovery.

`@n'

Acts like a structure variable containing information on the line numbers and column numbers of the nth component of the current rule. The structure has four members, like this:

```
struct {
  int first_line, last_line;
  int first_column, last_column;
};
```

Thus, to get the starting line number of the third component, use `@3.first_line'.

In order for the members of this structure to contain valid information, you must make `yylex` supply this information about each token. If you need only certain members, then `yylex` need only fill in those members.

The use of this feature makes the parser noticeably slower.

Go to the previous, next section.

Go to the previous, next section.

The Bison Parser Algorithm

As Bison reads tokens, it pushes them onto a stack along with their semantic values. The stack is called the parser stack. Pushing a token is traditionally called shifting.

For example, suppose the infix calculator has read `1 + 5 *', with a `3' to come. The stack will have four elements, one for each token that was shifted.

But the stack does not always have an element for each token read. When the last n tokens and groupings shifted match the components of a grammar rule, they can be combined according to that rule. This is called reduction. Those tokens and groupings are replaced on the stack by a single grouping whose symbol is the result (left hand side) of that rule. Running the rule's action is part of the process of reduction, because this is what computes the semantic value of the resulting grouping.

For example, if the infix calculator's parser stack contains this:

```
1 + 5 * 3
```

and the next input token is a newline character, then the last three elements can be reduced to 15 via the rule:

```
expr: expr '*' expr;
```

Then the stack contains just these three elements:

```
1 + 15
```

At this point, another reduction can be made, resulting in the single value 16. Then the newline token can be shifted.

The parser tries, by shifts and reductions, to reduce the entire input down to a single grouping whose symbol is the grammar's start-symbol (see section Languages and Context-Free Grammars).

This kind of parser is known in the literature as a bottom-up parser.

Look-Ahead Tokens

The Bison parser does *not* always reduce immediately as soon as the last n tokens and groupings match a rule. This is because such a simple strategy is inadequate to handle most languages. Instead, when a reduction is possible, the parser sometimes "looks ahead" at the next token in order to decide what to do.

When a token is read, it is not immediately shifted; first it becomes the look-ahead token, which is not on the stack. Now the parser can perform one or more reductions of tokens and groupings on the stack, while the look-ahead token remains off to the side. When no more reductions should take place, the

look-ahead token is shifted onto the stack. This does not mean that all possible reductions have been done; depending on the token type of the look-ahead token, some rules may choose to delay their application.

Here is a simple case where look-ahead is needed. These three rules define expressions which contain binary addition operators and postfix unary factorial operators (`!'), and allow parentheses for grouping.

```
expr:     term '+' expr
        | term
        ;

term:     '(' expr ')'
        | term '!'
        | NUMBER
        ;
```

Suppose that the tokens `1 + 2' have been read and shifted; what should be done? If the following token is `)', then the first three tokens must be reduced to form an `expr`. This is the only valid course, because shifting the `)' would produce a sequence of symbols `term ')'`, and no rule allows this.

If the following token is `!', then it must be shifted immediately so that `2 !' can be reduced to make a `term`. If instead the parser were to reduce before shifting, `1 + 2' would become an `expr`. It would then be impossible to shift the `!' because doing so would produce on the stack the sequence of symbols `expr '!'`. No rule allows that sequence.

The current look-ahead token is stored in the variable `yychar`. See section Special Features for Use in Actions.

Shift/Reduce Conflicts

Suppose we are parsing a language which has if-then and if-then-else statements, with a pair of rules like this:

```
if_stmt:
          IF expr THEN stmt
        | IF expr THEN stmt ELSE stmt
        ;
```

Here we assume that `IF`, `THEN` and `ELSE` are terminal symbols for specific keyword tokens.

When the `ELSE` token is read and becomes the look-ahead token, the contents of the stack (assuming the input is valid) are just right for reduction by the first rule. But it is also legitimate to shift the `ELSE`, because that would lead to eventual reduction by the second rule.

This situation, where either a shift or a reduction would be valid, is called a shift/reduce conflict. Bison is designed to resolve these conflicts by choosing to shift, unless otherwise directed by operator precedence declarations. To see the reason for this, let's contrast it with the other alternative.

Since the parser prefers to shift the `ELSE`, the result is to attach the else-clause to the innermost if-statement, making these two inputs equivalent:

```
if x then if y then win (); else lose;

if x then do; if y then win (); else lose; end;
```

But if the parser chose to reduce when possible rather than shift, the result would be to attach the else-clause to the outermost if-statement, making these two inputs equivalent:

```
if x then if y then win (); else lose;

if x then do; if y then win (); end; else lose;
```

The conflict exists because the grammar as written is ambiguous: either parsing of the simple nested if-statement is legitimate. The established convention is that these ambiguities are resolved by attaching the else-clause to the innermost if-statement; this is what Bison accomplishes by choosing to shift rather than reduce. (It would ideally be cleaner to write an unambiguous grammar, but that is very hard to do in this case.) This particular ambiguity was first encountered in the specifications of Algol 60 and is called the "dangling `else`" ambiguity.

To avoid warnings from Bison about predictable, legitimate shift/reduce conflicts, use the `%expect n` declaration. There will be no warning as long as the number of shift/reduce conflicts is exactly n. See section Suppressing Conflict Warnings.

The definition of `if_stmt` above is solely to blame for the conflict, but the conflict does not actually appear without additional rules. Here is a complete Bison input file that actually manifests the conflict:

```
%token IF THEN ELSE variable
%%
stmt:     expr
        | if_stmt
        ;

if_stmt:
          IF expr THEN stmt
        | IF expr THEN stmt ELSE stmt
        ;

expr:     variable
        ;
```

Operator Precedence

Another situation where shift/reduce conflicts appear is in arithmetic expressions. Here shifting is not always the preferred resolution; the Bison declarations for operator precedence allow you to specify when to shift and when to reduce.

When Precedence is Needed

Consider the following ambiguous grammar fragment (ambiguous because the input `1 - 2 * 3' can be parsed in two different ways):

```
expr:     expr '-' expr
        | expr '*' expr
        | expr '<' expr
        | '(' expr ')'
        ...
        ;
```

Suppose the parser has seen the tokens `1', `-' and `2'; should it reduce them via the rule for the addition operator? It depends on the next token. Of course, if the next token is `)', we must reduce; shifting is invalid because no single rule can reduce the token sequence `- 2 )' or anything starting with that. But if the next token is `*' or `<', we have a choice: either shifting or reduction would allow the parse to complete, but with different results.

To decide which one Bison should do, we must consider the results. If the next operator token op is shifted, then it must be reduced first in order to permit another opportunity to reduce the sum. The result is (in effect) `1 - (2 op 3)'. On the other hand, if the subtraction is reduced before shifting op, the result is `(1 - 2) op 3'. Clearly, then, the choice of shift or reduce should depend on the relative precedence of the operators `-' and op: `*' should be shifted first, but not `<'.

What about input such as `1 - 2 - 5'; should this be `(1 - 2) - 5' or should it be `1 - (2 - 5)'? For most operators we prefer the former, which is called left association. The latter alternative, right association, is desirable for assignment operators. The choice of left or right association is a matter of whether the parser chooses to shift or reduce when the stack contains `1 - 2' and the look-ahead token is `-': shifting makes right-associativity.

Specifying Operator Precedence

Bison allows you to specify these choices with the operator precedence declarations `%left` and `%right`. Each such declaration contains a list of tokens, which are operators whose precedence and associativity is being declared. The `%left` declaration makes all those operators left-associative and the `%right` declaration makes them right-associative. A third alternative is `%nonassoc`, which declares that it is a syntax error to find the same operator twice "in a row".

The relative precedence of different operators is controlled by the order in which they are declared. The first `%left` or `%right` declaration in the file declares the operators whose precedence is lowest, the

next such declaration declares the operators whose precedence is a little higher, and so on.

Precedence Examples

In our example, we would want the following declarations:

```
%left '<'
%left '-'
%left '*'
```

In a more complete example, which supports other operators as well, we would declare them in groups of equal precedence. For example, `'+'` is declared with `'-'`:

```
%left '<' '>' '=' NE LE GE
%left '+' '-'
%left '*' '/'
```

(Here `NE` and so on stand for the operators for "not equal" and so on. We assume that these tokens are more than one character long and therefore are represented by names, not character literals.)

How Precedence Works

The first effect of the precedence declarations is to assign precedence levels to the terminal symbols declared. The second effect is to assign precedence levels to certain rules: each rule gets its precedence from the last terminal symbol mentioned in the components. (You can also specify explicitly the precedence of a rule. See section Context-Dependent Precedence.)

Finally, the resolution of conflicts works by comparing the precedence of the rule being considered with that of the look-ahead token. If the token's precedence is higher, the choice is to shift. If the rule's precedence is higher, the choice is to reduce. If they have equal precedence, the choice is made based on the associativity of that precedence level. The verbose output file made by `-v' (see section Invoking Bison) says how each conflict was resolved.

Not all rules and not all tokens have precedence. If either the rule or the look-ahead token has no precedence, then the default is to shift.

Context-Dependent Precedence

Often the precedence of an operator depends on the context. This sounds outlandish at first, but it is really very common. For example, a minus sign typically has a very high precedence as a unary operator, and a somewhat lower precedence (lower than multiplication) as a binary operator.

The Bison precedence declarations, `%left`, `%right` and `%nonassoc`, can only be used once for a given token; so a token has only one precedence declared in this way. For context-dependent precedence, you need to use an additional mechanism: the `%prec` modifier for rules.

The `%prec` modifier declares the precedence of a particular rule by specifying a terminal symbol wh precedence should be used for that rule. It's not necessary for that symbol to appear otherwise in the The modifier's syntax is:

```
%prec terminal-symbol
```

and it is written after the components of the rule. Its effect is to assign the rule the precedence of terminal-symbol, overriding the precedence that would be deduced for it in the ordinary way. The altered rule precedence then affects how conflicts involving that rule are resolved (see section Operator Precedence).

Here is how `%prec` solves the problem of unary minus. First, declare a precedence for a fictitious terminal symbol named `UMINUS`. There are no tokens of this type, but the symbol serves to stand for its precedence:

```
...
%left '+' '-'
%left '*'
%left UMINUS
```

Now the precedence of `UMINUS` can be used in specific rules:

```
exp:    ...
        | exp '-' exp
        ...
        | '-' exp %prec UMINUS
```

Parser States

The function `yyparse` is implemented using a finite-state machine. The values pushed on the parser stack are not simply token type codes; they represent the entire sequence of terminal and nonterminal symbols at or near the top of the stack. The current state collects all the information about previous input which is relevant to deciding what to do next.

Each time a look-ahead token is read, the current parser state together with the type of look-ahead token are looked up in a table. This table entry can say, "Shift the look-ahead token." In this case, it also specifies the new parser state, which is pushed onto the top of the parser stack. Or it can say, "Reduce using rule number n." This means that a certain number of tokens or groupings are taken off the top of the stack, and replaced by one grouping. In other words, that number of states are popped from the stack, and one new state is pushed.

There is one other alternative: the table can say that the look-ahead token is erroneous in the current state. This causes error processing to begin (see section Error Recovery).

Reduce/Reduce Conflicts

A reduce/reduce conflict occurs if there are two or more rules that apply to the same sequence of input. This usually indicates a serious error in the grammar.

For example, here is an erroneous attempt to define a sequence of zero or more `word` groupings.

```
sequence: /* empty */
                { printf ("empty sequence\n"); }
        | maybeword
        | sequence word
                { printf ("added word %s\n", $2); }
        ;

maybeword: /* empty */
                { printf ("empty maybeword\n"); }
        | word
                { printf ("single word %s\n", $1); }
        ;
```

The error is an ambiguity: there is more than one way to parse a single `word` into a `sequence`. It could be reduced to a `maybeword` and then into a `sequence` via the second rule. Alternatively, nothing-at-all could be reduced into a `sequence` via the first rule, and this could be combined with the `word` using the third rule for `sequence`.

There is also more than one way to reduce nothing-at-all into a `sequence`. This can be done directly via the first rule, or indirectly via `maybeword` and then the second rule.

You might think that this is a distinction without a difference, because it does not change whether any particular input is valid or not. But it does affect which actions are run. One parsing order runs the second rule's action; the other runs the first rule's action and the third rule's action. In this example, the output of the program changes.

Bison resolves a reduce/reduce conflict by choosing to use the rule that appears first in the grammar, but it is very risky to rely on this. Every reduce/reduce conflict must be studied and usually eliminated. Here is the proper way to define `sequence`:

```
sequence: /* empty */
                { printf ("empty sequence\n"); }
        | sequence word
                { printf ("added word %s\n", $2); }
        ;
```

Here is another common error that yields a reduce/reduce conflict:

```
sequence: /* empty */
```

```
        | sequence words
        | sequence redirects
        ;

words:    /* empty */
        | words word
        ;

redirects:/* empty */
        | redirects redirect
        ;
```

The intention here is to define a sequence which can contain either `word` or `redirect` groupings. The individual definitions of `sequence`, `words` and `redirects` are error-free, but the three together make a subtle ambiguity: even an empty input can be parsed in infinitely many ways!

Consider: nothing-at-all could be a `words`. Or it could be two `words` in a row, or three, or any number. It could equally well be a `redirects`, or two, or any number. Or it could be a `words` followed by three `redirects` and another `words`. And so on.

Here are two ways to correct these rules. First, to make it a single level of sequence:

```
sequence: /* empty */
        | sequence word
        | sequence redirect
        ;
```

Second, to prevent either a `words` or a `redirects` from being empty:

```
sequence: /* empty */
        | sequence words
        | sequence redirects
        ;

words:    word
        | words word
        ;

redirects:redirect
        | redirects redirect
        ;
```

Mysterious Reduce/Reduce Conflicts

Sometimes reduce/reduce conflicts can occur that don't look warranted. Here is an example:

```
%token ID

%%
def:    param_spec return_spec ','
        ;
param_spec:
                type
        |       name_list ':' type
        ;
return_spec:
                type
        |       name ':' type
        ;
type:           ID
        ;
name:           ID
        ;
name_list:
                name
        |       name ',' name_list
        ;
```

It would seem that this grammar can be parsed with only a single token of look-ahead: when a `param_spec` is being read, an `ID` is a `name` if a comma or colon follows, or a `type` if another `ID` follows. In other words, this grammar is LR(1).

However, Bison, like most parser generators, cannot actually handle all LR(1) grammars. In this grammar, two contexts, that after an `ID` at the beginning of a `param_spec` and likewise at the beginning of a `return_spec`, are similar enough that Bison assumes they are the same. They appear similar because the same set of rules would be active--the rule for reducing to a `name` and that for reducing to a `type`. Bison is unable to determine at that stage of processing that the rules would require different look-ahead tokens in the two contexts, so it makes a single parser state for them both. Combining the two contexts causes a conflict later. In parser terminology, this occurrence means that the grammar is not LALR(1).

In general, it is better to fix deficiencies than to document them. But this particular deficiency is intrinsically hard to fix; parser generators that can handle LR(1) grammars are hard to write and tend to produce parsers that are very large. In practice, Bison is more useful as it is now.

When the problem arises, you can often fix it by identifying the two parser states that are being confused, and adding something to make them look distinct. In the above example, adding one rule to `return_spec` as follows makes the problem go away:

```
%token BOGUS
...
%%
...
return_spec:
          type
        |    name ':' type
        /* This rule is never used.  */
        |    ID BOGUS
        ;
```

This corrects the problem because it introduces the possibility of an additional active rule in the context after the `ID` at the beginning of `return_spec`. This rule is not active in the corresponding context in a `param_spec`, so the two contexts receive distinct parser states. As long as the token `BOGUS` is never generated by `yylex`, the added rule cannot alter the way actual input is parsed.

In this particular example, there is another way to solve the problem: rewrite the rule for `return_spec` to use `ID` directly instead of via `name`. This also causes the two confusing contexts to have different sets of active rules, because the one for `return_spec` activates the altered rule for `return_spec` rather than the one for `name`.

```
param_spec:
          type
        |    name_list ':' type
        ;
return_spec:
          type
        |    ID ':' type
        ;
```

Stack Overflow, and How to Avoid It

The Bison parser stack can overflow if too many tokens are shifted and not reduced. When this happens, the parser function `yyparse` returns a nonzero value, pausing only to call `yyerror` to report the overflow.

By defining the macro `YYMAXDEPTH`, you can control how deep the parser stack can become before a stack overflow occurs. Define the macro with a value that is an integer. This value is the maximum number of tokens that can be shifted (and not reduced) before overflow. It must be a constant expression whose value is known at compile time.

The stack space allowed is not necessarily allocated. If you specify a large value for `YYMAXDEPTH`, the parser actually allocates a small stack at first, and then makes it bigger by stages as needed. This increasing allocation happens automatically and silently. Therefore, you do not need to make `YYMAXDEPTH` painfully small merely to save space for ordinary inputs that do not need much stack.

The default value of YYMAXDEPTH, if you do not define it, is 10000.

You can control how much stack is allocated initially by defining the macro YYINITDEPTH. This value too must be a compile-time constant integer. The default is 200.

Go to the previous, next section.

Go to the previous, next section.

Error Recovery

It is not usually acceptable to have a program terminate on a parse error. For example, a compiler should recover sufficiently to parse the rest of the input file and check it for errors; a calculator should accept another expression.

In a simple interactive command parser where each input is one line, it may be sufficient to allow `yyparse` to return 1 on error and have the caller ignore the rest of the input line when that happens (and then call `yyparse` again). But this is inadequate for a compiler, because it forgets all the syntactic context leading up to the error. A syntax error deep within a function in the compiler input should not cause the compiler to treat the following line like the beginning of a source file.

You can define how to recover from a syntax error by writing rules to recognize the special token `error`. This is a terminal symbol that is always defined (you need not declare it) and reserved for error handling. The Bison parser generates an `error` token whenever a syntax error happens; if you have provided a rule to recognize this token in the current context, the parse can continue.

For example:

```
stmnts:  /* empty string */
        | stmnts '\n'
        | stmnts exp '\n'
        | stmnts error '\n'
```

The fourth rule in this example says that an error followed by a newline makes a valid addition to any `stmnts`.

What happens if a syntax error occurs in the middle of an `exp`? The error recovery rule, interpreted strictly, applies to the precise sequence of a `stmnts`, an `error` and a newline. If an error occurs in the middle of an `exp`, there will probably be some additional tokens and subexpressions on the stack after the last `stmnts`, and there will be tokens to read before the next newline. So the rule is not applicable in the ordinary way.

But Bison can force the situation to fit the rule, by discarding part of the semantic context and part of the input. First it discards states and objects from the stack until it gets back to a state in which the `error` token is acceptable. (This means that the subexpressions already parsed are discarded, back to the last complete `stmnts`.) At this point the `error` token can be shifted. Then, if the old look-ahead token is not acceptable to be shifted next, the parser reads tokens and discards them until it finds a token which is acceptable. In this example, Bison reads and discards input until the next newline so that the fourth rule can apply.

The choice of error rules in the grammar is a choice of strategies for error recovery. A simple and useful strategy is simply to skip the rest of the current input line or current statement if an error is detected:

```
stmnt: error ';'  /* on error, skip until ';' is read */
```

It is also useful to recover to the matching close-delimiter of an opening-delimiter that has already been parsed. Otherwise the close-delimiter will probably appear to be unmatched, and generate another, spurious error message:

```
primary:  '(' expr ')'
        | '(' error ')'
        ...
        ;
```

Error recovery strategies are necessarily guesses. When they guess wrong, one syntax error often leads to another. In the above example, the error recovery rule guesses that an error is due to bad input within one `stmnt`. Suppose that instead a spurious semicolon is inserted in the middle of a valid `stmnt`. After the error recovery rule recovers from the first error, another syntax error will be found straightaway, since the text following the spurious semicolon is also an invalid `stmnt`.

To prevent an outpouring of error messages, the parser will output no error message for another syntax error that happens shortly after the first; only after three consecutive input tokens have been successfully shifted will error messages resume.

Note that rules which accept the `error` token may have actions, just as any other rules can.

You can make error messages resume immediately by using the macro `yyerrok` in an action. If you do this in the error rule's action, no error messages will be suppressed. This macro requires no arguments; `yyerrok;' is a valid C statement.

The previous look-ahead token is reanalyzed immediately after an error. If this is unacceptable, then the macro `yyclearin` may be used to clear this token. Write the statement `yyclearin;' in the error rule's action.

For example, suppose that on a parse error, an error handling routine is called that advances the input stream to some point where parsing should once again commence. The next symbol returned by the lexical scanner is probably correct. The previous look-ahead token ought to be discarded with `yyclearin;'.

The macro `YYRECOVERING` stands for an expression that has the value 1 when the parser is recovering from a syntax error, and 0 the rest of the time. A value of 1 indicates that error messages are currently suppressed for new syntax errors.

Go to the previous, next section.

Go to the previous, next section.

Handling Context Dependencies

The Bison paradigm is to parse tokens first, then group them into larger syntactic units. In many languages, the meaning of a token is affected by its context. Although this violates the Bison paradigm, certain techniques (known as kludges) may enable you to write Bison parsers for such languages.

(Actually, "kludge" means any technique that gets its job done but is neither clean nor robust.)

Semantic Info in Token Types

The C language has a context dependency: the way an identifier is used depends on what its current meaning is. For example, consider this:

```
foo (x);
```

This looks like a function call statement, but if `foo` is a typedef name, then this is actually a declaration of `x`. How can a Bison parser for C decide how to parse this input?

The method used in GNU C is to have two different token types, `IDENTIFIER` and `TYPENAME`. When `yylex` finds an identifier, it looks up the current declaration of the identifier in order to decide which token type to return: `TYPENAME` if the identifier is declared as a typedef, `IDENTIFIER` otherwise.

The grammar rules can then express the context dependency by the choice of token type to recognize. `IDENTIFIER` is accepted as an expression, but `TYPENAME` is not. `TYPENAME` can start a declaration, but `IDENTIFIER` cannot. In contexts where the meaning of the identifier is *not* significant, such as in declarations that can shadow a typedef name, either `TYPENAME` or `IDENTIFIER` is accepted--there is one rule for each of the two token types.

This technique is simple to use if the decision of which kinds of identifiers to allow is made at a place close to where the identifier is parsed. But in C this is not always so: C allows a declaration to redeclare a typedef name provided an explicit type has been specified earlier:

```
typedef int foo, bar, lose;
static foo (bar);        /* redeclare bar as static variable */
static int foo (lose);   /* redeclare foo as function */
```

Unfortunately, the name being declared is separated from the declaration construct itself by a complicated syntactic structure--the "declarator".

As a result, the part of Bison parser for C needs to be duplicated, with all the nonterminal names changed: once for parsing a declaration in which a typedef name can be redefined, and once for parsing a declaration in which that can't be done. Here is a part of the duplication, with actions omitted for brevity:

```
initdcl:
          declarator maybeasm '='
          init
        | declarator maybeasm
        ;

notype_initdcl:
          notype_declarator maybeasm '='
          init
        | notype_declarator maybeasm
        ;
```

Here `initdcl` can redeclare a typedef name, but `notype_initdcl` cannot. The distinction between `declarator` and `notype_declarator` is the same sort of thing.

There is some similarity between this technique and a lexical tie-in (described next), in that information which alters the lexical analysis is changed during parsing by other parts of the program. The difference is here the information is global, and is used for other purposes in the program. A true lexical tie-in has a special-purpose flag controlled by the syntactic context.

Lexical Tie-ins

One way to handle context-dependency is the lexical tie-in: a flag which is set by Bison actions, whose purpose is to alter the way tokens are parsed.

For example, suppose we have a language vaguely like C, but with a special construct `hex (hex-expr)'. After the keyword `hex` comes an expression in parentheses in which all integers are hexadecimal. In particular, the token `a1b' must be treated as an integer rather than as an identifier if it appears in that context. Here is how you can do it:

```
%{
int hexflag;
%}
%%
...
expr:   IDENTIFIER
        | constant
        | HEX '('
                { hexflag = 1; }
          expr ')'
                { hexflag = 0;
                   $$ = $4; }
        | expr '+' expr
                { $$ = make_sum ($1, $3); }
        ...
        ;
```

```
constant:
          INTEGER
        | STRING
        ;
```

Here we assume that `yylex` looks at the value of `hexflag`; when it is nonzero, all integers are parsed in hexadecimal, and tokens starting with letters are parsed as integers if possible.

The declaration of `hexflag` shown in the C declarations section of the parser file is needed to make it accessible to the actions (see section The C Declarations Section). You must also write the code in `yylex` to obey the flag.

Lexical Tie-ins and Error Recovery

Lexical tie-ins make strict demands on any error recovery rules you have. See section Error Recovery.

The reason for this is that the purpose of an error recovery rule is to abort the parsing of one construct and resume in some larger construct. For example, in C-like languages, a typical error recovery rule is to skip tokens until the next semicolon, and then start a new statement, like this:

```
stmt:   expr ';'
        | IF '(' expr ')' stmt { ... }
        ...
        error ';'
                { hexflag = 0; }
        ;
```

If there is a syntax error in the middle of a `hex (expr)' construct, this error rule will apply, and then the action for the completed `hex (expr)' will never run. So `hexflag` would remain set for the entire rest of the input, or until the next `hex` keyword, causing identifiers to be misinterpreted as integers.

To avoid this problem the error recovery rule itself clears `hexflag`.

There may also be an error recovery rule that works within expressions. For example, there could be a rule which applies within parentheses and skips to the close-parenthesis:

```
expr:   ...
        | '(' expr ')'
                { $$ = $2; }
        | '(' error ')'
        ...
```

If this rule acts within the `hex` construct, it is not going to abort that construct (since it applies to an inner level of parentheses within the construct). Therefore, it should not clear the flag: the rest of the `hex` construct should be parsed with the flag still in effect.

What if there is an error recovery rule which might abort out of the `hex` construct or might not, depending on circumstances? There is no way you can write the action to determine whether a `hex` construct is being aborted or not. So if you are using a lexical tie-in, you had better make sure your error recovery rules are not of this kind. Each rule must be such that you can be sure that it always will, or always won't, have to clear the flag.

Go to the previous, next section.

Go to the previous, next section.

Debugging Your Parser

If a Bison grammar compiles properly but doesn't do what you want when it runs, the `yydebug` parser-trace feature can help you figure out why.

To enable compilation of trace facilities, you must define the macro `YYDEBUG` when you compile the parser. You could use `-DYYDEBUG=1' as a compiler option or you could put `#define YYDEBUG 1' in the C declarations section of the grammar file (see section The C Declarations Section). Alternatively, use the `-t' option when you run Bison (see section Invoking Bison). We always define `YYDEBUG` so that debugging is always possible.

The trace facility uses `stderr`, so you must add `#include <stdio.h>` to the C declarations section unless it is already there.

Once you have compiled the program with trace facilities, the way to request a trace is to store a nonzero value in the variable `yydebug`. You can do this by making the C code do it (in `main`, perhaps), or you can alter the value with a C debugger.

Each step taken by the parser when `yydebug` is nonzero produces a line or two of trace information, written on `stderr`. The trace messages tell you these things:

- Each time the parser calls `yylex`, what kind of token was read.
- Each time a token is shifted, the depth and complete contents of the state stack (see section Parser States).
- Each time a rule is reduced, which rule it is, and the complete contents of the state stack afterward.

To make sense of this information, it helps to refer to the listing file produced by the Bison `-v' option (see section Invoking Bison). This file shows the meaning of each state in terms of positions in various rules, and also what each state will do with each possible input token. As you read the successive trace messages, you can see that the parser is functioning according to its specification in the listing file. Eventually you will arrive at the place where something undesirable happens, and you will see which parts of the grammar are to blame.

The parser file is a C program and you can use C debuggers on it, but it's not easy to interpret what it is doing. The parser function is a finite-state machine interpreter, and aside from the actions it executes the same code over and over. Only the values of variables show where in the grammar it is working.

The debugging information normally gives the token type of each token read, but not its semantic value. You can optionally define a macro named `YYPRINT` to provide a way to print the value. If you define `YYPRINT`, it should take three arguments. The parser will pass a standard I/O stream, the numeric code for the token type, and the token value (from `yylval`).

Here is an example of `YYPRINT` suitable for the multi-function calculator (see section Declarations for `mfcalc`):

```
#define YYPRINT(file, type, value)   yyprint (file, type, value)

static void
yyprint (file, type, value)
     FILE *file;
     int type;
     YYSTYPE value;
{
  if (type == VAR)
    fprintf (file, " %s", value.tptr->name);
  else if (type == NUM)
    fprintf (file, " %d", value.val);
}
```

Go to the previous, next section.

Go to the previous, next section.

Invoking Bison

The usual way to invoke Bison is as follows:

```
bison infile
```

Here infile is the grammar file name, which usually ends in `.y'. The parser file's name is made by replacing the `.y' with `.tab.c'. Thus, the `bison foo.y' filename yields `foo.tab.c', and the `bison hack/foo.y' filename yields `hack/foo.tab.c'.

Bison Options

Bison supports both traditional single-letter options and mnemonic long option names. Long option names are indicated with `--' instead of `-'. Abbreviations for option names are allowed as long as they are unique. When a long option takes an argument, like `--file-prefix', connect the option name and the argument with `='.

Here is a list of options that can be used with Bison, alphabetized by short option. It is followed by a cross key alphabetized by long option.

`-b file-prefix'

`--file-prefix=prefix'

> Specify a prefix to use for all Bison output file names. The names are chosen as if the input file were named `prefix.c'.

`-d'

`--defines'

> Write an extra output file containing macro definitions for the token type names defined in the grammar and the semantic value type YYSTYPE, as well as a few `extern` variable declarations.
>
> If the parser output file is named `name.c' then this file is named `name.h'.
>
> This output file is essential if you wish to put the definition of `yylex` in a separate source file, because `yylex` needs to be able to refer to token type codes and the variable `yylval`. See section Semantic Values of Tokens.

`-l'

`--no-lines'

> Don't put any `#line` preprocessor commands in the parser file. Ordinarily Bison puts them in the parser file so that the C compiler and debuggers will associate errors with your source file, the grammar file. This option causes them to associate errors with the parser file, treating it as an independent source file in its own right.

`-n'

`--no-parser'

Do not include any C code in the parser file; generate tables only. The parser file contains just `#define` directives and static variable declarations.

This option also tells Bison to write the C code for the grammar actions into a file named `` `filename.act' ``, in the form of a brace-surrounded body fit for a `switch` statement.

`-o outfile'

`--output-file=outfile'

Specify the name outfile for the parser file.

The other output files' names are constructed from outfile as described under the `-v' and `-d' options.

`-p prefix'

`--name-prefix=prefix'

Rename the external symbols used in the parser so that they start with prefix instead of `yy'. The precise list of symbols renamed is `yyparse`, `yylex`, `yyerror`, `yynerrs`, `yylval`, `yychar` and `yydebug`.

For example, if you use `-p c', the names become `cparse`, `clex`, and so on.

See section Multiple Parsers in the Same Program.

`-r'

`--raw'

Pretend that `%raw` was specified. See section Bison Declaration Summary.

`-t'

`--debug'

Output a definition of the macro `YYDEBUG` into the parser file, so that the debugging facilities are compiled. See section Debugging Your Parser.

`-v'

`--verbose'

Write an extra output file containing verbose descriptions of the parser states and what is done for each type of look-ahead token in that state.

This file also describes all the conflicts, both those resolved by operator precedence and the unresolved ones.

The file's name is made by removing `.tab.c' or `.c' from the parser output file name, and adding `.output' instead.

Therefore, if the input file is `` `foo.y' ``, then the parser file is called `` `foo.tab.c' `` by default. As a consequence, the verbose output file is called `` `foo.output' ``.

`-V'

`--version'

Print the version number of Bison and exit.

`-h'

`--help'

Print a summary of the command-line options to Bison and exit.

`-y'

`--yacc'

`--fixed-output-files'

Equivalent to `-o y.tab.c'; the parser output file is called `y.tab.c', and the other outputs are called `y.output' and `y.tab.h'. The purpose of this option is to imitate Yacc's output file name conventions. Thus, the following shell script can substitute for Yacc:

```
bison -y $*
```

Option Cross Key

Here is a list of options, alphabetized by long option, to help you find the corresponding short option.

Invoking Bison under VMS

The command line syntax for Bison on VMS is a variant of the usual Bison command syntax--adapted to fit VMS conventions.

To find the VMS equivalent for any Bison option, start with the long option, and substitute a `/' for the leading `--', and substitute a `_' for each `-' in the name of the long option. For example, the following invocation under VMS:

```
bison /debug/name_prefix=bar foo.y
```

is equivalent to the following command under POSIX.

```
bison --debug --name-prefix=bar foo.y
```

The VMS file system does not permit filenames such as `foo.tab.c'. In the above example, the output file would instead be named `foo_tab.c'.

Go to the previous, next section.

Go to the previous, next section.

Bison Symbols

`error`

A token name reserved for error recovery. This token may be used in grammar rules so as to allow the Bison parser to recognize an error in the grammar without halting the process. In effect, a sentence containing an error may be recognized as valid. On a parse error, the token `error` becomes the current look-ahead token. Actions corresponding to `error` are then executed, and the look-ahead token is reset to the token that originally caused the violation. See section Error Recovery.

`YYABORT`

Macro to pretend that an unrecoverable syntax error has occurred, by making `yyparse` return 1 immediately. The error reporting function `yyerror` is not called. See section The Parser Function `yyparse`.

`YYACCEPT`

Macro to pretend that a complete utterance of the language has been read, by making `yyparse` return 0 immediately. See section The Parser Function `yyparse`.

`YYBACKUP`

Macro to discard a value from the parser stack and fake a look-ahead token. See section Special Features for Use in Actions.

`YYERROR`

Macro to pretend that a syntax error has just been detected: call `yyerror` and then perform normal error recovery if possible (see section Error Recovery), or (if recovery is impossible) make `yyparse` return 1. See section Error Recovery.

`YYERROR_VERBOSE`

Macro that you define with `#define` in the Bison declarations section to request verbose, specific error message strings when `yyerror` is called.

`YYINITDEPTH`

Macro for specifying the initial size of the parser stack. See section Stack Overflow, and How to Avoid It.

`YYLEX_PARAM`

Macro for specifying an extra argument (or list of extra arguments) for `yyparse` to pass to `yylex`. See section Calling Conventions for Pure Parsers.

`YYLTYPE`

Macro for the data type of `yylloc`; a structure with four members. See section Textual Positions of Tokens.

`yyltype`

Default value for YYLTYPE.

`YYMAXDEPTH`

Macro for specifying the maximum size of the parser stack. See section Stack Overflow, and How to Avoid It.

`YYPARSE_PARAM`

Macro for specifying the name of a parameter that `yyparse` should accept. See section Calling Conventions for Pure Parsers.

`YYRECOVERING`

Macro whose value indicates whether the parser is recovering from a syntax error. See section Special Features for Use in Actions.

`YYSTYPE`

Macro for the data type of semantic values; `int` by default. See section Data Types of Semantic Values.

`yychar`

External integer variable that contains the integer value of the current look-ahead token. (In a pure parser, it is a local variable within `yyparse`.) Error-recovery rule actions may examine this variable. See section Special Features for Use in Actions.

`yyclearin`

Macro used in error-recovery rule actions. It clears the previous look-ahead token. See section Error Recovery.

`yydebug`

External integer variable set to zero by default. If `yydebug` is given a nonzero value, the parser will output information on input symbols and parser action. See section Debugging Your Parser.

`yyerrok`

Macro to cause parser to recover immediately to its normal mode after a parse error. See section Error Recovery.

`yyerror`

User-supplied function to be called by `yyparse` on error. The function receives one argument, a pointer to a character string containing an error message. See section The Error Reporting Function `yyerror`.

`yylex`

User-supplied lexical analyzer function, called with no arguments to get the next token. See section The Lexical Analyzer Function `yylex`.

`yylval`

External variable in which `yylex` should place the semantic value associated with a token. (In a pure parser, it is a local variable within `yyparse`, and its address is passed to `yylex`.) See section Semantic Values of Tokens.

`yylloc`

External variable in which `yylex` should place the line and column numbers associated with a token. (In a pure parser, it is a local variable within `yyparse`, and its address is passed to `yylex`.) You can ignore this variable if you don't use the `@' feature in the grammar actions. See section Textual Positions of Tokens.

`yynerrs`

Global variable which Bison increments each time there is a parse error. (In a pure parser, it is a local variable within `yyparse`.) See section The Error Reporting Function `yyerror`.

`yyparse`

The parser function produced by Bison; call this function to start parsing. See section The Parser Function `yyparse`.

`%left`

Bison declaration to assign left associativity to token(s). See section Operator Precedence.

`%no_lines`

Bison declaration to avoid generating `#line` directives in the parser file. See section Bison Declaration Summary.

`%nonassoc`

Bison declaration to assign nonassociativity to token(s). See section Operator Precedence.

`%prec`

Bison declaration to assign a precedence to a specific rule. See section Context-Dependent Precedence.

`%pure_parser`

Bison declaration to request a pure (reentrant) parser. See section A Pure (Reentrant) Parser.

`%raw`

Bison declaration to use Bison internal token code numbers in token tables instead of the usual Yacc-compatible token code numbers. See section Bison Declaration Summary.

`%right`

Bison declaration to assign right associativity to token(s). See section Operator Precedence.

`%start`

Bison declaration to specify the start symbol. See section The Start-Symbol.

`%token`

Bison declaration to declare token(s) without specifying precedence. See section Token Type Names.

`%token_table`

Bison declaration to include a token name table in the parser file. See section Bison Declaration Summary.

`%type`

Bison declaration to declare nonterminals. See section Nonterminal Symbols.

`%union`

Bison declaration to specify several possible data types for semantic values. See section The Collection of Value Types.

These are the punctuation and delimiters used in Bison input:

`%%'

Delimiter used to separate the grammar rule section from the Bison declarations section or the additional C code section. See section The Overall Layout of a Bison Grammar.

`%{ %}'

All code listed between `%{' and `%}' is copied directly to the output file uninterpreted. Such code forms the "C declarations" section of the input file. See section Outline of a Bison Grammar.

`/*...*/'

Comment delimiters, as in C.

`:'

Separates a rule's result from its components. See section Syntax of Grammar Rules.

`;'

Terminates a rule. See section Syntax of Grammar Rules.

`|'

Separates alternate rules for the same result nonterminal. See section Syntax of Grammar Rules.

Go to the previous, next section.

TOC

Glossary

Backus-Naur Form (BNF)

Formal method of specifying context-free grammars. BNF was first used in the ALGOL-60 report, 1963. See section Languages and Context-Free Grammars.

Context-free grammars

Grammars specified as rules that can be applied regardless of context. Thus, if there is a rule which says that an integer can be used as an expression, integers are allowed *anywhere* an expression is permitted. See section Languages and Context-Free Grammars.

Dynamic allocation

Allocation of memory that occurs during execution, rather than at compile time or on entry to a function.

Empty string

Analogous to the empty set in set theory, the empty string is a character string of length zero.

Finite-state stack machine

A "machine" that has discrete states in which it is said to exist at each instant in time. As input to the machine is processed, the machine moves from state to state as specified by the logic of the machine. In the case of the parser, the input is the language being parsed, and the states correspond to various stages in the grammar rules. See section The Bison Parser Algorithm.

Grouping

A language construct that is (in general) grammatically divisible; for example, `expression' or `declaration' in C. See section Languages and Context-Free Grammars.

Infix operator

An arithmetic operator that is placed between the operands on which it performs some operation.

Input stream

A continuous flow of data between devices or programs.

Language construct

One of the typical usage schemas of the language. For example, one of the constructs of the C language is the `if` statement. See section Languages and Context-Free Grammars.

Left associativity

Operators having left associativity are analyzed from left to right: `a+b+c' first computes `a+b' and then combines with `c'. See section Operator Precedence.

Left recursion

A rule whose result symbol is also its first component symbol; for example, `expseq1 : expseq1 ',' exp;'. See section Recursive Rules.

Left-to-right parsing

Parsing a sentence of a language by analyzing it token by token from left to right. See section Bison Parser Algorithm.

Lexical analyzer (scanner)

A function that reads an input stream and returns tokens one by one. See section The Lexical Analyzer Function `yylex`.

Lexical tie-in

A flag, set by actions in the grammar rules, which alters the way tokens are parsed. See section Lexical Tie-ins.

Literal string token

A token which constists of two or more fixed characters. See section Symbols, Terminal and Nonterminal.

Look-ahead token

A token already read but not yet shifted. See section Look-Ahead Tokens.

LALR(1)

The class of context-free grammars that Bison (like most other parser generators) can handle; a subset of LR(1). See section Mysterious Reduce/Reduce Conflicts.

LR(1)

The class of context-free grammars in which at most one token of look-ahead is needed to disambiguate the parsing of any piece of input.

Nonterminal symbol

A grammar symbol standing for a grammatical construct that can be expressed through rules in terms of smaller constructs; in other words, a construct that is not a token. See section Symbols, Terminal and Nonterminal.

Parse error

An error encountered during parsing of an input stream due to invalid syntax. See section Error Recovery.

Parser

A function that recognizes valid sentences of a language by analyzing the syntax structure of a set of tokens passed to it from a lexical analyzer.

Postfix operator

An arithmetic operator that is placed after the operands upon which it performs some operation.

Reduction

Replacing a string of nonterminals and/or terminals with a single nonterminal, according to a grammar rule. See section The Bison Parser Algorithm.

Reentrant

A reentrant subprogram is a subprogram which can be in invoked any number of times in parallel, without interference between the various invocations. See section A Pure (Reentrant) Parser.

Reverse polish notation

A language in which all operators are postfix operators.

Right recursion

A rule whose result symbol is also its last component symbol; for example, `expseq1: exp ',' expseq1;'. See section Recursive Rules.

Semantics

In computer languages, the semantics are specified by the actions taken for each instance of the language, i.e., the meaning of each statement. See section Defining Language Semantics.

Shift

A parser is said to shift when it makes the choice of analyzing further input from the stream rather than reducing immediately some already-recognized rule. See section The Bison Parser Algorithm.

Single-character literal

A single character that is recognized and interpreted as is. See section From Formal Rules to Bison Input.

Start symbol

The nonterminal symbol that stands for a complete valid utterance in the language being parsed. The start symbol is usually listed as the first nonterminal symbol in a language specification. See section The Start-Symbol.

Symbol table

A data structure where symbol names and associated data are stored during parsing to allow for recognition and use of existing information in repeated uses of a symbol. See section Multi-Function Calculator: `mfcalc`.

Token

A basic, grammatically indivisible unit of a language. The symbol that describes a token in the grammar is a terminal symbol. The input of the Bison parser is a stream of tokens which comes from the lexical analyzer. See section Symbols, Terminal and Nonterminal.

Terminal symbol

A grammar symbol that has no rules in the grammar and therefore is grammatically indivisible. The piece of text it represents is a token. See section Languages and Context-Free Grammars.

GNU GENERAL PUBLIC LICENSE

Version 1, February 1989

Preamble

The license agreements of most software companies try to keep users at the mercy of those companies. By contrast, our General Public License is intended to guarantee your freedom to share and change free software--to make sure the software is free for all its users. The General Public License applies to the Free Software Foundation's software and to any other program whose authors commit to using it. You can use it for your programs, too.

When we speak of free software, we are referring to freedom, not price. Specifically, the General Public License is designed to make sure that you have the freedom to give away or sell copies of free software, that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of a such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must tell them their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS

1. This License Agreement applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any work containing the Program or a portion of it, either verbatim or with modifications. Each licensee is addressed as "you".
2. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this General Public License and to the absence of any warranty; and give any other recipients of the Program a copy of this General Public License along with the Program. You may charge a fee for the physical act of transferring a copy.
3. You may modify your copy or copies of the Program or any portion of it, and copy and distribute such modifications under the terms of Paragraph 1 above, provided that you also do the following:
   - cause the modified files to carry prominent notices stating that you changed the files and the date of any change; and
   - cause the whole of any work that you distribute or publish, that in whole or in part contains the Program or any part thereof, either with or without modifications, to be licensed at no charge to all third parties under the terms of this General Public License (except that you may choose to grant warranty protection to some or all third parties, at your option).
   - If the modified program normally reads commands interactively when run, you must cause it, when started running for such interactive use in the simplest and most usual way, to print or display an announcement including an appropriate copyright notice and a notice that there is no warranty (or else, saying that you provide a warranty) and that users may redistribute the program under these conditions, and telling the user how to view a copy of this General Public License.
   - You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

   Mere aggregation of another independent work with the Program (or its derivative) on a volume of a storage or distribution medium does not bring the other work under the scope of these terms.
4. You may copy and distribute the Program (or a portion or derivative of it, under Paragraph 2) in object code or executable form under the terms of Paragraphs 1 and 2 above provided that you also do one of the following:
   - accompany it with the complete corresponding machine-readable source code, which must be distributed under the terms of Paragraphs 1 and 2 above; or,
   - accompany it with a written offer, valid for at least three years, to give any third party free (except for a nominal charge for the cost of distribution) a complete machine-readable copy of the corresponding source code, to be distributed under the terms of Paragraphs 1 and 2 above; or,
   - accompany it with the information you received as to where the corresponding source code may be obtained. (This alternative is allowed only for noncommercial distribution and only

if you received the program in object code or executable form alone.)

Source code for a work means the preferred form of the work for making modifications to it. For an executable file, complete source code means all the source code for all modules it contains, but, as a special exception, it need not include source code for modules which are standard libraries that accompany the operating system on which the executable file runs, or for standard header files or definitions files that accompany that operating system.

5. You may not copy, modify, sublicense, distribute or transfer the Program except as expressly provided under this General Public License. Any attempt otherwise to copy, modify, sublicense, distribute or transfer the Program is void, and will automatically terminate your rights to use the Program under this License. However, parties who have received copies, or rights to use copies, from you under this General Public License will not have their licenses terminated so long as such parties remain in full compliance.
6. By copying, distributing or modifying the Program (or any work based on the Program) you indicate your acceptance of this license to do so, and all its terms and conditions.
7. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein.
8. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

   Each version is given a distinguishing version number. If the Program specifies a version number of the license which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of the license, you may choose any version ever published by the Free Software Foundation.
9. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

NO WARRANTY

10. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS

WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.

11. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

Go to the next section.

Go to the previous, next section.

Getting Started

This chapter provides a general overview of Calc, the GNU Emacs Calculator: What it is, how to start it and how to exit from it, and what are the various ways that it can be used.

What is Calc?

Calc is an advanced calculator and mathematical tool that runs as part of the GNU Emacs environment. Very roughly based on the HP-28/48 series of calculators, its many features include:

- Choice of algebraic or RPN (stack-based) entry of calculations.
- Arbitrary precision integers and floating-point numbers.
- Arithmetic on rational numbers, complex numbers (rectangular and polar), error forms with standard deviations, open and closed intervals, vectors and matrices, dates and times, infinities, sets, quantities with units, and algebraic formulas.
- Mathematical operations such as logarithms and trigonometric functions.
- Programmer's features (bitwise operations, non-decimal numbers).
- Financial functions such as future value and internal rate of return.
- Number theoretical features such as prime factorization and arithmetic modulo *M* for any *M*.
- Algebraic manipulation features, including symbolic calculus.
- Moving data to and from regular editing buffers.
- "Embedded mode" for manipulating Calc formulas and data directly inside any editing buffer.
- Graphics using GNUPLOT, a versatile (and free) plotting program.
- Easy programming using keyboard macros, algebraic formulas, algebraic rewrite rules, or extended Emacs Lisp.

Calc tries to include a little something for everyone; as a result it is large and might be intimidating to the first-time user. If you plan to use Calc only as a traditional desk calculator, all you really need to read is the "Getting Started" chapter of this manual and possibly the first few sections of the tutorial. As you become more comfortable with the program you can learn its additional features. In terms of efficiency, scope and depth, Calc cannot replace a powerful tool like Mathematica. But Calc has the advantages of convenience, portability, and availability of the source code. And, of course, it's free!

About This Manual

This document serves as a complete description of the GNU Emacs Calculator. It works both as an introduction for novices, and as a reference for experienced users. While it helps to have some experience with GNU Emacs in order to get the most out of Calc, this manual ought to be readable even if you don't know or use Emacs regularly.

The manual is divided into three major parts: the "Getting Started" chapter you are reading now, the Calc

tutorial (chapter 2), and the Calc reference manual (the remaining chapters and appendices).

If you are in a hurry to use Calc, there is a brief "demonstration" below which illustrates the major features of Calc in just a couple of pages. If you don't have time to go through the full tutorial, this will show you everything you need to know to begin. See section A Demonstration of Calc.

The tutorial chapter walks you through the various parts of Calc with lots of hands-on examples and explanations. If you are new to Calc and you have some time, try going through at least the beginning of the tutorial. The tutorial includes about 70 exercises with answers. These exercises give you some guided practice with Calc, as well as pointing out some interesting and unusual ways to use its features.

The reference section discusses Calc in complete depth. You can read the reference from start to finish if you want to learn every aspect of Calc. Or, you can look in the table of contents or the Concept Index to find the parts of the manual that discuss the things you need to know.

Every Calc keyboard command is listed in the Calc Summary, and also in the Key Index. Algebraic functions, M-x commands, and variables also have their own indices. @c{Each} In the printed manual, each paragraph that is referenced in the Key or Function Index is marked in the margin with its index entry.

You can access this manual on-line at any time within Calc by pressing the h i key sequence. Outside of the Calc window, you can press M-# i to read the manual on-line. Also, you can jump directly to the Tutorial by pressing h t or M-# t, or to the Summary by pressing h s or M-# s. Within Calc, you can also go to the part of the manual describing any Calc key, function, or variable using h k, h f, or h v, respectively. See section Help Commands.

Printed copies of this manual are also available from the Free Software Foundation.

Notations Used in This Manual

This section describes the various notations that are used throughout the Calc manual.

In keystroke sequences, uppercase letters mean you must hold down the shift key while typing the letter. Keys pressed with Control held down are shown as C-x. Keys pressed with Meta held down are shown as M-x. Other notations are RET for the Return key, SPC for the space bar, TAB for the Tab key, DEL for the Delete key, and LFD for the Line-Feed key.

(If you don't have the LFD or TAB keys on your keyboard, the C-j and C-i keys are equivalent to them, respectively. If you don't have a Meta key, look for Alt or Extend Char. You can also press ESC or C-[first to get the same effect, so that M-x, ESC x, and C-[x are all equivalent.)

Sometimes the RET key is not shown when it is "obvious" that you must press RET to proceed. For example, the RET is usually omitted in key sequences like M-x calc-keypad RET.

Commands are generally shown like this: p (`calc-precision`) or M-# k (`calc-keypad`). This means that the command is normally used by pressing the p key or M-# k key sequence, but it also has the full-name equivalent shown, e.g., M-x calc-precision.

Commands that correspond to functions in algebraic notation are written: C (`calc-cos`) [`cos`]. This means the C key is equivalent to M-x calc-cos, and that the corresponding function in an algebraic-style formula would be `cos(x)'.

A few commands don't have key equivalents: `calc-sincos` [`sincos`].

A Demonstration of Calc

This section will show some typical small problems being solved with Calc. The focus is more on demonstration than explanation, but everything you see here will be covered more thoroughly in the Tutorial.

To begin, start Emacs if necessary (usually the command `emacs` does this), and type M-# c (or ESC # c) to start the Calculator. (See section Starting Calc, if this doesn't work for you.)

Be sure to type all the sample input exactly, especially noting the difference between lower-case and upper-case letters. Remember, RET, TAB, DEL, and SPC are the Return, Tab, Delete, and Space keys.

RPN calculation. In RPN, you type the input number(s) first, then the command to operate on the numbers.

Type 2 RET 3 + Q to compute @c{$\sqrt{2+3} = 2.2360679775$} the square root of 2+3, which is 2.2360679775.

Type P 2 ^ to compute @c{$\pi^2 = 9.86960440109$} the value of `pi' squared, 9.86960440109.

Type TAB to exchange the order of these two results.

Type - I H S to subtract these results and compute the Inverse Hyperbolic sine of the difference, 2.72996136574.

Type DEL to erase this result.

Algebraic calculation. You can also enter calculations using conventional "algebraic" notation. To enter an algebraic formula, use the apostrophe key.

Type ' sqrt(2+3) RET to compute @c{$\sqrt{2+3}$} the square root of 2+3.

Type ' pi^2 RET to enter @c{π^2} `pi' squared. To evaluate this symbolic formula as a number, type =.

Type ' arcsinh($ - $$) RET to subtract the second-most-recent result from the most-recent and compute the Inverse Hyperbolic sine.

Keypad mode. If you are using the X window system, press M-# k to get Keypad mode. (If you don't use X, skip to the next section.)

Click on the 2, ENTER, 3, +, and SQRT "buttons" using your left mouse button.

Click on PI, 2, and `y^x`.

Click on INV, then ENTER to swap the two results.

Click on -, INV, HYP, and SIN.

Click on <- to erase the result, then click OFF to turn the Keypad Calculator off.

Grabbing data. Type M-# x if necessary to exit Calc. Now select the following numbers as an Emacs region: "Mark" the front of the list by typing control-SPC or control-@ there, then move to the other end of the list. (Either get this list from the on-line copy of this manual, accessed by M-# i, or just type these

numbers into a scratch file.) Now type M-# g to "grab" these numbers into Calc.

```
1.23  1.97
1.6   2
1.19  1.08
```

The result `[1.23, 1.97, 1.6, 2, 1.19, 1.08]' is a Calc "vector." Type V R + to compute the sum of these numbers.

Type U to Undo this command, then type V R * to compute the product of the numbers.

You can also grab data as a rectangular matrix. Place the cursor on the upper-leftmost `1' and set the mark, then move to just after the lower-right `8' and press M-# r.

Type v t to transpose this @c{3×2} 3x2 matrix into a @c{2×3} 2x3 matrix. Type v u to unpack the rows into two separate vectors. Now type V R + TAB V R + to compute the sums of the two original columns. (There is also a special grab-and-sum-columns command, M-# :.)

Units conversion. Units are entered algebraically. Type ' 43 mi/hr RET to enter the quantity 43 miles-per-hour. Type u c km/hr RET. Type u c m/s RET.

Date arithmetic. Type t N to get the current date and time. Type 90 + to find the date 90 days from now. Type ' <25 dec 87> RET to enter a date, then - 7 / to see how many weeks have passed since then.

Algebra. Algebraic entries can also include formulas or equations involving variables. Type ' [x + y = a, x y = 1] RET to enter a pair of equations involving three variables. (Note the leading apostrophe in this example; also, note that the space between `x y' is required.) Type a S x,y RET to solve these equations for the variables x and y.

Type d B to view the solutions in more readable notation. Type d C to view them in C language notation, and d T to view them in the notation for the TeX typesetting system. Type d N to return to normal notation.

Type 7.5, then s l a RET to let a = 7.5 in these formulas. (That's a letter l, not a numeral 1.)

Help functions. You can read about any command in the on-line manual. Type M-# c to return to Calc after each of these commands: h k t N to read about the t N command, h f sqrt RET to read about the `sqrt` function, and h s to read the Calc summary.

Press DEL repeatedly to remove any leftover results from the stack. To exit from Calc, press q or M-# c again.

Using Calc

Calc has several user interfaces that are specialized for different kinds of tasks. As well as Calc's standard interface, there are Quick Mode, Keypad Mode, and Embedded Mode.

Calc must be installed before it can be used. See section Installation, for instructions on setting up and installing Calc. We will assume you or someone on your system has already installed Calc as described there.

Starting Calc

On most systems, you can type M-# to start the Calculator. The notation M-# is short for Meta-#. On most keyboards this means holding down the Meta (or Alt) and Shift keys while typing 3.

Once again, if you don't have a Meta key on your keyboard you can type ESC first, then #, to accomplish the same thing. If you don't even have an ESC key, you can fake it by holding down Control or CTRL while typing a left square bracket (that's C-[in Emacs notation).

M-# is a prefix key; when you press it, Emacs waits for you to press a second key to complete the command. In this case, you will follow M-# with a letter (upper- or lower-case, it doesn't matter for M-#) that says which Calc interface you want to use.

To get Calc's standard interface, type M-# c. To get Keypad Mode, type M-# k. Type M-# ? to get a brief list of the available options, and type a second ? to get a complete list.

To ease typing, M-# M-# (or M-# # if that's easier) also works to start Calc. It starts the same interface (either M-# c or M-# k) that you last used, selecting the M-# c interface by default. (If your installation has a special function key set up to act like M-#, hitting that function key twice is just like hitting M-# M-#.)

If M-# doesn't work for you, you can always type explicit commands like M-x calc (for the standard user interface) or M-x calc-keypad (for Keypad Mode). First type M-x (that's Meta with the letter x), then, at the prompt, type the full command (like calc-keypad) and press Return.

If you type M-x calc and Emacs still doesn't recognize the command (it will say `[No match]' when you try to press RET), then Calc has not been properly installed.

The same commands (like M-# c or M-# M-#) that start the Calculator also turn it off if it is already on.

The Standard Calc Interface

Calc's standard interface acts like a traditional RPN calculator, operated by the normal Emacs keyboard. When you type M-# c to start the Calculator, the Emacs screen splits into two windows with the file you were editing on top and Calc on the bottom.

--%%-Calc: 12 Deg       (Calculator)----All-----  --%%-Emacs: *Calc Trail*
```

In this figure, the mode-line for `myfile' has moved up and the "Calculator" window has appeared b it. As you can see, Calc actually makes two windows side-by-side. The lefthand one is called the stack window and the righthand one is called the trail window. The stack holds the numbers involved in the calculation you are currently performing. The trail holds a complete record of all calculations you have done. In a desk calculator with a printer, the trail corresponds to the paper tape that records what you do.

In this case, the trail shows that four numbers (17.3, 3, 2, and 4) were first entered into the Calculator, then the 2 and 4 were multiplied to get 8, then the 3 and 8 were subtracted to get -5. (The `>' symbol shows that this was the most recent calculation.) The net result is the two numbers 17.3 and -5 sitting on the stack.

Most Calculator commands deal explicitly with the stack only, but there is a set of commands that allow you to search back through the trail and retrieve any previous result.

Calc commands use the digits, letters, and punctuation keys. Shifted (i.e., upper-case) letters are different from lowercase letters. Some letters are prefix keys that begin two-letter commands. For example, e means "enter exponent" and shifted E means e^x. With the d ("display modes") prefix the letter "e" takes on very different meanings: d e means "engineering notation" and d E means "eqn language mode."

There is nothing stopping you from switching out of the Calc window and back into your editing window, say by using the Emacs C-x o (`other-window`) command. When the cursor is inside a regular window, Emacs acts just like normal. When the cursor is in the Calc stack or trail windows, keys are interpreted as Calc commands.

When you quit by pressing M-# c a second time, the Calculator windows go away but the actual Stack and Trail are not gone, just hidden. When you press M-# c once again you will get the same stack and trail contents you had when you last used the Calculator.

The Calculator does not remember its state between Emacs sessions. Thus if you quit Emacs and start it again, M-# c will give you a fresh stack and trail. There is a command (m m) that lets you save your favorite mode settings between sessions, though. One of the things it saves is which user interface (standard or Keypad) you last used; otherwise, a freshly started Emacs will always treat M-# M-# the same as M-# c.

The q key is another equivalent way to turn the Calculator off.

If you type M-# b first and then M-# c, you get a full-screen version of Calc (`full-calc`) in which the stack and trail windows are still side-by-side but are now as tall as the whole Emacs screen. When you press q or M-# c again to quit, the file you were editing before reappears. The M-# b key switches back and forth between "big" full-screen mode and the normal partial-screen mode.

Finally, M-# o (`calc-other-window`) is like M-# c except that the Calc window is not selected. The buffer you were editing before remains selected instead. M-# o is a handy way to switch out of Calc momentarily to edit your file; type M-# c to switch back into Calc when you are done.

Quick Mode (Overview)

Quick Mode is a quick way to use Calc when you don't need the full complexity of the stack and trail. To use it, type M-# q (`quick-calc`) in any regular editing buffer.

Quick Mode is very simple: It prompts you to type any formula in standard algebraic notation (like `4 - 2/3') and then displays the result at the bottom of the Emacs screen (*3.33333333333* in this case). You are then back in the same editing buffer you were in before, ready to continue editing or to type M-# q again to do

another quick calculation. The result of the calculation will also be in the Emacs "kill ring" so that a C-y command at this point will yank the result into your editing buffer.

Calc mode settings affect Quick Mode, too, though you will have to go into regular Calc (with M-# c) to change the mode settings.

See section "Quick Calculator" Mode, for further information.

Keypad Mode (Overview)

Keypad Mode is a mouse-based interface to the Calculator. It is designed for use with the X window system. If you don't have X, you will have to operate keypad mode with your arrow keys (which is probably more trouble than it's worth).

Type M-# k to turn Keypad Mode on or off. Once again you get two new windows, this time on the righthand side of the screen instead of at the bottom. The upper window is the familiar Calc Stack; the lower window is a picture of a typical calculator keypad.

```
|--- Emacs Calculator Mode ---
|2:  17.3
|1:  -5
|    .
|--%%-Calc: 12 Deg       (Calcul
|----+-----Calc 2.00-----+----1

```

@begingroup @ifdim@hsize=5in @advance@hsize-2.2in @else @advance@hsize-3.05in @advance@vsize.1in @fi

Keypad Mode is much easier for beginners to learn, because there is no need to memorize lots of obscure key sequences. But not all commands in regular Calc are available on the Keypad. You can always switch the cursor into the Calc stack window to use standard Calc commands if you need. Serious Calc users, though, often find they prefer the standard interface over Keypad Mode.

To operate the Calculator, just click on the "buttons" of the keypad using your left mouse button. To en the two numbers shown here you would click 1 7 . 3 ENTER 5 +/- ENTER; to add them together you w then click + (to get 12.3 on the stack).

If you click the right mouse button, the top three rows of the keypad change to show other sets of commands, such as advanced math functions, vector operations, and operations on binary numbers.

@endgroup Because Keypad Mode doesn't use the regular keyboard, Calc leaves the cursor in your original editing buffer. You can type in this buffer in the usual way while also clicking on the Calculator keypad. One advantage of Keypad Mode is that you don't need an explicit command to switch between editing and calculating.

If you press M-# b first, you get a full-screen Keypad Mode (`full-calc-keypad`) with three windows: The keypad in the lower left, the stack in the lower right, and the trail on top.

See section "Keypad" Mode, for further information.

Standalone Operation

If you are not in Emacs at the moment but you wish to use Calc, you must start Emacs first. If all you want is to run Calc, you can give the commands:

```
emacs -f full-calc
```

or

```
emacs -f full-calc-keypad
```

which run a full-screen Calculator (as if by M-# b M-# c) or a full-screen X-based Calculator (as if by M-# b M-# k). In standalone operation, quitting the Calculator (by pressing q or clicking on the keypad EXIT button) quits Emacs itself.

Embedded Mode (Overview)

Embedded Mode is a way to use Calc directly from inside an editing buffer. Suppose you have a formula written as part of a document like this:

```
The derivative of

                                    ln(ln(x))

is
```

and you wish to have Calc compute and format the derivative for you and store this derivative in the buffer automatically. To do this with Embedded Mode, first copy the formula down to where you want the result to be:

```
The derivative of
```

```
                                ln(ln(x))
```

is

```
                                ln(ln(x))
```

Now, move the cursor onto this new formula and press M-# e. Calc will read the formula (using the surrounding blank lines to tell how much text to read), then push this formula (invisibly) onto the Calc stack. The cursor will stay on the formula in the editing buffer, but the buffer's mode line will change to look like the Calc mode line (with mode indicators like `12 Deg' and so on). Even though you are still in your editing buffer, the keyboard now acts like the Calc keyboard, and any new result you get is copied from the stack back into the buffer. To take the derivative, you would type a d x RET.

```
The derivative of

                                ln(ln(x))

is

1 / ln(x) x
```

To make this look nicer, you might want to press d = to center the formula, and even d B to use "big" display mode.

```
The derivative of

                                ln(ln(x))

is
% [calc-mode: justify: center]
% [calc-mode: language: big]

                                   1
                                -------
                                ln(x) x
```

Calc has added annotations to the file to help it remember the modes that were used for this formula. They are formatted like comments in the TeX typesetting language, just in case you are using TeX. (In this example TeX is not being used, so you might want to move these comments up to the top of the file or otherwise put them out of the way.)

As an extra flourish, we can add an equation number using a righthand label: Type d } (1) RET.

```
% [calc-mode: justify: center]
% [calc-mode: language: big]
% [calc-mode: right-label: " (1)"]
```

$$\frac{1}{\ln(x)\ x} \qquad (1)$$

TOC

To leave Embedded Mode, type M-# e again. The mode line and keyboard will revert to the way they were before. (If you have actually been trying this as you read along, you'll want to press M-# 0 [with the digit zero] now to reset the modes you changed.)

The related command M-# w operates on a single word, which generally means a single number, inside text. It uses any non-numeric characters rather than blank lines to delimit the formula it reads. Here's an example of its use:

```
A slope of one-third corresponds to an angle of 1 degrees.
```

Place the cursor on the `1', then type M-# w to enable Embedded Mode on that number. Now type 3 / (to get one-third), and I T (the Inverse Tangent converts a slope into an angle), then M-# w again to exit Embedded mode.

```
A slope of one-third corresponds to an angle of 18.4349488229 degrees.
```

See section Embedded Mode, for full details.

Other M-# Commands

Two more Calc-related commands are M-# g and M-# r, which "grab" data from a selected region of a buffer into the Calculator. The region is defined in the usual Emacs way, by a "mark" placed at one end of the region, and the Emacs cursor or "point" placed at the other.

The M-# g command reads the region in the usual left-to-right, top-to-bottom order. The result is packaged into a Calc vector of numbers and placed on the stack. Calc (in its standard user interface) is then started. Type v u if you want to unpack this vector into separate numbers on the stack. Also, C-u M-# g interprets the region as a single number or formula.

The M-# r command reads a rectangle, with the point and mark defining opposite corners of the rectangle. The result is a matrix of numbers on the Calculator stack.

Complementary to these is M-# y, which "yanks" the value at the top of the Calc stack back into an editing buffer. If you type M-# y while in such a buffer, the value is yanked at the current position. If you type M-# y while in the Calc buffer, Calc makes an educated guess as to which editing buffer you want to use. The Calc window does not have to be visible in order to use this command, as long as there is something on the Calc stack.

Here, for reference, is the complete list of M-# commands. The shift, control, and meta keys are ignored for the keystroke following M-#.

Commands for turning Calc on and off:

#

Turn Calc on or off, employing the same user interface as last time.

C

Turn Calc on or off using its standard bottom-of-the-screen interface. If Calc is already turned on but the cursor is not in the Calc window, move the cursor into the window.

O

Same as C, but don't select the new Calc window. If Calc is already turned on and the cursor is in the Calc window, move it out of that window.

B

Control whether M-# c and M-# k use the full screen.

Q

Use Quick Mode for a single short calculation.

K

Turn Calc Keypad mode on or off.

E

Turn Calc Embedded mode on or off at the current formula.

J

Turn Calc Embedded mode on or off, select the interesting part.

W

Turn Calc Embedded mode on or off at the current word (number).

Z

Turn Calc on in a user-defined way, as defined by a Z I command.

X

Quit Calc; turn off standard, Keypad, or Embedded mode if on. (This is like q or OFF inside of Calc.)

Commands for moving data into and out of the Calculator:

G

Grab the region into the Calculator as a vector.

R

Grab the rectangular region into the Calculator as a matrix.

:

Grab the rectangular region and compute the sums of its columns.

_

Grab the rectangular region and compute the sums of its rows.

Y

Yank a value from the Calculator into the current editing buffer.

Commands for use with Embedded Mode:

A

"Activate" the current buffer. Locate all formulas that contain `:=' or `=>' symbols and record their locations so that they can be updated automatically as variables are changed.

D

Duplicate the current formula immediately below and select the duplicate.

F
: Insert a new formula at the current point.

N
: Move the cursor to the next active formula in the buffer.

P
: Move the cursor to the previous active formula in the buffer.

U
: Update (i.e., as if by the = key) the formula at the current point.

`
: Edit (as if by `calc-edit`) the formula at the current point.

Miscellaneous commands:

I
: Run the Emacs Info system to read the Calc manual. (This is the same as h i inside of Calc.)

T
: Run the Emacs Info system to read the Calc Tutorial.

S
: Run the Emacs Info system to read the Calc Summary.

L
: Load Calc entirely into memory. (Normally the various parts are loaded only as they are needed.)

M
: Read a region of written keystroke names (like `C-n a b c RET') and record them as the current keyboard macro.

0
: (This is the "zero" digit key.) Reset the Calculator to its default state: Empty stack, and default mode settings. With any prefix argument, reset everything but the stack.

History and Acknowledgements

Calc was originally started as a two-week project to occupy a lull in the author's schedule. Basically, a friend asked if I remembered the value of @c{2^{32}} 2^32. I didn't offhand, but I said, "that's easy, just call up an `xcalc`." `Xcalc` duly reported that the answer to our question was `4.294967e+09'---with no way to see the full ten digits even though we knew they were there in the program's memory! I was so annoyed, I vowed to write a calculator of my own, once and for all.

I chose Emacs Lisp, a) because I had always been curious about it and b) because, being only a text editor extension language after all, Emacs Lisp would surely reach its limits long before the project got too far out of hand.

To make a long story short, Emacs Lisp turned out to be a distressingly solid implementation of Lisp, and the humble task of calculating turned out to be more open-ended than one might have expected.

Emacs Lisp doesn't have built-in floating point math, so it had to be simulated in software. In fact, Emacs

integers will only comfortably fit six decimal digits or so--not enough for a decent calculator. So I had to write my own high-precision integer code as well, and once I had this I figured that arbitrary-size integers were just as easy as large integers. Arbitrary floating-point precision was the logical next step. Also, since the large integer arithmetic was there anyway it seemed only fair to give the user direct access to it, which in turn made it practical to support fractions as well as floats. All these features inspired me to look around for other data types that might be worth having.

Around this time, my friend Rick Koshi showed me his nifty new HP-28 calculator. It allowed the user to manipulate formulas as well as numerical quantities, and it could also operate on matrices. I decided that these would be good for Calc to have, too. And once things had gone this far, I figured I might as well take a look at serious algebra systems like Mathematica, Macsyma, and Maple for further ideas. Since these systems did far more than I could ever hope to implement, I decided to focus on rewrite rules and other programming features so that users could implement what they needed for themselves.

Rick complained that matrices were hard to read, so I put in code to format them in a 2D style. Once these routines were in place, Big mode was obligatory. Gee, what other language modes would be useful?

Scott Hemphill and Allen Knutson, two friends with a strong mathematical bent, contributed ideas and algorithms for a number of Calc features including modulo forms, primality testing, and float-to-fraction conversion.

Units were added at the eager insistence of Mass Sivilotti. Later, Ulrich Mueller at CERN and Przemek Klosowski at NIST provided invaluable expert assistance with the units table. As far as I can remember, the idea of using algebraic formulas and variables to represent units dates back to an ancient article in Byte magazine about muMath, an early algebra system for microcomputers.

Many people have contributed to Calc by reporting bugs and suggesting features, large and small. A few deserve special mention: Tim Peters, who helped develop the ideas that led to the selection commands, rewrite rules, and many other algebra features; @c{Fran\c cois} Francois Pinard, who contributed an early prototype of the Calc Summary appendix as well as providing valuable suggestions in many other areas of Calc; Carl Witty, whose eagle eyes discovered many typographical and factual errors in the Calc manual; Tim Kay, who drove the development of Embedded mode; Ove Ewerlid, who made many suggestions relating to the algebra commands and contributed some code for polynomial operations; Randal Schwartz, who suggested the `calc-eval` function; Robert J. Chassell, who suggested the Calc Tutorial and exercises; and Juha Sarlin, who first worked out how to split Calc into quickly-loading parts.

Among the books used in the development of Calc were Knuth's *Art of Computer Programming* (especially volume II, *Seminumerical Algorithms*); *Numerical Recipes* by Press, Flannery, Teukolsky, and Vetterling; Bevington's *Data Reduction and Error Analysis for the Physical Sciences*; *Concrete Mathematics* by Graham, Knuth, and Patashnik; Steele's *Common Lisp, the Language*; the *CRC Standard Math Tables* (William H. Beyer, ed.); and Abramowitz and Stegun's venerable *Handbook of Mathematical Functions*. I consulted the user's manuals for the HP-28 and HP-48 calculators, as well as for the programs Mathematica, SMP, Macsyma, Maple, MathCAD, Gnuplot, and others. Also, of course, Calc could not have been written without the excellent *GNU Emacs Lisp Reference Manual*, by Bil Lewis and Dan LaLiberte.

Final thanks go to Richard Stallman, without whose fine implementations of the Emacs editor, language, and environment, Calc would have been finished in two weeks.

Tutorial

This chapter explains how to use Calc and its many features, in a step-by-step, tutorial way. You are encouraged to run Calc and work along with the examples as you read (see section Starting Calc). If you are already familiar with advanced calculators, you may wish to skip on to the rest of this manual.

This tutorial describes the standard user interface of Calc only. The "Quick Mode" and "Keypad Mode" interfaces are fairly self-explanatory. See section Embedded Mode, for a description of the "Embedded Mode" interface.

The easiest way to read this tutorial on-line is to have two windows on your Emacs screen, one with Calc and one with the Info system. (If you have a printed copy of the manual you can use that instead.) Press M-# c to turn Calc on or to switch into the Calc window, and press M-# i to start the Info system or to switch into its window.

This tutorial is designed to be done in sequence. But the rest of this manual does not assume you have gone through the tutorial. The tutorial does not cover everything in the Calculator, but it touches on most general areas.

The Calc Summary at the end of the reference manual includes some blank space for your own use. You may wish to keep notes there as you learn Calc.

Basic Tutorial

In this section, we learn how RPN and algebraic-style calculations work, how to undo and redo an operation done by mistake, and how to control various modes of the Calculator.

RPN Calculations and the Stack

The central component of an RPN calculator is the stack. A calculator stack is like a stack of dishes. New dishes (numbers) are added at the top of the stack, and numbers are normally only removed from the top of the stack.

In an operation like 2+3, the 2 and 3 are called the operands and the + is the operator. In an RPN calculator you always enter the operands first, then the operator. Each time you type a number, Calc adds or pushes it onto the top of the Stack. When you press an operator key like +, Calc pops the appropriate number of operands from the stack and pushes back the result.

Thus we could add the numbers 2 and 3 in an RPN calculator by typing: 2 RET 3 RET +. (The RET key, Return, corresponds to the ENTER key on traditional RPN calculators.) Try this now if you wish; type M-# c to switch into the Calc window (you can type M-# c again or M-# o to switch back to the Tutorial window). The first four keystrokes "push" the numbers 2 and 3 onto the stack. The + key "pops" the top two numbers from the stack, adds them, and pushes the result (5) back onto the stack. Here's how the stack will look at various points throughout the calculation:

```
    .          1:  2          2:  2          1:  5              .
                   .          1:  3              .
                                  .

  M-# c          2 RET          3 RET          +              DEL
```

The `.' symbol is a marker that represents the top of the stack. Note that the "top" of the stack is really shown at the bottom of the Stack window. This may seem backwards, but it turns out to be less distracting in regular use.

The numbers `1:' and `2:' on the left are stack level numbers. Old RPN calculators always had four stack levels called x, y, z, and t. Calc's stack can grow as large as you like, so it uses numbers instead of letters. Some stack-manipulation commands accept a numeric argument that says which stack level to work on. Normal commands like + always work on the top few levels of the stack.

The Stack buffer is just an Emacs buffer, and you can move around in it using the regular Emacs motion commands. But no matter where the cursor is, even if you have scrolled the `.' marker out of view, most Calc commands always move the cursor back down to level 1 before doing anything. It is possible to move the `.' marker upwards through the stack, temporarily "hiding" some numbers from commands like +. This is called stack truncation and we will not cover it in this tutorial; see section Truncating the Stack, if you are interested.

You don't really need the second RET in 2 RET 3 RET +. That's because if you type any operator name or other non-numeric key when you are entering a number, the Calculator automatically enters that number and then does the requested command. Thus 2 RET 3 + will work just as well.

Examples in this tutorial will often omit RET even when the stack displays shown would only happen if you did press RET:

```
1:  2          2:  2          1:  5
    .          1:  3              .
                   .

  2 RET            3              +
```

Here, after pressing 3 the stack would really show `1: 2' with `Calc: 3' in the minibuffer. In these situations, you can press the optional RET to see the stack as the figure shows.

(*) **Exercise 1.** (This tutorial will include exercises at various points. Try them if you wish. Answers to all the exercises are located at the end of the Tutorial chapter. Each exercise will include a cross-reference to its particular answer. If you are reading with the Emacs Info system, press f and the exercise number to go to the answer, then the letter l to return to where you were.)

Here's the first exercise: What will the keystrokes 1 RET 2 RET 3 RET 4 + * - compute? (`*' is the symbol for multiplication.) Figure it out by hand, then try it with Calc to see if you're right. See section RPN Tutorial Exercise 1. (*)

(*) **Exercise 2.** Compute @c{$(2\times4) + (7\times9.4) + {5\over4}$} 2*4 + 7*9.5 + 5/4 using the stack. See section RPN Tutorial Exercise 2. (*)

The DEL key is called Backspace on some keyboards. It is whatever key you would use to correct a simple typing error when regularly using Emacs. The DEL key pops and throws away the top value on the stack.

(You can still get that value back from the Trail if you should need it later on.) There are many places in t tutorial where we assume you have used DEL to erase the results of the previous example at the beginnin new example. In the few places where it is really important to use DEL to clear away old results, the text wi remind you to do so.

(It won't hurt to let things accumulate on the stack, except that whenever you give a display-mode-changing command Calc will have to spend a long time reformatting such a large stack.)

Since the - key is also an operator (it subtracts the top two stack elements), how does one enter a negative number? Calc uses the _ (underscore) key to act like the minus sign in a number. So, typing -5 RET won't work because the - key will try to do a subtraction, but _5 RET works just fine.

You can also press n, which means "change sign." It changes the number at the top of the stack (or the number being entered) from positive to negative or vice-versa: 5 n RET.

If you press RET when you're not entering a number, the effect is to duplicate the top number on the stack. Consider this calculation:

```
1:  3          2:  3          1:  9          2:  9          1:  81
    .          1:  3              .          1:  9              .
                   .                             .

  3 RET            RET              *              RET              *
```

(Of course, an easier way to do this would be 3 RET 4 ^, to raise 3 to the fourth power.)

The space-bar key (denoted SPC here) performs the same function as RET; you could replace all three occurrences of RET in the above example with SPC and the effect would be the same.

Another stack manipulation key is TAB. This exchanges the top two stack entries. Suppose you have computed 2 RET 3 + to get 5, and then you realize what you really wanted to compute was 20 / (2+3).

```
1:  5          2:  5          2:  20         1:  4
    .          1:  20         1:  5              .
                   .                 .

 2 RET 3 +         20             TAB              /
```

Planning ahead, the calculation would have gone like this:

```
1:  20         2:  20         3:  20         2:  20         1:  4
    .          1:  2          2:  2          1:  5              .
                   .          1:  3              .
                                 .

  20 RET          2 RET            3              +              /
```

A related stack command is M-TAB (hold META and type TAB). It rotates the top three elements of the stack upward, bringing the object in level 3 to the top.

```
1:  10          2:  10          3:  10          3:  20          3:  30
    .           1:  20          2:  20          2:  30          2:  10
                    .           1:  30          1:  10          1:  20
                                    .               .               .

  10 RET          20 RET          30 RET          M-TAB           M-TAB
```

(*) **Exercise 3.** Suppose the numbers 10, 20, and 30 are on the stack. Figure out how to add one to the number in level 2 without affecting the rest of the stack. Also figure out how to add one to the number in level 3. See section RPN Tutorial Exercise 3. (*)

Operations like +, -, *, /, and ^ pop two arguments from the stack and push a result. Operations like n and Q (square root) pop a single number and push the result. You can think of them as simply operating on the top element of the stack.

```
1:  3           1:  9           2:  9           1:  25          1:  5
    .               .           1:  16              .               .
                                    .

  3 RET           RET *           4 RET RET *         +               Q
```

(Note that capital Q means to hold down the Shift key while typing q. Remember, plain unshifted q is the Quit command.)

Here we've used the Pythagorean Theorem to determine the hypotenuse of a right triangle. Calc actually has a built-in command for that called f h, but let's suppose we can't remember the necessary keystrokes. We can still enter it by its full name using M-x notation:

```
1:  3           2:  3           1:  5
    .           1:  4               .
                    .

  3 RET           4 RET       M-x calc-hypot
```

All Calculator commands begin with the word `calc-'. Since it gets tiring to type this, Calc provides an x key which is just like the regular Emacs M-x key except that it types the `calc-' prefix for you:

```
1:  3           2:  3           1:  5
    .           1:  4               .
                    .

  3 RET           4 RET          x hypot
```

What happens if you take the square root of a negative number?

```
1:  4           1:  -4          1:  (0, 2)
    .               .               .

  4 RET             n               Q
```

The notation (a, b) represents a complex number. Complex numbers are more traditionally written @c{$a i$} a + b i; Calc can display in this format, too, but for now we'll stick to the (a, b) notation.

If you don't know how complex numbers work, you can safely ignore this feature. Complex numbers only arise from operations that would be errors in a calculator that didn't have complex numbers. (For example, taking the square root or logarithm of a negative number produces a complex result.)

Complex numbers are entered in the notation shown. The (and , and) keys manipulate "incomplete complex numbers."

```
1:  ( ...      2:  ( ...      1:  (2, ...    1:  (2, ...    1:  (2, 3)
    .          1:  2              .              3              .
                   .                             .

    (              2              ,              3              )
```

You can perform calculations while entering parts of incomplete objects. However, an incomplete object cannot actually participate in a calculation:

```
1:  ( ...      2:  ( ...      3:  ( ...      1:  ( ...      1:  ( ...
    .          1:  2          2:  2              5              5
                   .          1:  3              .              .
                                  .
                                                             (error)
    (              2 RET          3              +              +
```

Adding 5 to an incomplete object makes no sense, so the last command produces an error message and leaves the stack the same.

Incomplete objects can't participate in arithmetic, but they can be moved around by the regular stack commands.

```
2:  2          3:  2          3:  3          1:  ( ...      1:  (2, 3)
1:  3          2:  3          2:  ( ...          2              .
    .          1:  ( ...      1:  2              3
                   .              .              .

2 RET 3 RET        (              M-TAB          M-TAB          )
```

Note that the , (comma) key did not have to be used here. When you press) all the stack entries between the incomplete entry and the top are collected, so there's never really a reason to use the comma. It's up to you.

(*) **Exercise 4.** To enter the complex number (2, 3), your friend Joe typed (2 , SPC 3). What happened? (Joe thought of a clever way to correct his mistake in only two keystrokes, but it didn't quite work. Try it to find out why.) See section RPN Tutorial Exercise 4. (*)

Vectors are entered the same way as complex numbers, but with square brackets in place of parentheses. We'll meet vectors again later in the tutorial.

Any Emacs command can be given a numeric prefix argument by typing a series of META-digits beforehand.

If META is awkward for you, you can instead type C-u followed by the necessary digits. Numeric prefix arguments can be negative, as in M-- M-3 M-5 or C-u - 3 5. Calc commands use numeric prefix arguments in a variety of ways. For example, a numeric prefix on the + operator adds any number of stack entries at once:

```
1:  10          2:  10          3:  10          3:  10          1:  60
    .           1:  20          2:  20          2:  20              .
                    .           1:  30          1:  30
                                    .               .

  10 RET          20 RET          30 RET          C-u 3           +
```

For stack manipulation commands like RET, a positive numeric prefix argument operates on the top n stack entries at once. A negative argument operates on the entry in level n only. An argument of zero operates on the entire stack. In this example, we copy the second-to-top element of the stack:

```
1:  10          2:  10          3:  10          3:  10          4:  10
    .           1:  20          2:  20          2:  20          3:  20
                    .           1:  30          1:  30          2:  30
                                    .               .           1:  20
                                                                    .

  10 RET          20 RET          30 RET          C-u -2          RET
```

Another common idiom is M-0 DEL, which clears the stack. (The M-0 numeric prefix tells DEL to operate on the entire stack.)

Algebraic-Style Calculations

If you are not used to RPN notation, you may prefer to operate the Calculator in "algebraic mode," which is closer to the way non-RPN calculators work. In algebraic mode, you enter formulas in traditional 2+3 notation.

You don't really need any special "mode" to enter algebraic formulas. You can enter a formula at any time by pressing the apostrophe (') key. Answer the prompt with the desired formula, then press RET. The formula is evaluated and the result is pushed onto the RPN stack. If you don't want to think in RPN at all, you can enter your whole computation as a formula, read the result from the stack, then press DEL to delete it from the stack.

Try pressing the apostrophe key, then 2+3+4, then RET. The result should be the number 9.

Algebraic formulas use the operators `+', `-', `*', `/', and `^'. You can use parentheses to make the order of evaluation clear. In the absence of parentheses, `^' is evaluated first, then `*', then `/', then finally `+' and `-'. For example, the expression

```
2 + 3*4*5 / 6*7^8 - 9
```

is equivalent to

```
2 + ((3*4*5) / (6*(7^8)) - 9
```

or, in large mathematical notation,

The result of this expression will be the number *-6.99999826533*.

Calc's order of evaluation is the same as for most computer languages, except that `*' binds more strongly than `/', as the above example shows. As in normal mathematical notation, the `*' symbol can often be omitted: `2 a' is the same as `2*a'.

Operators at the same level are evaluated from left to right, except that `^' is evaluated from right to left. Thus, `2-3-4' is equivalent to `(2-3)-4' or *-5*, whereas `2^3^4' is equivalent to `2^(3^4)' (a very large integer; try it!).

If you tire of typing the apostrophe all the time, there is an "algebraic mode" you can select in which Calc automatically senses when you are about to type an algebraic expression. To enter this mode, press the two letters m a. (An `Alg' indicator should appear in the Calc window's mode line.)

Press m a, then 2+3+4 with no apostrophe, then RET.

In algebraic mode, when you press any key that would normally begin entering a number (such as a digit, a decimal point, or the _ key), or if you press (or [, Calc automatically begins an algebraic entry.

Functions which do not have operator symbols like `+' and `*' must be entered in formulas using function-call notation. For example, the function name corresponding to the square-root key Q is `sqrt`. To compute a square root in a formula, you would use the notation `sqrt(x)'.

Press the apostrophe, then type sqrt(5*2) - 3. The result should be 0.16227766017.

Note that if the formula begins with a function name, you need to use the apostrophe even if you are in algebraic mode. If you type arcsin out of the blue, the a r will be taken as an Algebraic Rewrite command, and the csin will be taken as the name of the rewrite rule to use!

Some people prefer to enter complex numbers and vectors in algebraic form because they find RPN entry with incomplete objects to be too distracting, even though they otherwise use Calc as an RPN calculator.

Still in algebraic mode, type:

```
1:  (2, 3)      2:  (2, 3)      1:  (8, -1)     2:  (8, -1)     1:  (9, -1)
    .           1:  (1, -2)         .           1:  1               .
                    .                               .

 (2,3) RET       (1,-2) RET          *               1 RET           +
```

Algebraic mode allows us to enter complex numbers without pressing an apostrophe first, but it also means we need to press RET after every entry, even for a simple number like 1.

(You can type C-u m a to enable a special "incomplete algebraic mode" in which the (and [keys use algebraic entry even though regular numeric keys still use RPN numeric entry. There is also a "total algebraic mode," started by typing m t, in which all normal keys begin algebraic entry. You must then use the META key to type Calc commands: M-m t to get back out of total algebraic mode, M-q to quit, etc.)

If you're still in algebraic mode, press m a again to turn it off.

Actual non-RPN calculators use a mixture of algebraic and RPN styles. In general, operators of two numbers (like + and *) use algebraic form, but operators of one number (like n and Q) use RPN form. Also, a non-RPN

calculator allows you to see the intermediate results of a calculation as you go along. You can accomplish in Calc by performing your calculation as a series of algebraic entries, using the $ sign to tie them together an algebraic formula, $ represents the number on the top of the stack. Here, we perform the calculation @c{$\sqrt{2\times4+1}$} sqrt(2*4+1), which on a traditional calculator would be done by pressing 2 * 4 + 1 = and then the square-root key.

```
1:  8          1:  9          1:  3
    .              .              .

  ' 2*4 RET      $+1 RET        Q
```

Notice that we didn't need to press an apostrophe for the $+1, because the dollar sign always begins an algebraic entry.

(*) **Exercise 1.** How could you get the same effect as pressing Q but using an algebraic entry instead? How about if the Q key on your keyboard were broken? See section Algebraic Entry Tutorial Exercise 1. (*)

The notations $$, $$$, and so on stand for higher stack entries. For example, ' $$+$ RET is just like typing +.

Algebraic formulas can include variables. To store in a variable, press s s, then type the variable name, then press RET. (There are actually two flavors of store command: s s stores a number in a variable but also leaves the number on the stack, while s t removes a number from the stack and stores it in the variable.) A variable name should consist of one or more letters or digits, beginning with a letter.

```
1:  17             .          1:  a + a^2    1:  306
    .                             .              .

    17          s t a RET       ' a+a^2 RET    =
```

The = key evaluates a formula by replacing all its variables by the values that were stored in them.

For RPN calculations, you can recall a variable's value on the stack either by entering its name as a formula and pressing =, or by using the s r command.

```
1:  17         2:  17         3:  17         2:  17         1:  306
    .          1:  17         2:  17         1:  289            .
               .              1:  2              .
                                 .

  s r a RET      ' a RET =      2              ^              +
```

If you press a single digit for a variable name (as in s t 3, you get one of ten quick variables `q0` through `q9`. They are "quick" simply because you don't have to type the letter `q` or the RET after their names. In fact, you can type simply s 3 as a shorthand for s s 3, and likewise for t 3 and r 3.

Any variables in an algebraic formula for which you have not stored values are left alone, even when you evaluate the formula.

```
1:  2 a + 2 b      1:  34 + 2 b
    .                  .
```

```
' 2a+2b RET          =
```

Calls to function names which are undefined in Calc are also left alone, as are calls for which the value is undefined.

```
1:  2 + log10(0) + log10(x) + log10(5, 6) + foo(3)
    .

' log10(100) + log10(0) + log10(x) + log10(5,6) + foo(3) RET
```

In this example, the first call to `log10` works, but the other calls are not evaluated. In the second call, the logarithm is undefined for that value of the argument; in the third, the argument is symbolic, and in the fourth, there are too many arguments. In the fifth case, there is no function called `foo`. You will see a "Wrong number of arguments" message referring to `log10(5,6)'. Press the w ("why") key to see any other messages that may have arisen from the last calculation. In this case you will get "logarithm of zero," then "number expected: `x`". Calc automatically displays the first message only if the message is sufficiently important; for example, Calc considers "wrong number of arguments" and "logarithm of zero" to be important enough to report automatically, while a message like "number expected: `x`" will only show up if you explicitly press the w key.

(*) **Exercise 2.** Joe entered the formula `2 x y', stored 5 in `x`, pressed =, and got the expected result, `10 y'. He then tried the same for the formula `2 x (1+y)', expecting `10 (1+y)', but it didn't work. Why not? See section Algebraic Entry Tutorial Exercise 2. (*)

(*) **Exercise 3.** What result would you expect 1 RET 0 / to give? What if you then type 0 *? See section Algebraic Entry Tutorial Exercise 3. (*)

One interesting way to work with variables is to use the evaluates-to (`=>') operator. It works like this: Enter a formula algebraically in the usual way, but follow the formula with an `=>' symbol. (There is also an s = command which builds an `=>' formula using the stack.) On the stack, you will see two copies of the formula with an `=>' between them. The lefthand formula is exactly like you typed it; the righthand formula has been evaluated as if by typing =.

```
2:  2 + 3 => 5                      2:  2 + 3 => 5
1:  2 a + 2 b => 34 + 2 b           1:  2 a + 2 b => 20 + 2 b
    .                                   .

' 2+3 => RET  ' 2a+2b RET s =          10 s t a RET
```

Notice that the instant we stored a new value in `a`, all `=>' operators already on the stack that referred to a were updated to use the new value. With `=>', you can push a set of formulas on the stack, then change the variables experimentally to see the effects on the formulas' values.

You can also "unstore" a variable when you are through with it:

```
2:  2 + 5 => 5
1:  2 a + 2 b => 2 a + 2 b
    .
```

```
    s u a RET
```

We will encounter formulas involving variables and functions again when we discuss the algebra and calculus features of the Calculator.

Undo and Redo

If you make a mistake, you can usually correct it by pressing shift-U, the "undo" command. First, clear the stack (M-0 DEL) and exit and restart Calc (M-# M-# M-# M-#) to make sure things start off with a clean slate. Now:

```
1:  2          2:  2          1:  8          2:  2          1:  6
    .          1:  3              .          1:  3              .
                   .                             .

   2 RET           3              ^              U              *
```

You can undo any number of times. Calc keeps a complete record of all you have done since you last opened the Calc window. After the above example, you could type:

```
1:  6          2:  2          1:  2              .              .
    .          1:  3              .
                   .
                                                        (error)
                   U              U              U              U
```

You can also type D to "redo" a command that you have undone mistakenly.

```
    .          1:  2          2:  2          1:  6          1:  6
                   .          1:  3              .              .
                                  .
                                                        (error)
                   D              D              D              D
```

It was not possible to redo past the 6, since that was placed there by something other than an undo command.

You can think of undo and redo as a sort of "time machine." Press U to go backward in time, D to go forward. If you go backward and do something (like *) then, as any science fiction reader knows, you have changed your future and you cannot go forward again. Thus, the inability to redo past the 6 even though there was an earlier undo command.

You can always recall an earlier result using the Trail. We've ignored the trail so far, but it has been faithfully recording everything we did since we loaded the Calculator. If the Trail is not displayed, press t d now to turn it on.

Let's try grabbing an earlier result. The 8 we computed was undone by a U command, and was lost even to Redo when we pressed *, but it's still there in the trail. There should be a little `>' arrow (the trail pointer) resting on the last trail entry. If there isn't, press t] to reset the trail pointer. Now, press t p to move the arrow onto the line containing 8, and press t y to "yank" that number back onto the stack.

If you press t] again, you will see that even our Yank command went into the trail.

Let's go further back in time. Earlier in the tutorial we computed a huge integer using the formula `2^3^4'. We don't remember what it was, but the first digits were "241". Press t r (which stands for trail-search-reverse), then type 241. The trail cursor will jump back to the next previous occurrence of the string "241" in the trail. This is just a regular Emacs incremental search; you can now press C-s or C-r to continue the search forwards or backwards as you like.

To finish the search, press RET. This halts the incremental search and leaves the trail pointer at the thing we found. Now we can type t y to yank that number onto the stack. If we hadn't remembered the "241", we could simply have searched for 2^3^4, then pressed RET t n to halt and then move to the next item.

You may have noticed that all the trail-related commands begin with the letter t. (The store-and-recall commands, on the other hand, all began with s.) Calc has so many commands that there aren't enough keys for all of them, so various commands are grouped into two-letter sequences where the first letter is called the prefix key. If you type a prefix key by accident, you can press C-g to cancel it. (In fact, you can press C-g to cancel almost anything in Emacs.) To get help on a prefix key, press that key followed by ?. Some prefixes have several lines of help, so you need to press ? repeatedly to see them all.

Try pressing t ? now. You will see a line of the form,

```
trail/time: Display; Fwd, Back; Next, Prev, Here, [, ]; Yank:  [MORE]  t-
```

The word "trail" indicates that the t prefix key contains trail-related commands. Each entry on the line shows one command, with a single capital letter showing which letter you press to get that command. We have used t n, t p, t], and t y so far. The `[MORE]' means you can press ? again to see more t-prefix comands. Notice that the commands are roughly divided (by semicolons) into related groups.

When you are in the help display for a prefix key, the prefix is still active. If you press another key, like y for example, it will be interpreted as a t y command. If all you wanted was to look at the help messages, press C-g afterwards to cancel the prefix.

One more way to correct an error is by editing the stack entries. The actual Stack buffer is marked read-only and must not be edited directly, but you can press ` (the backquote or accent grave) to edit a stack entry.

Try entering `3.141439' now. If this is supposed to represent pi, it's got several errors. Press ` to edit this number. Now use the normal Emacs cursor motion and editing keys to change the second 4 to a 5, and to transpose the 3 and the 9. When you press RET, the number on the stack will be replaced by your new number. This works for formulas, vectors, and all other types of values you can put on the stack. The ` key also works during entry of a number or algebraic formula.

Mode-Setting Commands

Calc has many types of modes that affect the way it interprets your commands or the way it displays data. We have already seen one mode, namely algebraic mode. There are many others, too; we'll try some of the most common ones here.

Perhaps the most fundamental mode in Calc is the current precision. Notice the `12' on the Calc window's mode line:

```
--%%-Calc: 12 Deg       (Calculator)----All------
```

Most of the symbols there are Emacs things you don't need to worry about, but the `12' and the `Deg' are mode indicators. The `12' means that calculations should always be carried to 12 significant figures. That is why, when we type 1 RET 7 /, we get 0.142857142857 with exactly 12 digits, not counting leading and trailing zeros.

You can set the precision to anything you like by pressing p, then entering a suitable number. Try pressing p 30 RET, then doing 1 RET 7 / again:

```
1:  0.142857142857
2:  0.142857142857142857142857142857
    .
```

Although the precision can be set arbitrarily high, Calc always has to have *some* value for the current precision. After all, the true value 1/7 is an infinitely repeating decimal; Calc has to stop somewhere.

Of course, calculations are slower the more digits you request. Press p 12 now to set the precision back down to the default.

Calculations always use the current precision. For example, even though we have a 30-digit value for 1/7 on the stack, if we use it in a calculation in 12-digit mode it will be rounded down to 12 digits before it is used. Try it; press RET to duplicate the number, then 1 +. Notice that the RET key didn't round the number, because it doesn't do any calculation. But the instant we pressed +, the number was rounded down.

```
1:  0.142857142857
2:  0.142857142857142857142857142857
3:  1.14285714286
    .
```

In fact, since we added a digit on the left, we had to lose one digit on the right from even the 12-digit value of 1/7.

How did we get more than 12 digits when we computed `2^3^4'? The answer is that Calc makes a distinction between integers and floating-point numbers, or floats. An integer is a number that does not contain a decimal point. There is no such thing as an "infinitely repeating fraction integer," so Calc doesn't have to limit itself. If you asked for `2^10000' (don't try this!), you would have to wait a long time but you would eventually get an exact answer. If you ask for `2.^10000', you will quickly get an answer which is correct only to 12 places. The decimal point tells Calc that it should use floating-point arithmetic to get the answer, not exact integer arithmetic.

You can use the F (`calc-floor`) command to convert a floating-point value to an integer, and c f (`calc-float`) to convert an integer to floating-point form.

Let's try entering that last calculation:

```
1:  2.          2:  2.          1:  1.99506311689e3010
    .           1:  10000           .
                    .
```

```
  2.0 RET          10000 RET      ^
```

Notice the letter `e' in there. It represents "times ten to the power of," and is used by Calc automatically whenever writing the number out fully would introduce more extra zeros than you probably want to see. You can enter numbers in this notation, too.

```
1:  2.          2:  2.          1:  1.99506311678e3010
    .           1:  10000.          .
                    .

  2.0 RET          1e4 RET        ^
```

Hey, the answer is different! Look closely at the middle columns of the two examples. In the first, the stack contained the exact integer 10000, but in the second it contained a floating-point value with a decimal point. When you raise a number to an integer power, Calc uses repeated squaring and multiplication to get the answer. When you use a floating-point power, Calc uses logarithms and exponentials. As you can see, a slight error crept in during one of these methods. Which one should we trust? Let's raise the precision a bit and find out:

```
    .           1:  2.          2:  2.          1:  1.9950631168808 28e3010
                    .           1:  10000.          .
                                    .

 p 16 RET         2. RET          1e4            ^    p 12 RET
```

Presumably, it doesn't matter whether we do this higher-precision calculation using an integer or floating-point power, since we have added enough "guard digits" to trust the first 12 digits no matter what. And the verdict is... Integer powers were more accurate; in fact, the result was only off by one unit in the last place.

Calc does many of its internal calculations to a slightly higher precision, but it doesn't always bump the precision up enough. In each case, Calc added about two digits of precision during its calculation and then rounded back down to 12 digits afterward. In one case, it was enough; in the the other, it wasn't. If you really need x digits of precision, it never hurts to do the calculation with a few extra guard digits.

What if we want guard digits but don't want to look at them? We can set the float format. Calc supports four major formats for floating-point numbers, called normal, fixed-point, scientific notation, and engineering notation. You get them by pressing d n, d f, d s, and d e, respectively. In each case, you can supply a numeric prefix argument which says how many digits should be displayed. As an example, let's put a few numbers onto the stack and try some different display modes. First, use M-0 DEL to clear the stack, then enter the four numbers shown here:

```
4:  12345       4:  12345       4:  12345       4:  12345       4:  12345
3:  12345.      3:  12300.      3:  1.2345e4    3:  1.23e4      3:  12345.000
2:  123.45      2:  123.        2:  1.2345e2    2:  1.23e2      2:  123.450
1:  12.345      1:  12.3        1:  1.2345e1    1:  1.23e1      1:  12.345
    .               .               .               .               .

   d n           M-3 d n         d s           M-3 d s         M-3 d f
```

Notice that when we typed M-3 d n, the numbers were rounded down to three significant digits, but then w we typed d s all five significant figures reappeared. The float format does not affect how numbers are stor only affects how they are displayed. Only the current precision governs the actual rounding of numbers in the Calculator's memory.

Engineering notation, not shown here, is like scientific notation except the exponent (the power-of-ten part) is always adjusted to be a multiple of three (as in "kilo," "micro," etc.). As a result there will be one, two, or three digits before the decimal point.

Whenever you change a display-related mode, Calc redraws everything in the stack. This may be slow if there are many things on the stack, so Calc allows you to type shift-H before any mode command to prevent it from updating the stack. Anything Calc displays after the mode-changing command will appear in the new format.

```
4:  12345      4:  12345      4:  12345      4:  12345      4:  12345
3:  12345.000  3:  12345.000  3:  12345.000  3:  1.2345e4   3:  12345.
2:  123.450    2:  123.450    2:  1.2345e1   2:  1.2345e1   2:  123.45
1:  12.345     1:  1.2345e1   1:  1.2345e2   1:  1.2345e2   1:  12.345
    .              .              .              .              .

    H d s          DEL U          TAB            d SPC          d n
```

Here the H d s command changes to scientific notation but without updating the screen. Deleting the top stack entry and undoing it back causes it to show up in the new format; swapping the top two stack entries reformats both entries. The d SPC command refreshes the whole stack. The d n command changes back to the normal float format; since it doesn't have an H prefix, it also updates all the stack entries to be in d n format.

Notice that the integer 12345 was not affected by any of the float formats. Integers are integers, and are always displayed exactly.

Large integers have their own problems. Let's look back at the result of 2^3^4.

```
241785163922925834941235 2
```

Quick--how many digits does this have? Try typing d g:

```
2,417,851,639,229,258,349,412,352
```

Now how many digits does this have? It's much easier to tell! We can actually group digits into clumps of any size. Some people prefer M-5 d g:

```
24178,51639,22925,83494,12352
```

Let's see what happens to floating-point numbers when they are grouped. First, type p 25 RET to make sure we have enough precision to get ourselves into trouble. Now, type 1e13 /:

```
24,17851,63922.9258349412352
```

The integer part is grouped but the fractional part isn't. Now try M-- M-5 d g (that's meta-minus-sign, meta-five):

```
24,17851,63922.92583,49412,352
```

If you find it hard to tell the decimal point from the commas, try changing the grouping character to a space with d , SPC:

```
24 17851 63922.92583 49412 352
```

Type d , , to restore the normal grouping character, then d g again to turn grouping off. Also, press p 12 to restore the default precision.

Press U enough times to get the original big integer back. (Notice that U does not undo each mode-setting command; if you want to undo a mode-setting command, you have to do it yourself.) Now, type d r 16 RET:

```
16#2000000000000000000
```

The number is now displayed in hexadecimal, or "base-16" form. Suddenly it looks pretty simple; this should be no surprise, since we got this number by computing a power of two, and 16 is a power of 2. In fact, we can use d r 2 RET to see it in actual binary form:

```
2#1000000000000000000000000000000000000000000000000000000000000000 ...
```

We don't have enough space here to show all the zeros! They won't fit on a typical screen, either, so you will have to use horizontal scrolling to see them all. Press < and > to scroll the stack window left and right by half its width. Another way to view something large is to press ` (back-quote) to edit the top of stack in a separate window. (Press M-# M-# when you are done.)

You can enter non-decimal numbers using the # symbol, too. Let's see what the hexadecimal number `5FE' looks like in binary. Type 16#5FE (the letters can be typed in upper or lower case; they will always appear in upper case). It will also help to turn grouping on with d g:

```
2#101,1111,1110
```

Notice that d g groups by fours by default if the display radix is binary or hexadecimal, but by threes if it is decimal, octal, or any other radix.

Now let's see that number in decimal; type d r 10:

```
1,534
```

Numbers are not *stored* with any particular radix attached. They're just numbers; they can be entered in any radix, and are always displayed in whatever radix you've chosen with d r. The current radix applies to integers, fractions, and floats.

(*) **Exercise 1.** Your friend Joe tried to enter one-third as `3#0.1' in d r 3 mode with a precision of 12. He got `3#0.0222222...' (with 25 2's) in the display. When he multiplied that by three, he got `3#0.222222...' instead of the expected `3#1'. Next, Joe entered `3#0.2' and, to his great relief, saw `3#0.2' on the screen. But when he typed 2 /, he got `3#0.10000001' (some zeros omitted). What's going on here? See section Modes Tutorial Exercise 1. (*)

(*) **Exercise 2.** Scientific notation works in non-decimal modes in the natural way (the exponent is a power of

the radix instead of a power of ten, although the exponent itself is always written in decimal). Thus `8#1.2 = 8#1230.0'. Suppose we have the hexadecimal number `f.e8f' times 16 to the 15th power: We write `16#f.e8fe15'. What is wrong with this picture? What could we write instead that would work better? See section Modes Tutorial Exercise 2. (*)

The m prefix key has another set of modes, relating to the way Calc interprets your inputs and does computations. Whereas d-prefix modes generally affect the way things look, m-prefix modes affect the way they are actually computed.

The most popular m-prefix mode is the angular mode. Notice the `Deg' indicator in the mode line. This means that if you use a command that interprets a number as an angle, it will assume the angle is measured in degrees. For example,

```
1:  45          1:  0.707106781187   1:  0.500000000001    1:  0.5
    .               .                    .                     .

    45              S                    2 ^                   c 1
```

The shift-S command computes the sine of an angle. The sine of 45 degrees is @c{$\sqrt{2}/2$} sqrt(2)/2; squaring this yields 2/4 = 0.5. However, there has been a slight roundoff error because the representation of @c{$\sqrt{2}/2$} sqrt(2)/2 wasn't exact. The c 1 command is a handy way to clean up numbers in this case; it temporarily reduces the precision by one digit while it re-rounds the number on the top of the stack.

(*) **Exercise 3.** Your friend Joe computed the sine of 45 degrees as shown above, then, hoping to avoid an inexact result, he increased the precision to 16 digits before squaring. What happened? See section Modes Tutorial Exercise 3. (*)

To do this calculation in radians, we would type m r first. (The indicator changes to `Rad'.) 45 degrees corresponds to pi/4 radians. To get @c{π} pi, press the P key. (Once again, this is a shifted capital P. Remember, unshifted p sets the precision.)

```
1:  3.14159265359   1:  0.785398163398   1:  0.707106781187
    .                   .                   .

    P                   4 /       m r       S
```

Likewise, inverse trigonometric functions generate results in either radians or degrees, depending on the current angular mode.

```
1:  0.707106781187   1:  0.785398163398   1:  45.
    .                    .                   .

    .5 Q         m r     I S         m d     U I S
```

Here we compute the Inverse Sine of @c{$\sqrt{0.5}$} sqrt(0.5), first in radians, then in degrees.

Use c d and c r to convert a number from radians to degrees and vice-versa.

```
1:  45          1:  0.785398163397     1:  45.
```

```
    .               .                   .

    45              c r                 c d
```

Another interesting mode is fraction mode. Normally, dividing two integers produces a floating-point result if the quotient can't be expressed as an exact integer. Fraction mode causes integer division to produce a fraction, i.e., a rational number, instead.

```
2:  12          1:  1.33333333333    1:  4:3
1:  9               .                    .
    .

 12 RET 9           /           m f      U /      m f
```

In the first case, we get an approximate floating-point result. In the second case, we get an exact fractional result (four-thirds).

You can enter a fraction at any time using : notation. (Calc uses : instead of / as the fraction separator because / is already used to divide the top two stack elements.) Calculations involving fractions will always produce exact fractional results; fraction mode only says what to do when dividing two integers.

(*) **Exercise 4.** If fractional arithmetic is exact, why would you ever use floating-point numbers instead? See section Modes Tutorial Exercise 4. (*)

Typing m f doesn't change any existing values in the stack. In the above example, we had to Undo the division and do it over again when we changed to fraction mode. But if you use the evaluates-to operator you can get commands like m f to recompute for you.

```
1:  12 / 9 => 1.33333333333    1:  12 / 9 => 1.333    1:  12 / 9 => 4:3
    .                              .                      .

   ' 12/9 => RET                   p 4 RET                m f
```

In this example, the righthand side of the `=>' operator on the stack is recomputed when we change the precision, then again when we change to fraction mode. All `=>' expressions on the stack are recomputed every time you change any mode that might affect their values.

Arithmetic Tutorial

In this section, we explore the arithmetic and scientific functions available in the Calculator.

The standard arithmetic commands are +, -, *, /, and ^. Each normally takes two numbers from the top of the stack and pushes back a result. The n and & keys perform change-sign and reciprocal operations, respectively.

```
1:  5           1:  0.2         1:  5.          1:  -5.         1:  5.
    .               .               .               .               .

    5               &               &               n               n
```

You can apply a "binary operator" like + across any number of stack entries by giving it a numeric prefix. can also apply it pairwise to several stack elements along with the top one if you use a negative prefix.

```
3:  2          1:  9          3:  2          4:  2          3:  12
2:  3              .          2:  3          3:  3          2:  13
1:  4                         1:  4          2:  4          1:  14
    .                             .          1:  10             .
                                                 .

2 RET 3 RET 4     M-3 +           U              10          M-- M-3 +
```

You can apply a "unary operator" like & to the top n stack entries with a numeric prefix, too.

```
3:  2          3:  0.5                3:  0.5
2:  3          2:  0.333333333333     2:  3.
1:  4          1:  0.25               1:  4.
    .              .                      .

2 RET 3 RET 4      M-3 &                  M-2 &
```

Notice that the results here are left in floating-point form. We can convert them back to integers by pressing F, the "floor" function. This function rounds down to the next lower integer. There is also R, which rounds to the nearest integer.

```
7:  2.         7:  2          7:  2
6:  2.4        6:  2          6:  2
5:  2.5        5:  2          5:  3
4:  2.6        4:  2          4:  3
3:  -2.        3:  -2         3:  -2
2:  -2.4       2:  -3         2:  -2
1:  -2.6       1:  -3         1:  -3
    .              .              .

                  M-7 F          U M-7 R
```

Since dividing-and-flooring (i.e., "integer quotient") is such a common operation, Calc provides a special command for that purpose, the backslash \. Another common arithmetic operator is %, which computes the remainder that would arise from a \ operation, i.e., the "modulo" of two numbers. For example,

```
2:  1234       1:  12         2:  1234       1:  34
1:  100            .          1:  100            .
    .                             .

1234 RET 100       \              U              %
```

These commands actually work for any real numbers, not just integers.

```
2:  3.1415     1:  3          2:  3.1415     1:  0.1415
```

```
1:  1              .          1:  1              .
    .                             .

3.1415 RET 1       \              U              %
```

(*) **Exercise 1.** The \ command would appear to be a frill, since you could always do the same thing with / F. Think of a situation where this is not true---/ F would be inadequate. Now think of a way you could get around the problem if Calc didn't provide a \ command. See section Arithmetic Tutorial Exercise 1. (*)

We've already seen the Q (square root) and S (sine) commands. Other commands along those lines are C (cosine), T (tangent), E (e^x) and L (natural logarithm). These can be modified by the I (inverse) and H (hyperbolic) prefix keys.

Let's compute the sine and cosine of an angle, and verify the identity @c{$\sin^2x + \cos^2x = 1$} sin(x)^2 + cos(x)^2 = 1. We'll arbitrarily pick -*64* degrees as a good value for x. With the angular mode set to degrees (type m d), do:

```
2:  -64        2:  -64        2:  -0.89879   2:  -0.89879   1:  1.
1:  -64        1:  -0.89879   1:  -64        1:  0.43837        .
    .              .              .              .

 64 n RET RET      S              TAB            C              f h
```

(For brevity, we're showing only five digits of the results here. You can of course do these calculations to any precision you like.)

Remember, f h is the `calc-hypot`, or square-root of sum of squares, command.

Another identity is @c{$\displaystyle\tan x = {\sin x \over \cos x}$} tan(x) = sin(x) / cos(x).

```
2:  -0.89879   1:  -2.0503    1:  -64.
1:  0.43837        .              .
    .

    U              /              I T
```

A physical interpretation of this calculation is that if you move 0.89879 units downward and 0.43837 units to the right, your direction of motion is -*64* degrees from horizontal. Suppose we move in the opposite direction, up and to the left:

```
2:  -0.89879   2:  0.89879    1:  -2.0503    1:  -64.
1:  0.43837    1:  -0.43837       .              .
    .              .

    U U            M-2 n          /              I T
```

How can the angle be the same? The answer is that the / operation loses information about the signs of its inputs. Because the quotient is negative, we know exactly one of the inputs was negative, but we can't tell which one. There is an f T [`arctan2`] function which computes the inverse tangent of the quotient of a pair

of numbers. Since you feed it the two original numbers, it has enough information to give you a full 360-degree answer.

```
2:  0.89879    1:  116.       3:  116.       2:  116.       1:  180.
1:  -0.43837       .          2:  -0.89879   1:  -64.           .
    .                         1:  0.43837        .
                                  .

    U U            f T          M-RET M-2 n       f T            -
```

The resulting angles differ by 180 degrees; in other words, they point in opposite directions, just as we would expect.

The META-RET we used in the third step is the "last-arguments" command. It is sort of like Undo, except that it restores the arguments of the last command to the stack without removing the command's result. It is useful in situations like this one, where we need to do several operations on the same inputs. We could have accomplished the same thing by using M-2 RET to duplicate the top two stack elements right after the U U, then a pair of M-TAB commands to cycle the 116 up around the duplicates.

A similar identity is supposed to hold for hyperbolic sines and cosines, except that it is the *difference* cosh(x)^2 - sinh(x)^2 that always equals one. Let's try to verify this identity.

```
2:  -64        2:  -64        2:  -64        2:  9.7192e54  2:  9.7192e54
1:  -64        1:  -3.1175e27 1:  9.7192e54  1:  -64        1:  9.7192e54
    .              .              .              .              .

 64 n RET RET      H C            2 ^            TAB            H S 2 ^
```

Something's obviously wrong, because when we subtract these numbers the answer will clearly be zero! But if you think about it, if these numbers *did* differ by one, it would be in the 55th decimal place. The difference we seek has been lost entirely to roundoff error.

We could verify this hypothesis by doing the actual calculation with, say, 60 decimal places of precision. This will be slow, but not enormously so. Try it if you wish; sure enough, the answer is 0.99999, reasonably close to 1.

Of course, a more reasonable way to verify the identity is to use a more reasonable value for x!

Some Calculator commands use the Hyperbolic prefix for other purposes. The logarithm and exponential functions, for example, work to the base e normally but use base-10 instead if you use the Hyperbolic prefix.

```
1:  1000       1:  6.9077     1:  1000       1:  3
    .              .              .              .

    1000           L              U              H L
```

First, we mistakenly compute a natural logarithm. Then we undo and compute a common logarithm instead.

The B key computes a general base-b logarithm for any value of b.

```
2:  1000        1:  3           1:  1000.       2:  1000.       1:  6.9077
1:  10              .               .           1:  2.71828         .
    .                                               .

 1000 RET 10        B               H E             H P             B
```

Here we first use B to compute the base-10 logarithm, then use the "hyperbolic" exponential as a cheap hack to recover the number 1000, then use B again to compute the natural logarithm. Note that P with the hyperbolic prefix pushes the constant e onto the stack.

You may have noticed that both times we took the base-10 logarithm of 1000, we got an exact integer result. Calc always tries to give an exact rational result for calculations involving rational numbers where possible. But when we used H E, the result was a floating-point number for no apparent reason. In fact, if we had computed 10 RET 3 ^ we *would* have gotten an exact integer 1000. But the H E command is rigged to generate a floating-point result all of the time so that 1000 H E will not waste time computing a thousand-digit integer when all you probably wanted was `1e1000'.

(*) **Exercise 2.** Find a pair of integer inputs to the B command for which Calc could find an exact rational result but doesn't. See section Arithmetic Tutorial Exercise 2. (*)

The Calculator also has a set of functions relating to combinatorics and statistics. You may be familiar with the factorial function, which computes the product of all the integers up to a given number.

```
1:  100         1:  93326215443...      1:  100.        1:  9.3326e157
    .               .                       .               .

    100             !                       U c f           !
```

Recall, the c f command converts the integer or fraction at the top of the stack to floating-point format. If you take the factorial of a floating-point number, you get a floating-point result accurate to the current precision. But if you give ! an exact integer, you get an exact integer result (158 digits long in this case).

If you take the factorial of a non-integer, Calc uses a generalized factorial function defined in terms of Euler's Gamma function gamma(n) (which is itself available as the f g command).

```
3:  4.          3:  24.                 1:  5.5         1:  52.342777847
2:  4.5         2:  52.3427777847           .               .
1:  5.          1:  120.
    .               .

                    M-3 !                M-0 DEL 5.5        f g
```

Here we verify the identity @c{$n! = \Gamma(n+1)$} n! = gamma(n+1).

The binomial coefficient n-choose-m@c{ or $\displaystyle {n \choose m}$} is defined by n! / m! (n-m)! for all reals n and m. The intermediate results in this formula can become quite large even if the final result is small; the k c command computes a binomial coefficient in a way that avoids large intermediate values.

The k prefix key defines several common functions out of combinatorics and number theory. Here we compute the binomial coefficient 30-choose-20, then determine its prime factorization.

```
2:  30          1:  30045015    1:  [3, 3, 5, 7, 11, 13, 23, 29]
1:  20              .               .
    .

 30 RET 20          k c             k f
```

You can verify these prime factors by using v u to "unpack" this vector into 8 separate stack entries, then M-8 * to multiply them back together. The result is the original number, 30045015.

Suppose a program you are writing needs a hash table with at least 10000 entries. It's best to use a prime number as the actual size of a hash table. Calc can compute the next prime number after 10000:

```
1:  10000       1:  10007       1:  9973
    .               .               .

    10000           k n             I k n
```

Just for kicks we've also computed the next prime *less* than 10000.

See section Financial Functions, for a description of the Calculator commands that deal with business and financial calculations (functions like `pv`, `rate`, and `sln`).

See section Binary Number Functions, to read about the commands for operating on binary numbers (like `and`, `xor`, and `lsh`).

Vector/Matrix Tutorial

A vector is a list of numbers or other Calc data objects. Calc provides a large set of commands that operate on vectors. Some are familiar operations from vector analysis. Others simply treat a vector as a list of objects.

Vector Analysis

If you add two vectors, the result is a vector of the sums of the elements, taken pairwise.

```
1:  [1, 2, 3]       2:  [1, 2, 3]       1:  [8, 8, 3]
    .               1:  [7, 6, 0]           .
                        .

    [1,2,3]  s 1        [7 6 0]  s 2        +
```

Note that we can separate the vector elements with either commas or spaces. This is true whether we are using incomplete vectors or algebraic entry. The s 1 and s 2 commands save these vectors so we can easily reuse them later.

If you multiply two vectors, the result is the sum of the products of the elements taken pairwise. This is called the dot product of the vectors.

```
2:  [1, 2, 3]       1:  19
```

```
1:  [7, 6, 0]          .
    .

    r 1 r 2            *
```

The dot product of two vectors is equal to the product of their lengths times the cosine of the angle between them. (Here the vector is interpreted as a line from the origin (0,0,0) to the specified point in three-dimensional space.) The A (absolute value) command can be used to compute the length of a vector.

```
3:  19             3:  19          1:  0.550782    1:  56.579
2:  [1, 2, 3]      2:  3.741657        .               .
1:  [7, 6, 0]      1:  9.219544
    .                  .

    M-RET              M-2 A           * /             I C
```

First we recall the arguments to the dot product command, then we compute the absolute values of the top two stack entries to obtain the lengths of the vectors, then we divide the dot product by the product of the lengths to get the cosine of the angle. The inverse cosine finds that the angle between the vectors is about 56 degrees.

The cross product of two vectors is a vector whose length is the product of the lengths of the inputs times the sine of the angle between them, and whose direction is perpendicular to both input vectors. Unlike the dot product, the cross product is defined only for three-dimensional vectors. Let's double-check our computation of the angle using the cross product.

```
2:  [1, 2, 3]  3:  [-18, 21, -8]  1:  [-0.52, 0.61, -0.23]  1:  56.579
1:  [7, 6, 0]  2:  [1, 2, 3]          .                         .
    .          1:  [7, 6, 0]
               .

    r 1 r 2        V C  s 3  M-RET    M-2 A * /                 A I S
```

First we recall the original vectors and compute their cross product, which we also store for later reference. Now we divide the vector by the product of the lengths of the original vectors. The length of this vector should be the sine of the angle; sure enough, it is!

Vector-related commands generally begin with the v prefix key. Some are uppercase letters and some are lowercase. To make it easier to type these commands, the shift-V prefix key acts the same as the v key. (See section General Mode Commands, for a way to make all prefix keys have this property.)

If we take the dot product of two perpendicular vectors we expect to get zero, since the cosine of 90 degrees is zero. Let's check that the cross product is indeed perpendicular to both inputs:

```
2:  [1, 2, 3]      1:  0          2:  [7, 6, 0]      1:  0
1:  [-18, 21, -8]      .          1:  [-18, 21, -8]      .
    .                             .

    r 1 r 3            *          DEL r 2 r 3            *
```

(*) **Exercise 1.** Given a vector on the top of the stack, what keystrokes would you use to normalize the ve
i.e., to reduce its length to one without changing its direction? See section Vector Tutorial Exercise 1. (*)

(*) **Exercise 2.** Suppose a certain particle can be at any of several positions along a ruler. You have a list of those positions in the form of a vector, and another list of the probabilities for the particle to be at the corresponding positions. Find the average position of the particle. See section Vector Tutorial Exercise 2. (*)

Matrices

A matrix is just a vector of vectors, all the same length. This means you can enter a matrix using nested brackets. You can also use the semicolon character to enter a matrix. We'll show both methods here:

```
1:  [ [ 1, 2, 3 ]                1:  [ [ 1, 2, 3 ]
      [ 4, 5, 6 ] ]                     [ 4, 5, 6 ] ]
    .                                 .

  [[1 2 3] [4 5 6]]                 ' [1 2 3; 4 5 6] RET
```

We'll be using this matrix again, so type s 4 to save it now.

Note that semicolons work with incomplete vectors, but they work better in algebraic entry. That's why we use the apostrophe in the second example.

When two matrices are multiplied, the lefthand matrix must have the same number of columns as the righthand matrix has rows. Row i, column j of the result is effectively the dot product of row i of the left matrix by column j of the right matrix.

If we try to duplicate this matrix and multiply it by itself, the dimensions are wrong and the multiplication cannot take place:

```
1:  [ [ 1, 2, 3 ]   * [ [ 1, 2, 3 ]
      [ 4, 5, 6 ] ]     [ 4, 5, 6 ] ]
    .

    RET *
```

Though rather hard to read, this is a formula which shows the product of two matrices. The `*' function, having invalid arguments, has been left in symbolic form.

We can multiply the matrices if we transpose one of them first.

```
2:  [ [ 1, 2, 3 ]       1:  [ [ 14, 32 ]      1:  [ [ 17, 22, 27 ]
      [ 4, 5, 6 ] ]           [ 32, 77 ] ]          [ 22, 29, 36 ]
1:  [ [ 1, 4 ]            .                       [ 27, 36, 45 ] ]
      [ 2, 5 ]                                  .
      [ 3, 6 ] ]
    .

    U v t                 *                   U TAB *
```

Matrix multiplication is not commutative; indeed, switching the order of the operands can even change th dimensions of the result matrix, as happened here!

If you multiply a plain vector by a matrix, it is treated as a single row or column depending on which side of the matrix it is on. The result is a plain vector which should also be interpreted as a row or column as appropriate.

```
2:  [ [ 1, 2, 3 ]      1:  [14, 32]
      [ 4, 5, 6 ] ]        .
1:  [1, 2, 3]
    .

    r 4 r 1              *
```

Multiplying in the other order wouldn't work because the number of rows in the matrix is different from the number of elements in the vector.

(*) **Exercise 1.** Use `*' to sum along the rows of the above @c{$2\times3$} 2x3 matrix to get [6, 15]. Now use `*' to sum along the columns to get [5, 7, 9]. See section Matrix Tutorial Exercise 1. (*)

An identity matrix is a square matrix with ones along the diagonal and zeros elsewhere. It has the property that multiplication by an identity matrix, on the left or on the right, always produces the original matrix.

```
1:  [ [ 1, 2, 3 ]      2:  [ [ 1, 2, 3 ]      1:  [ [ 1, 2, 3 ]
      [ 4, 5, 6 ] ]          [ 4, 5, 6 ] ]          [ 4, 5, 6 ] ]
    .                  1:  [ [ 1, 0, 0 ]        .
                           [ 0, 1, 0 ]
                           [ 0, 0, 1 ] ]
                       .

    r 4                v i 3 RET              *
```

If a matrix is square, it is often possible to find its inverse, that is, a matrix which, when multiplied by the original matrix, yields an identity matrix. The & (reciprocal) key also computes the inverse of a matrix.

```
1:  [ [ 1, 2, 3 ]      1:  [ [   -2.4,     1.2,   -0.2 ]
      [ 4, 5, 6 ]            [    2.8,    -1.4,    0.4 ]
      [ 7, 6, 0 ] ]          [ -0.73333, 0.53333, -0.2 ] ]
    .                    .

    r 4 r 2 |  s 5       &
```

The vertical bar | concatenates numbers, vectors, and matrices together. Here we have used it to add a new row onto our matrix to make it square.

We can multiply these two matrices in either order to get an identity.

```
1:  [ [ 1., 0., 0. ]      1:  [ [ 1., 0., 0. ]
      [ 0., 1., 0. ]            [ 0., 1., 0. ]
```

```
      [ 0., 0., 1. ] ]          [ 0., 0., 1. ] ]
    .                         .

    M-RET  *                  U TAB *
```

Matrix inverses are related to systems of linear equations in algebra. Suppose we had the following set of equations:

This can be cast into the matrix equation,

We can solve this system of equations by multiplying both sides by the inverse of the matrix. Calc can do this all in one step:

```
2:  [6, 2, 3]          1:  [-12.6, 15.2, -3.93333]
1:  [ [ 1, 2, 3 ]          .
      [ 4, 5, 6 ]
      [ 7, 6, 0 ] ]
    .

    [6,2,3] r 5            /
```

The result is the [a, b, c] vector that solves the equations. (Dividing by a square matrix is equivalent to multiplying by its inverse.)

Let's verify this solution:

```
2:  [ [ 1, 2, 3 ]              1:  [6., 2., 3.]
      [ 4, 5, 6 ]                  .
      [ 7, 6, 0 ] ]
1:  [-12.6, 15.2, -3.93333]
    .

    r 5  TAB                       *
```

Note that we had to be careful about the order in which we multiplied the matrix and vector. If we multiplied in the other order, Calc would assume the vector was a row vector in order to make the dimensions come out right, and the answer would be incorrect. If you don't feel safe letting Calc take either interpretation of your vectors, use explicit @c{$N\times1$} Nx1 or @c{$1\times N$} 1xN matrices instead. In this case, you would enter the original column vector as `[[6], [2], [3]]' or `[6; 2; 3]'.

(*) **Exercise 2.** Algebraic entry allows you to make vectors and matrices that include variables. Solve the following system of equations to get expressions for x and y in terms of a and b.

See section Matrix Tutorial Exercise 2. (*)

(*) **Exercise 3.** A system of equations is "over-determined" if it has more equations than variables. It is often the case that there are no values for the variables that will satisfy all the equations at once, but it is still useful to find a set of values which "nearly" satisfy all the equations. In terms of matrix equations, you can't solve A X = B directly because the matrix A is not square for an over-determined system. Matrix inversion works only for square matrices. One common trick is to multiply both sides on the left by the transpose of A: Now @c{$A^T A$} trn(A)*A is a square matrix so a solution is possible. It turns out that the X vector you

compute in this way will be a "least-squares" solution, which can be regarded as the "closest" solution to t set of equations. Use Calc to solve the following over-determined system:

See section Matrix Tutorial Exercise 3. (*)

Vectors as Lists

Although Calc has a number of features for manipulating vectors and matrices as mathematical objects, you can also treat vectors as simple lists of values. For example, we saw that the k f command returns a vector which is a list of the prime factors of a number.

You can pack and unpack stack entries into vectors:

```
3:  10          1:  [10, 20, 30]      3:  10
2:  20              .                 2:  20
1:  30                                1:  30
    .                                     .

                  M-3 v p                 v u
```

You can also build vectors out of consecutive integers, or out of many copies of a given value:

```
1:  [1, 2, 3, 4]    2:  [1, 2, 3, 4]    2:  [1, 2, 3, 4]
    .               1:  17              1:  [17, 17, 17, 17]
                        .                   .

    v x 4 RET           17                  v b 4 RET
```

You can apply an operator to every element of a vector using the map command.

```
1:  [17, 34, 51, 68]   1:  [289, 1156, 2601, 4624]  1:  [17, 34, 51, 68]
    .                      .                            .

    V M *                  2 V M ^                      V M Q
```

In the first step, we multiply the vector of integers by the vector of 17's elementwise. In the second step, we raise each element to the power two. (The general rule is that both operands must be vectors of the same length, or else one must be a vector and the other a plain number.) In the final step, we take the square root of each element.

(*) **Exercise 1.** Compute a vector of powers of two from @c{2^{-4}} 2^-4 to 2^4. See section List Tutorial Exercise 1. (*)

You can also reduce a binary operator across a vector. For example, reducing `*' computes the product of all the elements in the vector:

```
1:  123123      1:  [3, 7, 11, 13, 41]      1:  123123
    .               .                           .
```

```
    123123          k f                             V R *
```

In this example, we decompose 123123 into its prime factors, then multiply those factors together again to yield the original number.

We could compute a dot product "by hand" using mapping and reduction:

```
2:  [1, 2, 3]     1:  [7, 12, 0]     1:  19
1:  [7, 6, 0]         .                  .
    .

    r 1 r 2           V M *              V R +
```

Recalling two vectors from the previous section, we compute the sum of pairwise products of the elements to get the same answer for the dot product as before.

A slight variant of vector reduction is the accumulate operation, V U. This produces a vector of the intermediate results from a corresponding reduction. Here we compute a table of factorials:

```
1:  [1, 2, 3, 4, 5, 6]    1:  [1, 2, 6, 24, 120, 720]
    .                         .

    v x 6 RET                 V U *
```

Calc allows vectors to grow as large as you like, although it gets rather slow if vectors have more than about a hundred elements. Actually, most of the time is spent formatting these large vectors for display, not calculating on them. Try the following experiment (if your computer is very fast you may need to substitute a larger vector size).

```
1:  [1, 2, 3, 4, ...      1:  [2, 3, 4, 5, ...
    .                         .

    v x 500 RET               1 V M +
```

Now press v . (the letter v, then a period) and try the experiment again. In v . mode, long vectors are displayed "abbreviated" like this:

```
1:  [1, 2, 3, ..., 500]   1:  [2, 3, 4, ..., 501]
    .                         .

    v x 500 RET               1 V M +
```

(where now the `...' is actually part of the Calc display). You will find both operations are now much faster. But notice that even in v . mode, the full vectors are still shown in the Trail. Type t . to cause the trail to abbreviate as well, and try the experiment one more time. Operations on long vectors are now quite fast! (But of course if you use t . you will lose the ability to get old vectors back using the t y command.)

An easy way to view a full vector when v . mode is active is to press ` (back-quote) to edit the vector; editing always works with the full, unabbreviated value.

As a larger example, let's try to fit a straight line to some data, using the method of least squares. (Calc has built-in command for least-squares curve fitting, but we'll do it by hand here just to practice working with vectors.) Suppose we have the following list of values in a file we have loaded into Emacs:

```
  x         y
 --       ---
 1.34    0.234
 1.41    0.298
 1.49    0.402
 1.56    0.412
 1.64    0.466
 1.73    0.473
 1.82    0.601
 1.91    0.519
 2.01    0.603
 2.11    0.637
 2.22    0.645
 2.33    0.705
 2.45    0.917
 2.58    1.009
 2.71    0.971
 2.85    1.062
 3.00    1.148
 3.15    1.157
 3.32    1.354
```

If you are reading this tutorial in printed form, you will find it easiest to press M-# i to enter the on-line Info version of the manual and find this table there. (Press g, then type List Tutorial, to jump straight to this section.)

Position the cursor at the upper-left corner of this table, just to the left of the 1.34. Press C-@ to set the mark. (On your system this may be C-2, C-SPC, or NUL.) Now position the cursor to the lower-right, just after the 1.354. You have now defined this region as an Emacs "rectangle." Still in the Info buffer, type M-# r. This command (`calc-grab-rectangle`) will pop you back into the Calculator, with the contents of the rectangle you specified in the form of a matrix.

```
1:  [ [ 1.34, 0.234 ]
      [ 1.41, 0.298 ]
      ...
```

(You may wish to use v . mode to abbreviate the display of this large matrix.)

We want to treat this as a pair of lists. The first step is to transpose this matrix into a pair of rows. Remember, a matrix is just a vector of vectors. So we can unpack the matrix into a pair of row vectors on the stack.

```
1:  [ [ 1.34,  1.41,  1.49,  ... ]     2:  [1.34, 1.41, 1.49, ... ]
      [ 0.234, 0.298, 0.402, ... ] ]   1:  [0.234, 0.298, 0.402, ... ]
    .                                      .
```

```
    v t                                         v u
```

Let's store these in quick variables 1 and 2, respectively.

```
1:  [1.34, 1.41, 1.49, ... ]          .
    .

    t 2                                 t 1
```

(Recall that t 2 is a variant of s 2 that removes the stored value from the stack.)

In a least squares fit, the slope m is given by the formula

where @c{$\sum x$} sum(x) represents the sum of all the values of x. While there is an actual `sum` function in Calc, it's easier to sum a vector using a simple reduction. First, let's compute the four different sums that this formula uses.

```
1:  41.63                   1:  98.0003
    .                           .

 r 1 V R +   t 3             r 1 2 V M ^ V R +   t 4

1:  13.613                  1:  33.36554
    .                           .

 r 2 V R +   t 5             r 1 r 2 V M * V R +   t 6
```

Finally, we also need N, the number of data points. This is just the length of either of our lists.

```
1:  19
    .

 r 1 v l   t 7
```

(That's v followed by a lower-case l.)

Now we grind through the formula:

```
1:  633.94526  2:  633.94526  1:  67.23607
    .          1:  566.70919      .
                   .

 r 7 r 6 *      r 3 r 5 *          -

2:  67.23607   3:  67.23607   2:  67.23607   1:  0.52141679
1:  1862.0057  2:  1862.0057  1:  128.9488       .
    .          1:  1733.0569      .
```

```
                    .

 r 7 r 4 *      r 3 2 ^           -              /   t 8
```

That gives us the slope m. The y-intercept b can now be found with the simple formula,

```
1:  13.613     2:  13.613     1:  -8.09358   1:  -0.425978
    .          1:  21.70658       .              .
                   .

   r 5            r 8 r 3 *       -              r 7 /   t 9
```

Let's "plot" this straight line approximation, @c{$y \approx m x + b$} m x + b, and compare it with the original data.

```
1:  [0.699, 0.735, ... ]    1:  [0.273, 0.309, ... ]
    .                           .

    r 1 r 8 *                   r 9 +    s 0
```

Notice that multiplying a vector by a constant, and adding a constant to a vector, can be done without mapping commands since these are common operations from vector algebra. As far as Calc is concerned, we've just been doing geometry in 19-dimensional space!

We can subtract this vector from our original y vector to get a feel for the error of our fit. Let's find the maximum error:

```
1:  [0.0387, 0.0112, ... ]   1:  [0.0387, 0.0112, ... ]   1:  0.0897
    .                            .                           .

    r 2 -                        V M A                       V R X
```

First we compute a vector of differences, then we take the absolute values of these differences, then we reduce the `max` function across the vector. (The `max` function is on the two-key sequence f x; because it is so common to use `max` in a vector operation, the letters X and N are also accepted for `max` and `min` in this context. In general, you answer the V M or V R prompt with the actual key sequence that invokes the function you want. You could have typed V R f x or even V R x max RET if you had preferred.)

If your system has the GNUPLOT program, you can see graphs of your data and your straight line to see how well they match. (If you have GNUPLOT 3.0, the following instructions will work regardless of the kind of display you have. Some GNUPLOT 2.0, non-X-windows systems may require additional steps to view the graphs.)

Let's start by plotting the original data. Recall the "*x*" and "*y*" vectors onto the stack and press g f. This "fast" graphing command does everything you need to do for simple, straightforward plotting of data.

```
2:  [1.34, 1.41, 1.49, ... ]
1:  [0.234, 0.298, 0.402, ... ]
    .
```

```
    r 1 r 2    g f
```

If all goes well, you will shortly get a new window containing a graph of the data. (If not, contact your GNUPLOT or Calc installer to find out what went wrong.) In the X window system, this will be a separate graphics window. For other kinds of displays, the default is to display the graph in Emacs itself using rough character graphics. Press q when you are done viewing the character graphics.

Next, let's add the line we got from our least-squares fit:

```
2:  [1.34, 1.41, 1.49, ... ]
1:  [0.273, 0.309, 0.351, ... ]
    .

    DEL r 0    g a  g p
```

It's not very useful to get symbols to mark the data points on this second curve; you can type g S g p to remove them. Type g q when you are done to remove the X graphics window and terminate GNUPLOT.

(*) **Exercise 2.** An earlier exercise showed how to do least squares fitting to a general system of equations. Our 19 data points are really 19 equations of the form y_i = m x_i + b for different pairs of (x_i,y_i). Use the matrix-transpose method to solve for m and b, duplicating the above result. See section List Tutorial Exercise 2. (*)

(*) **Exercise 3.** If the input data do not form a rectangle, you can use M-# g (`calc-grab-region`) to grab the data the way Emacs normally works with regions--it reads left-to-right, top-to-bottom, treating line breaks the same as spaces. Use this command to find the geometric mean of the following numbers. (The geometric mean is the nth root of the product of n numbers.)

```
2.3  6  22  15.1  7
  15  14  7.5
  2.5
```

The M-# g command accepts numbers separated by spaces or commas, with or without surrounding vector brackets. See section List Tutorial Exercise 3. (*)

```
1:  [1, 2, 3, 4, 5, 6, 7]      1:  [0, 1, 2, 3, 4, 5, 6]
    .                              .

    v x 7 RET                      1 -

1:  [1, -6, 15, -20, 15, -6, 1]          1:  0
    .                                        .

    V M ' (-1)^$ choose(6,$) RET             V R +
```

The V M ' command prompts you to enter any algebraic expression to define the function to map over the vector. The symbol `$' inside this expression represents the argument to the function. The Calculator applies

this formula to each element of the vector, substituting each element's value for the `$' sign(s) in turn.

To define a two-argument function, use `$$' for the first argument and `$' for the second: V M ' $$-$ RET is equivalent to V M -. This is analogous to regular algebraic entry, where `$$' would refer to the next-to-top stack entry and `$' would refer to the top stack entry, and ' $$-$ RET would act exactly like -.

Notice that the V M ' command has recorded two things in the trail: The result, as usual, and also a funny-looking thing marked `oper' that represents the operator function you typed in. The function is enclosed in `< >' brackets, and the argument is denoted by a `#' sign. If there were several arguments, they would be shown as `#1', `#2', and so on. (For example, V M ' $$-$ will put the function `<#1 - #2>' on the trail.) This object is a "nameless function"; you can use nameless `< >' notation to answer the V M ' prompt if you like. Nameless function notation has the interesting, occasionally useful property that a nameless function is not actually evaluated until it is used. For example, V M ' $+random(2.0) evaluates `random(2.0)' once and adds that random number to all elements of the vector, but V M ' <#+random(2.0)> evaluates the `random(2.0)' separately for each vector element.

Another group of operators that are often useful with V M are the relational operators: a =, for example, compares two numbers and gives the result 1 if they are equal, or 0 if not. Similarly, a < checks for one number being less than another.

Other useful vector operations include v v, to reverse a vector end-for-end; V S, to sort the elements of a vector into increasing order; and v r and v c, to extract one row or column of a matrix, or (in both cases) to extract one element of a plain vector. With a negative argument, v r and v c instead delete one row, column, or vector element.

(*) **Exercise 4.** The kth divisor function is the sum of the kth powers of all the divisors of an integer n. Figure out a method for computing the divisor function for reasonably small values of n. As a test, the 0th and 1st divisor functions of 30 are 8 and 72, respectively. See section List Tutorial Exercise 4. (*)

(*) **Exercise 5.** The k f command produces a list of prime factors for a number. Sometimes it is important to know that a number is square-free, i.e., that no prime occurs more than once in its list of prime factors. Find a sequence of keystrokes to tell if a number is square-free; your method should leave 1 on the stack if it is, or 0 if it isn't. See section List Tutorial Exercise 5. (*)

(*) **Exercise 6.** Build a list of lists that looks like the following diagram. (You may wish to use the v / command to enable multi-line display of vectors.)

```
1:  [ [1],
      [1, 2],
      [1, 2, 3],
      [1, 2, 3, 4],
      [1, 2, 3, 4, 5],
      [1, 2, 3, 4, 5, 6] ]
```

See section List Tutorial Exercise 6. (*)

(*) **Exercise 7.** Build the following list of lists.

```
1:  [ [0],
      [1, 2],
```

```
[3, 4, 5],
[6, 7, 8, 9],
[10, 11, 12, 13, 14],
[15, 16, 17, 18, 19, 20] ]
```

See section List Tutorial Exercise 7. (*)

(*) **Exercise 8.** Compute a list of values of Bessel's J1 function `besJ(1,x)' for x from 0 to 5 in steps of 0.25. Find the value of x (from among the above set of values) for which `besJ(1,x)' is a maximum. Use an "automatic" method, i.e., just reading along the list by hand to find the largest value is not allowed! (There is an a X command which does this kind of thing automatically; see section Numerical Solutions.) See section List Tutorial Exercise 8. (*)

(*) **Exercise 9.** You are given an integer in the range 0 <= N < 10^m for m=12 (i.e., an integer of less than twelve digits). Convert this integer into a vector of m digits, each in the range from 0 to 9. In vector-of-digits notation, add one to this integer to produce a vector of m+1 digits (since there could be a carry out of the most significant digit). Convert this vector back into a regular integer. A good integer to try is 25129925999. See section List Tutorial Exercise 9. (*)

(*) **Exercise 10.** Your friend Joe tried to use V R a = to test if all numbers in a list were equal. What happened? How would you do this test? See section List Tutorial Exercise 10. (*)

(*) **Exercise 11.** The area of a circle of radius one is @c{π} pi. The area of the @c{2×2} 2x2 square that encloses that circle is 4. So if we throw *N* darts at random points in the square, about @c{$\pi/4$} pi/4 of them will land inside the circle. This gives us an entertaining way to estimate the value of @c{π} pi. The k r command picks a random number between zero and the value on the stack. We could get a random floating-point number between *-1* and 1 by typing 2.0 k r 1 -. Build a vector of 100 random (x,y) points in this square, then use vector mapping and reduction to count how many points lie inside the unit circle. Hint: Use the v b command. See section List Tutorial Exercise 11. (*)

(*) **Exercise 12.** The matchstick problem provides another way to calculate @c{π} pi. Say you have an infinite field of vertical lines with a spacing of one inch. Toss a one-inch matchstick onto the field. The probability that the matchstick will land crossing a line turns out to be @c{$2/\pi$} 2/pi. Toss 100 matchsticks to estimate pi. (If you want still more fun, the probability that the GCD (k g) of two large integers is one turns out to be @c{$6/\pi^2$} 6/pi^2. That provides yet another way to estimate @c{π} pi.) See section List Tutorial Exercise 12. (*)

(*) **Exercise 13.** An algebraic entry of a string in double-quote marks, `'"hello"', creates a vector of the numerical (ASCII) codes of the characters (here, [104, 101, 108, 108, 111]). Sometimes it is convenient to compute a hash code of a string, which is just an integer that represents the value of that string. Two equal strings have the same hash code; two different strings probably have different hash codes. (For example, Calc has over 400 function names, but Emacs can quickly find the definition for any given name because it has sorted the functions into "buckets" by their hash codes. Sometimes a few names will hash into the same bucket, but it is easier to search among a few names than among all the names.) One popular hash function is computed as follows: First set h = 0. Then, for each character from the string in turn, set h = 3h + c_i where c_i is the character's ASCII code. If we have 511 buckets, we then take the hash code modulo 511 to get the bucket number. Develop a simple command or commands for converting string vectors into hash codes. The hash code for `'"Testing, 1, 2, 3"' is 1960915098, which modulo 511 is 121. See section List Tutorial Exercise 13. (*)

(*) **Exercise 14.** The H V R and H V U commands do nested function evaluations. H V U takes a starting value and a number of steps n from the stack; it then applies the function you give to the starting value 0, up to n times and returns a vector of the results. Use this command to create a "random walk" of 50 steps. Start with the two-dimensional point (0,0); then take one step a random distance between *-1* and 1 in both x and y; then take another step, and so on. Use the g f command to display this random walk. Now modify your random walk to walk a unit distance, but in a random direction, at each step. (Hint: The `sincos` function returns a vector of the cosine and sine of an angle.) See section List Tutorial Exercise 14. (*)

Types Tutorial

Calc understands a variety of data types as well as simple numbers. In this section, we'll experiment with each of these types in turn.

The numbers we've been using so far have mainly been either integers or floats. We saw that floats are usually a good approximation to the mathematical concept of real numbers, but they are only approximations and are susceptible to roundoff error. Calc also supports fractions, which can exactly represent any rational number.

```
1:  3628800     2:  3628800     1:  518400:7    1:  518414:7    1:  7:518414
    .           1:  49              .               .               .
                    .

    10 !            49 RET          :               2 +             &
```

The : command divides two integers to get a fraction; / would normally divide integers to get a floating-point result. Notice we had to type RET between the 49 and the : since the : would otherwise be interpreted as part of a fraction beginning with 49.

You can convert between floating-point and fractional format using c f and c F:

```
1:  1.35027217629e-5    1:  7:518414
    .                       .

    c f                     c F
```

The c F command replaces a floating-point number with the "simplest" fraction whose floating-point representation is the same, to within the current precision.

```
1:  3.14159265359   1:  1146408:364913   1:  3.1416   1:  355:113
    .                   .                   .           .

    P                   c F      DEL        p 5 RET P       c F
```

(*) **Exercise 1.** A calculation has produced the result 1.26508260337. You suspect it is the square root of the product of @c{π} pi and some rational number. Is it? (Be sure to allow for roundoff error!) See section Types Tutorial Exercise 1. (*)

Complex numbers can be stored in both rectangular and polar form.

```
1:  -9      1:  (0, 3)     1:  (3; 90.)    1:  (6; 90.)    1:  (2.4495; 45.
    .           .              .               .               .

    9 n         Q              c p             2 *             Q
```

The square root of *-9* is by default rendered in rectangular form (0 + 3i), but we can convert it to polar form (3 with a phase angle of 90 degrees). All the usual arithmetic and scientific operations are defined on both types of complex numbers.

Another generalized kind of number is infinity. Infinity isn't really a number, but it can sometimes be treated like one. Calc uses the symbol `inf` to represent positive infinity, i.e., a value greater than any real number. Naturally, you can also write `-inf' for minus infinity, a value less than any real number. The word `inf` can only be input using algebraic entry.

```
2:  inf         2:  -inf        2:  -inf        2:  -inf        1:  nan
1:  -17         1:  -inf        1:  -inf        1:  inf             .
    .               .               .               .

' inf RET 17 n      *  RET          72 +            A               +
```

Since infinity is infinitely large, multiplying it by any finite number (like *-17*) has no effect, except that since *-17* is negative, it changes a plus infinity to a minus infinity. ("A huge positive number, multiplied by *-17*, yields a huge negative number.") Adding any finite number to infinity also leaves it unchanged. Taking an absolute value gives us plus infinity again. Finally, we add this plus infinity to the minus infinity we had earlier. If you work it out, you might expect the answer to be *-72* for this. But the 72 has been completely lost next to the infinities; by the time we compute `inf - inf' the finite difference between them, if any, is indetectable. So we say the result is indeterminate, which Calc writes with the symbol `nan` (for Not A Number).

Dividing by zero is normally treated as an error, but you can get Calc to write an answer in terms of infinity by pressing m i to turn on "infinite mode."

```
3:  nan         2:  nan         2:  nan         2:  nan         1:  nan
2:  1           1:  1 / 0       1:  uinf        1:  uinf            .
1:  0               .               .               .
    .

  1 RET 0           /         m i     U /             17 n *          +
```

Dividing by zero normally is left unevaluated, but after m i it instead gives an infinite result. The answer is actually `uinf`, "undirected infinity." If you look at a graph of 1 / x around x = 0, you'll see that it goes toward plus infinity as you approach zero from above, but toward minus infinity as you approach from below. Since we said only 1 / 0, Calc knows that the answer is infinite but not in which direction. That's what `uinf` means. Notice that multiplying `uinf` by a negative number still leaves plain `uinf`; there's no point in saying `-uinf' because the sign of `uinf` is unknown anyway. Finally, we add `uinf` to our `nan`, yielding `nan` again. It's easy to see that, because `nan` means "totally unknown" while `uinf` means "unknown sign but known to be infinite," the more mysterious `nan` wins out when it is combined with `uinf`, or, for that matter, with anything else.

(*) **Exercise 2.** Predict what Calc will answer for each of these formulas: `inf / inf', `exp(inf)', `exp(-inf)', `sqrt(-inf)', `sqrt(uinf)', `abs(uinf)', `ln(0)'. See section Types Tutorial Exercise 2. (*)

(*) **Exercise 3.** We saw that `inf - inf = nan', which stands for an unknown value. Can `nan' stand for a complex number? Can it stand for infinity? See section Types Tutorial Exercise 3. (*)

HMS forms represent a value in terms of hours, minutes, and seconds.

```
1:  2@ 30' 0"      1:  3@ 30' 0"      2:  3@ 30' 0"      1:  2.
    .                  .              1:  1@ 45' 0."         .
                                          .

  2@ 30' RET           1 +                RET 2 /            /
```

HMS forms can also be used to hold angles in degrees, minutes, and seconds.

```
1:  0.5         1:  26.56505    1:  26@ 33' 54.18"    1:  0.44721
    .               .               .                     .

    0.5             I T             c h                   S
```

First we convert the inverse tangent of 0.5 to degrees-minutes-seconds form, then we take the sine of that angle. Note that the trigonometric functions will accept HMS forms directly as input.

(*) **Exercise 4.** The Beatles' *Abbey Road* is 47 minutes and 26 seconds long, and contains 17 songs. What is the average length of a song on *Abbey Road*? If the Extended Disco Version of *Abbey Road* added 20 seconds to the length of each song, how long would the album be? See section Types Tutorial Exercise 4. (*)

A date form represents a date, or a date and time. Dates must be entered using algebraic entry. Date forms are surrounded by `< >' symbols; most standard formats for dates are recognized.

```
2:  <Sun Jan 13, 1991>                    1:  2.25
1:  <6:00pm Thu Jan 10, 1991>                 .
    .

' <13 Jan 1991>, <1/10/91, 6pm> RET           -
```

In this example, we enter two dates, then subtract to find the number of days between them. It is also possible to add an HMS form or a number (of days) to a date form to get another date form.

```
1:  <4:45:59pm Mon Jan 14, 1991>      1:  <2:50:59am Thu Jan 17, 1991>
    .                                     .

    t N                                   2 + 10@ 5' +
```

The t N ("now") command pushes the current date and time on the stack; then we add two days, ten hours and five minutes to the date and time. Other date-and-time related commands include t J, which does Julian day conversions, t W, which finds the beginning of the week in which a date form lies, and t I, which increments a date by one or several months. See section Date Arithmetic, for more.

(*) **Exercise 5.** How many days until the next Friday the 13th? See section Types Tutorial Exercise 5. (*)

(*) **Exercise 6.** How many leap years will there be between now and the year 10001 A.D.? See section Types Tutorial Exercise 6. (*)

An error form represents a mean value with an attached standard deviation, or error estimate. Suppose our measurements indicate that a certain telephone pole is about 30 meters away, with an estimated error of 1 meter, and 8 meters tall, with an estimated error of 0.2 meters. What is the slope of a line from here to the top of the pole, and what is the equivalent angle in degrees?

```
1:  8 +/- 0.2    2:  8 +/- 0.2   1:  0.266 +/- 0.011   1:  14.93 +/- 0.594
    .            1:  30 +/- 1        .                      .
                     .

    8 p .2 RET       30 p 1          /                      I T
```

This means that the angle is about 15 degrees, and, assuming our original error estimates were valid standard deviations, there is about a 60% chance that the result is correct within 0.59 degrees.

(*) **Exercise 7.** The volume of a torus (a donut shape) is 2 pi^2 R r^2 where R is the radius of the circle that defines the center of the tube and r is the radius of the tube itself. Suppose R is 20 cm and r is 4 cm, each known to within 5 percent. What is the volume and the relative uncertainty of the volume? See section Types Tutorial Exercise 7. (*)

An interval form represents a range of values. While an error form is best for making statistical estimates, intervals give you exact bounds on an answer. Suppose we additionally know that our telephone pole is definitely between 28 and 31 meters away, and that it is between 7.7 and 8.1 meters tall.

```
1:  [7.7 .. 8.1]  2:  [7.7 .. 8.1]  1:  [0.24 .. 0.28]  1:  [13.9 .. 16.1]
    .             1:  [28 .. 31]        .                     .
                      .

  [ 7.7 .. 8.1 ]    [ 28 .. 31 ]        /                     I T
```

If our bounds were correct, then the angle to the top of the pole is sure to lie in the range shown.

The square brackets around these intervals indicate that the endpoints themselves are allowable values. In other words, the distance to the telephone pole is between 28 and 31, *inclusive*. You can also make an interval that is exclusive of its endpoints by writing parentheses instead of square brackets. You can even make an interval which is inclusive ("closed") on one end and exclusive ("open") on the other.

```
1:  [1 .. 10)    1:  (0.1 .. 1]   2:  (0.1 .. 1]   1:  (0.2 .. 3)
    .                .            1:  [2 .. 3)          .
                                      .

  [ 1 .. 10 )        &              [ 2 .. 3 )          *
```

The Calculator automatically keeps track of which end values should be open and which should be closed. You can also make infinite or semi-infinite intervals by using `-inf' or `inf' for one or both endpoints.

(*) **Exercise 8.** What answer would you expect from `1 / (0 .. 10)'? What about `1 / (-10 .. 0)'? What about `1 / [0 .. 10]' (where the interval actually includes zero)? What about `1 / (-10 .. 10)'? See section Types Tutorial Exercise 8. (*)

(*) **Exercise 9.** Two easy ways of squaring a number are RET * and 2 ^. Normally these produce the same answer. Would you expect this still to hold true for interval forms? If not, which of these will result in a larger interval? See section Types Tutorial Exercise 9. (*)

A modulo form is used for performing arithmetic modulo *M*. For example, arithmetic involving time is generally done modulo 12 or 24 hours.

```
1:  17 mod 24     1:  3 mod 24      1:  21 mod 24     1:  9 mod 24
    .                 .                 .                 .

    17 M 24 RET       10 +              n                 5 /
```

In this last step, Calc has found a new number which, when multiplied by 5 modulo 24, produces the original number, 21. If *M* is prime it is always possible to find such a number. For non-prime *M* like 24, it is only sometimes possible.

```
1:  10 mod 24     1:  16 mod 24     1:  1000000...    1:  16
    .                 .                 .                 .

    10 M 24 RET       100 ^             10 RET 100 ^      24 %
```

These two calculations get the same answer, but the first one is much more efficient because it avoids the huge intermediate value that arises in the second one.

(*) **Exercise 10.** A theorem of Pierre de Fermat says that @c{\w{$x^{n-1} \bmod n = 1$}} x^(n-1) mod n = 1 if n is a prime number and x is an integer less than n. If n is *not* a prime number, this will *not* be true for most values of x. Thus we can test informally if a number is prime by trying this formula for several values of x. Use this test to tell whether the following numbers are prime: 811749613, 15485863. See section Types Tutorial Exercise 10. (*)

It is possible to use HMS forms as parts of error forms, intervals, modulo forms, or as the phase part of a polar complex number. For example, the `calc-time` command pushes the current time of day on the stack as an HMS/modulo form.

```
1:  17@ 34' 45" mod 24@ 0' 0"     1:  6@ 22' 15" mod 24@ 0' 0"
    .                                 .

    x time RET                        n
```

This calculation tells me it is six hours and 22 minutes until midnight.

(*) **Exercise 11.** A rule of thumb is that one year is about @c{$\pi \times 10^7$} pi * 10^7 seconds. What time will it be that many seconds from right now? See section Types Tutorial Exercise 11. (*)

(*) **Exercise 12.** You are preparing to order packaging for the CD release of the Extended Disco Version of *Abbey Road*. You are told that the songs will actually be anywhere from 20 to 60 seconds longer than the

originals. One CD can hold about 75 minutes of music. Should you order single or double packages? See section Types Tutorial Exercise 12. (*)

Another kind of data the Calculator can manipulate is numbers with units. This isn't strictly a new data type; it's simply an application of algebraic expressions, where we use variables with suggestive names like `cm' and `in' to represent units like centimeters and inches.

```
1:  2 in        1:  5.08 cm      1:  0.027778 fath   1:  0.0508 m
    .               .                .                   .

    ' 2in RET       u c cm RET       u c fath RET        u b
```

We enter the quantity "2 inches" (actually an algebraic expression which means two times the variable `in'), then we convert it first to centimeters, then to fathoms, then finally to "base" units, which in this case means meters.

```
1:  9 acre     1:  3 sqrt(acre)   1:  190.84 m   1:  190.84 m + 30 cm
    .              .                  .              .

 ' 9 acre RET      Q                  u s            ' $+30 cm RET

1:  191.14 m     1:  36536.3046 m^2    1:  365363046 cm^2
    .                .                     .

    u s              2 ^                   u c cgs
```

Since units expressions are really just formulas, taking the square root of `acre' is undefined. After all, `acre' might be an algebraic variable that you will someday assign a value. We use the "units-simplify" command to simplify the expression with variables being interpreted as unit names.

In the final step, we have converted not to a particular unit, but to a units system. The "cgs" system uses centimeters instead of meters as its standard unit of length.

There is a wide variety of units defined in the Calculator.

```
1:  55 mph     1:  88.5139 kph   1:  88.5139 km / hr   1:  8.201407e-8 c
    .              .                 .                    .

 ' 55 mph RET      u c kph RET       u c km/hr RET        u c c RET
```

We express a speed first in miles per hour, then in kilometers per hour, then again using a slightly more explicit notation, then finally in terms of fractions of the speed of light.

Temperature conversions are a bit more tricky. There are two ways to interpret "20 degrees Fahrenheit"---it could mean an actual temperature, or it could mean a change in temperature. For normal units there is no difference, but temperature units have an offset as well as a scale factor and so there must be two explicit commands for them.

```
1:  20 degF       1:  11.1111 degC     1:  -20:3 degC    1:  -6.666 deg
    .                 .                    .                 .

  ' 20 degF RET       u c degC RET         U u t degC RET    c f
```

First we convert a change of 20 degrees Fahrenheit into an equivalent change in degrees Celsius (or Centigrade). Then, we convert the absolute temperature 20 degrees Fahrenheit into Celsius. Since this comes out as an exact fraction, we then convert to floating-point for easier comparison with the other result.

For simple unit conversions, you can put a plain number on the stack. Then u c and u t will prompt for both old and new units. When you use this method, you're responsible for remembering which numbers are in which units:

```
1:  55         1:  88.5139              1:  8.201407e-8
    .              .                        .

    55             u c mph RET kph RET      u c km/hr RET c RET
```

To see a complete list of built-in units, type u v. Press M-# c again to re-enter the Calculator when you're done looking at the units table.

(*) **Exercise 13.** How many seconds are there really in a year? See section Types Tutorial Exercise 13. (*)

(*) **Exercise 14.** Supercomputer designs are limited by the speed of light (and of electricity, which is nearly as fast). Suppose a computer has a 4.1 ns (nanosecond) clock cycle, and its cabinet is one meter across. Is speed of light going to be a significant factor in its design? See section Types Tutorial Exercise 14. (*)

(*) **Exercise 15.** Sam the Slug normally travels about five yards in an hour. He has obtained a supply of Power Pills; each Power Pill he eats doubles his speed. How many Power Pills can he swallow and still travel legally on most US highways? See section Types Tutorial Exercise 15. (*)

Algebra and Calculus Tutorial

This section shows how to use Calc's algebra facilities to solve equations, do simple calculus problems, and manipulate algebraic formulas.

Basic Algebra

If you enter a formula in algebraic mode that refers to variables, the formula itself is pushed onto the stack. You can manipulate formulas as regular data objects.

```
1:  2 x^2 - 6       1:  6 - 2 x^2       1:  (6 - 2 x^2) (3 x^2 + y)
    .                   .                   .

    ' 2x^2-6 RET        n                   ' 3x^2+y RET *
```

(*) **Exercise 1.** Do ' x RET Q 2 ^ and ' x RET 2 ^ Q both wind up with the same result (`x')? Why or why not? See section Algebra Tutorial Exercise 1. (*)

There are also commands for doing common algebraic operations on formulas. Continuing with the formu from the last example,

```
1:  18 x^2 + 6 y - 6 x^4 - 2 x^2 y    1:  (18 - 2 y) x^2 - 6 x^4 + 6 y
    .                                     .

    a x                                   a c x RET
```

First we "expand" using the distributive law, then we "collect" terms involving like powers of x.

Let's find the value of this expression when x is 2 and y is one-half.

```
1:  17 x^2 - 6 x^4 + 3      1:  -25
    .                           .

    1:2 s l y RET               2 s l x RET
```

The s l command means "let"; it takes a number from the top of the stack and temporarily assigns it as the value of the variable you specify. It then evaluates (as if by the = key) the next expression on the stack. After this command, the variable goes back to its original value, if any.

(An earlier exercise in this tutorial involved storing a value in the variable x; if this value is still there, you will have to unstore it with s u x RET before the above example will work properly.)

Let's find the maximum value of our original expression when y is one-half and x ranges over all possible values. We can do this by taking the derivative with respect to x and examining values of x for which the derivative is zero. If the second derivative of the function at that value of x is negative, the function has a local maximum there.

```
1:  17 x^2 - 6 x^4 + 3      1:  34 x - 24 x^3
    .                           .

    U DEL  s 1                  a d x RET   s 2
```

Well, the derivative is clearly zero when x is zero. To find the other root(s), let's divide through by x and then solve:

```
1:  (34 x - 24 x^3) / x    1:  34 x / x - 24 x^3 / x    1:  34 - 24 x^2
    .                          .                            .

    ' x RET /                  a x                          a s

1:  34 - 24 x^2 = 0        1:  x = 1.19023
    .                          .

    0 a =  s 3                 a S x RET
```

Notice the use of a s to "simplify" the formula. When the default algebraic simplifications don't do enough,

you can use a s to tell Calc to spend more time on the job.

Now we compute the second derivative and plug in our values of x:

```
1:  1.19023          2:  1.19023          2:  1.19023
    .                1:  34 x - 24 x^3    1:  34 - 72 x^2
                         .                    .

    a .                  r 2                  a d x RET s 4
```

(The a . command extracts just the righthand side of an equation. Another method would have been to use v u to unpack the equation `x = 1.19' to `x' and `1.19', then use M-- M-2 DEL to delete the `x'.)

```
2:  34 - 72 x^2   1:  -68.          2:  34 - 72 x^2     1:  34
1:  1.19023           .             1:  0                   .
    .                                   .

    TAB                 s l x RET       U DEL 0             s l x RET
```

The first of these second derivatives is negative, so we know the function has a maximum value at x = 1.19023. (The function also has a local *minimum* at x = 0.)

When we solved for x, we got only one value even though 34 - 24 x^2 = 0 is a quadratic equation that ought to have two solutions. The reason is that a S normally returns a single "principal" solution. If it needs to come up with an arbitrary sign (as occurs in the quadratic formula) it picks +. If it needs an arbitrary integer, it picks zero. We can get a full solution by pressing H (the Hyperbolic flag) before a S.

```
1:  34 - 24 x^2 = 0    1:  x = 1.19023 s1      1:  x = -1.19023
    .                      .                       .

    r 3                    H a S x RET  s 5         1 n  s l s1 RET
```

Calc has invented the variable `s1' to represent an unknown sign; it is supposed to be either *+1* or *-1*. Here we have used the "let" command to evaluate the expression when the sign is negative. If we plugged this into our second derivative we would get the same, negative, answer, so x = -1.19023 is also a maximum.

To find the actual maximum value, we must plug our two values of x into the original formula.

```
2:  17 x^2 - 6 x^4 + 3    1:  24.08333 s1^2 - 12.04166 s1^4 + 3
1:  x = 1.19023 s1            .
    .

    r 1 r 5                   s l RET
```

(Here we see another way to use s l; if its input is an equation with a variable on the lefthand side, then s l treats the equation like an assignment to that variable if you don't give a variable name.)

It's clear that this will have the same value for either sign of `s1`, but let's work it out anyway, just for the exercise:

```
2:  [-1, 1]              1:  [15.04166, 15.04166]
1:  24.08333 s1^2 ...        .
    .

  [ 1 n , 1 ] TAB            V M $ RET
```

Here we have used a vector mapping operation to evaluate the function at several values of `s1' at once. V M $ is like V M ' except that it takes the formula from the top of the stack. The formula is interpreted as a function to apply across the vector at the next-to-top stack level. Since a formula on the stack can't contain `$' signs, Calc assumes the variables in the formula stand for different arguments. It prompts you for an argument list, giving the list of all variables in the formula in alphabetical order as the default list. In this case the default is `(s1)', which is just what we want so we simply press RET at the prompt.

If there had been several different values, we could have used V R X to find the global maximum.

Calc has a built-in a P command that solves an equation using H a S and returns a vector of all the solutions. It simply automates the job we just did by hand. Applied to our original cubic polynomial, it would produce the vector of solutions [1.19023, -1.19023, 0]. (There is also an a X command which finds a local maximum of a function. It uses a numerical search method rather than examining the derivatives, and thus requires you to provide some kind of initial guess to show it where to look.)

(*) **Exercise 2.** Given a vector of the roots of a polynomial (such as the output of an a P command), what sequence of commands would you use to reconstruct the original polynomial? (The answer will be unique to within a constant multiple; choose the solution where the leading coefficient is one.) See section Algebra Tutorial Exercise 2. (*)

The m s command enables "symbolic mode," in which formulas like `sqrt(5)' that can't be evaluated exactly are left in symbolic form rather than giving a floating-point approximate answer. Fraction mode (m f) is also useful when doing algebra.

```
2:  34 x - 24 x^3        2:  34 x - 24 x^3
1:  34 x - 24 x^3        1:  [sqrt(51) / 6, sqrt(51) / -6, 0]
    .                        .

    r 2  RET     m s  m f    a P x RET
```

One more mode that makes reading formulas easier is "Big mode."

```
                3
2:  34 x - 24 x

     ____   ____
    V 51   V 51
1:  [-----, -----, 0]
       6      -6

    .

    d B
```

Here things like powers, square roots, and quotients and fractions are displayed in a two-dimensional pict form. Calc has other language modes as well, such as C mode, FORTRAN mode, and TeX mode.

```
2:  34*x - 24*pow(x, 3)                2:  34*x - 24*x**3
1:  {sqrt(51) / 6, sqrt(51) / -6, 0}   1:  /sqrt(51) / 6, sqrt(51) / -6, 0/
    .                                      .

    d C                                    d F

3:  34 x - 24 x^3
2:  [{\sqrt{51} \over 6}, {\sqrt{51} \over -6}, 0]
1:  {2 \over 3} \sqrt{5}
    .

    d T   ' 2 \sqrt{5} \over 3 RET
```

As you can see, language modes affect both entry and display of formulas. They affect such things as the names used for built-in functions, the set of arithmetic operators and their precedences, and notations for vectors and matrices.

Notice that `sqrt(51)' may cause problems with older implementations of C and FORTRAN, which would require something more like `sqrt(51.0)'. It is always wise to check over the formulas produced by the various language modes to make sure they are fully correct.

Type m s, m f, and d N to reset these modes. (You may prefer to remain in Big mode, but all the examples in the tutorial are shown in normal mode.)

What is the area under the portion of this curve from x = 1 to 2? This is simply the integral of the function:

```
1:  17 x^2 - 6 x^4 + 3      1:  5.6666 x^3 - 1.2 x^5 + 3 x
    .                           .

    r 1                         a i x
```

We want to evaluate this at our two values for x and subtract. One way to do it is again with vector mapping and reduction:

```
2:  [2, 1]             1:  [12.93333, 7.46666]    1:  5.46666
1:  5.6666 x^3 ...         .                          .

   [ 2 , 1 ] TAB           V M $ RET                  V R -
```

(*) **Exercise 3.** Find the integral from 1 to y of @c{$x \sin \pi x$} x sin(pi x) (where the sine is calculated in radians). Find the values of the integral for integers y from 1 to 5. See section Algebra Tutorial Exercise 3. (*)

Calc's integrator can do many simple integrals symbolically, but many others are beyond its capabilities. Suppose we wish to find the area under the curve @c{$\sin x \ln x$} sin(x) ln(x) over the same range of x. If you entered this formula and typed a i x RET (don't bother to try this), Calc would work for a long time but

would be unable to find a solution. In fact, there is no closed-form solution to this integral. Now what do you do?

One approach would be to do the integral numerically. It is not hard to do this by hand using vector mapping and reduction. It is rather slow, though, since the sine and logarithm functions take a long time. We can save some time by reducing the working precision.

```
3:  10                  1:  [1, 1.1, 1.2,  ...  , 1.8, 1.9]
2:  1                       .
1:  0.1
    .

 10 RET 1 RET .1 RET        C-u v x
```

(Note that we have used the extended version of v x; we could also have used plain v x as follows: v x 10 RET 9 + .1 *.)

```
2:  [1, 1.1, ... ]              1:  [0., 0.084941, 0.16993, ... ]
1:  sin(x) ln(x)                    .
    .

    ' sin(x) ln(x) RET  s 1    m r  p 5 RET   V M $ RET

1:  3.4195     0.34195
    .          .

    V R +      0.1 *
```

(If you got wildly different results, did you remember to switch to radians mode?)

Here we have divided the curve into ten segments of equal width; approximating these segments as rectangular boxes (i.e., assuming the curve is nearly flat at that resolution), we compute the areas of the boxes (height times width), then sum the areas. (It is faster to sum first, then multiply by the width, since the width is the same for every box.)

The true value of this integral turns out to be about 0.374, so we're not doing too well. Let's try another approach.

```
1:  sin(x) ln(x)    1:  0.84147 x - 0.84147 + 0.11957 (x - 1)^2 - ...
    .                   .

    r 1                 a t x=1 RET 4 RET
```

Here we have computed the Taylor series expansion of the function about the point x=1. We can now integrate this polynomial approximation, since polynomials are easy to integrate.

```
1:  0.42074 x^2 + ...    1:  [-0.0446, -0.42073]      1:  0.3761
    .                        .                            .
```

```
    a i x RET           [ 2 , 1 ] TAB  V M $ RET        V R -
```

Better! By increasing the precision and/or asking for more terms in the Taylor series, we can get a result as accurate as we like. (Taylor series converge better away from singularities in the function such as the one at `ln(0)`, so it would also help to expand the series about the points x=2 or x=1.5 instead of x=1.)

(*) **Exercise 4.** Our first method approximated the curve by stairsteps of width 0.1; the total area was then the sum of the areas of the rectangles under these stairsteps. Our second method approximated the function by a polynomial, which turned out to be a better approximation than stairsteps. A third method is Simpson's rule, which is like the stairstep method except that the steps are not required to be flat. Simpson's rule boils down to the formula,

where n (which must be even) is the number of slices and h is the width of each slice. These are 10 and 0.1 in our example. For reference, here is the corresponding formula for the stairstep method:

Compute the integral from 1 to 2 of @c{$\sin x \ln x$} sin(x) ln(x) using Simpson's rule with 10 slices. See section Algebra Tutorial Exercise 4. (*)

Calc has a built-in a I command for doing numerical integration. It uses Romberg's method, which is a more sophisticated cousin of Simpson's rule. In particular, it knows how to keep refining the result until the current precision is satisfied.

Aside from the commands we've seen so far, Calc also provides a large set of commands for operating on parts of formulas. You indicate the desired sub-formula by placing the cursor on any part of the formula before giving a selection command. Selections won't be covered in the tutorial; see section Selecting Sub-Formulas, for details and examples.

Rewrite Rules

No matter how many built-in commands Calc provided for doing algebra, there would always be something you wanted to do that Calc didn't have in its repertoire. So Calc also provides a rewrite rule system that you can use to define your own algebraic manipulations.

Suppose we want to simplify this trigonometric formula:

```
1:  1 / cos(x) - sin(x) tan(x)
    .

    ' 1/cos(x) - sin(x) tan(x) RET   s 1
```

If we were simplifying this by hand, we'd probably replace the `tan' with a `sin/cos' first, then combine over a common denominator. There is no Calc command to do the former; the a n algebra command will do the latter but we'll do both with rewrite rules just for practice.

Rewrite rules are written with the `:=' symbol.

```
1:  1 / cos(x) - sin(x)^2 / cos(x)
    .
```

```
    a r tan(a) := sin(a)/cos(a) RET
```

(The "assignment operator" `:=' has several uses in Calc. All by itself the formula `tan(a) := sin(a)/cos(a)' doesn't do anything, but when it is given to the a r command, that command interprets it as a rewrite rule.)

The lefthand side, `tan(a)', is called the pattern of the rewrite rule. Calc searches the formula on the stack for parts that match the pattern. Variables in a rewrite pattern are called meta-variables, and when matching the pattern each meta-variable can match any sub-formula. Here, the meta-variable `a' matched the actual variable `x'.

When the pattern part of a rewrite rule matches a part of the formula, that part is replaced by the righthand side with all the meta-variables substituted with the things they matched. So the result is `sin(x) / cos(x)'. Calc's normal algebraic simplifications then mix this in with the rest of the original formula.

To merge over a common denominator, we can use another simple rule:

```
1:  (1 - sin(x)^2) / cos(x)
    .

    a r a/x + b/x := (a+b)/x RET
```

This rule points out several interesting features of rewrite patterns. First, if a meta-variable appears several times in a pattern, it must match the same thing everywhere. This rule detects common denominators because the same meta-variable `x' is used in both of the denominators.

Second, meta-variable names are independent from variables in the target formula. Notice that the meta-variable `x' here matches the subformula `cos(x)'; Calc never confuses the two meanings of `x'.

And third, rewrite patterns know a little bit about the algebraic properties of formulas. The pattern called for a sum of two quotients; Calc was able to match a difference of two quotients by matching `a = 1', `b = -sin(x)^2', and `x = cos(x)'.

We could just as easily have written `a/x - b/x := (a-b)/x' for the rule. It would have worked just the same in all cases. (If we really wanted the rule to apply only to `+' or only to `-', we could have used the `plain` symbol. See section Algebraic Properties of Rewrite Rules, for some examples of this.)

One more rewrite will complete the job. We want to use the identity `sin(x)^2 + cos(x)^2 = 1', but of course we must first rearrange the identity in a way that matches our formula. The obvious rule would be `1 - sin(x)^2 := cos(x)^2', but a little thought shows that the rule `sin(x)^2 := 1 - cos(x)^2' will also work. The latter rule has a more general pattern so it will work in many other situations, too.

```
1:  (1 + cos(x)^2 - 1) / cos(x)          1:  cos(x)
    .                                        .

    a r sin(x)^2 := 1 - cos(x)^2 RET         a s
```

You may ask, what's the point of using the most general rule if you have to type it in every time anyway? The answer is that Calc allows you to store a rewrite rule in a variable, then give the variable name in the a r command. In fact, this is the preferred way to use rewrites. For one, if you need a rule once you'll most likely need it again later. Also, if the rule doesn't work quite right you can simply Undo, edit the variable, and run the rule again without having to retype it.

```
' tan(x) := sin(x)/cos(x) RET      s t tsc RET
' a/x + b/x := (a+b)/x RET         s t merge RET
' sin(x)^2 := 1 - cos(x)^2 RET     s t sinsqr RET

1:  1 / cos(x) - sin(x) tan(x)     1:  cos(x)
    .                                  .

    r 1                a r tsc RET  a r merge RET  a r sinsqr RET  a s
```

To edit a variable, type s e and the variable name, use regular Emacs editing commands as necessary, then type M-# M-# or C-c C-c to store the edited value back into the variable. You can also use s e to create a new variable if you wish.

Notice that the first time you use each rule, Calc puts up a "compiling" message briefly. The pattern matcher converts rules into a special optimized pattern-matching language rather than using them directly. This allows a r to apply even rather complicated rules very efficiently. If the rule is stored in a variable, Calc compiles it only once and stores the compiled form along with the variable. That's another good reason to store your rules in variables rather than entering them on the fly.

(*) **Exercise 1.** Type m s to get symbolic mode, then enter the formula `(2 + sqrt(2)) / (1 + sqrt(2))'. Using a rewrite rule, simplify this formula by multiplying both sides by the conjugate `1 - sqrt(2)'. The result will have to be expanded by the distributive law; do this with another rewrite. See section Rewrites Tutorial Exercise 1. (*)

The a r command can also accept a vector of rewrite rules, or a variable containing a vector of rules.

```
1:  [tsc, merge, sinsqr]           1:  [tan(x) := sin(x) / cos(x), ... ]
    .                                  .

    ' [tsc,merge,sinsqr] RET           =

1:  1 / cos(x) - sin(x) tan(x)     1:  cos(x)
    .                                  .

    s t trig RET  r 1                  a r trig RET  a s
```

Calc tries all the rules you give against all parts of the formula, repeating until no further change is possible. (The exact order in which things are tried is rather complex, but for simple rules like the ones we've used here the order doesn't really matter. See section Nested Formulas with Rewrite Rules.)

Calc actually repeats only up to 100 times, just in case your rule set has gotten into an infinite loop. You can give a numeric prefix argument to a r to specify any limit. In particular, M-1 a r does only one rewrite at a time.

```
1:  1 / cos(x) - sin(x)^2 / cos(x)     1:  (1 - sin(x)^2) / cos(x)
    .                                      .
```

```
    r 1  M-1 a r trig RET                    M-1 a r trig RET
```

You can type M-0 a r if you want no limit at all on the number of rewrites that occur.

Rewrite rules can also be conditional. Simply follow the rule with a `::' symbol and the desired condition. For example,

```
1:  exp(2 pi i) + exp(3 pi i) + exp(4 pi i)
    .

    ' exp(2 pi i) + exp(3 pi i) + exp(4 pi i) RET

1:  1 + exp(3 pi i) + 1
    .

    a r exp(k pi i) := 1 :: k % 2 = 0 RET
```

(Recall, `k % 2' is the remainder from dividing `k' by 2, which will be zero only when `k' is an even integer.)

An interesting point is that the variables `pi' and `i' were matched literally rather than acting as meta-variables. This is because they are special-constant variables. The special constants `e', `phi', and so on also match literally. A common error with rewrite rules is to write, say, `f(a,b,c,d,e) := g(a+b+c+d+e)', expecting to match any `f' with five arguments but in fact matching only when the fifth argument is literally `e'!

Rewrite rules provide an interesting way to define your own functions. Suppose we want to define `fib(n)' to produce the nth Fibonacci number. The first two Fibonacci numbers are each 1; later numbers are formed by summing the two preceding numbers in the sequence. This is easy to express in a set of three rules:

```
' [fib(1) := 1, fib(2) := 1, fib(n) := fib(n-1) + fib(n-2)] RET  s t fib

1:  fib(7)                1:  13
    .                         .

    ' fib(7) RET              a r fib RET
```

One thing that is guaranteed about the order that rewrites are tried is that, for any given subformula, earlier rules in the rule set will be tried for that subformula before later ones. So even though the first and third rules both match `fib(1)', we know the first will be used preferentially.

This rule set has one dangerous bug: Suppose we apply it to the formula `fib(x)'? (Don't actually try this.) The third rule will match `fib(x)' and replace it with `fib(x-1) + fib(x-2)'. Each of these will then be replaced to get `fib(x-2) + 2 fib(x-3) + fib(x-4)', and so on, expanding forever. What we really want is to apply the third rule only when `n' is an integer greater than two. Type s e fib RET, then edit the third rule to:

```
fib(n) := fib(n-1) + fib(n-2) :: integer(n) :: n > 2
```

Now:

```
1:  fib(6) + fib(x) + fib(0)      1:  8 + fib(x) + fib(0)
```

```
    .                                   .

    ' fib(6)+fib(x)+fib(0) RET          a r fib RET
```

We've created a new function, `fib`, and a new command, a r fib RET, which means "evaluate all `fib` calls in this formula." To make things easier still, we can tell Calc to apply these rules automatically by storing them in the special variable `EvalRules`.

```
1:  [fib(1) := ...]     .                   1:  [8, 13]
    .                                           .

    s r fib RET         s t EvalRules RET    ' [fib(6), fib(7)] RET
```

It turns out that this rule set has the problem that it does far more work than it needs to when `n' is large. Consider the first few steps of the computation of `fib(6)':

```
fib(6) =
fib(5)                +                fib(4) =
fib(4)     +      fib(3)     +      fib(3)     +      fib(2) =
fib(3) + fib(2) + fib(2) + fib(1) + fib(2) + fib(1) + 1 = ...
```

Note that `fib(3)' appears three times here. Unless Calc's algebraic simplifier notices the multiple `fib(3)'s and combines them (and, as it happens, it doesn't), this rule set does lots of needless recomputation. To cure the problem, type `s e EvalRules` to edit the rules (or just s E, a shorthand command for editing `EvalRules`) and add another condition:

```
fib(n) := fib(n-1) + fib(n-2) :: integer(n) :: n > 2 :: remember
```

If a `:: remember' condition appears anywhere in a rule, then if that rule succeeds Calc will add another rule that describes that match to the front of the rule set. (Remembering works in any rule set, but for technical reasons it is most effective in `EvalRules`.) For example, if the rule rewrites `fib(7)' to something that evaluates to 13, then the rule `fib(7) := 13' will be added to the rule set.

Type ' fib(8) RET to compute the eighth Fibonacci number, then type s E again to see what has happened to the rule set.

With the `remember` feature, our rule set can now compute `fib(n)' in just n steps. In the process it builds up a table of all Fibonacci numbers up to n. After we have computed the result for a particular n, we can get it back (and the results for all smaller n) later in just one step.

All Calc operations will run somewhat slower whenever `EvalRules` contains any rules. You should type s u EvalRules RET now to un-store the variable.

(*) **Exercise 2.** Sometimes it is possible to reformulate a problem to reduce the amount of recursion necessary to solve it. Create a rule that, in about n simple steps and without recourse to the `remember` option, replaces `fib(n, 1, 1)' with `fib(1, x, y)' where x and y are the nth and n+1st Fibonacci numbers, respectively. This rule is rather clunky to use, so add a couple more rules to make the "user interface" the same as for our first version: enter `fib(n)', get back a plain number. See section Rewrites Tutorial Exercise 2. (*)

There are many more things that rewrites can do. For example, there are `&&&' and `|||' pattern operators that

create "and" and "or" combinations of rules. As one really simple example, we could combine our first tw Fibonacci rules thusly:

```
[fib(1 ||| 2) := 1, fib(n) := ... ]
```

That means "`fib` of something matching either 1 or 2 rewrites to 1."

You can also make meta-variables optional by enclosing them in `opt`. For example, the pattern `a + b x' matches `2 + 3 x' but not `2 + x' or `3 x' or `x'. The pattern `opt(a) + opt(b) x' matches all of these forms, filling in a default of zero for `a' and one for `b'.

(*) **Exercise 3.** Your friend Joe had `2 + 3 x' on the stack and tried to use the rule `opt(a) + opt(b) x := f(a, b, x)'. What happened? See section Rewrites Tutorial Exercise 3. (*)

(*) **Exercise 4.** Starting with a positive integer a, divide a by two if it is even, otherwise compute 3 a + 1. Now repeat this step over and over. A famous unproved conjecture is that for any starting a, the sequence always eventually reaches 1. Given the formula `seq(a, 0)', write a set of rules that convert this into `seq(1, n)' where n is the number of steps it took the sequence to reach the value 1. Now enhance the rules to accept `seq(a)' as a starting configuration, and to stop with just the number n by itself. Now make the result be a vector of values in the sequence, from a to 1. (The formula `x|y' appends the vectors x and y.) For example, rewriting `seq(6)' should yield the vector [6, 3, 10, 5, 16, 8, 4, 2, 1]. See section Rewrites Tutorial Exercise 4. (*)

(*) **Exercise 5.** Define, using rewrite rules, a function `nterms(x)' that returns the number of terms in the sum x, or 1 if x is not a sum. (A sum for our purposes is one or more non-sum terms separated by `+' or `-' signs, so that 2 - 3 (x + y) + x y is a sum of three terms.) See section Rewrites Tutorial Exercise 5. (*)

(*) **Exercise 6.** Calc considers the form 0^0 to be "indeterminate," and leaves it unevaluated (assuming infinite mode is not enabled). Some people prefer to define 0^0 = 1, so that the identity x^0 = 1 can safely be used for all x. Find a way to make Calc follow this convention. What happens if you now type m i to turn on infinite mode? See section Rewrites Tutorial Exercise 6. (*)

(*) **Exercise 7.** A Taylor series for a function is an infinite series that exactly equals the value of that function at values of x near zero.

The a t command produces a truncated Taylor series which is obtained by dropping all the terms higher than, say, x^2. Calc represents the truncated Taylor series as a polynomial in x. Mathematicians often write a truncated series using a "big-O" notation that records what was the lowest term that was truncated.

The meaning of O(x^3) is "a quantity which is negligibly small if x^3 is considered negligibly small as x goes to zero."

The exercise is to create rewrite rules that simplify sums and products of power series represented as `polynomial + O(var^n)'. For example, given `1 - x^2 / 2 + O(x^3)' and `x - x^3 / 6 + O(x^4)' on the stack, we want to be able to type * and get the result `x - 2:3 x^3 + O(x^4)'. Don't worry if the terms of the sum are rearranged or if a s needs to be typed after rewriting. (This one is rather tricky; the solution at the end of this chapter uses 6 rewrite rules. Hint: The `constant(x)' condition tests whether `x' is a number.) See section Rewrites Tutorial Exercise 7. (*)

See section Rewrite Rules, for the whole story on rewrite rules.

Programming Tutorial

The Calculator is written entirely in Emacs Lisp, a highly extensible language. If you know Lisp, you can program the Calculator to do anything you like. Rewrite rules also work as a powerful programming system. But Lisp and rewrite rules take a while to master, and often all you want to do is define a new function or repeat a command a few times. Calc has features that allow you to do these things easily.

One very limited form of programming is defining your own functions. Calc's Z F command allows you to define a function name and key sequence to correspond to any formula. Programming commands use the shift-Z prefix; the user commands they create use the lower case z prefix.

```
1:  1 + x + x^2 / 2 + x^3 / 6          1:  1 + x + x^2 / 2 + x^3 / 6
    .                                      .

    ' 1 + x + x^2/2! + x^3/3! RET          Z F e myexp RET RET RET y
```

This polynomial is a Taylor series approximation to `exp(x)'. The Z F command asks a number of questions. The above answers say that the key sequence for our function should be z e; the M-x equivalent should be `calc-myexp`; the name of the function in algebraic formulas should also be `myexp`; the default argument list `(x)' is acceptable; and finally y answers the question "leave it in symbolic form for non-constant arguments?"

```
1:  1.3495     2:  1.3495     3:  1.3495
    .          1:  1.34986    2:  1.34986
                   .          1:  myexp(a + 1)
                                  .

    .3 z e         .3 E           ' a+1 RET z e
```

First we call our new `exp` approximation with 0.3 as an argument, and compare it with the true `exp` function. Then we note that, as requested, if we try to give z e an argument that isn't a plain number, it leaves the `myexp` function call in symbolic form. If we had answered n to the final question, `myexp(a + 1)' would have evaluated by plugging in `a + 1' for `x' in the defining formula.

(*) **Exercise 1.** The "sine integral" function Si(x) is defined as the integral of `sin(t)/t' for t = 0 to x in radians. (It was invented because this integral has no solution in terms of basic functions; if you give it to Calc's a i command, it will ponder it for a long time and then give up.) We can use the numerical integration command, however, which in algebraic notation is written like `ninteg(f(t), t, 0, x)' with any integrand `f(t)'. Define a z s command and `Si` function that implement this. You will need to edit the default argument list a bit. As a test, `Si(1)' should return 0.946083. (Hint: `ninteg` will run a lot faster if you reduce the precision to, say, six digits beforehand.) See section Programming Tutorial Exercise 1. (*)

The simplest way to do real "programming" of Emacs is to define a keyboard macro. A keyboard macro is simply a sequence of keystrokes which Emacs has stored away and can play back on demand. For example, if you find yourself typing H a S x RET often, you may wish to program a keyboard macro to type this for you.

```
1:  y = sqrt(x)          1:  x = y^2
    .                        .
```

```
    ' y=sqrt(x) RET       C-x ( H a S x RET C-x )

1:  y = cos(x)          1:  x = s1 arccos(y) + 2 pi n1
    .                       .

    ' y=cos(x) RET          X
```

When you type C-x (, Emacs begins recording. But it is also still ready to execute your keystrokes, so you're really "training" Emacs by walking it through the procedure once. When you type C-x), the macro is recorded. You can now type X to re-execute the same keystrokes.

You can give a name to your macro by typing Z K.

```
1:  .             1:  y = x^4         1:  x = s2 sqrt(s1 sqrt(y))
                      .                   .

  Z K x RET           ' y=x^4 RET         z x
```

Notice that we use shift-Z to define the command, and lower-case z to call it up.

Keyboard macros can call other macros.

```
1:  abs(x)        1:  x = s1 y              1:  2 / x    1:  x = 2 / y
    .                 .                         .            .

 ' abs(x) RET   C-x ( ' y RET a = z x C-x )    ' 2/x RET       X
```

(*) **Exercise 2.** Define a keyboard macro to negate the item in level 3 of the stack, without disturbing the rest of the stack. See section Programming Tutorial Exercise 2. (*)

(*) **Exercise 3.** Define keyboard macros to compute the following functions:

1. Compute @c{$\displaystyle{\sin x \over x}$} sin(x) / x, where x is the number on the top of the stack.
2. Compute the base-b logarithm, just like the B key except the arguments are taken in the opposite order.
3. Produce a vector of integers from 1 to the integer on the top of the stack.

See section Programming Tutorial Exercise 3. (*)

(*) **Exercise 4.** Define a keyboard macro to compute the average (mean) value of a list of numbers. See section Programming Tutorial Exercise 4. (*)

In many programs, some of the steps must execute several times. Calc has looping commands that allow this. Loops are useful inside keyboard macros, but actually work at any time.

```
1:  x^6          2:  x^6        1: 360 x^2
    .            1:  4             .
                     .

  ' x^6 RET          4         Z < a d x RET Z >
```

Here we have computed the fourth derivative of x^6 by enclosing a derivative command in a "repeat loop" structure. This structure pops a repeat count from the stack, then executes the body of the loop that many times.

If you make a mistake while entering the body of the loop, type Z C-g to cancel the loop command.

Here's another example:

```
3:  1               2:  10946
2:  1               1:  17711
1:  20                  .
    .

1 RET RET 20        Z < TAB C-j + Z >
```

The numbers in levels 2 and 1 should be the 21st and 22nd Fibonacci numbers, respectively. (To see what's going on, try a few repetitions of the loop body by hand; C-j, also on the Line-Feed or LFD key if you have one, makes a copy of the number in level 2.)

A fascinating property of the Fibonacci numbers is that the nth Fibonacci number can be found directly by computing @c{$\phi^n / \sqrt{5}$} phi^n / sqrt(5) and then rounding to the nearest integer, where @c{ϕ} ("phi")} phi, the "golden ratio," is @c{$(1 + \sqrt{5}) / 2$} (1 + sqrt(5)) / 2. (For convenience, this constant is available from the `phi` variable, or the I H P command.)

```
1:  1.61803         1:  24476.0000409    1:  10945.9999817    1:  10946
    .                   .                    .                    .

    I H P               21 ^                 5 Q /                R
```

(*) **Exercise 5.** The continued fraction representation of @c{ϕ} phi is @c{$1 + 1/(1 + 1/(1 + 1/(\ldots)))$} 1 + 1/(1 + 1/(1 + 1/(...))). We can compute an approximate value by carrying this however far and then replacing the innermost @c{$1/(\ldots)$} 1/(...) by 1. Approximate phi using a twenty-term continued fraction. See section Programming Tutorial Exercise 5. (*)

(*) **Exercise 6.** Linear recurrences like the one for Fibonacci numbers can be expressed in terms of matrices. Given a vector [a, b] determine a matrix which, when multiplied by this vector, produces the vector [b, c], where a, b and c are three successive Fibonacci numbers. Now write a program that, given an integer n, computes the nth Fibonacci number using matrix arithmetic. See section Programming Tutorial Exercise 6. (*)

A more sophisticated kind of loop is the for loop. Suppose we wish to compute the 20th "harmonic" number, which is equal to the sum of the reciprocals of the integers from 1 to 20.

```
3:  0               1:  3.597739
2:  1                   .
1:  20
    .

0 RET 1 RET 20          Z ( & + 1 Z )
```

The "for" loop pops two numbers, the lower and upper limits, then repeats the body of the loop as an internal

counter increases from the lower limit to the upper one. Just before executing the loop body, it pushes the current loop counter. When the loop body finishes, it pops the "step," i.e., the amount by which to increment the loop counter. As you can see, our loop always uses a step of one.

This harmonic number function uses the stack to hold the running total as well as for the various loop housekeeping functions. If you find this disorienting, you can sum in a variable instead:

```
1:  0          2:  1                    .             1:  3.597739
    .          1:  20                                     .
                   .

    0 t 7        1 RET 20       Z ( & s + 7 1 Z )        r 7
```

The s + command adds the top-of-stack into the value in a variable (and removes that value from the stack).

It's worth noting that many jobs that call for a "for" loop can also be done more easily by Calc's high-level operations. Two other ways to compute harmonic numbers are to use vector mapping and reduction (v x 20, then V M &, then V R +), or to use the summation command a +. Both of these are probably easier than using loops. However, there are some situations where loops really are the way to go:

(*) **Exercise 7.** Use a "for" loop to find the first harmonic number which is greater than 4.0. See section Programming Tutorial Exercise 7. (*)

Of course, if we're going to be using variables in our programs, we have to worry about the programs clobbering values that the caller was keeping in those same variables. This is easy to fix, though:

```
    .          1:  0.6667        1:  0.6667      3:  0.6667
               .                   .               2:  3.597739
                                                   1:  0.6667
                                                       .

   Z `     p 4 RET 2 RET 3 /    s 7 s s a RET     Z '   r 7 s r a RET
```

When we type Z ` (that's a back-quote character), Calc saves its mode settings and the contents of the ten "quick variables" for later reference. When we type Z ' (that's an apostrophe now), Calc restores those saved values. Thus the p 4 and s 7 commands have no effect outside this sequence. Wrapping this around the body of a keyboard macro ensures that it doesn't interfere with what the user of the macro was doing. Notice that the contents of the stack, and the values of named variables, survive past the Z ' command.

The Bernoulli numbers are a sequence with the interesting property that all of the odd Bernoulli numbers are zero, and the even ones, while difficult to compute, can be roughly approximated by the formula @c{$\displaystyle{2 n! \over (2 \pi)^n}$} 2 n! / (2 pi)^n. Let's write a keyboard macro to compute (approximate) Bernoulli numbers. (Calc has a command, k b, to compute exact Bernoulli numbers, but this command is very slow for large n since the higher Bernoulli numbers are very large fractions.)

```
1:  10                1:  0.0756823
    .                     .

    10      C-x ( RET 2 % Z [ DEL 0 Z : ' 2 $! / (2 pi)^$ RET = Z ] C-x )
```

You can read Z [as "then," Z : as "else," and Z] as "end-if." There is no need for an explicit "if" comman
For the purposes of Z [, the condition is "true" if the value it pops from the stack is a nonzero number, or
"false" if it pops zero or something that is not a number (like a formula). Here we take our integer argument
modulo 2; this will be nonzero if we're asking for an odd Bernoulli number.

The actual tenth Bernoulli number is 5/66.

```
3:  0.0756823    1:  0          1:  0.25305    1:  0          1:  1.16659
2:  5:66             .              .              .              .
1:  0.0757575
    .

10 k b RET c f   M-0 DEL 11 X   DEL 12 X       DEL 13 X       DEL 14 X
```

Just to exercise loops a bit more, let's compute a table of even Bernoulli numbers.

```
3:  []             1:  [0.10132, 0.03079, 0.02340, 0.033197, ...]
2:  2                  .
1:  30
    .

 [ ] 2 RET 30          Z ( X | 2 Z )
```

The vertical-bar | is the vector-concatenation command. When we execute it, the list we are building will be in stack level 2 (initially this is an empty list), and the next Bernoulli number will be in level 1. The effect is to append the Bernoulli number onto the end of the list. (To create a table of exact fractional Bernoulli numbers, just replace X with k b in the above sequence of keystrokes.)

With loops and conditionals, you can program essentially anything in Calc. One other command that makes looping easier is Z /, which takes a condition from the stack and breaks out of the enclosing loop if the condition is true (non-zero). You can use this to make "while" and "until" style loops.

If you make a mistake when entering a keyboard macro, you can edit it using Z E. First, you must attach it to a key with Z K. One technique is to enter a throwaway dummy definition for the macro, then enter the real one in the edit command.

```
1:  3                  1:  3          Keyboard Macro Editor.
    .                      .          Original keys: 1 RET 2 +

                                      type "1\r"
                                      type "2"
                                      calc-plus

C-x ( 1 RET 2 + C-x )    Z K h RET    Z E h
```

This shows the screen display assuming you have the `macedit' keyboard macro editing package installed, which is usually the case since a copy of `macedit' comes bundled with Calc.

A keyboard macro is stored as a pure keystroke sequence. The `macedit' package (invoked by Z E) scans along the macro and tries to decode it back into human-readable steps. If a key or keys are simply shorthand

for some command with a M-x name, that name is shown. Anything that doesn't correspond to a M-x command is written as a `type' command.

Let's edit in a new definition, for computing harmonic numbers. First, erase the three lines of the old definition. Then, type in the new definition (or use Emacs M-w and C-y commands to copy it from this page of the Info file; you can skip typing the comments that begin with `#').

```
calc-kbd-push          # Save local values (Z `)
type "0"               # Push a zero
calc-store-into        # Store it in variable 1
type "1"
type "1"               # Initial value for loop
calc-roll-down         # This is the TAB key; swap initial & final
calc-kbd-for           # Begin "for" loop...
calc-inv               #   Take reciprocal
calc-store-plus        #   Add to accumulator
type "1"
type "1"               #   Loop step is 1
calc-kbd-end-for       # End "for" loop
calc-recall            # Now recall final accumulated value
type "1"
calc-kbd-pop           # Restore values (Z ')
```

Press M-# M-# to finish editing and return to the Calculator.

```
1:  20          1:  3.597739
    .               .

    20              z h
```

If you don't know how to write a particular command in `macedit' format, you can always write it as keystrokes in a `type' command. There is also a `keys' command which interprets the rest of the line as standard Emacs keystroke names. In fact, `macedit' defines a handy `read-kbd-macro' command which reads the current region of the current buffer as a sequence of keystroke names, and defines that sequence on the X (and C-x e) key. Because this is so useful, Calc puts this command on the M-# m key. Try reading in this macro in the following form: Press C-@ (or C-SPC) at one end of the text below, then type M-# m at the other.

```
Z ` 0 t 1
    1 TAB
    Z (  & s + 1  1 Z )
    r 1
Z '
```

(*) **Exercise 8.** A general algorithm for solving equations numerically is Newton's Method. Given the equation f(x) = 0 for any function f, and an initial guess x_0 which is reasonably close to the desired solution, apply this formula over and over:

where f'(x) is the derivative of f. The x values will quickly converge to a solution, i.e., eventually new_x and x

will be equal to within the limits of the current precision. Write a program which takes a formula involvin variable x, and an initial guess x_0, on the stack, and produces a value of x for which the formula is zero it to find a solution of @c{$\sin(\cos x) = 0.5$} sin(cos(x)) = 0.5 near x = 4.5. (Use angles measured in radians.) Note that the built-in a R (`calc-find-root`) command uses Newton's method when it is able. See section Programming Tutorial Exercise 8. (*)

(*) **Exercise 9.** The digamma function @c{$\psi(z)$ ("psi")} psi(z) is defined as the derivative of @c{$\ln \Gamma(z)$} ln(gamma(z)). For large values of z, it can be approximated by the infinite sum

where @c{$\sum$} sum represents the sum over n from 1 to infinity (or to some limit high enough to give the desired accuracy), and the `bern` function produces (exact) Bernoulli numbers. While this sum is not guaranteed to converge, in practice it is safe. An interesting mathematical constant is Euler's gamma, which is equal to about 0.5772. One way to compute it is by the formula, gamma = -psi(1). Unfortunately, 1 isn't a large enough argument for the above formula to work (5 is a much safer value for z). Fortunately, we can compute @c{$\psi(1)$} psi(1) from @c{$\psi(5)$} psi(5) using the recurrence @c{$\psi(z+1) = \psi(z) + {1 \over z}$} psi(z+1) = psi(z) + 1/z. Your task: Develop a program to compute @c{$\psi(z)$} psi(z); it should "pump up" z if necessary to be greater than 5, then use the above summation formula. Use looping commands to compute the sum. Use your function to compute @c{γ} gamma to twelve decimal places. (Calc has a built-in command for Euler's constant, I P, which you can use to check your answer.) See section Programming Tutorial Exercise 9. (*)

(*) **Exercise 10.** Given a polynomial in x and a number m on the stack, where the polynomial is of degree m or less (i.e., does not have any terms higher than x^m), write a program to convert the polynomial into a list-of-coefficients notation. For example, 5 x^4 + (x + 1)^2 with m = 6 should produce the list [1, 2, 1, 0, 5, 0, 0]. Also develop a way to convert from this form back to the standard algebraic form. See section Programming Tutorial Exercise 10. (*)

(*) **Exercise 11.** The Stirling numbers of the first kind are defined by the recurrences,

This can be implemented using a recursive program in Calc; the program must invoke itself in order to calculate the two righthand terms in the general formula. Since it always invokes itself with "simpler" arguments, it's easy to see that it must eventually finish the computation. Recursion is a little difficult with Emacs keyboard macros since the macro is executed before its definition is complete. So here's the recommended strategy: Create a "dummy macro" and assign it to a key with, e.g., Z K s. Now enter the true definition, using the z s command to call itself recursively, then assign it to the same key with Z K s. Now the z s command will run the complete recursive program. (Another way is to use Z E or M-# m (`read-kbd-macro`) to read the whole macro at once, thus avoiding the "training" phase.) The task: Write a program that computes Stirling numbers of the first kind, given n and m on the stack. Test it with *small* inputs like s(4,2). (There is a built-in command for Stirling numbers, k s, which you can use to check your answers.) See section Programming Tutorial Exercise 11. (*)

The programming commands we've seen in this part of the tutorial are low-level, general-purpose operations. Often you will find that a higher-level function, such as vector mapping or rewrite rules, will do the job much more easily than a detailed, step-by-step program can:

(*) **Exercise 12.** Write another program for computing Stirling numbers of the first kind, this time using rewrite rules. Once again, n and m should be taken from the stack. See section Programming Tutorial Exercise 12. (*)

This ends the tutorial section of the Calc manual. Now you know enough about Calc to use it effectively for many kinds of calculations. But Calc has many features that were not even touched upon in this tutorial. The rest of this manual tells the whole story.

Answers to Exercises

This section includes answers to all the exercises in the Calc tutorial.

RPN Tutorial Exercise 1

1 RET 2 RET 3 RET 4 + * -

The result is @c{$1 - (2 \times (3 + 4)) = -13$} 1 - (2 * (3 + 4)) = -13.

RPN Tutorial Exercise 2

2*4 + 7*9.5 + 5/4 = 75.75

After computing the intermediate term @c{$2\times4 = 8$} 2*4 = 8, you can leave that result on the stack while you compute the second term. With both of these results waiting on the stack you can then compute the final term, then press + + to add everything up.

```
2:  2          1:  8          3:  8          2:  8
1:  4              .          2:  7          1:  66.5
    .                         1:  9.5            .
                                  .

  2 RET 4          *          7 RET 9.5          *

4:  8          3:  8          2:  8          1:  75.75
3:  66.5       2:  66.5       1:  67.75          .
2:  5          1:  1.25           .
1:  4              .
    .

  5 RET 4          /              +              +
```

Alternatively, you could add the first two terms before going on with the third term.

```
2:  8          1:  74.5       3:  74.5       2:  74.5       1:  75.75
1:  66.5           .          2:  5          1:  1.25           .
    .                         1:  4              .
                                  .

   ...             +            5 RET 4          /              +
```

On an old-style RPN calculator this second method would have the advantage of using only three stack le
But since Calc's stack can grow arbitrarily large this isn't really an issue. Which method you choose is pu
matter of taste.

RPN Tutorial Exercise 3

The TAB key provides a way to operate on the number in level 2.

```
3:  10          3:  10          4:  10          3:  10          3:  10
2:  20          2:  30          3:  30          2:  30          2:  21
1:  30          1:  20          2:  20          1:  21          1:  30
    .               .           1:  1               .               .
                                    .

                   TAB              1              +               TAB
```

Similarly, M-TAB gives you access to the number in level 3.

```
3:  10          3:  21          3:  21          3:  30          3:  11
2:  21          2:  30          2:  30          2:  11          2:  21
1:  30          1:  10          1:  11          1:  21          1:  30
    .               .               .               .               .

                   M-TAB            1 +             M-TAB           M-TAB
```

RPN Tutorial Exercise 4

Either (2 , 3) or (2 SPC 3) would have worked, but using both the comma and the space at once yields:

```
1:  ( ...       2:  ( ...       1:  (2, ...     2:  (2, ...     2:  (2, ...
    .           1:  2               .           1:  (2, ...     1:  (2, 3)
                    .                               .               .

    (               2               ,               SPC             3 )
```

Joe probably tried to type TAB DEL to swap the extra incomplete object to the top of the stack and delete it. But a feature of Calc is that DEL on an incomplete object deletes just one component out of that object, so he had to press DEL twice to finish the job.

```
2:  (2, ...     2:  (2, 3)      2:  (2, 3)      1:  (2, 3)
1:  (2, 3)      1:  (2, ...     1:  ( ...           .
    .               .               .

                   TAB             DEL             DEL
```

(As it turns out, deleting the second-to-top stack entry happens often enough that Calc provides a special key, M-DEL, to do just that. M-DEL is just like TAB DEL, except that it doesn't exhibit the "feature" that tripped

poor Joe.)

Algebraic Entry Tutorial Exercise 1

Type ' sqrt($) RET.

If the Q key is broken, you could use ' $^0.5 RET. Or, RPN style, 0.5 ^.

(Actually, `$^1:2', using the fraction one-half as the power, is a closer equivalent, since `9^0.5' yields 3.0 whereas `sqrt(9)' and `9^1:2' yield the exact integer 3.)

Algebraic Entry Tutorial Exercise 2

In the formula `2 x (1+y)', `x' was interpreted as a function name with `1+y' as its argument. Assigning a value to a variable has no relation to a function by the same name. Joe needed to use an explicit `*' symbol here: `2 x*(1+y)'.

Algebraic Entry Tutorial Exercise 3

The result from 1 RET 0 / will be the formula 1 / 0. The "function" `/' cannot be evaluated when its second argument is zero, so it is left in symbolic form. When you now type 0 *, the result will be zero because Calc uses the general rule that "zero times anything is zero."

The m i command enables an infinite mode in which 1 / 0 results in a special symbol that represents "infinity." If you multiply infinity by zero, Calc uses another special new symbol to show that the answer is "indeterminate." See section Infinities, for further discussion of infinite and indeterminate values.

Modes Tutorial Exercise 1

Calc always stores its numbers in decimal, so even though one-third has an exact base-3 representation (`3#0.1'), it is still stored as 0.3333333 (chopped off after 12 or however many decimal digits) inside the calculator's memory. When this inexact number is converted back to base 3 for display, it may still be slightly inexact. When we multiply this number by 3, we get 0.999999, also an inexact value.

When Calc displays a number in base 3, it has to decide how many digits to show. If the current precision is 12 (decimal) digits, that corresponds to `12 / log10(3) = 25.15' base-3 digits. Because 25.15 is not an exact integer, Calc shows only 25 digits, with the result that stored numbers carry a little bit of extra information that may not show up on the screen. When Joe entered `3#0.2', the stored number 0.666666 happened to round to a pleasing value when it lost that last 0.15 of a digit, but it was still inexact in Calc's memory. When he divided by 2, he still got the dreaded inexact value 0.333333. (Actually, he divided 0.666667 by 2 to get 0.333334, which is why he got something a little higher than `3#0.1` instead of a little lower.)

If Joe didn't want to be bothered with all this, he could have typed M-24 d n to display with one less digit than the default. (If you give d n a negative argument, it uses default-minus-that, so M-- d n would be an easier way to get the same effect.) Those inexact results would still be lurking there, but they would now be rounded to nice, natural-looking values for display purposes. (Remember, `0.022222' in base 3 is like `0.099999' in base 10; rounding off one digit will round the number up to `0.1'.) Depending on the nature of your work, this hiding of the inexactness may be a benefit or a danger. With the d n command, Calc gives you the choice.

Incidentally, another consequence of all this is that if you type M-30 d n to display more digits than are "r there," you'll see garbage digits at the end of the number. (In decimal display mode, with decimally-stored numbers, these garbage digits are always zero so they vanish and you don't notice them.) Because Calc rounds off that 0.15 digit, there is the danger that two numbers could be slightly different internally but still look the same. If you feel uneasy about this, set the d n precision to be a little higher than normal; you'll get ugly garbage digits, but you'll always be able to tell two distinct numbers apart.

An interesting side note is that most computers store their floating-point numbers in binary, and convert to decimal for display. Thus everyday programs have the same problem: Decimal 0.1 cannot be represented exactly in binary (try it: 0.1 d 2), so `0.1 * 10' comes out as an inexact approximation to 1 on some machines (though they generally arrange to hide it from you by rounding off one digit as we did above). Because Calc works in decimal instead of binary, you can be sure that numbers that look exact *are* exact as long as you stay in decimal display mode.

It's not hard to show that any number that can be represented exactly in binary, octal, or hexadecimal is also exact in decimal, so the kinds of problems we saw in this exercise are likely to be severe only when you use a relatively unusual radix like 3.

Modes Tutorial Exercise 2

If the radix is 15 or higher, we can't use the letter `e' to mark the exponent because `e' is interpreted as a digit. When Calc needs to display scientific notation in a high radix, it writes `16#F.E8F*16.^15'. You can enter a number like this as an algebraic entry. Also, pressing e without any digits before it normally types 1e, but in a high radix it types 16.^ and puts you in algebraic entry: 16#f.e8f RET e 15 RET * is another way to enter this number.

The reason Calc puts a decimal point in the `16.^' is to prevent huge integers from being generated if the exponent is large (consider `16#1.23*16^1000', where we compute `16^1000' as a giant exact integer and then throw away most of the digits when we multiply it by the floating-point `16#1.23'). While this wouldn't normally matter for display purposes, it could give you a nasty surprise if you copied that number into a file and later moved it back into Calc.

Modes Tutorial Exercise 3

The answer he got was 0.5000000000006399.

The problem is not that the square operation is inexact, but that the sine of 45 that was already on the stack was accurate to only 12 places. Arbitrary-precision calculations still only give answers as good as their inputs.

The real problem is that there is no 12-digit number which, when squared, comes out to 0.5 exactly. The f [and f] commands decrease or increase a number by one unit in the last place (according to the current precision). They are useful for determining facts like this.

```
1:  0.707106781187      1:  0.500000000001
    .                       .

    45 S                    2 ^
```

```
1:  0.707106781187      1:  0.707106781186      1:  0.499999999999
    .                       .                       .

    U  DEL                  f [                     2 ^
```

A high-precision calculation must be carried out in high precision all the way. The only number in the original problem which was known exactly was the quantity 45 degrees, so the precision must be raised before anything is done after the number 45 has been entered in order for the higher precision to be meaningful.

Modes Tutorial Exercise 4

Many calculations involve real-world quantities, like the width and height of a piece of wood or the volume of a jar. Such quantities can't be measured exactly anyway, and if the data that is input to a calculation is inexact, doing exact arithmetic on it is a waste of time.

Fractions become unwieldy after too many calculations have been done with them. For example, the sum of the reciprocals of the integers from 1 to 10 is 7381:2520. The sum from 1 to 30 is 9304682830147:2329089562800. After a point it will take a long time to add even one more term to this sum, but a floating-point calculation of the sum will not have this problem.

Also, rational numbers cannot express the results of all calculations. There is no fractional form for the square root of two, so if you type 2 Q, Calc has no choice but to give you a floating-point answer.

Arithmetic Tutorial Exercise 1

Dividing two integers that are larger than the current precision may give a floating-point result that is inaccurate even when rounded down to an integer. Consider 123456789 / 2 when the current precision is 6 digits. The true answer is 61728394.5, but with a precision of 6 this will be rounded to @c{$12345700.0/2.0 = 61728500.0$} 12345700. / 2. = 61728500.. The result, when converted to an integer, will be off by 106.

Here are two solutions: Raise the precision enough that the floating-point round-off error is strictly to the right of the decimal point. Or, convert to fraction mode so that 123456789 / 2 produces the exact fraction 123456789:2, which can be rounded down by the F command without ever switching to floating-point format.

Arithmetic Tutorial Exercise 2

27 RET 9 B could give the exact result 3:2, but it does a floating-point calculation instead and produces 1.5.

Calc will find an exact result for a logarithm if the result is an integer or the reciprocal of an integer. But there is no efficient way to search the space of all possible rational numbers for an exact answer, so Calc doesn't try.

Vector Tutorial Exercise 1

Duplicate the vector, compute its length, then divide the vector by its length: RET A /.

```
1:  [1, 2, 3]  2:  [1, 2, 3]      1:  [0.27, 0.53, 0.80]  1:  1.
    .          1:  3.74165738677      .                       .
                   .
```

```
    r 1             RET A                 /                          A
```

The final A command shows that the normalized vector does indeed have unit length.

Vector Tutorial Exercise 2

The average position is equal to the sum of the products of the positions times their corresponding probabilities. This is the definition of the dot product operation. So all you need to do is to put the two vectors on the stack and press *.

Matrix Tutorial Exercise 1

The trick is to multiply by a vector of ones. Use r 4 [1 1 1] * to get the row sum. Similarly, use [1 1] r 4 * to get the column sum.

Matrix Tutorial Exercise 2

Just enter the righthand side vector, then divide by the lefthand side matrix as usual.

```
1:  [6, 10]    2:  [6, 10]          1:  [6 - 4 a / (b - a), 4 / (b - a) ]
    .          1:  [ [ 1, a ]           .
                     [ 1, b ] ]
                   .

' [6 10] RET     ' [1 a; 1 b] RET      /
```

This can be made more readable using d B to enable "big" display mode:

```
           4 a     4
1:  [6 - -----, -----]
         b - a   b - a
```

Type d N to return to "normal" display mode afterwards.

Matrix Tutorial Exercise 3

To solve @c{$A^T A \, X = A^T B$} trn(A) * A * X = trn(A) * B, first we compute A2 = trn(A) * A and @c{$B' = A^T B$} B2 = trn(A) * B; now, we have a system @c{$A' X = B'$} A2 * X = B2 which we can solve using Calc's `/' command.

The first step is to enter the coefficient matrix. We'll store it in quick variable number 7 for later reference. Next, we compute the B2 vector.

```
1:  [ [ 1, 2, 3 ]              2:  [ [ 1, 4, 7, 2 ]      1:  [57, 84, 96]
      [ 4, 5, 6 ]                    [ 2, 5, 6, 4 ]          .
      [ 7, 6, 0 ]                    [ 3, 6, 0, 6 ] ]
      [ 2, 4, 6 ] ]            1:  [6, 2, 3, 11]
    .                              .
```

```
' [1 2 3; 4 5 6; 7 6 0; 2 4 6] RET  s 7  v t  [6 2 3 11]   *
```

Now we compute the matrix @c{A'} A2 and divide.

```
2:  [57, 84, 96]          1:  [-11.64, 14.08, -3.64]
1:  [ [ 70, 72, 39 ]          .
      [ 72, 81, 60 ]
      [ 39, 60, 81 ] ]
    .

    r 7 v t r 7 *             /
```

(The actual computed answer will be slightly inexact due to round-off error.)

Notice that the answers are similar to those for the @c{3×3} 3x3 system solved in the text. That's because the fourth equation that was added to the system is almost identical to the first one multiplied by two. (If it were identical, we would have gotten the exact same answer since the @c{4×3} 4x3 system would be equivalent to the original @c{3×3} 3x3 system.)

Since the first and fourth equations aren't quite equivalent, they can't both be satisfied at once. Let's plug our answers back into the original system of equations to see how well they match.

```
2:  [-11.64, 14.08, -3.64]     1:  [5.6, 2., 3., 11.2]
1:  [ [ 1, 2, 3 ]                  .
      [ 4, 5, 6 ]
      [ 7, 6, 0 ]
      [ 2, 4, 6 ] ]
    .

    r 7                            TAB *
```

This is reasonably close to our original B vector, [6, 2, 3, 11].

List Tutorial Exercise 1

We can use v x to build a vector of integers. This needs to be adjusted to get the range of integers we desire. Mapping `-' across the vector will accomplish this, although it turns out the plain `-' key will work just as well.

```
2:  2                          2:  2
1:  [1, 2, 3, 4, 5, 6, 7, 8, 9]    1:  [-4, -3, -2, -1, 0, 1, 2, 3, 4]
    .                              .

    2  v x 9 RET                   5 V M -   or   5 -
```

Now we use V M ^ to map the exponentiation operator across the vector.

```
1:  [0.0625, 0.125, 0.25, 0.5, 1, 2, 4, 8, 16]
    .
```

```
    V M ^
```

List Tutorial Exercise 2

Given x and y vectors in quick variables 1 and 2 as before, the first job is to form the matrix that describes the problem.

Thus we want a @c{19×2} 19x2 matrix with our x vector as one column and ones as the other column. So, first we build the column of ones, then we combine the two columns to form our A matrix.

```
2:  [1.34, 1.41, 1.49, ... ]    1:  [ [ 1.34, 1 ]
1:  [1, 1, 1, ...]                  [ 1.41, 1 ]
    .                               [ 1.49, 1 ]
                                    ...

    r 1 1 v b 19 RET                M-2 v p v t   s 3
```

Now we compute @c{$A^T y$} trn(A) * y and @c{$A^T A$} trn(A) * A and divide.

```
1:  [33.36554, 13.613]    2:  [33.36554, 13.613]
    .                     1:  [ [ 98.0003, 41.63 ]
                                [  41.63,   19   ] ]
                              .

 v t r 2 *                    r 3 v t r 3 *
```

(Hey, those numbers look familiar!)

```
1:  [0.52141679, -0.425978]
    .

    /
```

Since we were solving equations of the form @c{$m \times x + b \times 1 = y$} m*x + b*1 = y, these numbers should be m and b, respectively. Sure enough, they agree exactly with the result computed using V M and V R!

The moral of this story: V M and V R will probably solve your problem, but there is often an easier way using the higher-level arithmetic functions!

In fact, there is a built-in a F command that does least-squares fits. See section Curve Fitting.

List Tutorial Exercise 3

Move to one end of the list and press C-@ (or C-SPC or whatever) to set the mark, then move to the other end of the list and type M-# g.

```
1:  [2.3, 6, 22, 15.1, 7, 15, 14, 7.5, 2.5]
```

```
    .
```

To make things interesting, let's assume we don't know at a glance how many numbers are in this list. Then we could type:

```
2:  [2.3, 6, 22, ... ]     2:  [2.3, 6, 22, ... ]
1:  [2.3, 6, 22, ... ]     1:  126356422.5
    .                          .

    RET                        V R *

2:  126356422.5            2:  126356422.5     1:  7.94652913734
1:  [2.3, 6, 22, ... ]     1:  9                   .
    .                          .

    TAB                        v l                 I ^
```

(The I ^ command computes the nth root of a number. You could also type & ^ to take the reciprocal of 9 and then raise the number to that power.)

List Tutorial Exercise 4

A number j is a divisor of n if @c{$n \mathbin{\hbox{\code{\%}}} j = 0$} `n % j = 0'. The first step is to get a vector that identifies the divisors.

```
2:  30                 2:  [0, 0, 0, 2, ...]    1:  [1, 1, 1, 0, ...]
1:  [1, 2, 3, 4, ...]  1:  0                        .
    .                      .

 30 RET v x 30 RET   s 1    V M %  0                V M a =  s 2
```

This vector has 1's marking divisors of 30 and 0's marking non-divisors.

The zeroth divisor function is just the total number of divisors. The first divisor function is the sum of the divisors.

```
1:  8      3:  8                  2:  8                    2:  8
           2:  [1, 2, 3, 4, ...]  1:  [1, 2, 3, 0, ...]   1:  72
           1:  [1, 1, 1, 0, ...]      .                        .
               .

   V R +       r 1 r 2                V M *                  V R +
```

Once again, the last two steps just compute a dot product for which a simple * would have worked equally well.

List Tutorial Exercise 5

The obvious first step is to obtain the list of factors with k f. This list will always be in sorted order, so if there are duplicates they will be right next to each other. A suitable method is to compare the list with a copy of itself shifted over by one.

```
1:  [3, 7, 7, 7, 19]   2:  [3, 7, 7, 7, 19]     2:  [3, 7, 7, 7, 19, 0]
    .                  1:  [3, 7, 7, 7, 19, 0]  1:  [0, 3, 7, 7, 7, 19]
                           .                        .

    19551 k f              RET 0 |                  TAB 0 TAB |

1:  [0, 0, 1, 1, 0, 0]   1:  2          1:  0
    .                        .              .

    V M a =                  V R +          0 a =
```

Note that we have to arrange for both vectors to have the same length so that the mapping operation works; no prime factor will ever be zero, so adding zeros on the left and right is safe. From then on the job is pretty straightforward.

Incidentally, Calc provides the @c{\dfn{M\"obius} μ} Moebius mu function which is zero if and only if its argument is square-free. It would be a much more convenient way to do the above test in practice.

List Tutorial Exercise 6

First use v x 6 RET to get a list of integers, then V M v x to get a list of lists of integers!

List Tutorial Exercise 7

Here's one solution. First, compute the triangular list from the previous exercise and type 1 - to subtract one from all the elements.

```
1:  [ [0],
      [0, 1],
      [0, 1, 2],
      ...

    1 -
```

The numbers down the lefthand edge of the list we desire are called the "triangular numbers" (now you know why!). The nth triangular number is the sum of the integers from 1 to n, and can be computed directly by the formula @c{$n (n+1) \over 2$} n * (n+1) / 2.

```
2:  [ [0], [0, 1], ... ]    2:  [ [0], [0, 1], ... ]
1:  [0, 1, 2, 3, 4, 5]      1:  [0, 1, 3, 6, 10, 15]
```

```
    .                               .

    v x 6 RET 1 -                   V M ' $ ($+1)/2 RET
```

Adding this list to the above list of lists produces the desired result:

```
1:  [ [0],
      [1, 2],
      [3, 4, 5],
      [6, 7, 8, 9],
      [10, 11, 12, 13, 14],
      [15, 16, 17, 18, 19, 20] ]
      .

      V M +
```

If we did not know the formula for triangular numbers, we could have computed them using a V U + command. We could also have gotten them the hard way by mapping a reduction across the original triangular list.

```
2:  [ [0], [0, 1], ... ]    2:  [ [0], [0, 1], ... ]
1:  [ [0], [0, 1], ... ]    1:  [0, 1, 3, 6, 10, 15]
    .                           .

    RET                         V M V R +
```

(This means "map a V R + command across the vector," and since each element of the main vector is itself a small vector, V R + computes the sum of its elements.)

List Tutorial Exercise 8

The first step is to build a list of values of x.

```
1:  [1, 2, 3, ..., 21]  1:  [0, 1, 2, ..., 20]  1:  [0, 0.25, 0.5, ..., 5]
    .                       .                       .

    v x 21 RET              1 -                     4 /  s 1
```

Next, we compute the Bessel function values.

```
1:  [0., 0.124, 0.242, ..., -0.328]
    .

    V M ' besJ(1,$) RET
```

(Another way to do this would be 1 TAB V M f j.)

A way to isolate the maximum value is to compute the maximum using V R X, then compare all the Bessel values with that maximum.

```
2:  [0., 0.124, 0.242, ... ]   1:  [0, 0, 0, ... ]    2:  [0, 0, 0, ...
1:  0.5801562                      .                   1:  1
    .                                                      .

    RET V R X                      V M a =                 RET V R +    DEL
```

It's a good idea to verify, as in the last step above, that only one value is equal to the maximum. (After all, a plot of @c{$\sin x$} sin(x) might have many points all equal to the maximum value, 1.)

The vector we have now has a single 1 in the position that indicates the maximum value of x. Now it is a simple matter to convert this back into the corresponding value itself.

```
2:  [0, 0, 0, ... ]          1:  [0, 0., 0., ... ]    1:  1.75
1:  [0, 0.25, 0.5, ... ]         .                        .
    .

    r 1                          V M *                    V R +
```

If a = had produced more than one 1 value, this method would have given the sum of all maximum x values; not very useful! In this case we could have used v m (`calc-mask-vector`) instead. This command deletes all elements of a "data" vector that correspond to zeros in a "mask" vector, leaving us with, in this example, a vector of maximum x values.

The built-in a X command maximizes a function using more efficient methods. Just for illustration, let's use a X to maximize `besJ(1,x)' over this same interval.

```
2:  besJ(1, x)                 1:  [1.84115, 0.581865]
1:  [0 .. 5]                       .
    .

' besJ(1,x), [0..5] RET            a X x RET
```

The output from a X is a vector containing the value of x that maximizes the function, and the function's value at that maximum. As you can see, our simple search got quite close to the right answer.

List Tutorial Exercise 9

Step one is to convert our integer into vector notation.

```
1:  25129925999            3:  25129925999
    .                      2:  10
                           1:  [11, 10, 9, ..., 1, 0]
                               .

    25129925999 RET            10 RET 12 RET v x 12 RET -

1:  25129925999              1:  [0, 2, 25, 251, 2512, ... ]
```

```
2:  [100000000000, ... ]          .
    .

    V M ^   s 1                   V M \
```

(Recall, the \ command computes an integer quotient.)

```
1:  [0, 2, 5, 1, 2, 9, 9, 2, 5, 9, 9, 9]
    .

    10 V M %   s 2
```

Next we must increment this number. This involves adding one to the last digit, plus handling carries. There is a carry to the left out of a digit if that digit is a nine and all the digits to the right of it are nines.

```
1:  [0, 0, 0, 0, 0, 1, 1, 0, 0, 1, 1, 1]   1:  [1, 1, 1, 0, 0, 1, ... ]
    .                                          .

    9 V M a =                                  v v

1:  [1, 1, 1, 0, 0, 0, ... ]   1:  [0, 0, 0, 0, 0, 0, 0, 0, 0, 1, 1, 1, 1]
    .                              .

    V U *                          v v 1 |
```

Accumulating * across a vector of ones and zeros will preserve only the initial run of ones. These are the carries into all digits except the rightmost digit. Concatenating a one on the right takes care of aligning the carries properly, and also adding one to the rightmost digit.

```
2:  [0, 0, 0, 0, ... ]     1:  [0, 0, 2, 5, 1, 2, 9, 9, 2, 6, 0, 0, 0]
1:  [0, 0, 2, 5, ... ]         .
    .

    0 r 2 |                    V M +  10 V M %
```

Here we have concatenated 0 to the *left* of the original number; this takes care of shifting the carries by one with respect to the digits that generated them.

Finally, we must convert this list back into an integer.

```
3:  [0, 0, 2, 5, ... ]         2:  [0, 0, 2, 5, ... ]
2:  1000000000000              1:  [1000000000000, 100000000000, ... ]
1:  [100000000000, ... ]           .
    .

    10 RET 12 ^  r 1               |
```

```
1:  [0, 0, 20000000000, 5000000000, ... ]    1:  25129926000
    .                                            .

    V M *                                        V R +
```

Another way to do this final step would be to reduce the formula `10 $$ + $' across the vector of digits.

```
1:  [0, 0, 2, 5, ... ]          1:  25129926000
    .                               .

                                    V R ' 10 $$ + $ RET
```

List Tutorial Exercise 10

For the list [a, b, c, d], the result is ((a = b) = c) = d, which will compare a and b to produce a 1 or 0, which is then compared with c to produce another 1 or 0, which is then compared with d. This is not at all what Joe wanted.

Here's a more correct method:

```
1:  [7, 7, 7, 8, 7]       2:  [7, 7, 7, 8, 7]
    .                         1:  7
                                  .

  ' [7,7,7,8,7] RET           RET v r 1 RET

1:  [1, 1, 1, 0, 1]       1:  0
    .                         .

    V M a =                   V R *
```

List Tutorial Exercise 11

The circle of unit radius consists of those points (x,y) for which x^2 + y^2 < 1. We start by generating a vector of x^2 and a vector of y^2.

We can make this go a bit faster by using the v . and t . commands.

```
2:  [2., 2., ..., 2.]          2:  [2., 2., ..., 2.]
1:  [2., 2., ..., 2.]          1:  [1.16, 1.98, ..., 0.81]
    .                              .

 v . t .  2. v b 100 RET RET       V M k r
```

```
2:  [2., 2., ..., 2.]          1:  [0.026, 0.96, ..., 0.036]
1:  [0.026, 0.96, ..., 0.036]  2:  [0.53, 0.81, ..., 0.094]
    .                              .

    1 -  2 V M ^                   TAB  V M k r  1 -  2 V M ^
```

Now we sum the x^2 and y^2 values, compare with 1 to get a vector of 1/0 truth values, then sum the truth values.

```
1:  [0.56, 1.78, ..., 0.13]    1:  [1, 0, ..., 1]    1:  84
    .                              .                     .

    +                              1 V M a <             V R +
```

The ratio 84/100 should approximate the ratio @c{$\pi/4$} pi/4.

```
1:  0.84       1:  3.36       2:  3.36       1:  1.0695
    .              .          1:  3.14159        .

    100 /          4 *            P              /
```

Our estimate, 3.36, is off by about 7%. We could get a better estimate by taking more points (say, 1000), but it's clear that this method is not very efficient!

(Naturally, since this example uses random numbers your own answer will be slightly different from the one shown here!)

If you typed v . and t . before, type them again to return to full-sized display of vectors.

List Tutorial Exercise 12

This problem can be made a lot easier by taking advantage of some symmetries. First of all, after some thought it's clear that the y axis can be ignored altogether. Just pick a random x component for one end of the match, pick a random direction @c{θ} theta, and see if x and @c{$x + \cos \theta$} x + cos(theta) (which is the x coordinate of the other endpoint) cross a line. The lines are at integer coordinates, so this happens when the two numbers surround an integer.

Since the two endpoints are equivalent, we may as well choose the leftmost of the two endpoints as x. Then theta is an angle pointing to the right, in the range -90 to 90 degrees. (We could use radians, but it would feel like cheating to refer to @c{$\pi/2$} pi/2 radians while trying to estimate @c{π} pi!)

In fact, since the field of lines is infinite we can choose the coordinates 0 and 1 for the lines on either side of the leftmost endpoint. The rightmost endpoint will be between 0 and 1 if the match does not cross a line, or between 1 and 2 if it does. So: Pick random x and @c{θ} theta, compute @c{$x + \cos \theta$} x + cos(theta), and count how many of the results are greater than one. Simple!

We can make this go a bit faster by using the v . and t . commands.

```
1:  [0.52, 0.71, ..., 0.72]    2:  [0.52, 0.71, ..., 0.72]
    .                          1:  [78.4, 64.5, ..., -42.9]
```

```
                                    .

v . t . 1. v b 100 RET  V M k r    180. v b 100 RET  V M k r  90 -
```

(The next step may be slow, depending on the speed of your computer.)

```
2:  [0.52, 0.71, ..., 0.72]    1:  [0.72, 1.14, ..., 1.45]
1:  [0.20, 0.43, ..., 0.73]        .
    .

    m d  V M C                     +

1:  [0, 1, ..., 1]       1:  0.64            1:  3.125
    .                        .                   .

    1 V M a >                V R + 100 /         2 TAB /
```

Let's try the third method, too. We'll use random integers up to one million. The k r command with an integer argument picks a random integer.

```
2:  [1000000, 1000000, ..., 1000000]   2:  [78489, 527587, ..., 814975]
1:  [1000000, 1000000, ..., 1000000]   1:  [324014, 358783, ..., 955450]
    .                                      .

    1000000 v b 100 RET RET                V M k r  TAB  V M k r

1:  [1, 1, ..., 25]      1:  [1, 1, ..., 0]     1:  0.56
    .                        .                       .

    V M k g                  1 V M a =               V R + 100 /

1:  10.714        1:  3.273
    .                 .

    6 TAB /           Q
```

For a proof of this property of the GCD function, see section 4.5.2, exercise 10, of Knuth's *Art of Computer Programming*, volume II.

If you typed v . and t . before, type them again to return to full-sized display of vectors.

List Tutorial Exercise 13

First, we put the string on the stack as a vector of ASCII codes.

```
1:  [84, 101, 115, ..., 51]
    .

    "Testing, 1, 2, 3 RET
```

Note that the " key, like $, initiates algebraic entry so there was no need to type an apostrophe. Also, Calc didn't mind that we omitted the closing ". (The same goes for all closing delimiters like) and] at the end of a formula.

We'll show two different approaches here. In the first, we note that if the input vector is [a, b, c, d], then the hash code is 3 (3 (3a + b) + c) + d = 27a + 9b + 3c + d. In other words, it's a sum of descending powers of three times the ASCII codes.

```
2:  [84, 101, 115, ..., 51]    2:  [84, 101, 115, ..., 51]
1:  16                         1:  [15, 14, 13, ..., 0]
    .                              .

    RET v l                        v x 16 RET -

2:  [84, 101, 115, ..., 51]    1:  1960915098    1:  121
1:  [14348907, ..., 1]             .                 .
    .

    3 TAB V M ^                    *                 511 %
```

Once again, * elegantly summarizes most of the computation. But there's an even more elegant approach: Reduce the formula 3 $$ + $ across the vector. Recall that this represents a function of two arguments that computes its first argument times three plus its second argument.

```
1:  [84, 101, 115, ..., 51]    1:  1960915098
    .                              .

    "Testing, 1, 2, 3 RET          V R ' 3$$+$ RET
```

If you did the decimal arithmetic exercise, this will be familiar. Basically, we're turning a base-3 vector of digits into an integer, except that our "digits" are much larger than real digits.

Instead of typing 511 % again to reduce the result, we can be cleverer still and notice that rather than computing a huge integer and taking the modulo at the end, we can take the modulo at each step without affecting the result. While this means there are more arithmetic operations, the numbers we operate on remain small so the operations are faster.

```
1:  [84, 101, 115, ..., 51]    1:  121
```

```
    .                                .

    "Testing, 1, 2, 3 RET            V R ' (3$$+$)%511 RET
```

Why does this work? Think about a two-step computation: 3 (3a + b) + c. Taking a result modulo 511 basically means subtracting off enough 511's to put the result in the desired range. So the result when we take the modulo after every step is,

for some suitable integers m and n. Expanding out by the distributive law yields

The m term in the latter formula is redundant because any contribution it makes could just as easily be made by the n term. So we can take it out to get an equivalent formula with n' = 3m + n,

which is just the formula for taking the modulo only at the end of the calculation. Therefore the two methods are essentially the same.

Later in the tutorial we will encounter modulo forms, which basically automate the idea of reducing every intermediate result modulo some value *M*.

List Tutorial Exercise 14

We want to use H V U to nest a function which adds a random step to an (x,y) coordinate. The function is a bit long, but otherwise the problem is quite straightforward.

```
2:  [0, 0]     1:  [ [    0,       0    ]
1:  50               [  0.4288, -0.1695 ]
    .                [ -0.4787, -0.9027 ]
                     ...

    [0,0] 50       H V U ' <# + [random(2.0)-1, random(2.0)-1]> RET
```

Just as the text recommended, we used `< >' nameless function notation to keep the two `random` calls from being evaluated before nesting even begins.

We now have a vector of [x, y] sub-vectors, which by Calc's rules acts like a matrix. We can transpose this matrix and unpack to get a pair of vectors, x and y, suitable for graphing.

```
2:  [ 0, 0.4288, -0.4787, ... ]
1:  [ 0, -0.1696, -0.9027, ... ]
    .

    v t  v u  g f
```

Incidentally, because the x and y are completely independent in this case, we could have done two separate commands to create our x and y vectors of numbers directly.

To make a random walk of unit steps, we note that `sincos` of a random direction exactly gives us an [x, y] step of unit length; in fact, the new nesting function is even briefer, though we might want to lower the precision a bit for it.

```
2:  [0, 0]      1:  [ [    0,      0    ]
1:  50                 [  0.1318, 0.9912 ]
    .                  [ -0.5965, 0.3061 ]
                       ...

    [0,0] 50   m d  p 6 RET   H V U ' <# + sincos(random(360.0))> RET
```

Another v t v u g f sequence will graph this new random walk.

An interesting twist on these random walk functions would be to use complex numbers instead of 2-vectors to represent points on the plane. In the first example, we'd use something like `random + random*(0,1)', and in the second we could use polar complex numbers with random phase angles. (This exercise was first suggested in this form by Randal Schwartz.)

Types Tutorial Exercise 1

If the number is the square root of @c{π} pi times a rational number, then its square, divided by @c{π} pi, should be a rational number.

```
1:  1.26508260337    1:  0.509433962268   1:  2486645810:4881193627
    .                    .                    .

                         2 ^ P /              c F
```

Technically speaking this is a rational number, but not one that is likely to have arisen in the original problem. More likely, it just happens to be the fraction which most closely represents some irrational number to within 12 digits.

But perhaps our result was not quite exact. Let's reduce the precision slightly and try again:

```
1:  0.509433962268     1:  27:53
    .                      .

    U p 10 RET             c F
```

Aha! It's unlikely that an irrational number would equal a fraction this simple to within ten digits, so our original number was probably sqrt(27 pi / 53).

Notice that we didn't need to re-round the number when we reduced the precision. Remember, arithmetic operations always round their inputs to the current precision before they begin.

Types Tutorial Exercise 2

`inf / inf = nan'. Perhaps `1' is the "obvious" answer. But if `17 inf = inf', then `17 inf / inf = inf / inf = 17', too.

`exp(inf) = inf'. It's tempting to say that the exponential of infinity must be "bigger" than "regular" infinity, but as far as Calc is concerned all infinities are as just as big. In other words, as x goes to infinity, e^x also goes to infinity, but the fact the e^x grows much faster than x is not relevant here.

`exp(-inf) = 0'. Here we have a finite answer even though the input is infinite.

`sqrt(-inf) = (0, 1) inf'. Remember that (0, 1) represents the imaginary number i. Here's a derivation: `sqrt(-inf) = sqrt((-1) * inf) = sqrt(-1) * sqrt(inf)'. The first part is, by definition, i; the second is `inf` because, once again, all infinities are the same size.

`sqrt(uinf) = uinf'. In fact, we do know something about the direction because `sqrt` is defined to return a value in the right half of the complex plane. But Calc has no notation for this, so it settles for the conservative answer `uinf`.

`abs(uinf) = inf'. No matter which direction x points, `abs(x)' always points along the positive real axis.

`ln(0) = -inf'. Here we have an infinite answer to a finite input. As in the 1 / 0 case, Calc will only use infinities here if you have turned on "infinite" mode. Otherwise, it will treat `ln(0)' as an error.

Types Tutorial Exercise 3

We can make `inf - inf' be any real number we like, say, a, just by claiming that we added a to the first infinity but not to the second. This is just as true for complex values of a, so `nan` can stand for a complex number. (And, similarly, `uinf` can stand for an infinity that points in any direction in the complex plane, such as `(0, 1) inf').

In fact, we can multiply the first `inf` by two. Surely `2 inf - inf = inf', but also `2 inf - inf = inf - inf = nan'. So `nan` can even stand for infinity. Obviously it's just as easy to make it stand for minus infinity as for plus infinity.

The moral of this story is that "infinity" is a slippery fish indeed, and Calc tries to handle it by having a very simple model for infinities (only the direction counts, not the "size"); but Calc is careful to write `nan` any time this simple model is unable to tell what the true answer is.

Types Tutorial Exercise 4

```
2:  0@ 47' 26"              1:  0@ 2' 47.411765"
1:  17                          .
    .

    0@ 47' 26" RET 17           /
```

The average song length is two minutes and 47.4 seconds.

```
2:  0@ 2' 47.411765"     1:  0@ 3' 7.411765"    1:  0@ 53' 6.000005"
1:  0@ 0' 20"                .                      .
    .

    20"                      +                      17 *
```

The album would be 53 minutes and 6 seconds long.

Types Tutorial Exercise 5

Let's suppose it's January 14, 1991. The easiest thing to do is to keep trying 13ths of months until Calc reports a Friday. We can do this by manually entering dates, or by using t I:

```
1:  <Wed Feb 13, 1991>    1:  <Wed Mar 13, 1991>   1:  <Sat Apr 13, 1991>
    .                         .                        .

    ' <2/13> RET       DEL    ' <3/13> RET             t I
```

(Calc assumes the current year if you don't say otherwise.)

This is getting tedious--we can keep advancing the date by typing t I over and over again, but let's automate the job by using vector mapping. The t I command actually takes a second "how-many-months" argument, which defaults to one. This argument is exactly what we want to map over:

```
2:  <Sat Apr 13, 1991>     1:  [<Mon May 13, 1991>, <Thu Jun 13, 1991>,
1:  [1, 2, 3, 4, 5, 6]          <Sat Jul 13, 1991>, <Tue Aug 13, 1991>,
    .                           <Fri Sep 13, 1991>, <Sun Oct 13, 1991>]
                                .

    v x 6 RET                   V M t I

1:  242
    .

' <sep 13> - <jan 14> RET
```

And the answer to our original question: 242 days to go.

Types Tutorial Exercise 6

The full rule for leap years is that they occur in every year divisible by four, except that they don't occur in years divisible by 100, except that they *do* in years divisible by 400. We could work out the answer by carefully counting the years divisible by four and the exceptions, but there is a much simpler way that works even if we don't know the leap year rule.

Let's assume the present year is 1991. Years have 365 days, except that leap years (whenever they occur) have 366 days. So let's count the number of days between now and then, and compare that to the number of years times 365. The number of extra days we find must be equal to the number of leap years there were.

```
1:  <Mon Jan 1, 10001>     2:  <Mon Jan 1, 10001>     1:  2925593
    .                      1:  <Tue Jan 1, 1991>          .
                               .

  ' <jan 1 10001> RET          ' <jan 1 1991> RET          -
```

```
3:  2925593        2:  2925593      2:  2925593      1:  1943
2:  10001          1:  8010         1:  2923650          .
1:  1991               .                .
    .

  10001 RET 1991       -                365 *            -
```

There will be 1943 leap years before the year 10001. (Assuming, of course, that the algorithm for computing leap years remains unchanged for that long. See section Date Forms, for some interesting background information in that regard.)

Types Tutorial Exercise 7

The relative errors must be converted to absolute errors so that `+/-' notation may be used.

```
1:  1.               2:  1.
    .                1:  0.2
                         .

    20 RET .05 *         4 RET .05 *
```

Now we simply chug through the formula.

```
1:  19.7392088022    1:  394.78 +/- 19.739    1:  6316.5 +/- 706.21
    .                    .                        .

    2 P 2 ^ *            20 p 1 *                 4 p .2 RET 2 ^ *
```

It turns out the v u command will unpack an error form as well as a vector. This saves us some retyping of numbers.

```
3:  6316.5 +/- 706.21     2:  6316.5 +/- 706.21
2:  6316.5                1:  0.1118
1:  706.21                    .
    .

    RET v u               TAB /
```

Thus the volume is 6316 cubic centimeters, within about 11 percent.

Types Tutorial Exercise 8

The first answer is pretty simple: `1 / (0 .. 10) = (0.1 .. inf)'. Since a number in the interval `(0 .. 10)' can get arbitrarily close to zero, its reciprocal can get arbitrarily large, so the answer is an interval that effectively means, "any number greater than 0.1" but with no upper bound.

The second answer, similarly, is `1 / (-10 .. 0) = (-inf .. -0.1)'.

Calc normally treats division by zero as an error, so that the formula `1 / 0' is left unsimplified. Our third

problem, `1 / [0 .. 10]', also (potentially) divides by zero because zero is now a member of the interval. So Calc leaves this one unevaluated, too.

If you turn on "infinite" mode by pressing m i, you will instead get the answer `[0.1 .. inf]', which includes infinity as a possible value.

The fourth calculation, `1 / (-10 .. 10)', has the same problem. Zero is buried inside the interval, but it's still a possible value. It's not hard to see that the actual result of `1 / (-10 .. 10)' will be either greater than *0.1*, or less than *-0.1*. Thus the interval goes from minus infinity to plus infinity, with a "hole" in it from *-0.1* to *0.1*. Calc doesn't have any way to represent this, so it just reports `[-inf .. inf]' as the answer. It may be disappointing to hear "the answer lies somewhere between minus infinity and plus infinity, inclusive," but that's the best that interval arithmetic can do in this case.

Types Tutorial Exercise 9

```
1:  [-3 .. 3]       2:  [-3 .. 3]     2:  [0 .. 9]
    .               1:  [0 .. 9]      1:  [-9 .. 9]
                        .                 .

    [ 3 n .. 3 ]        RET 2 ^           TAB RET *
```

In the first case the result says, "if a number is between *-3* and 3, its square is between 0 and 9." The second case says, "the product of two numbers each between *-3* and 3 is between *-9* and 9."

An interval form is not a number; it is a symbol that can stand for many different numbers. Two identical-looking interval forms can stand for different numbers.

The same issue arises when you try to square an error form.

Types Tutorial Exercise 10

Testing the first number, we might arbitrarily choose 17 for x.

```
1:  17 mod 811749613   2:  17 mod 811749613   1:  533694123 mod 811749613
    .                      811749612              .
                           .

    17 M 811749613 RET     811749612              ^
```

Since 533694123 is (considerably) different from 1, the number 811749613 must not be prime.

It's awkward to type the number in twice as we did above. There are various ways to avoid this, and algebraic entry is one. In fact, using a vector mapping operation we can perform several tests at once. Let's use this method to test the second number.

```
2:  [17, 42, 100000]              1:  [1 mod 15485863, 1 mod ... ]
1:  15485863                          .
    .
```

```
[17 42 100000] 15485863 RET              V M ' ($$ mod $)^($-1) RET
```

The result is three ones (modulo n), so it's very probable that 15485863 is prime. (In fact, this number is the millionth prime.)

Note that the functions `($$^($-1)) mod $' or `$$^($-1) % $' would have been hopelessly inefficient, since they would have calculated the power using full integer arithmetic.

Calc has a k p command that does primality testing. For small numbers it does an exact test; for large numbers it uses a variant of the Fermat test we used here. You can use k p repeatedly to prove that a large integer is prime with any desired probability.

Types Tutorial Exercise 11

There are several ways to insert a calculated number into an HMS form. One way to convert a number of seconds to an HMS form is simply to multiply the number by an HMS form representing one second:

```
1:  31415926.5359      2:  31415926.5359      1:  8726@ 38' 46.5359"
    .                  1:  0@ 0' 1"               .
                           .

    P 1e7 *                0@ 0' 1"               *

2:  8726@ 38' 46.5359"               1:  6@ 6' 2.5359" mod 24@ 0' 0"
1:  15@ 27' 16" mod 24@ 0' 0"            .
    .

    x time RET                           +
```

It will be just after six in the morning.

The algebraic `hms` function can also be used to build an HMS form:

```
1:  hms(0, 0, 10000000. pi)          1:  8726@ 38' 46.5359"
    .                                    .

  ' hms(0, 0, 1e7 pi) RET                =
```

The = key is necessary to evaluate the symbol `pi' to the actual number 3.14159...

Types Tutorial Exercise 12

As we recall, there are 17 songs of about 2 minutes and 47 seconds each.

```
2:  0@ 2' 47"                        1:  [0@ 3' 7" .. 0@ 3' 47"]
1:  [0@ 0' 20" .. 0@ 1' 0"]              .
    .
```

```
    [ 0@ 20" .. 0@ 1' ]                +

1:  [0@ 52' 59." .. 1@ 4' 19."]
    .

    17 *
```

No matter how long it is, the album will fit nicely on one CD.

Types Tutorial Exercise 13

Type ' 1 yr RET u c s RET. The answer is 31557600 seconds.

Types Tutorial Exercise 14

How long will it take for a signal to get from one end of the computer to the other?

```
1:  m / c          1:  3.3356 ns
    .                  .

 ' 1 m / c RET         u c ns RET
```

(Recall, `c' is a "unit" corresponding to the speed of light.)

```
1:  3.3356 ns      1:  0.81356 ns / ns      1:  0.81356
2:  4.1 ns             .                        .
    .

  ' 4.1 ns RET         /                        u s
```

Thus a signal could take up to 81 percent of a clock cycle just to go from one place to another inside the computer, assuming the signal could actually attain the full speed of light. Pretty tight!

Types Tutorial Exercise 15

The speed limit is 55 miles per hour on most highways. We want to find the ratio of Sam's speed to the US speed limit.

```
1:  55 mph         2:  55 mph           3:  11 hr mph / yd
    .              1:  5 yd / hr            .
                       .

  ' 55 mph RET       ' 5 yd/hr RET          /
```

The u s command cancels out these units to get a plain number. Now we take the logarithm base two to find the final answer, assuming that each successive pill doubles his speed.

```
1:  19360.        2:  19360.        1:  14.24
    .             1:  2                 .
                      .

    u s               2                 B
```

Thus Sam can take up to 14 pills without a worry.

Algebra Tutorial Exercise 1

The result `sqrt(x)^2' is simplified back to x by the Calculator, but `sqrt(x^2)' is not. (Consider what happens if x = -4.) If x is real, this formula could be simplified to `abs(x)', but for general complex arguments even that is not safe. (See section Declarations, for a way to tell Calc that x is known to be real.)

Algebra Tutorial Exercise 2

Suppose our roots are [a, b, c]. We want a polynomial which is zero when x is any of these values. The trivial polynomial x-a is zero when x=a, so the product (x-a)(x-b)(x-c) will do the job. We can use a c x to write this in a more familiar form.

```
1:  34 x - 24 x^3          1:  [1.19023, -1.19023, 0]
    .                          .

    r 2                        a P x RET

1:  [x - 1.19023, x + 1.19023, x]     1:  (x - 1.19023) (x + 1.19023) x
    .                                     .

    V M ' x-$ RET                         V R *

1:  x^3 - 1.41666 x        1:  34 x - 24 x^3
    .                          .

    a c x RET                  24 n *  a x
```

Sure enough, our answer (multiplied by a suitable constant) is the same as the original polynomial.

Algebra Tutorial Exercise 3

```
1:  x sin(pi x)          1:  (sin(pi x) - pi x cos(pi x)) / pi^2
    .                        .

  ' x sin(pi x) RET   m r   a i x RET
```

```
1:  [y, 1]
2:  (sin(pi x) - pi x cos(pi x)) / pi^2
    .

  ' [y,1] RET TAB

1:  [(sin(pi y) - pi y cos(pi y)) / pi^2, (sin(pi) - pi cos(pi)) / pi^2]
    .

    V M $ RET

1:  (sin(pi y) - pi y cos(pi y)) / pi^2 + (pi cos(pi) - sin(pi)) / pi^2
    .

    V R -

1:  (sin(3.14159 y) - 3.14159 y cos(3.14159 y)) / 9.8696 - 0.3183
    .

    =

1:  [0., -0.95493, 0.63662, -1.5915, 1.2732]
    .

    v x 5 RET  TAB  V M $ RET
```

Algebra Tutorial Exercise 4

The hard part is that V R + is no longer sufficient to add up all the contributions from the slices, since the slices have varying coefficients. So first we must come up with a vector of these coefficients. Here's one way:

```
2:  -1                2:  3                    1:  [4, 2, ..., 4]
1:  [1, 2, ..., 9]    1:  [-1, 1, ..., -1]         .
    .                     .

    1 n v x 9 RET         V M ^  3 TAB             -

1:  [4, 2, ..., 4, 1]     1:  [1, 4, 2, ..., 4, 1]
    .                         .
```

```
    1 |                              1 TAB |
```

Now we compute the function values. Note that for this method we need eleven values, including both endpoints of the desired interval.

```
2:  [1, 4, 2, ..., 4, 1]
1:  [1, 1.1, 1.2,  ...  , 1.8, 1.9, 2.]
    .

 11 RET 1 RET .1 RET  C-u v x

2:  [1, 4, 2, ..., 4, 1]
1:  [0., 0.084941, 0.16993, ... ]
    .

    ' sin(x) ln(x) RET   m r  p 5 RET   V M $ RET
```

Once again this calls for V M * V R +; a simple * does the same thing.

```
1:  11.22      1:  1.122      1:  0.374
    .              .              .

    *              .1 *           3 /
```

Wow! That's even better than the result from the Taylor series method.

Rewrites Tutorial Exercise 1

We'll use Big mode to make the formulas more readable.

```
                                                  ____
                                          2 + V 2
1:  (2 + sqrt(2)) / (1 + sqrt(2))     1:  --------
    .                                         ____
                                          1 + V 2

                                          .

  ' (2+sqrt(2)) / (1+sqrt(2)) RET         d B
```

Multiplying by the conjugate helps because (a+b) (a-b) = a^2 - b^2.

```
                ____   ____
1:  (2 + V 2 ) (V 2  - 1)
    .

  a r a/(b+c) := a*(b-c) / (b^2-c^2) RET
```

```
1:  2 + V 2  - 2                1:  V 2
    .                               .

  a r a*(b+c) := a*b + a*c          a s
```

(We could have used a x instead of a rewrite rule for the second step.)

The multiply-by-conjugate rule turns out to be useful in many different circumstances, such as when the denominator involves sines and cosines or the imaginary constant `i`.

Rewrites Tutorial Exercise 2

Here is the rule set:

```
[ fib(n) := fib(n, 1, 1) :: integer(n) :: n >= 1,
  fib(1, x, y) := x,
  fib(n, x, y) := fib(n-1, y, x+y) ]
```

The first rule turns a one-argument `fib` that people like to write into a three-argument `fib` that makes computation easier. The second rule converts back from three-argument form once the computation is done. The third rule does the computation itself. It basically says that if x and y are two consecutive Fibonacci numbers, then y and x+y are the next (overlapping) pair of Fibonacci numbers.

Notice that because the number n was "validated" by the conditions on the first rule, there is no need to put conditions on the other rules because the rule set would never get that far unless the input were valid. That further speeds computation, since no extra conditions need to be checked at every step.

Actually, a user with a nasty sense of humor could enter a bad three-argument `fib` call directly, say, `fib(0, 1, 1)', which would get the rules into an infinite loop. One thing that would help keep this from happening by accident would be to use something like `ZzFib' instead of `fib` as the name of the three-argument function.

Rewrites Tutorial Exercise 3

He got an infinite loop. First, Calc did as expected and rewrote `2 + 3 x' to `f(2, 3, x)'. Then it looked for ways to apply the rule again, and found that `f(2, 3, x)' looks like `a + b x' with `a = 0' and `b = 1', so it rewrote to `f(0, 1, f(2, 3, x))'. It then wrapped another `f(0, 1, ...)' around that, and so on, ad infinitum. Joe should have used M-1 a r to make sure the rule applied only once.

(Actually, even the first step didn't work as he expected. What Calc really gives for M-1 a r in this situation is `f(3 x, 1, 2)', treating 2 as the "variable," and `3 x' as a constant being added to it. While this may seem odd, it's just as valid a solution as the "obvious" one. One way to fix this would be to add the condition `:: variable(x)' to the rule, to make sure the thing that matches `x' is indeed a variable, or to change `x' to `quote(x)' on the lefthand side, so that the rule matches the actual variable `x' rather than letting `x' stand for something else.)

Rewrites Tutorial Exercise 4

Here is a suitable set of rules to solve the first part of the problem:

```
[ seq(n, c) := seq(n/2,  c+1) :: n%2 = 0,
  seq(n, c) := seq(3n+1, c+1) :: n%2 = 1 :: n > 1 ]
```

Given the initial formula `seq(6, 0)', application of these rules produces the following sequence of formulas:

```
seq( 3, 1)
seq(10, 2)
seq( 5, 3)
seq(16, 4)
seq( 8, 5)
seq( 4, 6)
seq( 2, 7)
seq( 1, 8)
```

whereupon neither of the rules match, and rewriting stops.

We can pretty this up a bit with a couple more rules:

```
[ seq(n) := seq(n, 0),
  seq(1, c) := c,
  ... ]
```

Now, given `seq(6)' as the starting configuration, we get 8 as the result.

The change to return a vector is quite simple:

```
[ seq(n) := seq(n, []) :: integer(n) :: n > 0,
  seq(1, v) := v | 1,
  seq(n, v) := seq(n/2,  v | n) :: n%2 = 0,
  seq(n, v) := seq(3n+1, v | n) :: n%2 = 1 ]
```

Given `seq(6)', the result is `[6, 3, 10, 5, 16, 8, 4, 2, 1]'.

Notice that the n > 1 guard is no longer necessary on the last rule since the n = 1 case is now detected by another rule. But a guard has been added to the initial rule to make sure the initial value is suitable before the computation begins.

While still a good idea, this guard is not as vitally important as it was for the `fib` function, since calling, say, `seq(x, [])' will not get into an infinite loop. Calc will not be able to prove the symbol `x' is either even or odd, so none of the rules will apply and the rewrites will stop right away.

Rewrites Tutorial Exercise 5

If x is the sum a + b, then `nterms(*x*)' must be `nterms(*a*)' plus `nterms(*b*)'. If x is not a sum, then `nterms(*x*)' = 1.

```
[ nterms(a + b) := nterms(a) + nterms(b),
  nterms(x)     := 1 ]
```

Here we have taken advantage of the fact that earlier rules always match before later rules; `nterms(x)' will only be tried if we already know that `x' is not a sum.

Rewrites Tutorial Exercise 6

Just put the rule `0^0 := 1' into `EvalRules'. For example, before making this definition we have:

```
2:  [-2, -1, 0, 1, 2]                 1:  [1, 1, 0^0, 1, 1]
1:  0                                     .
    .

    v x 5 RET  3 -  0                     V M ^
```

But then:

```
2:  [-2, -1, 0, 1, 2]                 1:  [1, 1, 1, 1, 1]
1:  0                                     .
    .

    U  ' 0^0:=1 RET s t EvalRules RET     V M ^
```

Perhaps more surprisingly, this rule still works with infinite mode turned on. Calc tries `EvalRules' before any built-in rules for a function. This allows you to override the default behavior of any Calc feature: Even though Calc now wants to evaluate 0^0 to `nan', your rule gets there first and evaluates it to 1 instead.

Just for kicks, try adding the rule `2+3 := 6' to `EvalRules'. What happens? (Be sure to remove this rule afterward, or you might get a nasty surprise when you use Calc to balance your checkbook!)

Rewrites Tutorial Exercise 7

Here is a rule set that will do the job:

```
[ a*(b + c) := a*b + a*c,
  opt(a) O(x^n) + opt(b) O(x^m) := O(x^n) :: n <= m
     :: constant(a) :: constant(b),
  opt(a) O(x^n) + opt(b) x^m := O(x^n) :: n <= m
     :: constant(a) :: constant(b),
  a O(x^n) := O(x^n) :: constant(a),
  x^opt(m) O(x^n) := O(x^(n+m)),
  O(x^n) O(x^m) := O(x^(n+m)) ]
```

If we really want the + and * keys to operate naturally on power series, we should put these rules in `EvalRules'. For testing purposes, it is better to put them in a different variable, say, `O', first.

The first rule just expands products of sums so that the rest of the rules can assume they have an expanded-out

polynomial to work with. Note that this rule does not mention `O' at all, so it will apply to any product-of- it encounters--this rule may surprise you if you put it into `EvalRules'!

In the second rule, the sum of two O's is changed to the smaller O. The optional constant coefficients are there mostly so that `O(x^2) - O(x^3)' and `O(x^3) - O(x^2)' are handled as well as `O(x^2) + O(x^3)'.

The third rule absorbs higher powers of `x' into O's.

The fourth rule says that a constant times a negligible quantity is still negligible. (This rule will also match `O(x^3) / 4', with `a = 1/4'.)

The fifth rule rewrites, for example, `x^2 O(x^3)' to `O(x^5)'. (It is easy to see that if one of these forms is negligible, the other is, too.) Notice the `x^opt(m)' to pick up terms like `x O(x^3)'. Optional powers will match `x' as `x^1' but not 1 as `x^0'. This turns out to be exactly what we want here.

The sixth rule is the corresponding rule for products of two O's.

Another way to solve this problem would be to create a new "data type" that represents truncated power series. We might represent these as function calls `series(coefs, x)' where coefs is a vector of coefficients for x^0, x^1, x^2, and so on. Rules would exist for sums and products of such `series' objects, and as an optional convenience could also know how to combine a `series' object with a normal polynomial. (With this, and with a rule that rewrites `O(x^n)' to the equivalent `series' form, you could still enter power series in exactly the same notation as before.) Operations on such objects would probably be more efficient, although the objects would be a bit harder to read.

Some other symbolic math programs provide a power series data type similar to this. Mathematica, for example, has an object that looks like `PowerSeries[x, x0, coefs, nmin, nmax, den]', where x0 is the point about which the power series is taken (we've been assuming this was always zero), and nmin, nmax, and den allow pseudo-power-series with fractional or negative powers. Also, the `PowerSeries' objects have a special display format that makes them look like `2 x^2 + O(x^4)' when they are printed out. (See section Compositions, for a way to do this in Calc, although for something as involved as this it would probably be better to write the formatting routine in Lisp.)

Programming Tutorial Exercise 1

Just enter the formula `ninteg(sin(t)/t, t, 0, x)', type Z F, and answer the questions. Since this formula contains two variables, the default argument list will be `(t x)'. We want to change this to `(x)' since t is really a dummy variable to be used within `ninteg'.

The exact keystrokes are Z F s Si RET RET C-b C-b DEL DEL RET y. (The C-b C-b DEL DEL are what fix the argument list.)

Programming Tutorial Exercise 2

One way is to move the number to the top of the stack, operate on it, then move it back: C-x (M-TAB n M-TAB M-TAB C-x).

Another way is to negate the top three stack entries, then negate again the top two stack entries: C-x (M-3 n M-2 n C-x).

Finally, it turns out that a negative prefix argument causes a command like n to operate on the specified stack

entry only, which is just what we want: C-x (M-- 3 n C-x).

Just for kicks, let's also do it algebraically: C-x (' -$$$, $$, $ RET C-x).

Programming Tutorial Exercise 3

Each of these functions can be computed using the stack, or using algebraic entry, whichever way you prefer:

Computing @c{$\displaystyle{\sin x \over x}$} sin(x) / x:

Using the stack: C-x (RET S TAB / C-x).

Using algebraic entry: C-x (' sin($)/$ RET C-x).

Computing the logarithm:

Using the stack: C-x (TAB B C-x)

Using algebraic entry: C-x (' log($,$$) RET C-x).

Computing the vector of integers:

Using the stack: C-x (1 RET 1 C-u v x C-x). (Recall that C-u v x takes the vector size, starting value, and increment from the stack.)

Alternatively: C-x (~ v x C-x). (The ~ key pops a number from the stack and uses it as the prefix argument for the next command.)

Using algebraic entry: C-x (' index($) RET C-x).

Programming Tutorial Exercise 4

Here's one way: C-x (RET V R + TAB v l / C-x).

Programming Tutorial Exercise 5

```
2:  1              1:  1.61803398502          2:  1.61803398502
1:  20                 .                      1:  1.61803398875
    .                                             .

   1 RET 20          Z < & 1 + Z >                 I H P
```

This answer is quite accurate.

Programming Tutorial Exercise 6

Here is the matrix:

```
[ [ 0, 1 ]   * [a, b] = [b, a + b]
  [ 1, 1 ] ]
```

Thus `[0, 1; 1, 1]^n * [1, 1]' computes Fibonacci numbers n+1 and n+2. Here's one program that does the

```
C-x ( ' [0, 1; 1, 1] ^ ($-1) * [1, 1] RET v u DEL C-x )
```

This program is quite efficient because Calc knows how to raise a matrix (or other value) to the power n in only @c{$\log_2 n$} log(n,2) steps. For example, this program can compute the 1000th Fibonacci number (a 209-digit integer!) in about 10 steps; even though the Z < ... Z > solution had much simpler steps, it would have required so many steps that it would not have been practical.

Programming Tutorial Exercise 7

The trick here is to compute the harmonic numbers differently, so that the loop counter itself accumulates the sum of reciprocals. We use a separate variable to hold the integer counter.

```
1:  1          2:  1       1:  .
    .          1:  4
                   .

    1 t 1       1 RET 4      Z ( t 2 r 1 1 + s 1 & Z )
```

The body of the loop goes as follows: First save the harmonic sum so far in variable 2. Then delete it from the stack; the for loop itself will take care of remembering it for us. Next, recall the count from variable 1, add one to it, and feed its reciprocal to the for loop to use as the step value. The for loop will increase the "loop counter" by that amount and keep going until the loop counter exceeds 4.

```
2:  31                  3:  31
1:  3.99498713092       2:  3.99498713092
    .                   1:  4.02724519544
                            .

    r 1 r 2                 RET 31 & +
```

Thus we find that the 30th harmonic number is 3.99, and the 31st harmonic number is 4.02.

Programming Tutorial Exercise 8

The first step is to compute the derivative f'(x) and thus the formula @c{$\displaystyle{x - {f(x) \over f'(x)}}$} x - f(x)/f'(x).

(Because this definition is long, it will be repeated in concise form below. You can use M-# m to load it from there. While you are entering a Z ` Z ' body in a macro, Calc simply collects keystrokes without executing them. In the following diagrams we'll pretend Calc actually executed the keystrokes as you typed them, just for purposes of illustration.)

```
2:  sin(cos(x)) - 0.5           3:  4.5
1:  4.5                         2:  sin(cos(x)) - 0.5
    .                           1:  -(sin(x) cos(cos(x)))
                                    .
```

```
' sin(cos(x))-0.5 RET 4.5  m r  C-x ( Z `  TAB RET a d x RET

2:  4.5
1:  x + (sin(cos(x)) - 0.5) / sin(x) cos(cos(x))
    .

    /  ' x RET TAB -   t 1
```

Now, we enter the loop. We'll use a repeat loop with a 20-repetition limit just in case the method fails to converge for some reason. (Normally, the Z / command will stop the loop before all 20 repetitions are done.)

```
1:  4.5         3:  4.5                     2:  4.5
    .           2:  x + (sin(cos(x)) ...    1:  5.24196456928
                1:  4.5                         .
                    .

  20 Z <          RET r 1 TAB                   s l x RET
```

This is the new guess for x. Now we compare it with the old one to see if we've converged.

```
3:  5.24196     2:  5.24196     1:  5.24196     1:  5.26345856348
2:  5.24196     1:  0               .               .
1:  4.5             .
    .

  RET M-TAB         a =             Z /             Z > Z ' C-x )
```

The loop converges in just a few steps to this value. To check the result, we can simply substitute it back into the equation.

```
2:  5.26345856348
1:  0.499999999997
    .

 RET ' sin(cos($)) RET
```

Let's test the new definition again:

```
2:  x^2 - 9           1:  3.
1:  1                     .
    .

  ' x^2-9 RET 1           X
```

Once again, here's the full Newton's Method definition:

```
C-x ( Z `  TAB RET a d x RET  /  ' x RET TAB -  t 1
           20 Z <  RET r 1 TAB  s l x RET
                   RET M-TAB  a =  Z /
              Z >
      Z '
C-x )
```

It turns out that Calc has a built-in command for applying a formula repeatedly until it converges to a number. See section Nesting and Fixed Points, to see how to use it.

Also, of course, a R is a built-in command that uses Newton's method (among others) to look for numerical solutions to any equation. See section Root Finding.

Programming Tutorial Exercise 9

The first step is to adjust z to be greater than 5. A simple "for" loop will do the job here. If z is less than 5, we reduce the problem using @c{$\psi(z) = \psi(z+1) - 1/z$} psi(z) = psi(z+1) - 1/z. We go on to compute @c{$\psi(z+1)$} psi(z+1), and remember to add back a factor of -1/z when we're done. This step is repeated until z > 5.

(Because this definition is long, it will be repeated in concise form below. You can use M-# m to load it from there. While you are entering a Z ` Z ' body in a macro, Calc simply collects keystrokes without executing them. In the following diagrams we'll pretend Calc actually executed the keystrokes as you typed them, just for purposes of illustration.)

```
1:  1.              1:  1.
    .                   .

 1.0 RET       C-x ( Z `  s 1  0 t 2
```

Here, variable 1 holds z and variable 2 holds the adjustment factor. If z < 5, we use a loop to increase it.

(By the way, we started with `1.0' instead of the integer 1 because otherwise the calculation below will try to do exact fractional arithmetic, and will never converge because fractions compare equal only if they are exactly equal, not just equal to within the current precision.)

```
3:  1.      2:  1.       1:  6.
2:  1.      1:  1            .
1:  5           .
    .

  RET 5       a <    Z [  5 Z (  & s + 2  1 s + 1  1 Z ) r 1  Z ]
```

Now we compute the initial part of the sum: @c{$\ln z - {1 \over 2z}$} ln(z) - 1/2z minus the adjustment factor.

```
2:  1.79175946923      2:  1.7084261359      1:  -0.57490719743
1:  0.0833333333333    1:  2.28333333333         .
    .                      .
```

```
    L  r 1 2 * &          -  r 2                -
```

Now we evaluate the series. We'll use another "for" loop counting up the value of 2 n. (Calc does have a summation command, a +, but we'll use loops just to get more practice with them.)

```
3:  -0.5749       3:  -0.5749       4:  -0.5749      2:  -0.5749
2:  2             2:  1:6           3:  1:6          1:  2.3148e-3
1:  40            1:  2             2:  2                .
    .                 .             1:  36.
                                        .

   2 RET 40        Z ( RET k b TAB     RET r 1 TAB ^      * /

3:  -0.5749       3:  -0.5772      2:  -0.5772     1:  -0.577215664892
2:  -0.5749       2:  -0.5772      1:  0               .
1:  2.3148e-3     1:  -0.5749          .
    .                 .

  TAB RET M-TAB       - RET M-TAB      a =     Z /    2  Z )  Z ' C-x )
```

This is the value of @c{$-\gamma$} - gamma, with a slight bit of roundoff error. To get a full 12 digits, let's use a higher precision:

```
2:  -0.577215664892      2:  -0.577215664892
1:  1.                   1:  -0.577215664901532

    1. RET                   p 16 RET X
```

Here's the complete sequence of keystrokes:

```
C-x ( Z `  s 1  0 t 2
           RET 5 a <  Z [  5 Z (  & s + 2  1 s + 1  1 Z ) r 1  Z ]
           L r 1 2 * & - r 2 -
           2 RET 40  Z (  RET k b TAB RET r 1 TAB ^ * /
                          TAB RET M-TAB - RET M-TAB a = Z /
                  2  Z )
      Z '
C-x )
```

Programming Tutorial Exercise 10

Taking the derivative of a term of the form x^n will produce a term like @c{$n x^{n-1}$} n x^(n-1). Taking the derivative of a constant produces zero. From this it is easy to see that the nth derivative of a polynomial, evaluated at x = 0, will equal the coefficient on the x^n term times n!.

(Because this definition is long, it will be repeated in concise form below. You can use M-# m to load it from

there. While you are entering a Z ` Z ' body in a macro, Calc simply collects keystrokes without executing them. In the following diagrams we'll pretend Calc actually executed the keystrokes as you typed them, ju for purposes of illustration.)

```
2:  5 x^4 + (x + 1)^2          3:  5 x^4 + (x + 1)^2
1:  6                          2:  0
    .                          1:  6
                                   .

  ' 5 x^4 + (x+1)^2 RET 6        C-x ( Z `  [ ] t 1  0 TAB
```

Variable 1 will accumulate the vector of coefficients.

```
2:  0              3:  0                  2:  5 x^4 + ...
1:  5 x^4 + ...    2:  5 x^4 + ...        1:  1
    .              1:  1                      .
                       .

   Z ( TAB         RET 0 s l x RET            M-TAB ! /  s | 1
```

Note that s | 1 appends the top-of-stack value to the vector in a variable; it is completely analogous to s + 1. We could have written instead, r 1 TAB | t 1.

```
1:  20 x^3 + 2 x + 2      1:  0         1:  [1, 2, 1, 0, 5, 0, 0]
    .                         .             .

    a d x RET                 1 Z )         DEL r 1  Z ' C-x )
```

To convert back, a simple method is just to map the coefficients against a table of powers of x.

```
2:  [1, 2, 1, 0, 5, 0, 0]    2:  [1, 2, 1, 0, 5, 0, 0]
1:  6                        1:  [0, 1, 2, 3, 4, 5, 6]
    .                            .

    6 RET                        1 + 0 RET 1 C-u v x

2:  [1, 2, 1, 0, 5, 0, 0]    2:  1 + 2 x + x^2 + 5 x^4
1:  [1, x, x^2, x^3, ... ]       .
    .

    ' x RET TAB V M ^            *
```

Once again, here are the whole polynomial to/from vector programs:

```
C-x ( Z `  [ ] t 1  0 TAB
           Z (  TAB RET 0 s l x RET M-TAB ! /  s | 1
                a d x RET
```

```
         1 Z ) r 1
      Z '
C-x )

C-x (  1 + 0 RET 1 C-u v x ' x RET TAB V M ^ *  C-x )
```

Programming Tutorial Exercise 11

First we define a dummy program to go on the z s key. The true z s key is supposed to take two numbers from the stack and return one number, so DEL as a dummy definition will make sure the stack comes out right.

```
2:  4          1:  4                          2:  4
1:  2              .                          1:  2
    .                                             .

  4 RET 2       C-x ( DEL C-x )  Z K s RET       2
```

The last step replaces the 2 that was eaten during the creation of the dummy z s command. Now we move on to the real definition. The recurrence needs to be rewritten slightly, to the form s(n,m) = s(n-1,m-1) - (n-1) s(n-1,m).

(Because this definition is long, it will be repeated in concise form below. You can use M-# m to load it from there.)

```
2:  4        4:  4       3:  4       2:  4
1:  2        3:  2       2:  2       1:  2
    .        2:  4       1:  0           .
             1:  2           .
                 .

  C-x (       M-2 RET        a =         Z [  DEL DEL 1  Z :

4:  4       2:  4                  2:  3      4:  3    4:  3    3:  3
3:  2       1:  2                  1:  2      3:  2    3:  2    2:  2
2:  2           .                      .      2:  3    2:  3    1:  3
1:  0                                         1:  2    1:  1        .
    .                                             .        .

  RET 0   a = Z [  DEL DEL 0  Z :  TAB 1 - TAB   M-2 RET     1 -      z s
```

(Note that the value 3 that our dummy z s produces is not correct; it is merely a placeholder that will do just as well for now.)

```
3:  3             4:  3          3:  3       2:  3      1:  -6
2:  3             3:  3          2:  3       1:  9          .
1:  2             2:  3          1:  3           .
    .             1:  2              .
```

```
                          .

 M-TAB M-TAB     TAB RET M-TAB          z s           *           -

1:  -6                          2:  4          1:  11      2:  11
    .                           1:  2              .       1:  11
                                    .                          .

  Z ] Z ] C-x )   Z K s RET      DEL 4 RET 2       z s      M-RET k s
```

Even though the result that we got during the definition was highly bogus, once the definition is complete the z s command gets the right answers.

Here's the full program once again:

```
C-x (  M-2 RET a =
       Z [  DEL DEL 1
       Z :  RET 0 a =
            Z [  DEL DEL 0
            Z :  TAB 1 - TAB M-2 RET 1 - z s
                 M-TAB M-TAB TAB RET M-TAB z s * -
            Z ]
       Z ]
C-x )
```

You can read this definition using M-# m (`read-kbd-macro`) followed by Z K s, without having to make a dummy definition first, because `read-kbd-macro` doesn't need to execute the definition as it reads it in. For this reason, `M-# m` is often the easiest way to create recursive programs in Calc.

Programming Tutorial Exercise 12

This turns out to be a much easier way to solve the problem. Let's denote Stirling numbers as calls of the function `s'.

First, we store the rewrite rules corresponding to the definition of Stirling numbers in a convenient variable:

```
s e StirlingRules RET
[ s(n,n) := 1  :: n >= 0,
  s(n,0) := 0  :: n > 0,
  s(n,m) := s(n-1,m-1) - (n-1) s(n-1,m) :: n >= m :: m >= 1 ]
C-c C-c
```

Now, it's just a matter of applying the rules:

```
2:  4          1:  s(4, 2)              1:  11
1:  2              .                        .
    .
```

```
4 RET 2       C-x (   ' s($$,$) RET     a r StirlingRules RET  C-x )
```

As in the case of the `fib` rules, it would be useful to put these rules in `EvalRules` and to add a `:: remember' condition to the last rule.

Go to the previous, next section.

Go to the previous, next section.

Introduction

This chapter is the beginning of the Calc reference manual. It covers basic concepts such as the stack, algebraic and numeric entry, undo, numeric prefix arguments, etc.

Basic Commands

To start the Calculator in its standard interface, type M-x calc. By default this creates a pair of small windows, `*Calculator*' and `*Calc Trail*'. The former displays the contents of the Calculator stack and is manipulated exclusively through Calc commands. It is possible (though not usually necessary) to create several Calc Mode buffers each of which has an independent stack, undo list, and mode settings. There is exactly one Calc Trail buffer; it records a list of the results of all calculations that have been done. The Calc Trail buffer uses a variant of Calc Mode, so Calculator commands still work when the trail buffer's window is selected. It is possible to turn the trail window off, but the `*Calc Trail*' buffer itself still exists and is updated silently. See section Trail Commands.

In most installations, the M-# c key sequence is a more convenient way to start the Calculator. Also, M-# M-# and M-# # are synonyms for M-# c unless you last used Calc in its "keypad" mode.

Most Calc commands use one or two keystrokes. Lower- and upper-case letters are distinct. Commands may also be entered in full M-x form; for some commands this is the only form. As a convenience, the x key (`calc-execute-extended-command`) is like M-x except that it enters the initial string `calc-' for you. For example, the following key sequences are equivalent: S, M-x calc-sin RET, x sin RET.

The Calculator exists in many parts. When you type M-# c, the Emacs "auto-load" mechanism will bring in only the first part, which contains the basic arithmetic functions. The other parts will be auto-loaded the first time you use the more advanced commands like trig functions or matrix operations. This is done to improve the response time of the Calculator in the common case when all you need to do is a little arithmetic. If for some reason the Calculator fails to load an extension module automatically, you can force it to load all the extensions by using the M-# L (`calc-load-everything`) command. See section Mode Settings.

If you type M-x calc or M-# c with any numeric prefix argument, the Calculator is loaded if necessary, but it is not actually started. If the argument is positive, the `` `calc-ext' `` extensions are also loaded if necessary. User-written Lisp code that wishes to make use of Calc's arithmetic routines can use `(calc 0)' or `(calc 1)' to auto-load the Calculator.

If you type M-# b, then next time you use M-# c you will get a Calculator that uses the full height of the Emacs screen. When full-screen mode is on, M-# c runs the `full-calc` command instead of `calc`. From the Unix shell you can type `emacs -f full-calc' to start a new Emacs specifically for use as a calculator. When Calc is started from the Emacs command line like this, Calc's normal "quit" commands actually quit Emacs itself.

The M-# o command is like M-# c except that the Calc window is not actually selected. If you are already in the Calc window, M-# o switches you out of it. (The regular Emacs C-x o command would also work for this, but it has a tendency to drop you into the Calc Trail window instead, which M-# o takes care not to do.)

For one quick calculation, you can type M-# q (`quick-calc`) which prompts you for a formula (like `2+3/4'). The result is displayed at the bottom of the Emacs screen without ever creating any special Calculator windows. See section "Quick Calculator" Mode.

Finally, if you are using the X window system you may want to try M-# k (`calc-keypad`) which runs Calc with a "calculator keypad" picture as well as a stack display. Click on the keys with the mouse to operate the calculator. See section "Keypad" Mode.

The q key (`calc-quit`) exits Calc Mode and closes the Calculator's window(s). It does not delete the Calculator buffers. If you type M-x calc again, the Calculator will reappear with the contents of the stack intact. Typing M-# c or M-# M-# again from inside the Calculator buffer is equivalent to executing `calc-quit`; you can think of M-# M-# as toggling the Calculator on and off.

The M-# x command also turns the Calculator off, no matter which user interface (standard, Keypad, or Embedded) is currently active. It also cancels `calc-edit` mode if used from there.

The d SPC key sequence (`calc-refresh`) redraws the contents of the Calculator buffer from memory. Use this if the contents of the buffer have been damaged somehow.

The o key (`calc-realign`) moves the cursor back to its "home" position at the bottom of the Calculator buffer.

The < and > keys are bound to `calc-scroll-left` and `calc-scroll-right`. These are just like the normal horizontal scrolling commands except that they scroll one half-screen at a time by default. (Calc formats its output to fit within the bounds of the window whenever it can.)

The { and } keys are bound to `calc-scroll-down` and `calc-scroll-up`. They scroll up or down by one-half the height of the Calc window.

The M-# 0 command (`calc-reset`; that's M-# followed by a zero) resets the Calculator to its default state. This clears the stack, resets all the modes, clears the caches (see section Caches), and so on. (It does *not* erase the values of any variables.) With a numeric prefix argument, M-# 0 preserves the contents of the stack but resets everything else.

The M-x calc-version command displays the current version number of Calc and the name of the person who installed it on your system. (This information is also present in the `*Calc Trail*' buffer, and in the output of the h h command.)

Help Commands

The ? key (`calc-help`) displays a series of brief help messages. Some keys (such as b and d) are prefix keys, like Emacs' ESC and C-x prefixes. You can type ? after a prefix to see a list of commands beginning with that prefix. (If the message includes `[MORE]', press ? again to see additional commands

for that prefix.)

The h h (`calc-full-help`) command displays all the ? responses at once. When printed, this makes a nice, compact (three pages) summary of Calc keystrokes.

In general, the h key prefix introduces various commands that provide help within Calc. Many of the h key functions are Calc-specific analogues to the C-h functions for Emacs help.

The h i (`calc-info`) command runs the Emacs Info system to read this manual on-line. This is basically the same as typing C-h i (the regular way to run the Info system), then, if Info is not already in the Calc manual, selecting the beginning of the manual. The M-# i command is another way to read the Calc manual; it is different from h i in that it works any time, not just inside Calc. The plain i key is also equivalent to h i, though this key is obsolete and may be replaced with a different command in a future version of Calc.

The h t (`calc-tutorial`) command runs the Info system on the Tutorial section of the Calc manual. It is like h i, except that it selects the starting node of the tutorial rather than the beginning of the whole manual. (It actually selects the node "Interactive Tutorial" which tells a few things about using the Info system before going on to the actual tutorial.) The M-# t key is equivalent to h t (but it works at all times).

The h s (`calc-info-summary`) command runs the Info system on the Summary node of the Calc manual. See section Calc Summary. The M-# s key is equivalent to h s.

The h k (`calc-describe-key`) command looks up a key sequence in the Calc manual. For example, h k H a S looks up the documentation on the H a S (`calc-solve-for`) command. This works by looking up the textual description of the key(s) in the Key Index of the manual, then jumping to the node indicated by the index.

Most Calc commands do not have traditional Emacs documentation strings, since the h k command is both more convenient and more instructive. This means the regular Emacs C-h k (`describe-key`) command will not be useful for Calc keystrokes.

The h c (`calc-describe-key-briefly`) command reads a key sequence and displays a brief one-line description of it at the bottom of the screen. It looks for the key sequence in the Summary node of the Calc manual; if it doesn't find the sequence there, it acts just like its regular Emacs counterpart C-h c (`describe-key-briefly`). For example, h c H a S gives the description:

```
H a S runs calc-solve-for:  a `H a S' v  => fsolve(a,v)  (?=notes)
```

which means the command H a S or H M-x calc-solve-for takes a value a from the stack, prompts for a value v, then applies the algebraic function `fsolve` to these values. The `?=notes' message means you can now type ? to see additional notes from the summary that apply to this command.

The h f (`calc-describe-function`) command looks up an algebraic function or a command name in the Calc manual. The prompt initially contains `calcFunc-'; follow this with an algebraic function name to look up that function in the Function Index. Or, backspace and enter a command name beginning with `calc-' to look it up in the Command Index. This command will also look up operator symbols that can appear in algebraic formulas, like `%' and `=>'.

The h v (`calc-describe-variable`) command looks up a variable in the Calc manual. The pr initially contains the `var-' prefix; just add a variable name like `pi` or `PlotRejects`.

The h b (`calc-describe-bindings`) command is just like C-h b, except that only local (Calc-related) key bindings are listed.

The h n or h C-n (`calc-view-news`) command displays the "news" or change history of Calc. This is kept in the file `` `README' ``, which Calc looks for in the same directory as the Calc source files.

The h C-c, h C-d, and h C-w keys display copying, distribution, and warranty information about Calc. These work by pulling up the appropriate parts of the "Copying" or "Reporting Bugs" sections of the manual.

Stack Basics

Calc uses RPN notation. If you are not familar with RPN, see section RPN Calculations and the Stack.

To add the numbers 1 and 2 in Calc you would type the keys: 1 RET 2 +. (RET corresponds to the ENTER key on most calculators.) The first three keystrokes "push" the numbers 1 and 2 onto the stack. The + key always "pops" the top two numbers from the stack, adds them, and pushes the result (3) back onto the stack. This number is ready for further calculations: 5 - pushes 5 onto the stack, then pops the 3 and 5, subtracts them, and pushes the result (-*2*).

Note that the "top" of the stack actually appears at the *bottom* of the buffer. A line containing a single `.' character signifies the end of the buffer; Calculator commands operate on the number(s) directly above this line. The d t (`calc-truncate-stack`) command allows you to move the `.' marker up and down in the stack; see section Truncating the Stack.

Stack elements are numbered consecutively, with number 1 being the top of the stack. These line numbers are ordinarily displayed on the lefthand side of the window. The d l (`calc-line-numbering`) command controls whether these numbers appear. (Line numbers may be turned off since they slow the Calculator down a bit and also clutter the display.)

The unshifted letter o (`calc-realign`) command repositions the cursor to its top-of-stack "home" position. It also undoes any horizontal scrolling in the window. If you give it a numeric prefix argument, it instead moves the cursor to the specified stack element.

The RET (or equivalent SPC) key is only required to separate two consecutive numbers. (After all, if you typed 1 2 by themselves the Calculator would enter the number 12.) If you press RET or SPC *not* right after typing a number, the key duplicates the number on the top of the stack. RET * is thus a handy way to square a number.

The DEL key pops and throws away the top number on the stack. The TAB key swaps the top two objects on the stack. See section Stack and Trail Commands, for descriptions of these and other stack-related commands.

Numeric Entry

Pressing a digit or other numeric key begins numeric entry using the minibuffer. The number is pushed on the stack when you press the RET or SPC keys. If you press any other non-numeric key, the number is pushed onto the stack and the appropriate operation is performed. If you press a numeric key which is not valid, the key is ignored.

There are three different concepts corresponding to the word "minus," typified by a-b (subtraction), -x (change-sign), and -5 (negative number). Calc uses three different keys for these operations, respectively: -, n, and _ (the underscore). The - key subtracts the two numbers on the top of the stack. The n key changes the sign of the number on the top of the stack or the number currently being entered. The _ key begins entry of a negative number or changes the sign of the number currently being entered. The following sequences all enter the number -5 onto the stack: 0 RET 5 -, 5 n RET, 5 RET n, _ 5 RET, 5 _ RET.

Some other keys are active during numeric entry, such as # for non-decimal numbers, : for fractions, and @ for HMS forms. These notations are described later in this manual with the corresponding data types. See section Data Types.

During numeric entry, the only editing key available is DEL.

Algebraic Entry

Calculations can also be entered in algebraic form. This is accomplished by typing the apostrophe key, ', followed by the expression in standard format: ' 2+3*4 RET computes 2+(3*4) = 14 and pushes that on the stack. If you wish you can ignore the RPN aspect of Calc altogether and simply enter algebraic expressions in this way. You may want to use DEL every so often to clear previous results off the stack.

You can press the apostrophe key during normal numeric entry to switch the half-entered number into algebraic entry mode. One reason to do this would be to use the full Emacs cursor motion and editing keys, which are available during algebraic entry but not during numeric entry.

In the same vein, during either numeric or algebraic entry you can press ` (backquote) to switch to `calc-edit` mode, where you complete your half-finished entry in a separate buffer. See section Editing Stack Entries.

If you prefer algebraic entry, you can use the command m a (`calc-algebraic-mode`) to set Algebraic mode. In this mode, digits and other keys that would normally start numeric entry instead start full algebraic entry; as long as your formula begins with a digit you can omit the apostrophe. Open parentheses and square brackets also begin algebraic entry. You can still do RPN calculations in this mode, but you will have to press RET to terminate every number: 2 RET 3 RET * 4 RET + would accomplish the same thing as 2*3+4 RET.

If you give a numeric prefix argument like C-u to the m a command, it enables Incomplete Algebraic mode; this is like regular Algebraic mode except that it applies to the (and [keys only. Numeric keys still begin a numeric entry in this mode.

The m t (`calc-total-algebraic-mode`) gives you an even stronger algebraic-entry mode, in which *all* regular letter and punctuation keys begin algebraic entry. Use this if you prefer typing sqrt( ) instead of Q, factor( ) instead of a f, and so on. To type regular Calc commands when you are in "total" algebraic mode, hold down the META key. Thus M-q is the command to quit Calc, M-p sets the precision, and M-m t (or M-m M-t, if you prefer) turns total algebraic mode back off again. Meta keys also terminate algebraic entry, so that 2+3 M-S is equivalent to 2+3 RET M-S. The symbol `Alg*' will appear in the mode line whenever you are in this mode.

Pressing ' (the apostrophe) a second time re-enters the previous algebraic formula. You can then use the normal Emacs editing keys to modify this formula to your liking before pressing RET.

Within a formula entered from the keyboard, the symbol $ represents the number on the top of the stack. If an entered formula contains any $ characters, the Calculator replaces the top of stack with that formula rather than simply pushing the formula onto the stack. Thus, ' 1+2 RET pushes 3 on the stack, and $*2 RET replaces it with 6. Note that the $ key always initiates algebraic entry; the ' is unnecessary if $ is the first character in the new formula.

Higher stack elements can be accessed from an entered formula with the symbols $$, $$$, and so on. The number of stack elements removed (to be replaced by the entered values) equals the number of dollar signs in the longest such symbol in the formula. For example, `$$+$$$' adds the second and third stack elements, replacing the top three elements with the answer. (All information about the top stack element is thus lost since no single `$' appears in this formula.)

A slightly different way to refer to stack elements is with a dollar sign followed by a number: `$1', `$2', and so on are much like `$', `$$', etc., except that stack entries referred to numerically are not replaced by the algebraic entry. That is, while `$+1' replaces 5 on the stack with 6, `$1+1' leaves the 5 on the stack and pushes an additional 6.

If a sequence of formulas are entered separated by commas, each formula is pushed onto the stack in turn. For example, `1,2,3' pushes those three numbers onto the stack (leaving the 3 at the top), and `$+1,$-1' replaces a 5 on the stack with 4 followed by 6. Also, `$,$$' exchanges the top two elements of the stack, just like the TAB key.

You can finish an algebraic entry with M-= or M-RET instead of RET. This uses = to evaluate the variables in each formula that goes onto the stack. (Thus ' pi RET pushes the variable `pi', but ' pi M-RET pushes 3.1415.)

If you finish your algebraic entry by pressing LFD (or C-j) instead of RET, Calc disables the default simplifications (as if by m O; see section Simplification Modes) while the entry is being pushed on the stack. Thus ' 1+2 RET pushes 3 on the stack, but ' 1+2 LFD pushes the formula 1+2; you might then press = when it is time to evaluate this formula.

"Quick Calculator" Mode

There is another way to invoke the Calculator if all you need to do is make one or two quick calculations. Type M-# q (or M-x quick-calc), then type any formula as an algebraic entry. The Calculator will compute the result and display it in the echo area, without ever actually putting up a Calc window.

You can use the $ character in a Quick Calculator formula to refer to the previous Quick Calculator result. Older results are not retained; the Quick Calculator has no effect on the full Calculator's stack or trail. If you compute a result and then forget what it was, just run `M-# q` again and enter `$' as the formula.

If this is the first time you have used the Calculator in this Emacs session, the M-# q command will create the `*Calculator*` buffer and perform all the usual initializations; it simply will refrain from putting that buffer up in a new window. The Quick Calculator refers to the `*Calculator*` buffer for all mode settings. Thus, for example, to set the precision that the Quick Calculator uses, simply run the full Calculator momentarily and use the regular p command.

If you use `M-# q` from inside the Calculator buffer, the effect is the same as pressing the apostrophe key (algebraic entry).

The result of a Quick calculation is placed in the Emacs "kill ring" as well as being displayed. A subsequent C-y command will yank the result into the editing buffer. You can also use this to yank the result into the next M-# q input line as a more explicit alternative to $ notation, or to yank the result into the Calculator stack after typing M-# c.

If you finish your formula by typing LFD (or C-j) instead of RET, the result is inserted immediately into the current buffer rather than going into the kill ring.

Quick Calculator results are actually evaluated as if by the = key (which replaces variable names by their stored values, if any). If the formula you enter is an assignment to a variable using the `:=' operator, say, `foo := 2 + 3' or `foo := foo + 1', then the result of the evaluation is stored in that Calc variable. See section Storing and Recalling.

If the result is an integer and the current display radix is decimal, the number will also be displayed in hex and octal formats. If the integer is in the range from 1 to 126, it will also be displayed as an ASCII character.

For example, the quoted character `"x"' produces the vector result `[120]' (because 120 is the ASCII code of the lower-case `x'; see section Strings). Since this is a vector, not an integer, it is displayed only according to the current mode settings. But running Quick Calc again and entering `120' will produce the result `120 (16#78, 8#170, x)' which shows the number in its decimal, hexadecimal, octal, and ASCII forms.

Please note that the Quick Calculator is not any faster at loading or computing the answer than the full Calculator; the name "quick" merely refers to the fact that it's much less hassle to use for small calculations.

Numeric Prefix Arguments

Many Calculator commands use numeric prefix arguments. Some, such as d s (`calc-sci-notation`), set a parameter to the value of the prefix argument or use a default if you don't use a prefix. Others (like d f (`calc-fix-notation`)) require an argument and prompt for a number if you don't give one as a prefix.

As a rule, stack-manipulation commands accept a numeric prefix argument which is interpreted as an index into the stack. A positive argument operates on the top n stack entries; a negative argument operates on the nth stack entry in isolation; and a zero argument operates on the entire stack.

Most commands that perform computations (such as the arithmetic and scientific functions) accept a numeric prefix argument that allows the operation to be applied across many stack elements. For unary operations (that is, functions of one argument like absolute value or complex conjugate), a positive prefix argument applies that function to the top n stack entries simultaneously, and a negative argument applies it to the nth stack entry only. For binary operations (functions of two arguments like addition, GCD, and vector concatenation), a positive prefix argument "reduces" the function across the top n stack elements (for example, C-u 5 + sums the top 5 stack entries; see section Reducing and Mapping Vectors), and a negative argument maps the next-to-top n stack elements with the top stack element as a second argument (for example, 7 c-u -5 + adds 7 to the top 5 stack elements). This feature is not available for operations which use the numeric prefix argument for some other purpose.

Numeric prefixes are specified the same way as always in Emacs: Press a sequence of META-digits, or press ESC followed by digits, or press C-u followed by digits. Some commands treat plain C-u (without any actual digits) specially.

You can type ~ (`calc-num-prefix`) to pop an integer from the top of the stack and enter it as the numeric prefix for the next command. For example, C-u 16 p sets the precision to 16 digits; an alternate (silly) way to do this would be 2 RET 4 ^ ~ p, i.e., compute 2 to the fourth power and set the precision to that value.

Conversely, if you have typed a numeric prefix argument the ~ key pushes it onto the stack in the form of an integer.

Undoing Mistakes

The shift-U key (`calc-undo`) undoes the most recent operation. If that operation added or dropped objects from the stack, those objects are removed or restored. If it was a "store" operation, you are queried whether or not to restore the variable to its original value. The U key may be pressed any number of times to undo successively farther back in time; with a numeric prefix argument it undoes a specified number of operations. The undo history is cleared only by the q (`calc-quit`) command. (Recall that M-# c is synonymous with `calc-quit` while inside the Calculator; this also clears the undo history.)

Currently the mode-setting commands (like `calc-precision`) are not undoable. You can undo past a point where you changed a mode, but you will need to reset the mode yourself.

The shift-D key (`calc-redo`) redoes an operation that was mistakenly undone. Pressing U with a negative prefix argument is equivalent to executing `calc-redo`. You can redo any number of times, up to the number of recent consecutive undo commands. Redo information is cleared whenever you give any command that adds new undo information, i.e., if you undo, then enter a number on the stack or make any other change, then it will be too late to redo.

The M-RET key (`calc-last-args`) is like undo in that it restores the arguments of the most recent command onto the stack; however, it does not remove the result of that command. Given a numeric

prefix argument, this command applies to the nth most recent command which removed items from t stack; it pushes those items back onto the stack.

The K (`calc-keep-args`) command provides a related function to M-RET. See section Stack and Trail Commands.

It is also possible to recall previous results or inputs using the trail. See section Trail Commands.

The standard Emacs C-_ undo key is recognized as a synonym for U.

Error Messages

Many situations that would produce an error message in other calculators simply create unsimplified formulas in the Emacs Calculator. For example, 1 RET 0 / pushes the formula 1 / 0; 0 L pushes the formula `ln(0)'. Floating-point overflow and underflow are also reasons for this to happen.

When a function call must be left in symbolic form, Calc usually produces a message explaining why. Messages that are probably surprising or indicative of user errors are displayed automatically. Other messages are simply kept in Calc's memory and are displayed only if you type w (`calc-why`). You can also press w if the same computation results in several messages. (The first message will end with `[w=more]' in this case.)

The d w (`calc-auto-why`) command controls when error messages are displayed automatically. (Calc effectively presses w for you after your computation finishes.) By default, this occurs only for "important" messages. The other possible modes are to report *all* messages automatically, or to report none automatically (so that you must always press w yourself to see the messages).

Multiple Calculators

It is possible to have any number of Calc Mode buffers at once. Usually this is done by executing M-x another-calc, which is similar to M-# c except that if a `*Calculator*' buffer already exists, a new, independent one with a name of the form `*Calculator*<n>' is created. You can also use the command `calc-mode` to put any buffer into Calculator mode, but this would ordinarily never be done.

The q (`calc-quit`) command does not destroy a Calculator buffer; it only closes its window. Use M-x kill-buffer to destroy a Calculator buffer.

Each Calculator buffer keeps its own stack, undo list, and mode settings such as precision, angular mode, and display formats. In Emacs terms, variables such as `calc-stack` are buffer-local variables. The global default values of these variables are used only when a new Calculator buffer is created. The `calc-quit` command saves the stack and mode settings of the buffer being quit as the new defaults.

There is only one trail buffer, `*Calc Trail*', used by all Calculator buffers.

Troubleshooting Commands

This section describes commands you can use in case a computation incorrectly fails or gives the wrong answer.

See section Reporting Bugs, if you find a problem that appears to be due to a bug or deficiency in Calc.

Autoloading Problems

The Calc program is split into many component files; components are loaded automatically as you use various commands that require them. Occasionally Calc may lose track of when a certain component is necessary; typically this means you will type a command and it won't work because some function you've never heard of was undefined.

If this happens, the easiest workaround is to type M-# L (`calc-load-everything`) to force all the parts of Calc to be loaded right away. This will cause Emacs to take up a lot more memory than it would otherwise, but it's guaranteed to fix the problem.

If you seem to run into this problem no matter what you do, or if even the M-# L command crashes, Calc may have been improperly installed. See section Installation, for details of the installation process.

Recursion Depth

Calc uses recursion in many of its calculations. Emacs Lisp keeps a variable `max-lisp-eval-depth` which limits the amount of recursion possible in an attempt to recover from program bugs. If a calculation ever halts incorrectly with the message "Computation got stuck or ran too long," use the M command (`calc-more-recursion-depth`) to increase this limit. (Of course, this will not help if the calculation really did get stuck due to some problem inside Calc.)

The limit is always increased (multiplied) by a factor of two. There is also an I M (`calc-less-recursion-depth`) command which decreases this limit by a factor of two, down to a minimum value of 200. The default value is 1000.

These commands also double or halve `max-specpdl-size`, another internal Lisp recursion limit. The minimum value for this limit is 600.

Caches

Calc saves certain values after they have been computed once. For example, the P (`calc-pi`) command initially "knows" the constant @c{π} pi to about 20 decimal places; if the current precision is greater than this, it will recompute @c{π} pi using a series approximation. This value will not need to be recomputed ever again unless you raise the precision still further. Many operations such as logarithms and sines make use of similarly cached values such as pi/4 and @c{$\ln 2$} ln(2). The visible effect of caching is that high-precision computations may seem to do extra work the first time. Other things cached include powers of two (for the binary arithmetic functions), matrix inverses and determinants, symbolic integrals, and data points computed by the graphing commands.

If you suspect a Calculator cache has become corrupt, you can use the `calc-flush-caches` command to reset all caches to the empty state. (This should only be necessary in the event of bugs in the Calculator.) The M-# 0 (with the zero key) command also resets caches along with all other aspects of the Calculator's state.

Debugging Calc

A few commands exist to help in the debugging of Calc commands. See section Programming, to see the various ways that you can write your own Calc commands.

The Z T (`calc-timing`) command turns on and off a mode in which the timing of slow commands is reported in the Trail. Any Calc command that takes two seconds or longer writes a line to the Trail showing how many seconds it took. This value is accurate only to within one second.

All steps of executing a command are included; in particular, time taken to format the result for display in the stack and trail is counted. Some prompts also count time taken waiting for them to be answered, while others do not; this depends on the exact implementation of the command. For best results, if you are timing a sequence that includes prompts or multiple commands, define a keyboard macro to run the whole sequence at once. Calc's X command (see section Programming with Keyboard Macros) will then report the time taken to execute the whole macro.

Another advantage of the X command is that while it is executing, the stack and trail are not updated from step to step. So if you expect the output of your test sequence to leave a result that may take a long time to format and you don't wish to count this formatting time, end your sequence with a DEL keystroke to clear the result from the stack. When you run the sequence with X, Calc will never bother to format the large result.

Another thing Z T does is to increase the Emacs variable `gc-cons-threshold` to a much higher value (two million; the usual default in Calc is 250,000) for the duration of each command. This generally prevents garbage collection during the timing of the command, though it may cause your Emacs process to grow abnormally large. (Garbage collection time is a major unpredictable factor in the timing of Emacs operations.)

Another command that is useful when debugging your own Lisp extensions to Calc is M-x calc-pass-errors, which disables the error handler that changes the "`max-lisp-eval-depth` exceeded" message to the much more friendly "Computation got stuck or ran too long." This handler interferes with the Emacs Lisp debugger's `debug-on-error` mode. Errors are reported in the handler itself rather than at the true location of the error. After you have executed `calc-pass-errors`, Lisp errors will be reported correctly but the user-friendly message will be lost.

Go to the previous, next section.

Go to the previous, next section.

Data Types

This chapter discusses the various types of objects that can be placed on the Calculator stack, how they are displayed, and how they are entered. (See section Data Type Formats, for information on how these data types are represented as underlying Lisp objects.)

Integers, fractions, and floats are various ways of describing real numbers. HMS forms also for many purposes act as real numbers. These types can be combined to form complex numbers, modulo forms, error forms, or interval forms. (But these last four types cannot be combined arbitrarily: error forms may not contain modulo forms, for example.) Finally, all these types of numbers may be combined into vectors, matrices, or algebraic formulas.

Integers

The Calculator stores integers to arbitrary precision. Addition, subtraction, and multiplication of integers always yields an exact integer result. (If the result of a division or exponentiation of integers is not an integer, it is expressed in fractional or floating-point form according to the current Fraction Mode. See section Fraction Mode.)

A decimal integer is represented as an optional sign followed by a sequence of digits. Grouping (see section Grouping Digits) can be used to insert a comma at every third digit for display purposes, but you must not type commas during the entry of numbers.

A non-decimal integer is represented as an optional sign, a radix between 2 and 36, a `#' symbol, and one or more digits. For radix 11 and above, the letters A through Z (upper- or lower-case) count as digits and do not terminate numeric entry mode. See section Radix Modes, for how to set the default radix for display of integers. Numbers of any radix may be entered at any time. If you press # at the beginning of a number, the current display radix is used.

Fractions

A fraction is a ratio of two integers. Fractions are traditionally written "2/3" but Calc uses the notation `2:3'. (The / key performs RPN division; the following two sequences push the number `2:3' on the stack: 2 : 3 RET, or 2 RET 3 / assuming Fraction Mode has been enabled.) When the Calculator produces a fractional result it always reduces it to simplest form, which may in fact be an integer.

Fractions may also be entered in a three-part form, where `2:3:4' represents two-and-three-quarters. See section Fraction Formats, for fraction display formats.

Non-decimal fractions are entered and displayed as `radix#num:denom' (or in the analogous three-part form). The numerator and denominator always use the same radix.

Floats

A floating-point number or float is a number stored in scientific notation. The number of significant digits in the fractional part is governed by the current floating precision (see section Precision). The range of acceptable values is from @c{$10^{-3999999}$} 10^-3999999 (inclusive) to @c{$10^{4000000}$} 10^4000000 (exclusive), plus the corresponding negative values and zero.

Calculations that would exceed the allowable range of values (such as `exp(exp(20))') are left in symbolic form by Calc. The messages "floating-point overflow" or "floating-point underflow" indicate that during the calculation a number would have been produced that was too large or too close to zero, respectively, to be represented by Calc. This does not necessarily mean the final result would have overflowed, just that an overflow occurred while computing the result. (In fact, it could report an underflow even though the final result would have overflowed!)

If a rational number and a float are mixed in a calculation, the result will in general be expressed as a float. Commands that require an integer value (such as k g [gcd]) will also accept integer-valued floats, i.e., floating-point numbers with nothing after the decimal point.

Floats are identified by the presence of a decimal point and/or an exponent. In general a float consists of an optional sign, digits including an optional decimal point, and an optional exponent consisting of an `e', an optional sign, and up to seven exponent digits. For example, `23.5e-2' is 23.5 times ten to the minus-second power, or 0.235.

Floating-point numbers are normally displayed in decimal notation with all significant figures shown. Exceedingly large or small numbers are displayed in scientific notation. Various other display options are available. See section Float Formats.

Floating-point numbers are stored in decimal, not binary. The result of each operation is rounded to the nearest value representable in the number of significant digits specified by the current precision, rounding away from zero in the case of a tie. Thus (in the default display mode) what you see is exactly what you get. Some operations such as square roots and transcendental functions are performed with several digits of extra precision and then rounded down, in an effort to make the final result accurate to the full requested precision. However, accuracy is not rigorously guaranteed. If you suspect the validity of a result, try doing the same calculation in a higher precision. The Calculator's arithmetic is not intended to be IEEE-conformant in any way.

While floats are always *stored* in decimal, they can be entered and displayed in any radix just like integers and fractions. The notation `radix#ddd.ddd' is a floating-point number whose digits are in the specified radix. Note that the `.' is more aptly referred to as a "radix point" than as a decimal point in this case. The number `8#123.4567' is defined as `8#1234567 * 8^-4'. If the radix is 14 or less, you can use `e' notation to write a non-decimal number in scientific notation. The exponent is written in decimal, and is considered to be a power of the radix: `8#1234567e-4'. If the radix is 15 or above, the letter `e' is a digit, so scientific notation must be written out, e.g., `16#123.4567*16^2'. The first two exercises of the Modes Tutorial explore some of the properties of non-decimal floats.

Complex Numbers

There are two supported formats for complex numbers: rectangular and polar. The default format is rectangular, displayed in the form `(real,imag)' where real is the real part and imag is the imaginary part, each of which may be any real number. Rectangular complex numbers can also be displayed in `a+bi' notation; see section Complex Formats.

Polar complex numbers are displayed in the form `(r;@c{θ} theta)' where r is the nonnegative magnitude and @c{θ} theta is the argument or phase angle. The range of @c{θ} theta depends on the current angular mode (see section Angular Modes); it is generally between *-180* and *+180* degrees or the equivalent range in radians.

Complex numbers are entered in stages using incomplete objects. See section Incomplete Objects.

Operations on rectangular complex numbers yield rectangular complex results, and similarly for polar complex numbers. Where the two types are mixed, or where new complex numbers arise (as for the square root of a negative real), the current Polar Mode is used to determine the type. See section Polar Mode.

A complex result in which the imaginary part is zero (or the phase angle is 0 or 180 degrees or @c{π} pi radians) is automatically converted to a real number.

Infinities

The word `inf` represents the mathematical concept of infinity. Calc actually has three slightly different infinity-like values: `inf`, `uinf`, and `nan`. These are just regular variable names (see section Variables); you should avoid using these names for your own variables because Calc gives them special treatment. Infinities, like all variable names, are normally entered using algebraic entry.

Mathematically speaking, it is not rigorously correct to treat "infinity" as if it were a number, but mathematicians often do so informally. When they say that `1 / inf = 0', what they really mean is that 1 / x, as x becomes larger and larger, becomes arbitrarily close to zero. So you can imagine that if x got "all the way to infinity," then 1 / x would go all the way to zero. Similarly, when they say that `exp(inf) = inf', they mean that @c{e^x} exp(x) grows without bound as x grows. The symbol `-inf' likewise stands for an infinitely negative real value; for example, we say that `exp(-inf) = 0'. You can have an infinity pointing in any direction on the complex plane: `sqrt(-inf) = i inf'.

The same concept of limits can be used to define 1 / 0. We really want the value that 1 / x approaches as x approaches zero. But if all we have is 1 / 0, we can't tell which direction x was coming from. If x was positive and decreasing toward zero, then we should say that `1 / 0 = inf'. But if x was negative and increasing toward zero, the answer is `1 / 0 = -inf'. In fact, x could be an imaginary number, giving the answer `i inf' or `-i inf'. Calc uses the special symbol `uinf' to mean undirected infinity, i.e., a value which is infinitely large but with an unknown sign (or direction on the complex plane).

Calc actually has three modes that say how infinities are handled. Normally, infinities never arise from calculations that didn't already have them. Thus, 1 / 0 is treated simply as an error and left unevaluated.

The m i (`calc-infinite-mode`) command (see section Infinite Mode) enables a mode in which evaluates to `uinf` instead. There is also an alternative type of infinite mode which says to treat zeros as if they were positive, so that `1 / 0 = inf'. While this is less mathematically correct, it may be the answer you want in some cases.

Since all infinities are "as large" as all others, Calc simplifies, e.g., `5 inf' to `inf'. Another example is `5 - inf = -inf', where the `-inf' is so large that adding a finite number like five to it does not affect it. Note that `a - inf' also results in `-inf'; Calc assumes that variables like `a` always stand for finite quantities. Just to show that infinities really are all the same size, note that `sqrt(inf) = inf^2 = exp(inf) = inf' in Calc's notation.

It's not so easy to define certain formulas like `0 * inf' and `inf / inf'. Depending on where these zeros and infinities came from, the answer could be literally anything. The latter formula could be the limit of x / x (giving a result of one), or 2 x / x (giving two), or x^2 / x (giving `inf`), or x / x^2 (giving zero). Calc uses the symbol `nan` to represent such an indeterminate value. (The name "nan" comes from analogy with the "NAN" concept of IEEE standard arithmetic; it stands for "Not A Number." This is somewhat of a misnomer, since `nan` *does* stand for some number or infinity, it's just that *which* number it stands for cannot be determined.) In Calc's notation, `0 * inf = nan' and `inf / inf = nan'. A few other common indeterminate expressions are `inf - inf' and `inf ^ 0'. Also, `0 / 0 = nan' if you have turned on "infinite mode" (as described above).

Infinities are especially useful as parts of intervals. See section Interval Forms.

Vectors and Matrices

The vector data type is flexible and general. A vector is simply a list of zero or more data objects. When these objects are numbers, the whole is a vector in the mathematical sense. When these objects are themselves vectors of equal (nonzero) length, the whole is a matrix. A vector which is not a matrix is referred to here as a plain vector.

A vector is displayed as a list of values separated by commas and enclosed in square brackets: `[1, 2, 3]'. Thus the following is a 2 row by 3 column matrix: `[[1, 2, 3], [4, 5, 6]]'. Vectors, like complex numbers, are entered as incomplete objects. See section Incomplete Objects. During algebraic entry, vectors are entered all at once in the usual brackets-and-commas form. Matrices may be entered algebraically as nested vectors, or using the shortcut notation `[1, 2, 3; 4, 5, 6]', with rows separated by semicolons. The commas may usually be omitted when entering vectors: `[1 2 3]'. Curly braces may be used in place of brackets: `{1, 2, 3}', but the commas are required in this case.

Traditional vector and matrix arithmetic is also supported; see section Basic Arithmetic and see section Vector/Matrix Functions. Many other operations are applied to vectors element-wise. For example, the complex conjugate of a vector is a vector of the complex conjugates of its elements.

Algebraic functions for building vectors include `vec(a, b, c)' to build `[a, b, c]', `cvec(a, n, m)' to build an @c{$n\times m$} nxm matrix of `a's, and `index(n)' to build a vector of integers from 1 to `n'.

Strings

Character strings are not a special data type in the Calculator. Rather, a string is represented simply as a vector all of whose elements are integers in the range 0 to 255 (ASCII codes). You can enter a string at any time by pressing the " key. Quotation marks and backslashes are written `\"' and `\\', respectively, inside strings. Other notations introduced by backslashes are:

`\a`	7	`\^@`	0
`\b`	8	`\^a-z`	1-26
`\e`	27	`\^[`	27
`\f`	12	`\^\\`	28
`\n`	10	`\^]`	29
`\r`	13	`\^^`	30
`\t`	9	`\^_`	31
		`\^?`	127

Finally, a backslash followed by three octal digits produces any character from its ASCII code.

Strings are normally displayed in vector-of-integers form. The d " (`calc-display-strings`) command toggles a mode in which any vectors of small integers are displayed as quoted strings instead.

The backslash notations shown above are also used for displaying strings. Characters 128 and above are not translated by Calc; unless you have an Emacs modified for 8-bit fonts, these will show up in backslash-octal-digits notation. For characters below 32, and for character 127, Calc uses the backslash-letter combination if there is one, or otherwise uses a `\^' sequence.

The only Calc feature that uses strings is compositions; see section Compositions. Strings also provide a convenient way to do conversions between ASCII characters and integers.

There is a `string` function which provides a different display format for strings. Basically, `string(s)', where s is a vector of integers in the proper range, is displayed as the corresponding string of characters with no surrounding quotation marks or other modifications. Thus `string("ABC")' (or `string([65 66 67])') will look like `ABC' on the stack. This happens regardless of whether d " has been used. The only way to turn it off is to use d U (unformatted language mode) which will display `string("ABC")' instead.

Control characters are displayed somewhat differently by `string`. Characters below 32, and character 127, are shown using `^' notation (same as shown above, but without the backslash). The quote and backslash characters are left alone, as are characters 128 and above.

The `bstring` function is just like `string` except that the resulting string is breakable across multiple lines if it doesn't fit all on one line. Potential break points occur at every space character in the string.

HMS Forms

HMS stands for Hours-Minutes-Seconds; when used as an angular argument, the interpretation is Degrees-Minutes-Seconds. All functions that operate on angles accept HMS forms. These are interpreted as degrees regardless of the current angular mode. It is also possible to use HMS as the angular mode so that calculated angles are expressed in degrees, minutes, and seconds.

The default format for HMS values is `hours@ mins' secs"'. During entry, the letters `h' (for "hours") or `o' (approximating the "degrees" symbol) are accepted as well as `@', `m' is accepted in place of `', and `s' is accepted in place of `"'. The hours value is an integer (or integer-valued float). The mins value is an integer or integer-valued float between 0 and 59. The secs value is a real number between 0 (inclusive) and 60 (exclusive). A positive HMS form is interpreted as hours + mins/60 + secs/3600. A negative HMS form is interpreted as - *hours* - mins/60 - secs/3600. Display format for HMS forms is quite flexible. See section HMS Formats.

HMS forms can be added and subtracted. When they are added to numbers, the numbers are interpreted according to the current angular mode. HMS forms can also be multiplied and divided by real numbers. Dividing two HMS forms produces a real-valued ratio of the two angles.

Just for kicks, M-x calc-time pushes the current time of day on the stack as an HMS form.

Date Forms

A date form represents a date and possibly an associated time. Simple date arithmetic is supported: Adding a number to a date produces a new date shifted by that many days; adding an HMS form to a date shifts it by that many hours. Subtracting two date forms computes the number of days between them (represented as a simple number). Many other operations, such as multiplying two date forms, are nonsensical and are not allowed by Calc.

Date forms are entered and displayed enclosed in `< >' brackets. The default format is, e.g., `<Wed Jan 9, 1991>' for dates, or `<3:32:20pm Wed Jan 9, 1991>' for dates with times. Input is flexible; date forms can be entered in any of the usual notations for dates and times. See section Date Formats.

Date forms are stored internally as numbers, specifically the number of days since midnight on the morning of January 1 of the year 1 AD. If the internal number is an integer, the form represents a date only; if the internal number is a fraction or float, the form represents a date and time. For example, `<6:00am Wed Jan 9, 1991>' is represented by the number 726842.25. The standard precision of 12 decimal digits is enough to ensure that a (reasonable) date and time can be stored without roundoff error.

If the current precision is greater than 12, date forms will keep additional digits in the seconds position. For example, if the precision is 15, the seconds will keep three digits after the decimal point. Decreasing the precision below 12 may cause the time part of a date form to become inaccurate. This can also happen if astronomically high years are used, though this will not be an issue in everyday (or even everymillenium) use. Note that date forms without times are stored as exact integers, so roundoff is never an issue for them.

You can use the v p (`calc-pack`) and v u (`calc-unpack`) commands to get at the numerical representation of a date form. See section Packing and Unpacking.

Date forms can go arbitrarily far into the future or past. Negative year numbers represent years BC. Calc uses a combination of the Gregorian and Julian calendars, following the history of Great Britain and the British colonies. This is the same calendar that is used by the `cal` program in most Unix implementations.

Some historical background: The Julian calendar was created by Julius Caesar in the year 46 BC as an attempt to fix the gradual drift caused by the lack of leap years in the calendar used until that time. The Julian calendar introduced an extra day in all years divisible by four. After some initial confusion, the calendar was adopted around the year we call 8 AD. Some centuries later it became apparent that the Julian year of 365.25 days was itself not quite right. In 1582 Pope Gregory XIII introduced the Gregorian calendar, which added the new rule that years divisible by 100, but not by 400, were not to be considered leap years despite being divisible by four. Many countries delayed adoption of the Gregorian calendar because of religious differences; in Britain it was put off until the year 1752, by which time the Julian calendar had fallen eleven days behind the true seasons. So the switch to the Gregorian calendar in early September 1752 introduced a discontinuity: The day after Sep 2, 1752 is Sep 14, 1752. Calc follows this convention. To take another example, Russia waited until 1918 before adopting the new calendar, and thus needed to remove thirteen days (between Feb 1, 1918 and Feb 14, 1918). This means that Calc's reckoning will be inconsistent with Russian history between 1752 and 1918, and similarly for various other countries.

Today's timekeepers introduce an occasional "leap second" as well, but Calc does not take these minor effects into account. (If it did, it would have to report a non-integer number of days between, say, `<12:00am Mon Jan 1, 1900>' and `<12:00am Sat Jan 1, 2000>'.)

Calc uses the Julian calendar for all dates before the year 1752, including dates BC when the Julian calendar technically had not yet been invented. Thus the claim that day number *-10000* is called "August 16, 28 BC" should be taken with a grain of salt.

Please note that there is no "year 0"; the day before `<Sat Jan 1, +1>' is `<Fri Dec 31, -1>'. These are days 0 and *-1* respectively in Calc's internal numbering scheme.

Another day counting system in common use is, confusingly, also called "Julian." It was invented in 1583 by Joseph Justus Scaliger, who named it in honor of his father Julius Caesar Scaliger. For obscure reasons he chose to start his day numbering on Jan 1, 4713 BC at noon, which in Calc's scheme is *-1721423.5* (recall that Calc starts at midnight instead of noon). Thus to convert a Calc date code obtained by unpacking a date form into a Julian day number, simply add 1721423.5. The Julian code for `6:00am Jan 9, 1991' is 2448265.75. The built-in t J command performs this conversion for you.

The Unix operating system measures time as an integer number of seconds since midnight, Jan 1, 1970. To convert a Calc date value into a Unix time stamp, first subtract 719164 (the code for `<Jan 1, 1970>'), then multiply by 86400 (the number of seconds in a day) and press R to round to the nearest integer. If you have a date form, you can simply subtract the day `<Jan 1, 1970>' instead of unpacking and subtracting 719164. Likewise, divide by 86400 and add `<Jan 1, 1970>' to convert from Unix time to a Calc date form. (Note that Unix normally maintains the time in the GMT time zone; you may need to subtract five hours to get New York time, or eight hours for California time. The same is usually true of

Julian day counts.) The built-in t U command performs these conversions.

Modulo Forms

A modulo form is a real number which is taken modulo (i.e., within an integer multiple of) some value M. Arithmetic modulo M often arises in number theory. Modulo forms are written `*a* `mod` *M*', where a and M are real numbers or HMS forms, and 0 <= a < M. In many applications a and M will be integers but this is not required.

Modulo forms are not to be confused with the modulo operator `%'. The expression `27 % 10' means to compute 27 modulo 10 to produce the result 7. Further computations treat this 7 as just a regular integer. The expression `27 mod 10' produces the result `7 mod 10'; further computations with this value are again reduced modulo 10 so that the result always lies in the desired range.

When two modulo forms with identical M's are added or multiplied, the Calculator simply adds or multiplies the values, then reduces modulo M. If one argument is a modulo form and the other a plain number, the plain number is treated like a compatible modulo form. It is also possible to raise modulo forms to powers; the result is the value raised to the power, then reduced modulo M. (When all values involved are integers, this calculation is done much more efficiently than actually computing the power and then reducing.)

Two modulo forms `*a* `mod` *M*' and `*b* `mod` *M*' can be divided if a, b, and M are all integers. The result is the modulo form which, when multiplied by `*b* `mod` *M*', produces `*a* `mod` *M*'. If there is no solution to this equation (which can happen only when M is non-prime), or if any of the arguments are non-integers, the division is left in symbolic form. Other operations, such as square roots, are not yet supported for modulo forms. (Note that, although `(*a* `mod` *M*)^.5' will compute a "modulo square root" in the sense of reducing @c{$\sqrt a$} sqrt(a) modulo M, this is not a useful definition from the number-theoretical point of view.)

To create a modulo form during numeric entry, press the shift-M key to enter the word `mod'. As a special convenience, pressing shift-M a second time automatically enters the value of M that was most recently used before. During algebraic entry, either type `mod' by hand or press M-m (that's META-m). Once again, pressing this a second time enters the current modulo.

You can also use v p and % to modify modulo forms. See section Building Vectors. See section Basic Arithmetic.

It is possible to mix HMS forms and modulo forms. For example, an HMS form modulo 24 could be used to manipulate clock times; an HMS form modulo 360 would be suitable for angles. Making the modulo M also be an HMS form eliminates troubles that would arise if the angular mode were inadvertently set to Radians, in which case `2@ 0' 0" mod 24' would be interpreted as two degrees modulo 24 radians!

Modulo forms cannot have variables or formulas for components. If you enter the formula `(x + 2) mod 5', Calc propagates the modulus to each of the coefficients: `(1 mod 5) x + (2 mod 5)'.

The algebraic function `makemod(a, m)' builds the modulo form `a mod m'.

Error Forms

An error form is a number with an associated standard deviation, as in `2.3 +/- 0.12'. The notation `*x* +/- @c{σ} sigma' stands for an uncertain value which follows a normal or Gaussian distribution of mean x and standard deviation or "error" @c{σ} sigma. Both the mean and the error can be either numbers or formulas. Generally these are real numbers but the mean may also be complex. If the error is negative or complex, it is changed to its absolute value. An error form with zero error is converted to a regular number by the Calculator.

All arithmetic and transcendental functions accept error forms as input. Operations on the mean-value part work just like operations on regular numbers. The error part for any function f(x) (such as @c{$\sin x$} sin(x)) is defined by the error of x times the derivative of f evaluated at the mean value of x. For a two-argument function f(x,y) (such as addition) the error is the square root of the sum of the squares of the errors due to x and y. Note that this definition assumes the errors in x and y are uncorrelated. A side effect of this definition is that `(2 +/- 1) * (2 +/- 1)' is not the same as `(2 +/- 1)^2'; the former represents the product of two independent values which happen to have the same probability distributions, and the latter is the product of one random value with itself. The former will produce an answer with less error, since on the average the two independent errors can be expected to cancel out.

Consult a good text on error analysis for a discussion of the proper use of standard deviations. Actual errors often are neither Gaussian-distributed nor uncorrelated, and the above formulas are valid only when errors are small. As an example, the error arising from `sin(*x* +/- @c{$\sigma$} *sigma*)' is `@c{σ\nobreak} *sigma* abs(cos(*x*))'. When x is close to zero, cos(x) is close to one so the error in the sine is close to @c{σ} sigma; this makes sense, since @c{$\sin x$} sin(x) is approximately x near zero, so a given error in x will produce about the same error in the sine. Likewise, near 90 degrees @c{$\cos x$} cos(x) is nearly zero and so the computed error is small: The sine curve is nearly flat in that region, so an error in x has relatively little effect on the value of @c{$\sin x$} sin(x). However, consider `sin(90 +/- 1000)'. The cosine of 90 is zero, so Calc will report zero error! We get an obviously wrong result because we have violated the small-error approximation underlying the error analysis. If the error in x had been small, the error in @c{$\sin x$} sin(x) would indeed have been negligible.

To enter an error form during regular numeric entry, use the p ("plus-or-minus") key to type the `+/-' symbol. (If you try actually typing `+/-' the + key will be interpreted as the Calculator's + command!) Within an algebraic formula, you can press M-p to type the `+/-' symbol, or type it out by hand.

Error forms and complex numbers can be mixed; the formulas shown above are used for complex numbers, too; note that if the error part evaluates to a complex number its absolute value (or the square root of the sum of the squares of the absolute values of the two error contributions) is used. Mathematically, this corresponds to a radially symmetric Gaussian distribution of numbers on the complex plane. However, note that Calc considers an error form with real components to represent a real number, not a complex distribution around a real mean.

Error forms may also be composed of HMS forms. For best results, both the mean and the error should be HMS forms if either one is.

The algebraic function `sdev(a, b)' builds the error form `a +/- b'.

Interval Forms

An interval is a subset of consecutive real numbers. For example, the interval `[2 .. 4]' represents all the numbers from 2 to 4, inclusive. If you multiply it by the interval `[0.5 .. 2]' you obtain `[1 .. 8]'. This calculation represents the fact that if you multiply some number in the range `[2 .. 4]' by some other number in the range `[0.5 .. 2]', your result will lie in the range from 1 to 8. Interval arithmetic is used to get a worst-case estimate of the possible range of values a computation will produce, given the set of possible values of the input.

The lower and upper limits of an interval must be either real numbers (or HMS or date forms), or symbolic expressions which are assumed to be real-valued, or `-inf' and `inf'. In general the lower limit must be less than the upper limit. A closed interval containing only one value, `[3 .. 3]', is converted to a plain number (3) automatically. An interval containing no values at all (such as `[3 .. 2]' or `[2 .. 2)') can be represented but is not guaranteed to behave well when used in arithmetic. Note that the interval `[3 .. inf)' represents all real numbers greater than or equal to 3, and `(-inf .. inf)' represents all real numbers. In fact, `[-inf .. inf]' represents all real numbers including the real infinities.

Intervals are entered in the notation shown here, either as algebraic formulas, or using incomplete forms. (See section Incomplete Objects.) In algebraic formulas, multiple periods in a row are collected from left to right, so that `1...1e2' is interpreted as `1.0 .. 1e2' rather than `1 .. 0.1e2'. Add spaces or zeros if you want to get the other interpretation. If you omit the lower or upper limit, a default of `-inf' or `inf' (respectively) is furnished.

"Infinite mode" also affects operations on intervals (see section Infinities). Calc will always introduce an open infinity, as in `1 / (0 .. 2] = [0.5 .. inf)'. But closed infinities, `1 / [0 .. 2] = [0.5 .. inf]', arise only in infinite mode; otherwise they are left unevaluated. Note that the "direction" of a zero is not an issue in this case since the zero is always assumed to be continuous with the rest of the interval. For intervals that contain zero inside them Calc is forced to give the result, `1 / (-2 .. 2) = [-inf .. inf]'.

While it may seem that intervals and error forms are similar, they are based on entirely different concepts of inexact quantities. An error form `*x* +/- @c{$\sigma$} *sigma*' means a variable is random, and its value could be anything but is "probably" within one @c{$\sigma$} *sigma* of the mean value x. An interval `[*a* .. *b*]' means a variable's value is unknown, but guaranteed to lie in the specified range. Error forms are statistical or "average case" approximations; interval arithmetic tends to produce "worst case" bounds on an answer.

Intervals may not contain complex numbers, but they may contain HMS forms or date forms.

See section Set Operations using Vectors, for commands that interpret interval forms as subsets of the set of real numbers.

The algebraic function `intv(n, a, b)' builds an interval form from `a' to `b'; `n' is an integer code which must be 0 for `(..)', 1 for `(..]', 2 for `[..)', or 3 for `[..]'.

Please note that in fully rigorous interval arithmetic, care would be taken to make sure that the computation of the lower bound rounds toward minus infinity, while upper bound computations round toward plus infinity. Calc's arithmetic always uses a round-to-nearest mode, which means that roundoff

errors could creep into an interval calculation to produce intervals slightly smaller than they ought to. For example, entering `[1..2]' and pressing Q 2 ^ should yield the interval `[1..2]' again, but in fact it yields the (slightly too small) interval `[1..1.9999999]' due to roundoff error.

Incomplete Objects

When (or [is typed to begin entering a complex number or vector, respectively, the effect is to push an incomplete complex number or vector onto the stack. The , key adds the value(s) at the top of the stack onto the current incomplete object. The) and] keys "close" the incomplete object after adding any values on the top of the stack in front of the incomplete object.

As a result, the sequence of keystrokes [2 , 3 RET 2 * , 9] pushes the vector `[2, 6, 9]' onto the stack. Likewise, ( 1 , 2 Q ) pushes the complex number `(1, 1.414)' (approximately).

If several values lie on the stack in front of the incomplete object, all are collected and appended to the object. Thus the , key is redundant: [2 RET 3 RET 2 * 9]. Some people prefer the equivalent SPC key to RET.

As a special case, typing , immediately after (, [, or , adds a zero or duplicates the preceding value in the list being formed. Typing DEL during incomplete entry removes the last item from the list.

The ; key is used in the same way as , to create polar complex numbers: (1 ; 2). When entering a vector, ; is useful for creating a matrix. In particular, [[1 , 2 ; 3 , 4 ; 5 , 6]] is equivalent to [[1 , 2] , [3 , 4] , [5 , 6]].

Incomplete entry is also used to enter intervals. For example, [2 .. 4) enters a semi-open interval. Note that when you type the first period, it will be interpreted as a decimal point, but when you type a second period immediately afterward, it is re-interpreted as part of the interval symbol. Typing .. corresponds to executing the `calc-dots` command.

If you find incomplete entry distracting, you may wish to enter vectors and complex numbers as algebraic formulas by pressing the apostrophe key.

Variables

A variable is somewhere between a storage register on a conventional calculator, and a variable in a programming language. (In fact, a Calc variable is really just an Emacs Lisp variable that contains a Calc number or formula.) A variable's name is normally composed of letters and digits. Calc also allows apostrophes and # signs in variable names. The Calc variable `foo` corresponds to the Emacs Lisp variable `var-foo`. Commands like s s (`calc-store`) that operate on variables can be made to use any arbitrary Lisp variable simply by backspacing over the `var-' prefix in the minibuffer.

In a command that takes a variable name, you can either type the full name of a variable, or type a single digit to use one of the special convenience variables `var-q0` through `var-q9`. For example, 3 s s 2 stores the number 3 in variable `var-q2`, and 3 s s foo RET stores that number in variable `var-foo`.

To push a variable itself (as opposed to the variable's value) on the stack, enter its name as an algebraic

expression using the apostrophe (') key. Variable names in algebraic formulas implicitly have `var-' prefixed to their names. The `#' character in variable names used in algebraic formulas corresponds to dash `-' in the Lisp variable name. If the name contains any dashes, the prefix `var-' is *not* automatically added. Thus the two formulas `foo + 1' and `var#foo + 1' both refer to the same variable.

The = (`calc-evaluate`) key "evaluates" a formula by replacing all variables in the formula which have been given values by a `calc-store` or `calc-let` command by their stored values. Other variables are left alone. Thus a variable that has not been stored acts like an abstract variable in algebra; a variable that has been stored acts more like a register in a traditional calculator. With a positive numeric prefix argument, = evaluates the top n stack entries; with a negative argument, = evaluates the nth stack entry.

A few variables are called special constants. Their names are `e', `pi', `i', `phi', and `gamma'. (See section Scientific Functions.) When they are evaluated with =, their values are calculated if necessary according to the current precision or complex polar mode. If you wish to use these symbols for other purposes, simply undefine or redefine them using `calc-store`.

The variables `inf', `uinf', and `nan' stand for infinite or indeterminate values. It's best not to use them as regular variables, since Calc uses special algebraic rules when it manipulates them. Calc displays a warning message if you store a value into any of these special variables.

See section Storing and Recalling, for a discussion of commands dealing with variables.

Formulas

When you press the apostrophe key you may enter any expression or formula in algebraic form. (Calc uses the terms "expression" and "formula" interchangeably.) An expression is built up of numbers, variable names, and function calls, combined with various arithmetic operators. Parentheses may be used to indicate grouping. Spaces are ignored within formulas, except that spaces are not permitted within variable names or numbers. Arithmetic operators, in order from highest to lowest precedence, and with their equivalent function names, are:

`_' [`subscr`] (subscripts);

postfix `%' [`percent`] (as in `25% = 0.25');

prefix `+' and `-' [`neg`] (as in `-x') and prefix `!' [`lnot`] (logical "not," as in `!x');

`+/-' [`sdev`] (the standard deviation symbol) and `mod' [`makemod`] (the symbol for modulo forms);

postfix `!' [`fact`] (factorial, as in `n!') and postfix `!!' [`dfact`] (double factorial);

`^' [`pow`] (raised-to-the-power-of);

`*' [`mul`];

`/' [`div`], `%' [`mod`] (modulo), and `\' [`idiv`] (integer division);

infix `+' [`add`] and `-' [`sub`] (as in `x-y');

`|' [`vconcat`] (vector concatenation);

relations `=' [`eq`], `!=' [`neq`], `<' [`lt`], `>' [`gt`], `<=' [`leq`], and `>=' [`geq`];

`&&' [`land`] (logical "and");

`||' [`lor`] (logical "or");

the C-style "if" operator `a?b:c' [`if`];

`!!!' [`pnot`] (rewrite pattern "not");

`&&&' [`pand`] (rewrite pattern "and");

`|||' [`por`] (rewrite pattern "or");

`:=' [`assign`] (for assignments and rewrite rules);

`::' [`condition`] (rewrite pattern condition);

`=>' [`evalto`].

Note that, unlike in usual computer notation, multiplication binds more strongly than division: `a*b/c*d' is equivalent to @c{$a b \over c d$} (a*b)/(c*d).

The multiplication sign `*' may be omitted in many cases. In particular, if the righthand side is a number, variable name, or parenthesized expression, the `*' may be omitted. Implicit multiplication has the same precedence as the explicit `*' operator. The one exception to the rule is that a variable name followed by a parenthesized expression, as in `f(x)', is interpreted as a function call, not an implicit `*'. In many cases you must use a space if you omit the `*': `2a' is the same as `2*a', and `a b' is the same as `a*b', but `ab' is a variable called `ab', *not* the product of `a' and `b'! Also note that `f (x)' is still a function call.

The rules are slightly different for vectors written with square brackets. In vectors, the space character is interpreted (like the comma) as a separator of elements of the vector. Thus `[ 2a b+c d ]' is equivalent to `[2*a, b+c, d]', whereas `2a b+c d' is equivalent to `2*a*b + c*d'. Note that spaces around the brackets, and around explicit commas, are ignored. To force spaces to be interpreted as multiplication you can enclose a formula in parentheses as in `[(a b) 2(c d)]', which is interpreted as `[a*b, 2*c*d]'. An implicit comma is also inserted between `][', as in the matrix `[[1 2][3 4]]'.

Vectors that contain commas (not embedded within nested parentheses or brackets) do not treat spaces specially: `[a b, 2 c d]' is a vector of two elements. Also, if it would be an error to treat spaces as separators, but not otherwise, then Calc will ignore spaces: `[a - b]' is a vector of one element, but `[a -b]' is a vector of two elements. Finally, vectors entered with curly braces instead of square brackets do not give spaces any special treatment. When Calc displays a vector that does not contain any commas, it will insert parentheses if necessary to make the meaning clear: `[(a b)]'.

The expression `5%-2' is ambiguous; is this five-percent minus two, or five modulo minus-two? Calc always interprets the leftmost symbol as an infix operator preferentially (modulo, in this case), so you would need to write `(5%)-2' to get the former interpretation.

A function call is, e.g., `sin(1+x)'. Function names follow the same rules as variable names except that

the default prefix `calcFunc-' is used (instead of `var-') for the internal Lisp form. Most mathematical Calculator commands like `calc-sin` have function equivalents like `sin`. If no Lisp function is def for a function called by a formula, the call is left as it is during algebraic manipulation: `f(x+y)' is left alone. Beware that many innocent-looking short names like `in` and `re` have predefined meanings which could surprise you; however, single letters or single letters followed by digits are always safe to use for your own function names. See section Index of Algebraic Functions.

In the documentation for particular commands, the notation H S (`calc-sinh`) [`sinh`] means that the key sequence H S, the command M-x calc-sinh, and the algebraic function `sinh(x)` all represent the same operation.

Commands that interpret ("parse") text as algebraic formulas include algebraic entry ('), editing commands like ` which parse the contents of the editing buffer when you finish, the M-# g and M-# r commands, the C-y command, the X window system "paste" mouse operation, and Embedded Mode. All of these operations use the same rules for parsing formulas; in particular, language modes (see section Language Modes) affect them all in the same way.

When you read a large amount of text into the Calculator (say a vector which represents a big set of rewrite rules; see section Rewrite Rules), you may wish to include comments in the text. Calc's formula parser ignores the symbol `%%' and anything following it on a line:

```
[ a + b,   %% the sum of "a" and "b"
  c + d,
  %% last line is coming up:
  e + f ]
```

This is parsed exactly the same as `[a + b, c + d, e + f]'.

See section Syntax Tables, for a way to create your own operators and other input notations. See section Compositions, for a way to create new display formats.

See section Algebra, for commands for manipulating formulas symbolically.

Stack and Trail Commands

This chapter describes the Calc commands for manipulating objects on the stack and in the trail buffer. (These commands operate on objects of any type, such as numbers, vectors, formulas, and incomplete objects.)

Stack Manipulation Commands

To duplicate the top object on the stack, press RET or SPC (two equivalent keys for the `calc-enter` command). Given a positive numeric prefix argument, these commands duplicate several elements at the top of the stack. Given a negative argument, these commands duplicate the specified element of the stack. Given an argument of zero, they duplicate the entire stack. For example, with `10 20 30' on the stack, RET creates `10 20 30 30', C-u 2 RET creates `10 20 30 20 30', C-u - 2 RET creates `10 20 30 20', and C-u 0 RET creates `10 20 30 10 20 30'.

The LFD (`calc-over`) command (on a key marked Line-Feed if you have it, else on C-j) is like `calc-enter` except that the sign of the numeric prefix argument is interpreted oppositely. Also, with no prefix argument the default argument is 2. Thus with `10 20 30' on the stack, LFD and C-u 2 LFD are both equivalent to C-u - 2 RET, producing `10 20 30 20'.

To remove the top element from the stack, press DEL (`calc-pop`). The C-d key is a synonym for DEL. (If the top element is an incomplete object with at least one element, the last element is removed from it.) Given a positive numeric prefix argument, several elements are removed. Given a negative argument, the specified element of the stack is deleted. Given an argument of zero, the entire stack is emptied. For example, with `10 20 30' on the stack, DEL leaves `10 20', C-u 2 DEL leaves `10', C-u - 2 DEL leaves `10 30', and C-u 0 DEL leaves an empty stack.

The M-DEL (`calc-pop-above`) command is to DEL what LFD is to RET: It interprets the sign of the numeric prefix argument in the opposite way, and the default argument is 2. Thus M-DEL by itself removes the second-from-top stack element, leaving the first, third, fourth, and so on; M-3 M-DEL deletes the third stack element.

To exchange the top two elements of the stack, press TAB (`calc-roll-down`). Given a positive numeric prefix argument, the specified number of elements at the top of the stack are rotated downward. Given a negative argument, the entire stack is rotated downward the specified number of times. Given an argument of zero, the entire stack is reversed top-for-bottom. For example, with `10 20 30 40 50' on the stack, TAB creates `10 20 30 50 40', C-u 3 TAB creates `10 20 50 30 40', C-u - 2 TAB creates `40 50 10 20 30', and C-u 0 TAB creates `50 40 30 20 10'.

The command M-TAB (`calc-roll-up`) is analogous to TAB except that it rotates upward instead of downward. Also, the default with no prefix argument is to rotate the top 3 elements. For example, with `10 20 30 40 50' on the stack, M-TAB creates `10 20 40 50 30', C-u 4 M-TAB creates `10 30 40 50 20', C-u - 2 M-TAB creates `30 40 50 10 20', and C-u 0 M-TAB creates `50 40 30 20 10'.

A good way to view the operation of TAB and M-TAB is in terms of moving a particular element to a new position in the stack. With a positive argument *n*, TAB moves the top stack element down to level *n*, making room for it by pulling all the intervening stack elements toward the top. M-TAB moves the element at level *n* up to the top. (Compare with LFD, which copies instead of moving the element in level *n*.)

With a negative argument *-n*, TAB rotates the stack to move the object in level *n* to the deepest place in the stack, and the object in level *n+1* to the top. M-TAB rotates the deepest stack element to be in level *n*, also putting the top stack element in level *n+1*.

See section Selecting Sub-Formulas, for a way to apply these commands to any portion of a vector or formula on the stack.

Editing Stack Entries

The backquote, ` (`calc-edit`) command creates a temporary buffer (`*Calc Edit*') for editing the top-of-stack value using regular Emacs commands. With a numeric prefix argument, it edits the specified number of stack entries at once. (An argument of zero edits the entire stack; a negative argument edits one specific stack entry.)

When you are done editing, press M-# M-# to finish and return to Calc. The RET and LFD keys also work to finish most sorts of editing, though in some cases Calc leaves RET with its usual meaning ("insert a newline") if it's a situation where you might want to insert new lines into the editing buffer. The traditional Emacs "finish" key sequence, C-c C-c, also works to finish editing and may be easier to type, depending on your keyboard.

When you finish editing, the Calculator parses the lines of text in the `*Calc Edit*' buffer as numbers or formulas, replaces the original stack elements in the original buffer with these new values, then kills the `*Calc Edit*' buffer. The original Calculator buffer continues to exist during editing, but for best results you should be careful not to change it until you have finished the edit. You can also cancel the edit by pressing M-# x.

The formula is normally reevaluated as it is put onto the stack. For example, editing `a + 2' to `3 + 2' and pressing M-# M-# will push 5 on the stack. If you use LFD to finish, Calc will put the result on the stack without evaluating it.

If you give a prefix argument to M-# M-# (or C-c C-c), Calc will not kill the `*Calc Edit*' buffer. You can switch back to that buffer and continue editing if you wish. However, you should understand that if you initiated the edit with `, the M-# M-# operation will be programmed to replace the top of the stack with the new edited value, and it will do this even if you have rearranged the stack in the meanwhile. This is not so much of a problem with other editing commands, though, such as s e (`calc-edit-variable`; see section Other Operations on Variables).

If the `calc-edit` command involves more than one stack entry, each line of the `*Calc Edit*' buffer is interpreted as a separate formula. Otherwise, the entire buffer is interpreted as one formula, with line breaks ignored. (You can use C-o or C-q C-j to insert a newline in the buffer without pressing RET.)

The ` key also works during numeric or algebraic entry. The text entered so far is moved to the `*Calc Edit*` buffer for more extensive editing than is convenient in the minibuffer.

Trail Commands

The commands for manipulating the Calc Trail buffer are two-key sequences beginning with the t prefix.

The t d (`calc-trail-display`) command turns display of the trail on and off. Normally the trail display is toggled on if it was off, off if it was on. With a numeric prefix of zero, this command always turns the trail off; with a prefix of one, it always turns the trail on. The other trail-manipulation commands described here automatically turn the trail on. Note that when the trail is off values are still recorded there; they are simply not displayed. To set Emacs to turn the trail off by default, type t d and then save the mode settings with m m (`calc-save-modes`).

The t i (`calc-trail-in`) and t o (`calc-trail-out`) commands switch the cursor into and out of the Calc Trail window. In practice they are rarely used, since the commands shown below are a more convenient way to move around in the trail, and they work "by remote control" when the cursor is still in the Calculator window.

There is a trail pointer which selects some entry of the trail at any given time. The trail pointer looks like a `>' symbol right before the selected number. The following commands operate on the trail pointer in various ways.

The t y (`calc-trail-yank`) command reads the selected value in the trail and pushes it onto the Calculator stack. It allows you to re-use any previously computed value without retyping. With a numeric prefix argument n, it yanks the value n lines above the current trail pointer.

The t < (`calc-trail-scroll-left`) and t > (`calc-trail-scroll-right`) commands horizontally scroll the trail window left or right by one half of its width.

The t n (`calc-trail-next`) and t p (`calc-trail-previous`) commands move the trail pointer down or up one line. The t f (`calc-trail-forward`) and t b (`calc-trail-backward`) commands move the trail pointer down or up one screenful at a time. All of these commands accept numeric prefix arguments to move several lines or screenfuls at a time.

The t [(`calc-trail-first`) and t] (`calc-trail-last`) commands move the trail pointer to the first or last line of the trail. The t h (`calc-trail-here`) command moves the trail pointer to the cursor position; unlike the other trail commands, t h works only when Calc Trail is the selected window.

The t m (`calc-trail-marker`) command allows you to enter a line of text of your own choosing into the trail. The text is inserted after the line containing the trail pointer; this usually means it is added to the end of the trail. Trail markers are useful mainly as the targets for later incremental searches in the trail.

The t k (`calc-trail-kill`) command removes the selected line from the trail. The line is saved in the Emacs kill ring suitable for yanking into another buffer, but it is not easy to yank the text back into the trail buffer. With a numeric prefix argument, this command kills the n lines below or above the selected one.

The t . (`calc-full-trail-vectors`) command is described elsewhere; see section Vector and Matrix Display Formats.

Keep Arguments

The K (`calc-keep-args`) command acts like a prefix for the following command. It prevents that command from removing its arguments from the stack. For example, after 2 RET 3 +, the stack contains the sole number 5, but after 2 RET 3 K +, the stack contains the arguments and the result: `2 3 5'.

This works for all commands that take arguments off the stack. As another example, K a s simplifies a formula, pushing the simplified version of the formula onto the stack after the original formula (rather than replacing the original formula).

Note that you could get the same effect by typing RET a s, copying the formula and then simplifying the copy. One difference is that for a very large formula the time taken to format the intermediate copy in RET a s could be noticeable; K a s would avoid this extra work.

Even stack manipulation commands are affected. TAB works by popping two values and pushing them back in the opposite order, so 2 RET 3 K TAB produces `2 3 3 2'.

A few Calc commands provide other ways of doing the same thing. For example, ' sin($) replaces the number on the stack with its sine using algebraic entry; to push the sine and keep the original argument you could use either ' sin($1) or K ' sin($). See section Algebraic Entry. Also, the s s command is effectively the same as K s t. See section Storing Variables.

Keyboard macros may interact surprisingly with the K prefix. If you have defined a keyboard macro to be, say, `Q +' to add one number to the square root of another, then typing K X will execute K Q +, probably not what you expected. The K prefix will apply to just the first command in the macro rather than the whole macro.

If you execute a command and then decide you really wanted to keep the argument, you can press M-RET (`calc-last-args`). This command pushes the last arguments that were popped by any command onto the stack. Note that the order of things on the stack will be different than with K: 2 RET 3 + M-RET leaves `5 2 3' on the stack instead of `2 3 5'. See section Undoing Mistakes.

Go to the previous, next section.

Go to the previous, next section.

Mode Settings

This chapter describes commands that set modes in the Calculator. They do not affect the contents of the stack, although they may change the *appearance* or *interpretation* of the stack's contents.

General Mode Commands

You can save all of the current mode settings in your `.emacs' file with the m m (`calc-save-modes`) command. This will cause Emacs to reestablish these modes each time it starts up. The modes saved in the file include everything controlled by the m and d prefix keys, the current precision and binary word size, whether or not the trail is displayed, the current height of the Calc window, and more. The current interface (used when you type M-# M-#) is also saved. If there were already saved mode settings in the file, they are replaced. Otherwise, the new mode information is appended to the end of the file.

The m R (`calc-mode-record-mode`) command tells Calc to record the new mode settings (as if by pressing m m) every time a mode setting changes. If Embedded Mode is enabled, other options are available; see section Mode Settings in Embedded Mode.

The m F (`calc-settings-file-name`) command allows you to choose a different place than your `.emacs' file for m m, Z P, and similar commands to save permanent information. You are prompted for a file name. All Calc modes are then reset to their default values, then settings from the file you named are loaded if this file exists, and this file becomes the one that Calc will use in the future for commands like m m. The default settings file name is `~/.emacs'. You can see the current file name by giving a blank response to the m F prompt. See also the discussion of the `calc-settings-file` variable; see section Installation.

If the file name you give contains the string `.emacs' anywhere inside it, m F will not automatically load the new file. This is because you are presumably switching to your `~/.emacs' file, which may contain other things you don't want to reread. You can give a numeric prefix argument of 1 to m F to force it to read the file no matter what its name. Conversely, an argument of *-1* tells m F *not* to read the new file. An argument of 2 or *-2* tells m F not to reset the modes to their defaults beforehand, which is useful if you intend your new file to have a variant of the modes present in the file you were using before.

The m x (`calc-always-load-extensions`) command enables a mode in which the first use of Calc loads the entire program, including all extensions modules. Otherwise, the extensions modules will not be loaded until the various advanced Calc features are used. Since this mode only has effect when Calc is first loaded, m x is usually followed by m m to make the mode-setting permanent. To load all of Calc just once, rather than always in the future, you can press M-# L.

The m S (`calc-shift-prefix`) command enables a mode in which all of Calc's letter prefix keys may be typed shifted as well as unshifted. If you are typing, say, a S (`calc-solve-for`) quite often

you might find it easier to turn this mode on so that you can type A S instead. When this mode is enabled, the commands that used to be on those single shifted letters (e.g., A (`calc-abs`)) can now be invoked by pressing the shifted letter twice: A A. Note that the v prefix key always works both shifted and unshifted, and the z and Z prefix keys are always distinct. Also, the h prefix is not affected by this mode. Press m S again to disable shifted-prefix mode.

Precision

The p (`calc-precision`) command controls the precision to which floating-point calculations are carried. The precision must be at least 3 digits and may be arbitrarily high, within the limits of memory and time. This affects only floats: Integer and rational calculations are always carried out with as many digits as necessary.

The p key prompts for the current precision. If you wish you can instead give the precision as a numeric prefix argument.

Many internal calculations are carried to one or two digits higher precision than normal. Results are rounded down afterward to the current precision. Unless a special display mode has been selected, floats are always displayed with their full stored precision, i.e., what you see is what you get. Reducing the current precision does not round values already on the stack, but those values will be rounded down before being used in any calculation. The c 0 through c 9 commands (see section Conversions) can be used to round an existing value to a new precision.

It is important to distinguish the concepts of precision and accuracy. In the normal usage of these words, the number 123.4567 has a precision of 7 digits but an accuracy of 4 digits. The precision is the total number of digits not counting leading or trailing zeros (regardless of the position of the decimal point). The accuracy is simply the number of digits after the decimal point (again not counting trailing zeros). In Calc you control the precision, not the accuracy of computations. If you were to set the accuracy instead, then calculations like `exp(100)' would generate many more digits than you would typically need, while `exp(-100)' would probably round to zero! In Calc, both these computations give you exactly 12 (or the requested number of) significant digits.

The only Calc features that deal with accuracy instead of precision are fixed-point display mode for floats (d f; see section Float Formats), and the rounding functions like `floor` and `round` (see section Integer Truncation). Also, c 0 through c 9 deal with both precision and accuracy depending on the magnitudes of the numbers involved.

If you need to work with a particular fixed accuracy (say, dollars and cents with two digits after the decimal point), one solution is to work with integers and an "implied" decimal point. For example, $8.99 divided by 6 would be entered 899 RET 6 /, yielding 149.833 (actually $1.49833 with our implied decimal point); pressing R would round this to 150 cents, i.e., $1.50.

See section Floats, for still more on floating-point precision and related issues.

Inverse and Hyperbolic Flags

There is no single-key equivalent to the `calc-arcsin` function. Instead, you must first press I (`calc-inverse`) to set the Inverse Flag, then press S (`calc-sin`). The I key actually toggles the Inverse Flag. When this flag is set, the word `Inv' appears in the mode line.

Likewise, the H key (`calc-hyperbolic`) sets or clears the Hyperbolic Flag, which transforms `calc-sin` into `calc-sinh`. If both of these flags are set at once, the effect will be `calc-arcsinh`. (The Hyperbolic flag is also used by some non-trigonometric commands; for example H L computes a base-10, instead of base-*e*, logarithm.)

Command names like `calc-arcsin` are provided for completeness, and may be executed with x or M-x. Their effect is simply to toggle the Inverse and/or Hyperbolic flags and then execute the corresponding base command (`calc-sin` in this case).

The Inverse and Hyperbolic flags apply only to the next Calculator command, after which they are automatically cleared. (They are also cleared if the next keystroke is not a Calc command.) Digits you type after I or H (or K) are treated as prefix arguments for the next command, not as numeric entries. The same is true of C-u, but not of the minus sign (K - means to subtract and keep arguments).

The third Calc prefix flag, K (keep-arguments), is discussed elsewhere. See section Keep Arguments.

Calculation Modes

The commands in this section are two-key sequences beginning with the m prefix. (That's the letter m, not the META key.) The `m a' (`calc-algebraic-mode`) command is described elsewhere (see section Algebraic Entry).

Angular Modes

The Calculator supports three notations for angles: radians, degrees, and degrees-minutes-seconds. When a number is presented to a function like `sin` that requires an angle, the current angular mode is used to interpret the number as either radians or degrees. If an HMS form is presented to `sin`, it is always interpreted as degrees-minutes-seconds.

Functions that compute angles produce a number in radians, a number in degrees, or an HMS form depending on the current angular mode. If the result is a complex number and the current mode is HMS, the number is instead expressed in degrees. (Complex-number calculations would normally be done in radians mode, though. Complex numbers are converted to degrees by calculating the complex result in radians and then multiplying by 180 over @c{π} pi.)

The m r (`calc-radians-mode`), m d (`calc-degrees-mode`), and m h (`calc-hms-mode`) commands control the angular mode. The current angular mode is displayed on the Emacs mode line. The default angular mode is degrees.

Polar Mode

The Calculator normally "prefers" rectangular complex numbers in the sense that rectangular form is used when the proper form can not be decided from the input. This might happen by multiplying a rectangular number by a polar one, by taking the square root of a negative real number, or by entering (2 SPC 3).

The m p (`calc-polar-mode`) command toggles complex-number preference between rectangular and polar forms. In polar mode, all of the above example situations would produce polar complex numbers.

Fraction Mode

Division of two integers normally yields a floating-point number if the result cannot be expressed as an integer. In some cases you would rather get an exact fractional answer. One way to accomplish this is to multiply fractions instead: 6 RET 1:4 * produces 3:2 even though 6 RET 4 / produces 1.5.

To set the Calculator to produce fractional results for normal integer divisions, use the m f (`calc-frac-mode`) command. For example, 8/4 produces 2 in either mode, but 6/4 produces 3:2 in Fraction Mode, 1.5 in Float Mode.

At any time you can use c f (`calc-float`) to convert a fraction to a float, or c F (`calc-fraction`) to convert a float to a fraction. See section Conversions.

Infinite Mode

The Calculator normally treats results like 1 / 0 as errors; formulas like this are left in unsimplified form. But Calc can be put into a mode where such calculations instead produce "infinite" results.

The m i (`calc-infinite-mode`) command turns this mode on and off. When the mode is off, infinities do not arise except in calculations that already had infinities as inputs. (One exception is that infinite open intervals like `[0 .. inf)' can be generated; however, intervals closed at infinity (`[0 .. inf]') will not be generated when infinite mode is off.)

With infinite mode turned on, `1 / 0' will generate `uinf`, an undirected infinity. See section Infinities, for a discussion of the difference between `inf` and `uinf`. Also, 0 / 0 evaluates to `nan`, the "indeterminate" symbol. Various other functions can also return infinities in this mode; for example, `ln(0) = -inf', and `gamma(-7) = uinf'. Once again, note that `exp(inf) = inf' regardless of infinite mode because this calculation has infinity as an input.

The m i command with a numeric prefix argument of zero, i.e., C-u 0 m i, turns on a "positive infinite mode" in which zero is treated as positive instead of being directionless. Thus, `1 / 0 = inf' and `-1 / 0 = -inf' in this mode. Note that zero never actually has a sign in Calc; there are no separate representations for *+0* and *-0*. Positive infinite mode merely changes the interpretation given to the single symbol, `0'. One consequence of this is that, while you might expect `1 / -0 = -inf', actually `1 / -0' is equivalent to `1 / 0', which is equal to positive `inf`.

Symbolic Mode

Calculations are normally performed numerically wherever possible. For example, the `calc-sqrt` command, or `sqrt` function in an algebraic expression, produces a numeric answer if the argument is a number or a symbolic expression if the argument is an expression: 2 Q pushes 1.4142 but ' x+1 RET Q pushes `sqrt(x+1)'.

In symbolic mode, controlled by the m s (`calc-symbolic-mode`) command, functions which would produce inexact, irrational results are left in symbolic form. Thus 16 Q pushes 4, but 2 Q pushes `sqrt(2)'.

The shift-N (`calc-eval-num`) command evaluates numerically the expression at the top of the stack, by temporarily disabling `calc-symbolic-mode` and executing = (`calc-evaluate`). Given a numeric prefix argument, it also sets the floating-point precision to the specified value for the duration of the command.

To evaluate a formula numerically without expanding the variables it contains, you can use the key sequence m s a v m s (this uses `calc-alg-evaluate`, which resimplifies but doesn't evaluate variables.)

Matrix and Scalar Modes

Calc sometimes makes assumptions during algebraic manipulation that are awkward or incorrect when vectors and matrices are involved. Calc has two modes, matrix mode and scalar mode, which modify its behavior around vectors in useful ways.

Press m v (`calc-matrix-mode`) once to enter matrix mode. In this mode, all objects are assumed to be matrices unless provably otherwise. One major effect is that Calc will no longer consider multiplication to be commutative. (Recall that in matrix arithmetic, `A*B' is not the same as `B*A'.) This assumption affects rewrite rules and algebraic simplification. Another effect of this mode is that calculations that would normally produce constants like 0 and 1 (e.g., a - a and a / a, respectively) will now produce function calls that represent "generic" zero or identity matrices: `idn(0)', `idn(1)'. The `idn` function `idn(a,n)' returns a times an nxn identity matrix; if n is omitted, it doesn't know what dimension to use and so the `idn` call remains in symbolic form. However, if this generic identity matrix is later combined with a matrix whose size is known, it will be converted into a true identity matrix of the appropriate size. On the other hand, if it is combined with a scalar (as in `idn(1) + 2'), Calc will assume it really was a scalar after all and produce, e.g., 3.

Press m v a second time to get scalar mode. Here, objects are assumed *not* to be vectors or matrices unless provably so. For example, normally adding a variable to a vector, as in `[x, y, z] + a', will leave the sum in symbolic form because as far as Calc knows, `a' could represent either a number or another 3-vector. In scalar mode, `a' is assumed to be a non-vector, and the addition is evaluated to `[x+a, y+a, z+a]'.

Press m v a third time to return to the normal mode of operation.

If you press m v with a numeric prefix argument n, you get a special "dimensioned matrix mode" in which matrices of unknown size are assumed to be nxn square matrices. Then, the function call `idn(1)' will expand into an actual matrix rather than representing a "generic" matrix.

Of course these modes are approximations to the true state of affairs, which is probably that some quantities will be matrices and others will be scalars. One solution is to "declare" certain variables or functions to be scalar-valued. See section Declarations, to see how to make declarations in Calc.

There is nothing stopping you from declaring a variable to be scalar and then storing a matrix in it; however, if you do, the results you get from Calc may not be valid. Suppose you let Calc get the result `[x+a, y+a, z+a]' shown above, and then stored `[1, 2, 3]' in `a'. The result would not be the same as for `[x, y, z] + [1, 2, 3]', but that's because you have broken your earlier promise to Calc that `a' would be scalar.

Another way to mix scalars and matrices is to use selections (see section Selecting Sub-Formulas). Use matrix mode when operating on your formula normally; then, to apply scalar mode to a certain part of the formula without affecting the rest just select that part, change into scalar mode and press = to resimplify the part under this mode, then change back to matrix mode before deselecting.

Automatic Recomputation

The evaluates-to operator, `=>', has the special property that any `=>' formulas on the stack are recomputed whenever variable values or mode settings that might affect them are changed. See section The Evaluates-To Operator.

The m C (`calc-auto-recompute`) command turns this automatic recomputation on and off. If you turn it off, Calc will not update `=>' operators on the stack (nor those in the attached Embedded Mode buffer, if there is one). They will not be updated unless you explicitly do so by pressing = or until you press m C to turn recomputation back on. (While automatic recomputation is off, you can think of m C m C as a command to update all `=>' operators while leaving recomputation off.)

To update `=>' operators in an Embedded buffer while automatic recomputation is off, use M-# u. See section Embedded Mode.

Working Messages

Since the Calculator is written entirely in Emacs Lisp, which is not designed for heavy numerical work, many operations are quite slow. The Calculator normally displays the message `Working...' in the echo area during any command that may be slow. In addition, iterative operations such as square roots and trigonometric functions display the intermediate result at each step. Both of these types of messages can be disabled if you find them distracting.

Type m w (`calc-working`) with a numeric prefix of 0 to disable all "working" messages. Use a numeric prefix of 1 to enable only the plain `Working...' message. Use a numeric prefix of 2 to see intermediate results as well. With no numeric prefix this displays the current mode.

While it may seem that the "working" messages will slow Calc down considerably, experiments have shown that their impact is actually quite small. But if your terminal is slow you may find that it helps to turn the messages off.

Simplification Modes

The current simplification mode controls how numbers and formulas are "normalized" when being taken from or pushed onto the stack. Some normalizations are unavoidable, such as rounding floating-point results to the current precision, and reducing fractions to simplest form. Others, such as simplifying a formula like a+a (or 2+3), are done by default but can be turned off when necessary.

When you press a key like + when 2 and 3 are on the stack, Calc pops these numbers, normalizes them, creates the formula 2+3, normalizes it, and pushes the result. Of course the standard rules for normalizing 2+3 will produce the result 5.

Simplification mode commands consist of the lower-case m prefix key followed by a shifted letter.

The m O (`calc-no-simplify-mode`) command turns off all optional simplifications. These would leave a formula like 2+3 alone. In fact, nothing except simple numbers are ever affected by normalization in this mode.

The m N (`calc-num-simplify-mode`) command turns off simplification of any formulas except those for which all arguments are constants. For example, 1+2 is simplified to 3, and a+(2-2) is simplified to a+0 but no further, since one argument of the sum is not a constant. Unfortunately, (a+2)-2 is *not* simplified because the top-level `-' operator's arguments are not both constant numbers (one of them is the formula a+2). A constant is a number or other numeric object (such as a constant error form or modulo form), or a vector all of whose elements are constant.

The m D (`calc-default-simplify-mode`) command restores the default simplifications for all formulas. This includes many easy and fast algebraic simplifications such as a+0 to a, and a + 2 a to 3 a, as well as evaluating functions like `deriv`(x^2, x) to 2 x.

The m B (`calc-bin-simplify-mode`) mode applies the default simplifications to a result and then, if the result is an integer, uses the b c (`calc-clip`) command to clip the integer according to the current binary word size. See section Binary Number Functions. Real numbers are rounded to the nearest integer and then clipped; other kinds of results (after the default simplifications) are left alone.

The m A (`calc-alg-simplify-mode`) mode does algebraic simplification; it applies all the default simplifications, and also the more powerful (and slower) simplifications made by a s (`calc-simplify`). See section Algebraic Simplifications.

The m E (`calc-ext-simplify-mode`) mode does "extended" algebraic simplification, as by the a e (`calc-simplify-extended`) command. See section "Unsafe" Simplifications.

The m U (`calc-units-simplify-mode`) mode does units simplification; it applies the command u s (`calc-simplify-units`), which in turn is a superset of a s. In this mode, variable names which are identifiable as unit names (like `mm' for "millimeters") are simplified with their unit definitions in mind.

A common technique is to set the simplification mode down to the lowest amount of simplification you will allow to be applied automatically, then use manual commands like a s and c c (`calc-clean`) to perform higher types of simplifications on demand. See section Programming with Formulas, for another sample use of no-simplification mode.

Declarations

A declaration is a statement you make that promises you will use a certain variable or function in a restricted way. This may give Calc the freedom to do things that it couldn't do if it had to take the fully general situation into account.

Declaration Basics

The s d (`calc-declare-variable`) command is the easiest way to make a declaration for a variable. This command prompts for the variable name, then prompts for the declaration. The default at the declaration prompt is the previous declaration, if any. You can edit this declaration, or press C-k to erase it and type a new declaration. (Or, erase it and press RET to clear the declaration, effectively "undeclaring" the variable.)

A declaration is in general a vector of type symbols and range values. If there is only one type symbol or range value, you can write it directly rather than enclosing it in a vector. For example, s d foo RET real RET declares `foo` to be a real number, and s d bar RET [int, const, [1..6]] RET declares `bar` to be a constant integer between 1 and 6. (Actually, you can omit the outermost brackets and Calc will provide them for you: s d bar RET int, const, [1..6] RET.)

Declarations in Calc are kept in a special variable called `Decls`. This variable encodes the set of all outstanding declarations in the form of a matrix. Each row has two elements: A variable or vector of variables declared by that row, and the declaration specifier as described above. You can use the s D command to edit this variable if you wish to see all the declarations at once. See section Other Operations on Variables, for a description of this command and the s p command that allows you to save your declarations permanently if you wish.

Items being declared can also be function calls. The arguments in the call are ignored; the effect is to say that this function returns values of the declared type for any valid arguments. The s d command declares only variables, so if you wish to make a function declaration you will have to edit the `Decls` matrix yourself.

For example, the declaration matrix

```
[ [ foo,       real       ]
  [ [j, k, n], int        ]
  [ f(1,2,3),  [0 .. inf) ] ]
```

declares that `foo` represents a real number, `j`, `k` and `n` represent integers, and the function `f` always returns a real number in the interval shown.

If there is a declaration for the variable `All`, then that declaration applies to all variables that are not otherwise declared. It does not apply to function names. For example, using the row `[All, real]' says that all your variables are real unless they are explicitly declared without `real` in some other row. The s d command declares `All` if you give a blank response to the variable-name prompt.

Kinds of Declarations

The type-specifier part of a declaration (that is, the second prompt in the s d command) can be a type symbol, an interval, or a vector consisting of zero or more type symbols followed by zero or more intervals or numbers that represent the set of possible values for the variable.

```
[ [ a, [1, 2, 3, 4, 5] ]
  [ b, [1 .. 5]        ]
  [ c, [int, 1 .. 5]   ] ]
```

Here `a` is declared to contain one of the five integers shown; `b` is any number in the interval from 1 to 5 (any real number since we haven't specified), and `c` is any integer in that interval. Thus the declarations for `a` and `c` are nearly equivalent (see below).

The type-specifier can be the empty vector `[]' to say that nothing is known about a given variable's value. This is the same as not declaring the variable at all except that it overrides any `All` declaration which would otherwise apply.

The initial value of `Decls` is the empty vector `[]'. If `Decls` has no stored value or if the value stored in it is not valid, it is ignored and there are no declarations as far as Calc is concerned. (The s d command will replace such a malformed value with a fresh empty matrix, `[]', before recording the new declaration.) Unrecognized type symbols are ignored.

The following type symbols describe what sorts of numbers will be stored in a variable:

`int`
: Integers.

`numint`
: Numerical integers. (Integers or integer-valued floats.)

`frac`
: Fractions. (Rational numbers which are not integers.)

`rat`
: Rational numbers. (Either integers or fractions.)

`float`
: Floating-point numbers.

`real`
: Real numbers. (Integers, fractions, or floats. Actually, intervals and error forms with real components also count as reals here.)

`pos`
: Positive real numbers. (Strictly greater than zero.)

`nonneg`
: Nonnegative real numbers. (Greater than or equal to zero.)

`number`

Numbers. (Real or complex.)

Calc uses this information to determine when certain simplifications of formulas are safe. For example, `(x^y)^z' cannot be simplified to `x^(y z)' in general; for example, `((-3)^2)^1:2' is 3, but `(-3)^(2*1:2) = (-3)^1' is *-3*. However, this simplification *is* safe if `z` is known to be an integer, or if `x` is known to be a nonnegative real number. If you have given declarations that allow Calc to deduce either of these facts, Calc will perform this simplification of the formula.

Calc can apply a certain amount of logic when using declarations. For example, `(x^y)^(2n+1)' will be simplified if `n` has been declared `int`; Calc knows that an integer times an integer, plus an integer, must always be an integer. (In fact, Calc would simplify `(-x)^(2n+1)' to `-(x^(2n+1))' since it is able to determine that `2n+1' must be an odd integer.)

Similarly, `(abs(x)^y)^z' will be simplified to `abs(x)^(y z)' because Calc knows that the `abs` function always returns a nonnegative real. If you had a `myabs` function that also had this property, you could get Calc to recognize it by adding the row `[myabs(), nonneg]' to the `Decls` matrix.

One instance of this simplification is `sqrt(x^2)' (since the `sqrt` function is effectively a one-half power). Normally Calc leaves this formula alone. After the command s d x RET real RET, however, it can simplify the formula to `abs(x)'. And after s d x RET nonneg RET, Calc can simplify this formula all the way to `x'.

If there are any intervals or real numbers in the type specifier, they comprise the set of possible values that the variable or function being declared can have. In particular, the type symbol `real` is effectively the same as the range `[-inf .. inf]' (note that infinity is included in the range of possible values); `pos` is the same as `(0 .. inf]', and `nonneg` is the same as `[0 .. inf]'. Saying `[real, [-5 .. 5]]' is redundant because the fact that the variable is real can be deduced just from the interval, but `[int, [-5 .. 5]]' and `[rat, [-5 .. 5]]' are useful combinations.

Note that the vector of intervals or numbers is in the same format used by Calc's set-manipulation commands. See section Set Operations using Vectors.

The type specifier `[1, 2, 3]' is equivalent to `[numint, 1, 2, 3]', *not* to `[int, 1, 2, 3]'. In other words, the range of possible values means only that the variable's value must be numerically equal to a number in that range, but not that it must be equal in type as well. Calc's set operations act the same way; `in(2, [1., 2., 3.])' and `in(1.5, [1:2, 3:2, 5:2])' both report "true."

If you use a conflicting combination of type specifiers, the results are unpredictable. An example is `[pos, [0 .. 5]]', where the interval does not lie in the range described by the type symbol.

"Real" declarations mostly affect simplifications involving powers like the one described above. Another case where they are used is in the a P command which returns a list of all roots of a polynomial; if the variable has been declared real, only the real roots (if any) will be included in the list.

"Integer" declarations are used for simplifications which are valid only when certain values are integers (such as `(x^y)^z' shown above).

Another command that makes use of declarations is a s, when simplifying equations and inequalities. It will cancel `x` from both sides of `a x = b x' only if it is sure `x` is non-zero, say, because it has a `pos`

declaration. To declare specifically that `x` is real and non-zero, use `[[-inf .. 0), (0 .. inf]]'. (There is n way in the current notation to say that `x` is nonzero but not necessarily real.) The a e command does "unsafe" simplifications, including cancelling `x' from the equation when `x' is not known to be nonzero.

Another set of type symbols distinguish between scalars and vectors.

`scalar`

The value is not a vector.

`vector`

The value is a vector.

`matrix`

The value is a matrix (a rectangular vector of vectors).

These type symbols can be combined with the other type symbols described above; `[int, matrix]' describes an object which is a matrix of integers.

Scalar/vector declarations are used to determine whether certain algebraic operations are safe. For example, `[a, b, c] + x' is normally not simplified to `[a + x, b + x, c + x]', but it will be if `x` has been declared `scalar`. On the other hand, multiplication is usually assumed to be commutative, but the terms in `x y' will never be exchanged if both `x` and `y` are known to be vectors or matrices. (Calc currently never distinguishes between `vector` and `matrix` declarations.)

See section Matrix and Scalar Modes, for a discussion of "matrix mode" and "scalar mode," which are similar to declaring `[All, matrix]' or `[All, scalar]' but much more convenient.

One more type symbol that is recognized is used with the H a d command for taking total derivatives of a formula. See section Calculus.

`const`

The value is a constant with respect to other variables.

Calc does not check the declarations for a variable when you store a value in it. However, storing *-3.5* in a variable that has been declared `pos`, `int`, or `matrix` may have unexpected effects; Calc may evaluate `sqrt(x^2)' to 3.5 if it substitutes the value first, or to -3.5 if `x` was declared `pos` and the formula `sqrt(x^2)' is simplified to `x' before the value is substituted. Before using a variable for a new purpose, it is best to use s d or s D to check to make sure you don't still have an old declaration for the variable that will conflict with its new meaning.

Functions for Declarations

Calc has a set of functions for accessing the current declarations in a convenient manner. These functions return 1 if the argument can be shown to have the specified property, or 0 if the argument can be shown *not* to have that property; otherwise they are left unevaluated. These functions are suitable for use with rewrite rules (see section Conditional Rewrite Rules) or programming constructs (see section Conditionals in Keyboard Macros). They can be entered only using algebraic notation. See section Logical Operations, for functions that perform other tests not related to declarations.

For example, `dint(17)' returns 1 because 17 is an integer, as do `dint(n)' and `dint(2 n - 3)' if `n' has b declared `int', but `dint(2.5)' and `dint(n + 0.5)' return 0. Calc consults knowledge of its own built-in functions as well as your own declarations: `dint(floor(x))' returns 1.

The `dint` function checks if its argument is an integer. The `dnatnum` function checks if its argument is a natural number, i.e., a nonnegative integer. The `dnumint` function checks if its argument is numerically an integer, i.e., either an integer or an integer-valued float. Note that these and the other data type functions also accept vectors or matrices composed of suitable elements, and that real infinities `inf' and `-inf' are considered to be integers for the purposes of these functions.

The `drat` function checks if its argument is rational, i.e., an integer or fraction. Infinities count as rational, but intervals and error forms do not.

The `dreal` function checks if its argument is real. This includes integers, fractions, floats, real error forms, and intervals.

The `dimag` function checks if its argument is imaginary, i.e., is mathematically equal to a real number times i.

The `dpos` function checks for positive (but nonzero) reals. The `dneg` function checks for negative reals. The `dnonneg` function checks for nonnegative reals, i.e., reals greater than or equal to zero. Note that the a s command can simplify an expression like x > 0 to 1 or 0 using `dpos`, and that a s is effectively applied to all conditions in rewrite rules, so the actual functions `dpos`, `dneg`, and `dnonneg` are rarely necessary.

The `dnonzero` function checks that its argument is nonzero. This includes all nonzero real or complex numbers, all intervals that do not include zero, all nonzero modulo forms, vectors all of whose elements are nonzero, and variables or formulas whose values can be deduced to be nonzero. It does not include error forms, since they represent values which could be anything including zero. (This is also the set of objects considered "true" in conditional contexts.)

The `deven` function returns 1 if its argument is known to be an even integer (or integer-valued float); it returns 0 if its argument is known not to be even (because it is known to be odd or a non-integer). The a s command uses this to simplify a test of the form `x % 2 = 0'. There is also an analogous `dodd` function.

The `drange` function returns a set (an interval or a vector of intervals and/or numbers; see section Set Operations using Vectors) that describes the set of possible values of its argument. If the argument is a variable or a function with a declaration, the range is copied from the declaration. Otherwise, the possible signs of the expression are determined using a method similar to `dpos`, etc., and a suitable set like `[0 .. inf]' is returned. If the expression is not provably real, the `drange` function remains unevaluated.

The `dscalar` function returns 1 if its argument is provably scalar, or 0 if its argument is provably non-scalar. It is left unevaluated if this cannot be determined. (If matrix mode or scalar mode are in effect, this function returns 1 or 0, respectively, if it has no other information.) When Calc interprets a condition (say, in a rewrite rule) it considers an unevaluated formula to be "false." Thus, `dscalar(a)' is "true" only if `a` is provably scalar, and `!dscalar(a)' is "true" only if `a` is provably non-scalar; both are "false" if there is insufficient information to tell.

Display Modes

The commands in this section are two-key sequences beginning with the d prefix. The d l (`calc-line-numbering`) and d b (`calc-line-breaking`) commands are described elsewhere; see section Stack Basics and see section Normal Language Modes, respectively. Display formats for vectors and matrices are also covered elsewhere; see section Vector and Matrix Display Formats.

One thing all display modes have in common is their treatment of the H prefix. This prefix causes any mode command that would normally refresh the stack to leave the stack display alone. The word "Dirty" will appear in the mode line when Calc thinks the stack display may not reflect the latest mode settings.

The d RET (`calc-refresh-top`) command reformats the top stack entry according to all the current modes. Positive prefix arguments reformat the top n entries; negative prefix arguments reformat the specified entry, and a prefix of zero is equivalent to d SPC (`calc-refresh`), which reformats the entire stack. For example, H d s M-2 d RET changes to scientific notation but reformats only the top two stack entries in the new mode.

The I prefix has another effect on the display modes. The mode is set only temporarily; the top stack entry is reformatted according to that mode, then the original mode setting is restored. In other words, I d s is equivalent to H d s d RET H d (old mode).

Radix Modes

Calc normally displays numbers in decimal (base-10 or radix-10) notation. Calc can actually display in any radix from two (binary) to 36. When the radix is above 10, the letters `A` to `Z` are used as digits. When entering such a number, letter keys are interpreted as potential digits rather than terminating numeric entry mode.

The key sequences d 2, d 8, d 6, and d 0 select binary, octal, hexadecimal, and decimal as the current display radix, respectively. Numbers can always be entered in any radix, though the current radix is used as a default if you press # without any initial digits. A number entered without a # is *always* interpreted as decimal.

To set the radix generally, use d r (`calc-radix`) and enter an integer from 2 to 36. You can specify the radix as a numeric prefix argument; otherwise you will be prompted for it.

Integers normally are displayed with however many digits are necessary to represent the integer and no more. The d z (`calc-leading-zeros`) command causes integers to be padded out with leading zeros according to the current binary word size. (See section Binary Number Functions, for a discussion of word size.) If the absolute value of the word size is w, all integers are displayed with at least enough digits to represent @c{2^w-1} (2^w)-1 in the current radix. (Larger integers will still be displayed in their entirety.)

Grouping Digits

Long numbers can be hard to read if they have too many digits. For example, the factorial of 30 is 33 digits long! Press d g (`calc-group-digits`) to enable grouping mode, in which digits are displayed in clumps of 3 or 4 (depending on the current radix) separated by commas.

The d g command toggles grouping on and off. With a numerix prefix of 0, this command displays the current state of the grouping flag; with an argument of minus one it disables grouping; with a positive argument N it enables grouping on every N digits. For floating-point numbers, grouping normally occurs only before the decimal point. A negative prefix argument -N enables grouping every N digits both before and after the decimal point.

The d , (`calc-group-char`) command allows you to choose any character as the grouping separator. The default is the comma character. If you find it difficult to read vectors of large integers grouped with commas, you may wish to use spaces or some other character instead. This command takes the next character you type, whatever it is, and uses it as the digit separator. As a special case, d , \ selects `\,' (TeX's thin-space symbol) as the digit separator.

Please note that grouped numbers will not generally be parsed correctly if re-read in textual form, say by the use of M-# y and M-# g. (See section Kill and Yank Functions, for details on these commands.) One exception is the `\,' separator, which doesn't interfere with parsing because it is ignored by TeX language mode.

Float Formats

Floating-point quantities are normally displayed in standard decimal form, with scientific notation used if the exponent is especially high or low. All significant digits are normally displayed. The commands in this section allow you to choose among several alternative display formats for floats.

The d n (`calc-normal-notation`) command selects the normal display format. All significant figures in a number are displayed. With a positive numeric prefix, numbers are rounded if necessary to that number of significant digits. With a negative numerix prefix, the specified number of significant digits less than the current precision is used. (Thus C-u -2 d n displays 10 digits if the current precision is 12.)

The d f (`calc-fix-notation`) command selects fixed-point notation. The numeric argument is the number of digits after the decimal point, zero or more. This format will relax into scientific notation if a nonzero number would otherwise have been rounded all the way to zero. Specifying a negative number of digits is the same as for a positive number, except that small nonzero numbers will be rounded to zero rather than switching to scientific notation.

The d s (`calc-sci-notation`) command selects scientific notation. A positive argument sets the number of significant figures displayed, of which one will be before and the rest after the decimal point. A negative argument works the same as for d n format. The default is to display all significant digits.

The d e (`calc-eng-notation`) command selects engineering notation. This is similar to scientific notation except that the exponent is rounded down to a multiple of three, with from one to three digits before the decimal point. An optional numeric prefix sets the number of significant digits to display, as

for d s.

It is important to distinguish between the current *precision* and the current *display format*. After the commands C-u 10 p and C-u 6 d n the Calculator computes all results to ten significant figures but displays only six. (In fact, intermediate calculations are often carried to one or two more significant figures, but values placed on the stack will be rounded down to ten figures.) Numbers are never actually rounded to the display precision for storage, except by commands like C-k and M-# y which operate on the actual displayed text in the Calculator buffer.

The d . (`calc-point-char`) command selects the character used as a decimal point. Normally this is a period; users in some countries may wish to change this to a comma. Note that this is only a display style; on entry, periods must always be used to denote floating-point numbers, and commas to separate elements in a list.

Complex Formats

There are three supported notations for complex numbers in rectangular form. The default is as a pair of real numbers enclosed in parentheses and separated by a comma: `(a,b)'. The d c (`calc-complex-notation`) command selects this style.

The other notations are d i (`calc-i-notation`), in which numbers are displayed in `a+bi' form, and d j (`calc-j-notation`) which displays the form `a+bj' preferred in some disciplines.

Complex numbers are normally entered in `(a,b)' format. If you enter `2+3i' as an algebraic formula, it will be stored as the formula `2 + 3 * i'. However, if you use = to evaluate this formula and you have not changed the variable `i', the `i' will be interpreted as `(0,1)' and the formula will be simplified to `(2,3)'. Other commands (like `calc-sin`) will *not* interpret the formula `2 + 3 * i' as a complex number. See section Variables, under "special constants."

Fraction Formats

Display of fractional numbers is controlled by the d o (`calc-over-notation`) command. By default, a number like eight thirds is displayed in the form `8:3'. The d o command prompts for a one- or two-character format. If you give one character, that character is used as the fraction separator. Common separators are `:' and `/'. (During input of numbers, the : key must be used regardless of the display format; in particular, the / is used for RPN-style division, *not* for entering fractions.)

If you give two characters, fractions use "integer-plus-fractional-part" notation. For example, the format `+/' would display eight thirds as `2+2/3'. If two colons are present in a number being entered, the number is interpreted in this form (so that the entries 2:2:3 and 8:3 are equivalent).

It is also possible to follow the one- or two-character format with a number. For example: `:10' or `+/3'. In this case, Calc adjusts all fractions that are displayed to have the specified denominator, if possible. Otherwise it adjusts the denominator to be a multiple of the specified value. For example, in `:6' mode the fraction 1:6 will be unaffected, but 2:3 will be displayed as 4:6, 1:2 will be displayed as 3:6, and 1:8 will be displayed as 3:24. Integers are also affected by this mode: 3 is displayed as 18:6. Note that the format `:1' writes fractions the same as `:', but it writes integers as n:1.

The fraction format does not affect the way fractions or integers are stored, only the way they appear the screen. The fraction format never affects floats.

HMS Formats

The d h (`calc-hms-notation`) command controls the display of HMS (hours-minutes-seconds) forms. It prompts for a string which consists basically of an "hours" marker, optional punctuation, a "minutes" marker, more optional punctuation, and a "seconds" marker. Punctuation is zero or more spaces, commas, or semicolons. The hours marker is one or more non-punctuation characters. The minutes and seconds markers must be single non-punctuation characters.

The default HMS format is `@ ' "', producing HMS values of the form `23@ 30' 15.75"'. The format `deg, ms' would display this same value as `23deg, 30m15.75s'. During numeric entry, the h or o keys are recognized as synonyms for @ regardless of display format. The m and s keys are recognized as synonyms for ' and ", respectively, but only if an @ (or h or o) has already been typed; otherwise, they have their usual meanings (m- prefix and s- prefix). Thus, 5 ", 0 @ 5 ", and 0 h 5 s are some of the ways to enter the quantity "five seconds." The ' key is recognized as "minutes" only if @ (or h or o) has already been pressed; otherwise it means to switch to algebraic entry.

Date Formats

The d d (`calc-date-notation`) command controls the display of date forms (see section Date Forms). It prompts for a string which contains letters that represent the various parts of a date and time. To show which parts should be omitted when the form represents a pure date with no time, parts of the string can be enclosed in `< >' marks. If you don't include `< >' markers in the format, Calc guesses at which parts, if any, should be omitted when formatting pure dates.

The default format is: `<H:mm:SSpp >Www Mmm D, YYYY'. An example string in this format is `3:32pm Wed Jan 9, 1991'. If you enter a blank format string, this default format is reestablished.

Calc uses `< >' notation for nameless functions as well as for dates. See section Specifying Operators. To avoid confusion with nameless functions, your date formats should avoid using the `#' character.

Date Formatting Codes

When displaying a date, the current date format is used. All characters except for letters and `<' and `>' are copied literally when dates are formatted. The portion between `< >' markers is omitted for pure dates, or included for date/time forms. Letters are interpreted according to the table below.

When dates are read in during algebraic entry, Calc first tries to match the input string to the current format either with or without the time part. The punctuation characters (including spaces) must match exactly; letter fields must correspond to suitable text in the input. If this doesn't work, Calc checks if the input is a simple number; if so, the number is interpreted as a number of days since Jan 1, 1 AD. Otherwise, Calc tries a much more relaxed and flexible algorithm which is described in the next section.

Weekday names are ignored during reading.

Two-digit year numbers are interpreted as lying in the range from 1941 to 2039. Years outside that ra are always entered and displayed in full. Year numbers with a leading `+' sign are always interpreted exactly, allowing the entry and display of the years 1 through 99 AD.

Here is a complete list of the formatting codes for dates:

Y

Year: "91" for 1991, "7" for 2007, "+23" for 23 AD.

YY

Year: "91" for 1991, "07" for 2007, "+23" for 23 AD.

BY

Year: "91" for 1991, " 7" for 2007, "+23" for 23 AD.

YYY

Year: "1991" for 1991, "23" for 23 AD.

YYYY

Year: "1991" for 1991, "+23" for 23 AD.

aa

Year: "ad" or blank.

AA

Year: "AD" or blank.

aaa

Year: "ad " or blank. (Note trailing space.)

AAA

Year: "AD " or blank.

aaaa

Year: "a.d." or blank.

AAAA

Year: "A.D." or blank.

bb

Year: "bc" or blank.

BB

Year: "BC" or blank.

bbb

Year: " bc" or blank. (Note leading space.)

BBB

Year: " BC" or blank.

bbbb

Year: "b.c." or blank.

BBBB

Year: "B.C." or blank.

M

Month: "8" for August.

MM

Month: "08" for August.

BM

Month: " 8" for August.

MMM

Month: "AUG" for August.

Mmm

Month: "Aug" for August.

mmm

Month: "aug" for August.

MMMM

Month: "AUGUST" for August.

Mmmm

Month: "August" for August.

D

Day: "7" for 7th day of month.

DD

Day: "07" for 7th day of month.

BD

Day: " 7" for 7th day of month.

W

Weekday: "0" for Sunday, "6" for Saturday.

WWW

Weekday: "SUN" for Sunday.

Www

Weekday: "Sun" for Sunday.

www

Weekday: "sun" for Sunday.

WWWW

Weekday: "SUNDAY" for Sunday.

Wwww

Weekday: "Sunday" for Sunday.

d

Day of year: "34" for Feb. 3.

ddd
: Day of year: "034" for Feb. 3.

bdd
: Day of year: " 34" for Feb. 3.

h
: Hour: "5" for 5 AM; "17" for 5 PM.

hh
: Hour: "05" for 5 AM; "17" for 5 PM.

bh
: Hour: " 5" for 5 AM; "17" for 5 PM.

H
: Hour: "5" for 5 AM and 5 PM.

HH
: Hour: "05" for 5 AM and 5 PM.

BH
: Hour: " 5" for 5 AM and 5 PM.

p
: AM/PM: "a" or "p".

P
: AM/PM: "A" or "P".

pp
: AM/PM: "am" or "pm".

PP
: AM/PM: "AM" or "PM".

pppp
: AM/PM: "a.m." or "p.m.".

PPPP
: AM/PM: "A.M." or "P.M.".

m
: Minutes: "7" for 7.

mm
: Minutes: "07" for 7.

bm
: Minutes: " 7" for 7.

s
: Seconds: "7" for 7; "7.23" for 7.23.

ss

Seconds: "07" for 7; "07.23" for 7.23.

bs

Seconds: " 7" for 7; " 7.23" for 7.23.

SS

Optional seconds: "07" for 7; blank for 0.

BS

Optional seconds: " 7" for 7; blank for 0.

N

Numeric date/time: "726842.25" for 6:00am Wed Jan 9, 1991.

n

Numeric date: "726842" for any time on Wed Jan 9, 1991.

J

Julian date/time: "2448265.75" for 6:00am Wed Jan 9, 1991.

j

Julian date: "2448266" for any time on Wed Jan 9, 1991.

U

Unix time: "663400800" for 6:00am Wed Jan 9, 1991.

X

Brackets suppression. An "X" at the front of the format causes the surrounding `< >' delimiters to be omitted when formatting dates. Note that the brackets are still required for algebraic entry.

If "SS" or "BS" (optional seconds) is preceded by a colon, the colon is also omitted if the seconds part is zero.

If "bb," "bbb" or "bbbb" or their upper-case equivalents appear in the format, then negative year numbers are displayed without a minus sign. Note that "aa" and "bb" are mutually exclusive. Some typical usages would be `YYYY AABB'; `AAAYYYYBBB'; `YYYYBBB'.

The formats "YY," "YYYY," "MM," "DD," "ddd," "hh," "HH," "mm," "ss," and "SS" actually match any number of digits during reading unless several of these codes are strung together with no punctuation in between, in which case the input must have exactly as many digits as there are letters in the format.

The "j," "J," and "U" formats do not make any time zone adjustment. They effectively use `julian(x,0)' and `unixtime(x,0)' to make the conversion; see section Date Arithmetic.

Free-Form Dates

When reading a date form during algebraic entry, Calc falls back on the algorithm described here if the input does not exactly match the current date format. This algorithm generally "does the right thing" and you don't have to worry about it, but it is described here in full detail for the curious.

Calc does not distinguish between upper- and lower-case letters while interpreting dates.

First, the time portion, if present, is located somewhere in the text and then removed. The remaining is then interpreted as the date.

A time is of the form `hh:mm:ss', possibly with the seconds part omitted and possibly with an AM/PM indicator added to indicate 12-hour time. If the AM/PM is present, the minutes may also be omitted. The AM/PM part may be any of the words `am', `pm', `noon', or `midnight'; each of these may be abbreviated to one letter, and the alternate forms `a.m.', `p.m.', and `mid' are also understood. Obviously `noon' and `midnight' are allowed only on 12:00:00. The words `noon', `mid', and `midnight' are also recognized with no number attached.

If there is no AM/PM indicator, the time is interpreted in 24-hour format.

To read the date portion, all words and numbers are isolated from the string; other characters are ignored. All words must be either month names or day-of-week names (the latter of which are ignored). Names can be written in full or as three-letter abbreviations.

Large numbers, or numbers with `+' or `-' signs, are interpreted as years. If one of the other numbers is greater than 12, then that must be the day and the remaining number in the input is therefore the month. Otherwise, Calc assumes the month, day and year are in the same order that they appear in the current date format. If the year is omitted, the current year is taken from the system clock.

If there are too many or too few numbers, or any unrecognizable words, then the input is rejected.

If there are any large numbers (of five digits or more) other than the year, they are ignored on the assumption that they are something like Julian dates that were included along with the traditional date components when the date was formatted.

One of the words `ad', `a.d.', `bc', or `b.c.' may optionally be used; the latter two are equivalent to a minus sign on the year value.

If you always enter a four-digit year, and use a name instead of a number for the month, there is no danger of ambiguity.

Standard Date Formats

There are actually ten standard date formats, numbered 0 through 9. Entering a blank line at the d d command's prompt gives you format number 1, Calc's usual format. You can enter any digit to select the other formats.

To create your own standard date formats, give a numeric prefix argument from 0 to 9 to the d d command. The format you enter will be recorded as the new standard format of that number, as well as becoming the new current date format. You can save your formats permanently with the m m command (see section Mode Settings).

0

`N' (Numerical format)

1

`<H:mm:SSpp >Www Mmm D, YYYY' (American format)

2

`D Mmm YYYY<, h:mm:SS>' (European format)

3

`Www Mmm BD< hh:mm:ss> YYYY' (Unix written date format)

4

`M/D/Y< H:mm:SSpp>' (American slashed format)

5

`D.M.Y< h:mm:SS>' (European dotted format)

6

`M-D-Y< H:mm:SSpp>' (American dashed format)

7

`D-M-Y< h:mm:SS>' (European dashed format)

8

`j<, h:mm:ss>' (Julian day plus time)

9

`YYddd< hh:mm:ss>' (Year-day format)

Truncating the Stack

The d t (`calc-truncate-stack`) command moves the `.' line that marks the top-of-stack up or down in the Calculator buffer. The number right above that line is considered to the be at the top of the stack. Any numbers below that line are "hidden" from all stack operations. This is similar to the Emacs "narrowing" feature, except that the values below the `.' are *visible*, just temporarily frozen. This feature allows you to keep several independent calculations running at once in different parts of the stack, or to apply a certain command to an element buried deep in the stack.

Pressing d t by itself moves the `.' to the line the cursor is on. Thus, this line and all those below it become hidden. To un-hide these lines, move down to the end of the buffer and press d t. With a positive numeric prefix argument n, d t hides the bottom n values in the buffer. With a negative argument, it hides all but the top n values. With an argument of zero, it hides zero values, i.e., moves the `.' all the way down to the bottom.

The d [(`calc-truncate-up`) and d] (`calc-truncate-down`) commands move the `.' up or down one line at a time (or several lines with a prefix argument).

Justification

Values on the stack are normally left-justified in the window. You can control this arrangement by typing d < (`calc-left-justify`), d > (`calc-right-justify`), or d = (`calc-center-justify`). For example, in right-justification mode, stack entries are displayed flush-right against the right edge of the window.

If you change the width of the Calculator window you may have to type d SPC (`calc-refresh`) to re-align right-justified or centered text.

Right-justification is especially useful together with fixed-point notation (see `d f`; `calc-fix-notation`). With these modes together, the decimal points on numbers will always line up.

With a numeric prefix argument, the justification commands give you a little extra control over the display. The argument specifies the horizontal "origin" of a display line. It is also possible to specify a maximum line width using the d b command (see section Normal Language Modes). For reference, the precise rules for formatting and breaking lines are given below. Notice that the interaction between origin and line width is slightly different in each justification mode.

In left-justified mode, the line is indented by a number of spaces given by the origin (default zero). If the result is longer than the maximum line width, if given, or too wide to fit in the Calc window otherwise, then it is broken into lines which will fit; each broken line is indented to the origin.

In right-justified mode, lines are shifted right so that the rightmost character is just before the origin, or just before the current window width if no origin was specified. If the line is too long for this, then it is broken; the current line width is used, if specified, or else the origin is used as a width if that is specified, or else the line is broken to fit in the window.

In centering mode, the origin is the column number of the center of each stack entry. If a line width is specified, lines will not be allowed to go past that width; Calc will either indent less or break the lines if necessary. If no origin is specified, half the line width or Calc window width is used.

Note that, in each case, if line numbering is enabled the display is indented an additional four spaces to make room for the line number. The width of the line number is taken into account when positioning according to the current Calc window width, but not when positioning by explicit origins and widths. In the latter case, the display is formatted as specified, and then uniformly shifted over four spaces to fit the line numbers.

Labels

The d { (`calc-left-label`) command prompts for a string, then displays that string to the left of every stack entry. If the entries are left-justified (see section Justification), then they will appear immediately after the label (unless you specified an origin greater than the length of the label). If the entries are centered or right-justified, the label appears on the far left and does not affect the horizontal position of the stack entry.

Give a blank string (with d { RET) to turn the label off.

The d } (`calc-right-label`) command similarly adds a label on the righthand side. It does not affect positioning of the stack entries unless they are right-justified. Also, if both a line width and an origin are given in right-justified mode, the stack entry is justified to the origin and the righthand label is justified to the line width.

One application of labels would be to add equation numbers to formulas you are manipulating in Calc and then copying into a document (possibly using Embedded Mode). The equations would typically be centered, and the equation numbers would be on the left or right as you prefer.

Language Modes

The commands in this section change Calc to use a different notation for entry and display of formulas, corresponding to the conventions of some other common language such as Pascal or TeX. Objects displayed on the stack or yanked from the Calculator to an editing buffer will be formatted in the current language; objects entered in algebraic entry or yanked from another buffer will be interpreted according to the current language.

The current language has no effect on things written to or read from the trail buffer, nor does it affect numeric entry. Only algebraic entry is affected. You can make even algebraic entry ignore the current language and use the standard notation by giving a numeric prefix, e.g., C-u '.

For example, suppose the formula `2*a[1] + atan(a[2])' occurs in a C program; elsewhere in the program you need the derivatives of this formula with respect to `a[1]' and `a[2]'. First, type d C to switch to C notation. Now use `C-u M-# g` to grab the formula into the Calculator, a d a[1] RET to differentiate with respect to the first variable, and M-# y to yank the formula for the derivative back into your C program. Press U to undo the differentiation and repeat with a d a[2] RET for the other derivative.

Without being switched into C mode first, Calc would have misinterpreted the brackets in `a[1]' and `a[2]', would not have known that `atan` was equivalent to Calc's built-in `arctan` function, and would have written the formula back with notations (like implicit multiplication) which would not have been legal for a C program.

As another example, suppose you are maintaining a C program and a TeX document, each of which needs a copy of the same formula. You can grab the formula from the program in C mode, switch to TeX mode, and yank the formula into the document in TeX math-mode format.

Language modes are selected by typing the letter d followed by a shifted letter key.

Normal Language Modes

The d N (`calc-normal-language`) command selects the usual notation for Calc formulas, as described in the rest of this manual. Matrices are displayed in a multi-line tabular format, but all other objects are written in linear form, as they would be typed from the keyboard.

The d O (`calc-flat-language`) command selects a language identical with the normal one, except that matrices are written in one-line form along with everything else. In some applications this form may be more suitable for yanking data into other buffers.

Even in one-line mode, long formulas or vectors will still be split across multiple lines if they exceed the width of the Calculator window. The d b (`calc-line-breaking`) command turns this line-breaking feature on and off. (It works independently of the current language.) If you give a numeric prefix argument of five or greater to the d b command, that argument will specify the line width used when breaking long lines.

The d B (`calc-big-language`) command selects a language which uses textual approximations to various mathematical notations, such as powers, quotients, and square roots:

```
  _____________
  | a + 1    2
  | ----- + c
\|    b
```

in place of `sqrt((a+1)/b + c^2)'.

Subscripts like `a_i' are displayed as actual subscripts in "big" mode. Double subscripts, `a_i_j' (`subscr(subscr(a, i), j)') are displayed as `a' with subscripts separated by commas: `i, j'. They must still be entered in the usual underscore notation.

One slight ambiguity of Big notation is that

```
  3
- -
  4
```

can represent either the negative rational number -3:4, or the actual expression `-(3/4)'; but the latter formula would normally never be displayed because it would immediately be evaluated to -3:4 or -0.75, so this ambiguity is not a problem in typical use.

Non-decimal numbers are displayed with subscripts. Thus there is no way to tell the difference between `16#C2' and `C2_16', though generally you will know which interpretation is correct. Logarithms `log(x,b)' and `log10(x)' also use subscripts in Big mode.

In Big mode, stack entries often take up several lines. To aid readability, stack entries are separated by a blank line in this mode. You may find it useful to expand the Calc window's height using C-x ^ (`enlarge-window`) or to make the Calc window the only one on the screen with C-x 1 (`delete-other-windows`).

Long lines are currently not rearranged to fit the window width in Big mode, so you may need to use the < and > keys to scroll across a wide formula. For really big formulas, you may even need to use { and } to scroll up and down.

The d U (`calc-unformatted-language`) command altogether disables the use of operator notation in formulas. In this mode, the formula shown above would be displayed:

```
sqrt(add(div(add(a, 1), b), pow(c, 2)))
```

These four modes differ only in display format, not in the format expected for algebraic entry. The standard Calc operators work in all four modes, and unformatted notation works in any language mode (except that Mathematica mode expects square brackets instead of parentheses).

C, FORTRAN, and Pascal Modes

The d C (`calc-c-language`) command selects the conventions of the C language for display and entry of formulas. This differs from the normal language mode in a variety of (mostly minor) ways. In particular, C language operators and operator precedences are used in place of Calc's usual ones. For example, `a^b' means `xor(a,b)' in C mode; a value raised to a power is written as a function call, `pow(a,b)'.

In C mode, vectors and matrices use curly braces instead of brackets. Octal and hexadecimal values are written with leading `0' or `0x' rather than using the `#' symbol. Array subscripting is translated into `subscr` calls, so that `a[i]' in C mode is the same as `a_i' in normal mode. Assignments turn into the `assign` function, which Calc normally displays using the `:=' symbol.

The variables `var-pi` and `var-e` would be displayed `pi' and `e' in normal mode, but in C mode they are displayed as `M_PI' and `M_E', corresponding to the names of constants typically provided in the `` `<math.h>' `` header. Functions whose names are different in C are translated automatically for entry and display purposes. For example, entering `asin(x)' will push the formula `arcsin(x)' onto the stack; this formula will be displayed as `asin(x)' as long as C mode is in effect.

The d P (`calc-pascal-language`) command selects Pascal conventions. Like C mode, Pascal mode interprets array brackets and uses a different table of operators. Hexadecimal numbers are entered and displayed with a preceding dollar sign. (Thus the regular meaning of $2 during algebraic entry does not work in Pascal mode, though $ (and $$, etc.) not followed by digits works the same as always.) No special provisions are made for other non-decimal numbers, vectors, and so on, since there is no universally accepted standard way of handling these in Pascal.

The d F (`calc-fortran-language`) command selects FORTRAN conventions. Various function names are transformed into FORTRAN equivalents. Vectors are written as `/1, 2, 3/', and may be entered this way or using square brackets. Since FORTRAN uses round parentheses for both function calls and array subscripts, Calc displays both in the same way; `a(i)' is interpreted as a function call upon reading, and subscripts must be entered as `subscr(a, i)'. Also, if the variable `a` has been declared to have type `vector` or `matrix` then `a(i)' will be parsed as a subscript. (See section Declarations.) Usually it doesn't matter, though; if you enter the subscript expression `a(i)' and Calc interprets it as a function call, you'll never know the difference unless you switch to another language mode or replace `a` with an actual vector (or unless `a` happens to be the name of a built-in function!).

Underscores are allowed in variable and function names in all of these language modes. The underscore here is equivalent to the `#' in normal mode, or to hyphens in the underlying Emacs Lisp variable names.

FORTRAN and Pascal modes normally do not adjust the case of letters in formulas. Most built-in Calc names use lower-case letters. If you use a positive numeric prefix argument with d P or d F, these modes will use upper-case letters exclusively for display, and will convert to lower-case on input. With a negative prefix, these modes convert to lower-case for display and input.

TeX Language Mode

The d T (`calc-tex-language`) command selects the conventions of "math mode" in the TeX typesetting language, by Donald Knuth. Formulas are entered and displayed in TeX notation, as in `\sin\left( a \over b \right)'. Math formulas are usually enclosed by `$ $' signs in TeX; these should be omitted when interfacing with Calc. To Calc, the `$' sign has the same meaning it always does in algebraic formulas (a reference to an existing entry on the stack).

Complex numbers are displayed as in `3 + 4i'. Fractions and quotients are written using `\over`; binomial coefficients are written with `\choose`. Interval forms are written with `\ldots`, and error forms are written with `\pm`. Absolute values are written as in `|x + 1|', and the floor and ceiling functions are written with `\lfloor`, `\rfloor`, etc. The words `\left` and `\right` are ignored when reading formulas in TeX mode. Both `inf` and `uinf` are written as `\infty`; when read, `\infty` always translates to `inf`.

Function calls are written the usual way, with the function name followed by the arguments in parentheses. However, functions for which TeX has special names (like `\sin`) will use curly braces instead of parentheses for very simple arguments. During input, curly braces and parentheses work equally well for grouping, but when the document is formatted the curly braces will be invisible. Thus the printed result is sin 2x but @c{$\sin(2 + x)$} sin(2 + x).

Function and variable names not treated specially by TeX are simply written out as-is, which will cause them to come out in italic letters in the printed document. If you invoke d T with a positive numeric prefix argument, names of more than one character will instead be written `\hbox{name}'. The `\hbox{ }' notation is ignored during reading. If you use a negative prefix argument, such function names are written `\name', and function names that begin with \ during reading have the \ removed. (Note that in this mode, long variable names are still written with `\hbox`. However, you can always make an actual variable name like `\bar` in any TeX mode.)

During reading, text of the form `\matrix{ ... }' is replaced by `[...]'. The same also applies to `\pmatrix` and `\bmatrix`. The symbol `&' is interpreted as a comma, and the symbols `\cr' and `\\' are interpreted as semicolons. During output, matrices are displayed in `\matrix{ a & b \\ c & d}' format; you may need to edit this afterwards to change `\matrix` to `\pmatrix` or `\\` to `\cr`.

Accents like `\tilde` and `\bar` translate into function calls internally (`tilde(x)', `bar(x)'). The `\underline` sequence is treated as an accent. The `\vec` accent corresponds to the function name `Vec`, because `vec` is the name of a built-in Calc function. The following table shows the accents in Calc, TeX, and eqn (described in the next section):

@begingroup @let@calcindexershow=@calcindexernoshow
@let@calcindexersh=@calcindexernoshow @endgroup

Calc	TeX	eqn
acute	\acute	
bar	\bar	bar
breve	\breve	

```
check     \check
dot       \dot          dot
dotdot    \ddot         dotdot
dyad                    dyad
grave     \grave
hat       \hat          hat
Prime                   prime
tilde     \tilde        tilde
under     \underline    under
Vec       \vec          vec
```

The `=>' (evaluates-to) operator appears as a `\to` symbol: `{a \to b}'. TeX defines `\to` as an alias for `\rightarrow`. However, if the `=>' is the top-level expression being formatted, a slightly different notation is used: `\evalto a \to b'. The `\evalto` word is ignored by Calc's input routines, and is undefined in TeX. You will typically want to include one of the following definitions at the top of a TeX file that uses `\evalto`:

```
\def\evalto{}
\def\evalto#1\to{}
```

The first definition formats evaluates-to operators in the usual way. The second causes only the b part to appear in the printed document; the a part and the arrow are hidden. Another definition you may wish to use is `\let\to=\Rightarrow' which causes `\to` to appear more like Calc's `=>' symbol. See section The Evaluates-To Operator, for a discussion of `evalto`.

The complete set of TeX control sequences that are ignored during reading is:

```
\hbox  \mbox  \text  \left  \right
\,  \>  \:  \;  \!  \quad  \qquad  \hfil  \hfill
\displaystyle  \textstyle  \dsize  \tsize
\scriptstyle  \scriptscriptstyle  \ssize  \ssize
\rm  \bf  \it  \sl  \roman  \bold  \italic  \slanted
\cal  \mit  \Cal  \Bbb  \frak  \goth
\evalto
```

Note that, because these symbols are ignored, reading a TeX formula into Calc and writing it back out may lose spacing and font information.

Also, the "discretionary multiplication sign" `\*' is read the same as `*'.

Here are some examples of how various Calc formulas are formatted in TeX:

```
sin(a^2 / b_i)
\sin\left( {a^2 \over b_i} \right)

[(3, 4), 3:4, 3 +/- 4, [3 .. inf)]
```

```
[3 + 4i, {3 \over 4}, 3 \pm 4, [3 \ldots \infty)]

[abs(a), abs(a / b), floor(a), ceil(a / b)]
[|a|, \left| a \over b \right|,
 \lfloor a \rfloor, \left\lceil a \over b \right\rceil]

[sin(a), sin(2 a), sin(2 + a), sin(a / b)]
[\sin{a}, \sin{2 a}, \sin(2 + a),
 \sin\left( {a \over b} \right)]
```

First with plain d T, then with C-u d T, then finally with C-u - d T (using the example definition `\def\foo#1{\tilde F(#1)}':

```
[f(a), foo(bar), sin(pi)]
[f(a), foo(bar), \sin{\pi}]
[f(a), \hbox{foo}(\hbox{bar}), \sin{\pi}]
[f(a), \foo{\hbox{bar}}, \sin{\pi}]
```

First with `\def\evalto{}', then with `\def\evalto#1\to{}':

```
2 + 3 => 5
\evalto 2 + 3 \to 5
```

First with standard `\to`, then with `\let\to\Rightarrow':

```
[2 + 3 => 5, a / 2 => (b + c) / 2]
[{2 + 3 \to 5}, {{a \over 2} \to {b + c \over 2}}]
```

Matrices normally, then changing `\matrix` to `\pmatrix`:

```
[ [ a / b, 0 ], [ 0, 2^(x + 1) ] ]
\matrix{ {a \over b} & 0 \\ 0 & 2^{(x + 1)} }
\pmatrix{ {a \over b} & 0 \\ 0 & 2^{(x + 1)} }
```

Eqn Language Mode

Eqn is another popular formatter for math formulas. It is designed for use with the TROFF text formatter, and comes standard with many versions of Unix. The d E (`calc-eqn-language`) command selects eqn notation.

The eqn language's main idiosyncrasy is that whitespace plays a significant part in the parsing of the language. For example, `sqrt x+1 + y' treats `x+1' as the argument of the `sqrt` operator. Eqn also

understands more conventional grouping using curly braces: `sqrt{x+1} + y'. Braces are required only when the argument contains spaces.

In Calc's eqn mode, however, curly braces are required to delimit arguments of operators like `sqrt`. The first of the above examples would treat only the `x' as the argument of `sqrt`, and in fact `sin x+1' would be interpreted as `sin * x + 1', because `sin` is not a special operator in the eqn language. If you always surround the argument with curly braces, Calc will never misunderstand.

Calc also understands parentheses as grouping characters. Another peculiarity of eqn's syntax makes it advisable to separate words with spaces from any surrounding characters that aren't curly braces, so Calc writes `sin ( x + y )' in eqn mode. (The spaces around `sin` are important to make eqn recognize that `sin` should be typeset in a roman font, and the spaces around `x` and `y` are a good idea just in case the eqn document has defined special meanings for these names, too.)

Powers and subscripts are written with the `sub` and `sup` operators, respectively. Note that the caret symbol `^' is treated the same as a space in eqn mode, as is the `~' symbol (these are used to introduce spaces of various widths into the typeset output of eqn).

As in TeX mode, Calc's formatter omits parentheses around the arguments of functions like `ln` and `sin` if they are "simple-looking"; in this case Calc surrounds the argument with braces, separated by a `~' from the function name: `sin~{x}'.

Font change codes (like `roman x') and positioning codes (like `~' and `down n x') are ignored by the eqn reader. Also ignored are the words `left`, `right`, `mark`, and `lineup`. Quotation marks in eqn mode input are treated the same as curly braces: `sqrt "1+x"' is equivalent to `sqrt {1+x}'; this is only an approximation to the true meaning of quotes in eqn, but it is good enough for most uses.

Accent codes (`x dot') are handled by treating them as function calls (`dot(x)') internally. See section TeX Language Mode for a table of these accent functions. The `prime` accent is treated specially if it occurs on a variable or function name: `f prime prime ( x prime )' is stored internally as `f''(x')'. For example, taking the derivative of `f(2 x)' with a d x will produce `2 f'(2 x)', which eqn mode will display as `2 f prime (2 x)'.

Assignments are written with the `<-' (left-arrow) symbol, and `evalto` operators are written with `->' or `evalto ... ->' (see section TeX Language Mode, for a discussion of this). The regular Calc symbols `:=' and `=>' are also recognized for these operators during reading.

Vectors in eqn mode use regular Calc square brackets, but matrices are formatted as `matrix { ccol { a above b } ... }'. The words `lcol` and `rcol` are recognized as synonyms for `ccol` during input, and are generated instead of `ccol` if the matrix justification mode so specifies.

Mathematica Language Mode

The d M (`calc-mathematica-language`) command selects the conventions of Mathematica, a powerful and popular mathematical tool from Wolfram Research, Inc. Notable differences in Mathematica mode are that the names of built-in functions are capitalized, and function calls use square brackets instead of parentheses. Thus the Calc formula `sin(2 x)' is entered and displayed `Sin[2 x]' in Mathematica mode.

Vectors and matrices use curly braces in Mathematica. Complex numbers are written `3 + 4 I'. The standard special constants in Calc are written `Pi`, `E`, `I`, `GoldenRatio`, `EulerGamma`, `Infinity`, `ComplexInfinity`, and `Indeterminate` in Mathematica mode. Non-decimal numbers are written, e.g., `16^^7fff'. Floating-point numbers in scientific notation are written `1.23*10.^3'. Subscripts use double square brackets: `a[[i]]'.

Maple Language Mode

The d W (`calc-maple-language`) command selects the conventions of Maple, another mathematical tool from the University of Waterloo.

Maple's language is much like C. Underscores are allowed in symbol names; square brackets are used for subscripts; explicit `*'s for multiplications are required. Use either `^' or `**' to denote powers.

Maple uses square brackets for lists and curly braces for sets. Calc interprets both notations as vectors, and displays vectors with square brackets. This means Maple sets will be converted to lists when they pass through Calc. As a special case, matrices are written as calls to the function `matrix`, given a list of lists as the argument, and can be read in this form or with all-capitals `MATRIX`.

The Maple interval notation `2 .. 3' has no surrounding brackets; Calc reads `2 .. 3' as the closed interval `[2 .. 3]', and writes any kind of interval as `2 .. 3'. This means you cannot see the difference between an open and a closed interval while in Maple display mode.

Maple writes complex numbers as `3 + 4*I'. Its special constants are `Pi`, `E`, `I`, and `infinity` (all three of `inf`, `uinf`, and `nan` display as `infinity`). Floating-point numbers are written `1.23*10.^3'.

Among things not currently handled by Calc's Maple mode are the various quote symbols, procedures and functional operators, and inert (`&') operators.

Compositions

There are several composition functions which allow you to get displays in a variety of formats similar to those in Big language mode. Most of these functions do not evaluate to anything; they are placeholders which are left in symbolic form by Calc's evaluator but are recognized by Calc's display formatting routines.

Two of these, `string` and `bstring`, are described elsewhere. See section Strings. For example, `string("ABC")' is displayed as `ABC'. When viewed on the stack it will be indistinguishable from the variable `ABC`, but internally it will be stored as `string([65, 66, 67])' and can still be manipulated this way; for example, the selection and vector commands j 1 v v j u would select the vector portion of this object and reverse the elements, then deselect to reveal a string whose characters had been reversed.

The composition functions do the same thing in all language modes (although their components will of course be formatted in the current language mode). The one exception is Unformatted mode (d U), which does not give the composition functions any special treatment. The functions are discussed here because of their relationship to the language modes.

Composition Basics

Compositions are generally formed by stacking formulas together horizontally or vertically in various ways. Those formulas are themselves compositions. TeX users will find this analogous to TeX's "boxes." Each multi-line composition has a baseline; horizontal compositions use the baselines to decide how formulas should be positioned relative to one another. For example, in the Big mode formula

```
           2
      a + b
17 + ------
       c
```

the second term of the sum is four lines tall and has line three as its baseline. Thus when the term is combined with 17, line three is placed on the same level as the baseline of 17.

Another important composition concept is precedence. This is an integer that represents the binding strength of various operators. For example, `*' has higher precedence (195) than `+' (180), which means that `(a * b) + c' will be formatted without the parentheses, but `a * (b + c)' will keep the parentheses.

The operator table used by normal and Big language modes has the following precedences:

```
_       1200   (subscripts)
%       1100   (as in n%)
-       1000   (as in -n)
!       1000   (as in !n)
mod      400
+/-      300
!!       210    (as in n!!)
!        210    (as in n!)
^        200
*        195    (or implicit multiplication)
/ % \    190
+ -      180    (as in a+b)
|        170
< =      160    (and other relations)
&&       110
||       100
? :       90
!!!       85
&&&       80
|||       75
:=        50
::        45
=>        40
```

The general rule is that if an operator with precedence n occurs as an argument to an operator with precedence m, then the argument is enclosed in parentheses if n < m. Top-level expressions and

expressions which are function arguments, vector components, etc., are formatted with precedence z
(so that they normally never get additional parentheses).

For binary left-associative operators like `+', the righthand argument is actually formatted with one-higher precedence than shown in the table. This makes sure `(a + b) + c' omits the parentheses, but the unnatural form `a + (b + c)' keeps its parentheses. Right-associative operators like `^' format the lefthand argument with one-higher precedence.

The `cprec` function formats an expression with an arbitrary precedence. For example, `cprec(abc, 185)' will combine into sums and products as follows: `7 + abc', `7 (abc)' (because this `cprec` form has higher precedence than addition, but lower precedence than multiplication).

A final composition issue is line breaking. Calc uses two different strategies for "flat" and "non-flat" compositions. A non-flat composition is anything that appears on multiple lines (not counting line breaking). Examples would be matrices and Big mode powers and quotients. Non-flat compositions are displayed exactly as specified. If they come out wider than the current window, you must use horizontal scrolling (< and >) to view them.

Flat compositions, on the other hand, will be broken across several lines if they are too wide to fit the window. Certain points in a composition are noted internally as break points. Calc's general strategy is to fill each line as much as possible, then to move down to the next line starting at the first break point that didn't fit. However, the line breaker understands the hierarchical structure of formulas. It will not break an "inner" formula if it can use an earlier break point from an "outer" formula instead. For example, a vector of sums might be formatted as:

```
[ a + b + c, d + e + f,
  g + h + i, j + k + l, m ]
```

If the `m' can fit, then so, it seems, could the `g'. But Calc prefers to break at the comma since the comma is part of a "more outer" formula. Calc would break at a plus sign only if it had to, say, if the very first sum in the vector had itself been too large to fit.

Of the composition functions described below, only `choriz` generates break points. The `bstring` function (see section Strings) also generates breakable items: A break point is added after every space (or group of spaces) except for spaces at the very beginning or end of the string.

Composition functions themselves count as levels in the formula hierarchy, so a `choriz` that is a component of a larger `choriz` will be less likely to be broken. As a special case, if a `bstring` occurs as a component of a `choriz` or `choriz`-like object (such as a vector or a list of arguments in a function call), then the break points in that `bstring` will be on the same level as the break points of the surrounding object.

Horizontal Compositions

The `choriz` function takes a vector of objects and composes them horizontally. For example, `choriz([17, a b/c, d])' formats as `17a b / cd' in normal language mode, or as

```
a b
```

```
17--d
   c
```

in Big language mode. This is actually one case of the general function `choriz(vec, sep, prec)', where either or both of sep and prec may be omitted. Prec gives the precedence to use when formatting each of the components of vec. The default precedence is the precedence from the surrounding environment.

Sep is a string (i.e., a vector of character codes as might be entered with `" "` notation) which should separate components of the composition. Also, if sep is given, the line breaker will allow lines to be broken after each occurrence of sep. If sep is omitted, the composition will not be breakable (unless any of its component compositions are breakable).

For example, `2 choriz([a, b c, d = e], " + ", 180)' is formatted as `2 a + b c + (d = e)'. To get the `choriz` to have precedence 180 "outwards" as well as "inwards," enclose it in a `cprec` form: `2 cprec(choriz(...), 180)' formats as `2 (a + b c + (d = e))'.

The baseline of a horizontal composition is the same as the baselines of the component compositions, which are all aligned.

Vertical Compositions

The `cvert` function makes a vertical composition. Each component of the vector is centered in a column. The baseline of the result is by default the top line of the resulting composition. For example, `f(cvert([a, bb, ccc]), cvert([a^2 + 1, b^2]))' formats in Big mode as

```
f( a ,  2    )
  bb   a  + 1
  ccc     2
         b
```

There are several special composition functions that work only as components of a vertical composition. The `cbase` function controls the baseline of the vertical composition; the baseline will be the same as the baseline of whatever component is enclosed in `cbase`. Thus `f(cvert([a, cbase(bb), ccc]), cvert([a^2 + 1, cbase(b^2)]))' displays as

```
         2
       a  + 1
   a       2
f(bb ,   b   )
  ccc
```

There are also `ctbase` and `cbbase` functions which make the baseline of the vertical composition equal to the top or bottom line (rather than the baseline) of that component. Thus `cvert([cbase(a / b)]) + cvert([ctbase(a / b)]) + cvert([cbbase(a / b)])' gives

```
        a
a       -
```

```
- + a + b
b   -
    b
```

There should be only one `cbase`, `ctbase`, or `cbbase` function in a given vertical composition. These functions can also be written with no arguments: `ctbase()' is a zero-height object which means the baseline is the top line of the following item, and `cbbase()' means the baseline is the bottom line of the preceding item.

The `crule` function builds a "rule," or horizontal line, across a vertical composition. By itself `crule()' uses `-' characters to build the rule. You can specify any other character, e.g., `crule("=")'. The argument must be a character code or vector of exactly one character code. It is repeated to match the width of the widest item in the stack. For example, a quotient with a thick line is `cvert([a + 1, cbase(crule("=")), b^2])':

```
a + 1
=====
  2
 b
```

Finally, the functions `clvert` and `crvert` act exactly like `cvert` except that the items are left- or right-justified in the stack. Thus `clvert([a, bb, ccc]) + crvert([a, bb, ccc])' gives:

```
a   +   a
bb     bb
ccc   ccc
```

Like `choriz`, the vertical compositions accept a second argument which gives the precedence to use when formatting the components. Vertical compositions do not support separator strings.

Other Compositions

The `csup` function builds a superscripted expression. For example, `csup(a, b)' looks the same as `a^b' does in Big language mode. This is essentially a horizontal composition of `a' and `b', where `b' is shifted up so that its bottom line is one above the baseline.

Likewise, the `csub` function builds a subscripted expression. This shifts `b' down so that its top line is one below the bottom line of `a' (note that this is not quite analogous to `csup`). Other arrangements can be obtained by using `choriz` and `cvert` directly.

The `cflat` function formats its argument in "flat" mode, as obtained by `d O', if the current language mode is normal or Big. It has no effect in other language modes. For example, `a^(b/c)' is formatted by Big mode like `csup(a, cflat(b/c))' to improve its readability.

The `cspace` function creates horizontal space. For example, `cspace(4)' is effectively the same as `string("   ")'. A second string (i.e., vector of characters) argument is repeated instead of the space character. For example, `cspace(4, "ab")' looks like `abababab'. If the second argument is not a string, it is formatted in the normal way and then several copies of that are composed together: `cspace(4, a^2)'

yields

```
 2 2 2 2
a a a a
```

If the number argument is zero, this is a zero-width object.

The `cvspace` function creates vertical space, or a vertical stack of copies of a certain string or formatted object. The baseline is the center line of the resulting stack. A numerical argument of zero will produce an object which contributes zero height if used in a vertical composition.

There are also `ctspace` and `cbspace` functions which create vertical space with the baseline the same as the baseline of the top or bottom copy, respectively, of the second argument. Thus `cvspace(2, a/b) + ctspace(2, a/b) + cbspace(2, a/b)' displays as:

```
          a
          -
a         b
-    a    a
b + - + -
a    b    b
-    a
b    -
     b
```

Information about Compositions

The functions in this section are actual functions; they compose their arguments according to the current language and other display modes, then return a certain measurement of the composition as an integer.

The `cwidth` function measures the width, in characters, of a composition. For example, `cwidth(a + b)' is 5, and `cwidth(a / b)' is 5 in normal mode, 1 in Big mode, and 11 in TeX mode (for `{a \over b}'). The argument may involve the composition functions described in this section.

The `cheight` function measures the height of a composition. This is the total number of lines in the argument's printed form.

The functions `cascent` and `cdescent` measure the amount of the height that is above (and including) the baseline, or below the baseline, respectively. Thus `cascent(x) + cdescent(x)' always equals `cheight(x)'. For a one-line formula like `a + b', `cascent` returns 1 and `cdescent` returns 0. For `a / b' in Big mode, `cascent` returns 2 and `cdescent` returns 1. The only formula for which `cascent` will return zero is `cvspace(0)' or equivalents.

User-Defined Compositions

The Z C (`calc-user-define-composition`) command lets you define the display format for any algebraic function. You provide a formula containing a certain number of argument variables on the

stack. Any time Calc formats a call to the specified function in the current language mode and with the number of arguments, Calc effectively replaces the function call with that formula with the arguments replaced.

Calc builds the default argument list by sorting all the variable names that appear in the formula into alphabetical order. You can edit this argument list before pressing RET if you wish. Any variables in the formula that do not appear in the argument list will be displayed literally; any arguments that do not appear in the formula will not affect the display at all.

You can define formats for built-in functions, for functions you have defined with Z F (see section Programming with Formulas), or for functions which have no definitions but are being used as purely syntactic objects. You can define different formats for each language mode, and for each number of arguments, using a succession of Z C commands. When Calc formats a function call, it first searches for a format defined for the current language mode (and number of arguments); if there is none, it uses the format defined for the Normal language mode. If neither format exists, Calc uses its built-in standard format for that function (usually just `func(args)').

If you execute Z C with the number 0 on the stack instead of a formula, any defined formats for the function in the current language mode will be removed. The function will revert to its standard format.

For example, the default format for the binomial coefficient function `choose(n, m)' in the Big language mode is

```
 n
( )
 m
```

You might prefer the notation,

```
 C
n m
```

To define this notation, first make sure you are in Big mode, then put the formula

```
choriz([cvert([cvspace(1), n]), C, cvert([cvspace(1), m])])
```

on the stack and type Z C. Answer the first prompt with `choose`. The second prompt will be the default argument list of `(C m n)'. Edit this list to be `(n m)' and press RET. Now, try it out: For example, turn simplification off with m O and enter `choose(a,b) + choose(7,3)' as an algebraic entry.

```
 C  +  C
a b   7 3
```

As another example, let's define the usual notation for Stirling numbers of the first kind, `stir1(n, m)'. This is just like the regular format for binomial coefficients but with square brackets instead of parentheses.

```
choriz([string("["), cvert([n, cbase(cvspace(1)), m]), string("]")]
```

Now type Z C stir1 RET, edit the argument list to `(n m)', and type RET.

The formula provided to Z C usually will involve composition functions, but it doesn't have to. Putting the formula `a + b + c' onto the stack and typing Z C foo RET RET would define the function `foo(x,y,z)' to display like `x + y + z'. This "sum" will act exactly like a real sum for all formatting purposes (it will be parenthesized the same, and so on). However it will be computationally unrelated to a sum. For example, the formula `2 * foo(1, 2, 3)' will display as `2 (1 + 2 + 3)'. Operator precedences have caused the "sum" to be written in parentheses, but the arguments have not actually been summed. (Generally a display format like this would be undesirable, since it can easily be confused with a real sum.)

The special function `eval` can be used inside a Z C composition formula to cause all or part of the formula to be evaluated at display time. For example, if the formula is `a + eval(b + c)', then `foo(1, 2, 3)' will be displayed as `1 + 5'. Evaluation will use the default simplifications, regardless of the current simplification mode. There are also `evalsimp` and `evalextsimp` which simplify as if by a s and a e (respectively). Note that these "functions" operate only in the context of composition formulas (and also in rewrite rules, where they serve a similar purpose; see section Rewrite Rules). On the stack, a call to `eval` will be left in symbolic form.

It is not a good idea to use `eval` except as a last resort. It can cause the display of formulas to be extremely slow. For example, while `eval(a + b)' might seem quite fast and simple, there are several situations where it could be slow. For example, `a' and/or `b' could be polar complex numbers, in which case doing the sum requires trigonometry. Or, `a' could be the factorial `fact(100)' which is unevaluated because you have typed m O; `eval` will evaluate it anyway to produce a large, unwieldy integer.

You can save your display formats permanently using the Z P command (see section Creating User Keys).

Syntax Tables

Syntax tables do for input what compositions do for output: They allow you to teach custom notations to Calc's formula parser. Calc keeps a separate syntax table for each language mode.

(Note that the Calc "syntax tables" discussed here are completely unrelated to the syntax tables described in the Emacs manual.)

The Z S (`calc-edit-user-syntax`) command edits the syntax table for the current language mode. If you want your syntax to work in any language, define it in the normal language mode. Type M-# M-# to finish editing the syntax table, or M-# x to cancel the edit. The m m command saves all the syntax tables along with the other mode settings; see section General Mode Commands.

Syntax Table Basics

Parsing is the process of converting a raw string of characters, such as you would type in during algebraic entry, into a Calc formula. Calc's parser works in two stages. First, the input is broken down into tokens, such as words, numbers, and punctuation symbols like `+', `:=', and `+/-'. Space between tokens is ignored (except when it serves to separate adjacent words). Next, the parser matches this string

of tokens against various built-in syntactic patterns, such as "an expression followed by `+' followed another expression" or "a name followed by `(', zero or more expressions separated by commas, and

A syntax table is a list of user-defined syntax rules, which allow you to specify new patterns to define your own favorite input notations. Calc's parser always checks the syntax table for the current language mode, then the table for the normal language mode, before it uses its built-in rules to parse an algebraic formula you have entered. Each syntax rule should go on its own line; it consists of a pattern, a `:=' symbol, and a Calc formula with an optional condition. (Syntax rules resemble algebraic rewrite rules, but the notation for patterns is completely different.)

A syntax pattern is a list of tokens, separated by spaces. Except for a few special symbols, tokens in syntax patterns are matched literally, from left to right. For example, the rule,

```
foo ( ) := 2+3
```

would cause Calc to parse the formula `4+foo()*5' as if it were `4+(2+3)*5'. Notice that the parentheses were written as two separate tokens in the rule. As a result, the rule works for both `foo()' and `foo ( )'. If we had written the rule as `foo () := 2+3', then Calc would treat `()' as a single, indivisible token, so that `foo( )' would not be recognized by the rule. (It would be parsed as a regular zero-argument function call instead.) In fact, this rule would also make trouble for the rest of Calc's parser: An unrelated formula like `bar()' would now be tokenized into `bar ()' instead of `bar ( )', so that the standard parser for function calls would no longer recognize it!

While it is possible to make a token with a mixture of letters and punctuation symbols, this is not recommended. It is better to break it into several tokens, as we did with `foo()' above.

The symbol `#' in a syntax pattern matches any Calc expression. On the righthand side, the things that matched the `#'s can be referred to as `#1', `#2', and so on (where `#1' matches the leftmost `#' in the pattern). For example, these rules match a user-defined function, prefix operator, infix operator, and postfix operator, respectively:

```
foo ( # ) := myfunc(#1)
foo # := myprefix(#1)
# foo # := myinfix(#1,#2)
# foo := mypostfix(#1)
```

Thus `foo(3)' will parse as `myfunc(3)', and `2+3 foo' will parse as `mypostfix(2+3)'.

It is important to write the first two rules in the order shown, because Calc tries rules in order from first to last. If the pattern `foo #' came first, it would match anything that could match the `foo (#)' rule, since an expression in parentheses is itself a valid expression. Thus the `foo ( # )' rule would never get to match anything. Likewise, the last two rules must be written in the order shown or else `3 foo 4' will be parsed as `mypostfix(3) * 4'. (Of course, the best way to avoid these ambiguities is not to use the same symbol in more than one way at the same time! In case you're not convinced, try the following exercise: How will the above rules parse the input `foo(3,4)', if at all? Work it out for yourself, then try it in Calc and see.)

Calc is quite flexible about what sorts of patterns are allowed. The only rule is that every pattern must

begin with a literal token (like `foo' in the first two patterns above), or with a `#' followed by a literal token (as in the last two patterns). After that, any mixture is allowed, although putting two `#'s in a r will not be very useful since two expressions with nothing between them will be parsed as one expression that uses implicit multiplication.

As a more practical example, Maple uses the notation `sum(a(i), i=1..10)' for sums, which Calc's Maple mode doesn't recognize at present. To handle this syntax, we simply add the rule,

```
sum ( # , # = # .. # ) := sum(#1,#2,#3,#4)
```

to the Maple mode syntax table. As another example, C mode can't read assignment operators like `++' and `*='. We can define these operators quite easily:

```
# *= # := muleq(#1,#2)
# ++ := postinc(#1)
++ # := preinc(#1)
```

To complete the job, we would use corresponding composition functions and Z C to cause these functions to display in their respective Maple and C notations. (Note that the C example ignores issues of operator precedence, which are discussed in the next section.)

You can enclose any token in quotes to prevent its usual interpretation in syntax patterns:

```
# ":=" # := becomes(#1,#2)
```

Quotes also allow you to include spaces in a token, although once again it is generally better to use two tokens than one token with an embedded space. To include an actual quotation mark in a quoted token, precede it with a backslash. (This also works to include backslashes in tokens.)

```
# "bad token" # "/\"\\" # := silly(#1,#2,#3)
```

This will parse `3 bad token 4 /"\ 5' to `silly(3,4,5)'.

The token # has a predefined meaning in Calc's formula parser; it is not legal to use `"#"' in a syntax rule. However, longer tokens that include the `#' character are allowed. Also, while `"$"' and `"\""' are allowed as tokens, their presence in the syntax table will prevent those characters from working in their usual ways (referring to stack entries and quoting strings, respectively).

Finally, the notation `%%' anywhere in a syntax table causes the rest of the line to be ignored as a comment.

Precedence

Different operators are generally assigned different precedences. By default, an operator defined by a rule like

```
# foo # := foo(#1,#2)
```

will have an extremely low precedence, so that `2*3+4 foo 5 == 6' will be parsed as `(2*3+4) foo (5 == 6)'. To change the precedence of an operator, use the notation `#/p' in place of `#', where p is an integer precedence level. For example, 185 lies between the precedences for `+' and `*', so if we change this rule to

```
#/185 foo #/186 := foo(#1,#2)
```

then `2+3 foo 4*5' will be parsed as `2+(3 foo (4*5))'. Also, because we've given the righthand expression slightly higher precedence, our new operator will be left-associative: `1 foo 2 foo 3' will be parsed as `(1 foo 2) foo 3'. By raising the precedence of the lefthand expression instead, we can create a right-associative operator.

See section Composition Basics, for a table of precedences of the standard Calc operators. For the precedences of operators in other language modes, look in the Calc source file `calc-lang.el'.

Advanced Syntax Patterns

To match a function with a variable number of arguments, you could write

```
foo ( # ) := myfunc(#1)
foo ( # , # ) := myfunc(#1,#2)
foo ( # , # , # ) := myfunc(#1,#2,#3)
```

but this isn't very elegant. To match variable numbers of items, Calc uses some notations inspired regular expressions and the "extended BNF" style used by some language designers.

```
foo ( { # }*, ) := apply(myfunc,#1)
```

The token `{' introduces a repeated or optional portion. One of the three tokens `}*', `}+', or `}?' ends the portion. These will match zero or more, one or more, or zero or one copies of the enclosed pattern, respectively. In addition, `}*' and `}+' can be followed by a separator token (with no space in between, as shown above). Thus `{ # }*,' matches nothing, or one expression, or several expressions separated by commas.

A complete `{ ... }' item matches as a vector of the items that matched inside it. For example, the above rule will match `foo(1,2,3)' to get `apply(myfunc,[1,2,3])'. The Calc `apply` function takes a function name and a vector of arguments and builds a call to the function with those arguments, so the net result is the formula `myfunc(1,2,3)'.

If the body of a `{ ... }' contains several `#'s (or nested `{ ... }' constructs), then the items will be strung together into the resulting vector. If the body does not contain anything but literal tokens, the result will always be an empty vector.

```
foo ( { # , # }+, ) := bar(#1)
foo ( { { # }*, }*; ) := matrix(#1)
```

will parse `foo(1,2,3,4)' as `bar([1,2,3,4])', and `foo(1,2;3,4)' as `matrix([[1,2],[3,4]])'. Also, after some

thought it's easy to see how this pair of rules will parse `foo(1,2,3)' as `matrix([[1,2,3]])', since the first rule will only match an even number of arguments. The rule

```
foo ( # { , # , # }? ) := bar(#1,#2)
```

will parse `foo(2,3,4)' as `bar(2,[3,4])', and `foo(2)' as `bar(2,[])'.

The notation `{ ... }?.' (note the trailing period) works just the same as regular `{ ... }?', except that it does not count as an argument; the following two rules are equivalent:

```
foo ( # , { also }? # ) := bar(#1,#3)
foo ( # , { also }?. # ) := bar(#1,#2)
```

Note that in the first case the optional text counts as `#2', which will always be an empty vector, but in the second case no empty vector is produced.

Another variant is `{ ... }?$', which means the body is optional only at the end of the input formula. All built-in syntax rules in Calc use this for closing delimiters, so that during algebraic entry you can type [sqrt(2), sqrt(3 RET, omitting the closing parenthesis and bracket. Calc does this automatically for trailing `)', `]', and `>' tokens in syntax rules, but you can use `{ ... }?$' explicitly to get this effect with any token (such as `"}"' or `end'). Like `{ ... }?.', this notation does not count as an argument. Conversely, you can use quotes, as in `")"', to prevent a closing-delimiter token from being automatically treated as optional.

Calc's parser does not have full backtracking, which means some patterns will not work as you might expect:

```
foo ( { # , }? # , # ) := bar(#1,#2,#3)
```

Here we are trying to make the first argument optional, so that `foo(2,3)' parses as `bar([],2,3)'. Unfortunately, Calc first tries to match `2,' against the optional part of the pattern, finds a match, and so goes ahead to match the rest of the pattern. Later on it will fail to match the second comma, but it doesn't know how to go back and try the other alternative at that point. One way to get around this would be to use two rules:

```
foo ( # , # , # ) := bar([#1],#2,#3)
foo ( # , # ) := bar([],#1,#2)
```

More precisely, when Calc wants to match an optional or repeated part of a pattern, it scans forward attempting to match that part. If it reaches the end of the optional part without failing, it "finalizes" its choice and proceeds. If it fails, though, it backs up and tries the other alternative. Thus Calc has "partial" backtracking. A fully backtracking parser would go on to make sure the rest of the pattern matched before finalizing the choice.

Conditional Syntax Rules

It is possible to attach a condition to a syntax rule. For example, the rules

```
foo ( # ) := ifoo(#1) :: integer(#1)
foo ( # ) := gfoo(#1)
```

will parse `foo(3)' as `ifoo(3)', but will parse `foo(3.5)' and `foo(x)' as calls to `gfoo'. Any number of conditions may be attached; all must be true for the rule to succeed. A condition is "true" if it evaluates to a nonzero number. See section Logical Operations, for a list of Calc functions like `integer' that perform logical tests.

The exact sequence of events is as follows: When Calc tries a rule, it first matches the pattern as usual. It then substitutes `#1', `#2', etc., in the conditions, if any. Next, the conditions are simplified and evaluated in order from left to right, as if by the a s algebra command (see section Simplifying Formulas). Each result is true if it is a nonzero number, or an expression that can be proven to be nonzero (see section Declarations). If the results of all conditions are true, the expression (such as `ifoo(#1)') has its `#'s substituted, and that is the result of the parse. If the result of any condition is false, Calc goes on to try the next rule in the syntax table.

Syntax rules also support `let' conditions, which operate in exactly the same way as they do in algebraic rewrite rules. See section Other Features of Rewrite Rules, for details. A `let' condition is always true, but as a side effect it defines a variable which can be used in later conditions, and also in the expression after the `:=' sign:

```
foo ( # ) := hifoo(x) :: let(x := #1 + 0.5) :: dnumint(x)
```

The `dnumint' function tests if a value is numerically an integer, i.e., either a true integer or an integer-valued float. This rule will parse `foo' with a half-integer argument, like `foo(3.5)', to a call like `hifoo(4.)'.

The lefthand side of a syntax rule `let' must be a simple variable, not the arbitrary pattern that is allowed in rewrite rules.

The `matches' function is also treated specially in syntax rule conditions (again, in the same way as in rewrite rules). See section Matching Commands. If the matching pattern contains meta-variables, then those meta-variables may be used in later conditions and in the result expression. The arguments to `matches' are not evaluated in this situation.

```
sum ( # , # ) := sum(#1,a,b,c) :: matches(#2, a=[b..c])
```

This is another way to implement the Maple mode `sum' notation. In this approach, we allow `#2' to equal the whole expression `i=1..10'. Then, we use `matches' to break it apart into its components. If the expression turns out not to match the pattern, the syntax rule will fail. Note that Z S always uses Calc's normal language mode for editing expressions in syntax rules, so we must use regular Calc notation for the interval `[b..c]' that will correspond to the Maple mode interval `1..10'.

The Modes Variable

The m g (`calc-get-modes`) command pushes onto the stack a vector of numbers that describes the various mode settings that are in effect. With a numeric prefix argument, it pushes only the nth mode, i.e., the nth element of this vector. Keyboard macros can use the m g command to modify their behavior based on the current mode settings.

The modes vector is also available in the special variable `Modes`. In other words, m g is like s r Modes RET. It will not work to store into this variable; in fact, if you do, `Modes` will cease to track the current modes. (The m g command will continue to work, however.)

In general, each number in this vector is suitable as a numeric prefix argument to the associated mode-setting command. (Recall that the ~ key takes a number from the stack and gives it as a numeric prefix to the next command.)

The elements of the modes vector are as follows:

1. Current precision. Default is 12; associated command is p.
2. Binary word size. Default is 32; associated command is b w.
3. Stack size (not counting the value about to be pushed by m g). This is zero if m g is executed with an empty stack.
4. Number radix. Default is 10; command is d r.
5. Floating-point format. This is the number of digits, plus the constant 0 for normal notation, 10000 for scientific notation, 20000 for engineering notation, or 30000 for fixed-point notation. These codes are acceptable as prefix arguments to the d n command, but note that this may lose information: For example, d s and C-u 12 d s have similar (but not quite identical) effects if the current precision is 12, but they both produce a code of 10012, which will be treated by d n as C-u 12 d s. If the precision then changes, the float format will still be frozen at 12 significant figures.
6. Angular mode. Default is 1 (degrees). Other values are 2 (radians) and 3 (HMS). The m d command accepts these prefixes.
7. Symbolic mode. Value is 0 or 1; default is 0. Command is m s.
8. Fraction mode. Value is 0 or 1; default is 0. Command is m f.
9. Polar mode. Value is 0 (rectangular) or 1 (polar); default is 0. Command is m p.
10. Matrix/scalar mode. Default value is *-1*. Value is 0 for scalar mode, *-2* for matrix mode, or *N* for @c{$N\times N$} *NxN* matrix mode. Command is m v.
11. Simplification mode. Default is 1. Value is *-1* for off (m O), 0 for m N, 2 for m B, 3 for m A, 4 for m E, or 5 for m U. The m D command accepts these prefixes.
12. Infinite mode. Default is *-1* (off). Value is 1 if the mode is on, or 0 if the mode is on with positive zeros. Command is m i.

For example, the sequence M-1 m g RET 2 + ~ p increases the precision by two, leaving a copy of the old precision on the stack. Later, ~ p will restore the original precision using that stack value. (This sequence might be especially useful inside a keyboard macro.)

As another example, M-3 m g 1 - ~ DEL deletes all but the oldest (bottommost) stack entry.

Yet another example: The HP-48 "round" command rounds a number to the current displayed precisi
You could roughly emulate this in Calc with the sequence M-5 m g 10000 % ~ c c. (This would not work for fixed-point mode, but it wouldn't be hard to do a full emulation with the help of the Z [and Z] programming commands. See section Conditionals in Keyboard Macros.)

The Calc Mode Line

This section is a summary of all symbols that can appear on the Calc mode line, the highlighted bar that appears under the Calc stack window (or under an editing window in Embedded Mode).

The basic mode line format is:

```
--%%-Calc: 12 Deg other modes       (Calculator)
```

The `%%' is the Emacs symbol for "read-only"; it shows that regular Emacs commands are not allowed to edit the stack buffer as if it were text.

The word `Calc:' changes to `CalcEmbed:' if Embedded Mode is enabled. The words after this describe the various Calc modes that are in effect.

The first mode is always the current precision, an integer. The second mode is always the angular mode, either `Deg`, `Rad`, or `Hms`.

Here is a complete list of the remaining symbols that can appear on the mode line:

`Alg`
: Algebraic mode (m a; see section Algebraic Entry).

`Alg[(`
: Incomplete algebraic mode (C-u m a).

`Alg*`
: Total algebraic mode (m t).

`Symb`
: Symbolic mode (m s; see section Symbolic Mode).

`Matrix`
: Matrix mode (m v; see section Matrix and Scalar Modes).

`Matrixn`
: Dimensioned matrix mode (C-u n m v).

`Scalar`
: Scalar mode (m v; see section Matrix and Scalar Modes).

`Polar`
: Polar complex mode (m p; see section Polar Mode).

`Frac`

Fraction mode (m f; see section Fraction Mode).

`Inf`
: Infinite mode (m i; see section Infinite Mode).

`+Inf`
: Positive infinite mode (C-u 0 m i).

`NoSimp`
: Default simplifications off (m O; see section Simplification Modes).

`NumSimp`
: Default simplifications for numeric arguments only (m N).

`BinSimpw`
: Binary-integer simplification mode; word size w (m B, b w).

`AlgSimp`
: Algebraic simplification mode (m A).

`ExtSimp`
: Extended algebraic simplification mode (m E).

`UnitSimp`
: Units simplification mode (m U).

`Bin`
: Current radix is 2 (d 2; see section Radix Modes).

`Oct`
: Current radix is 8 (d 8).

`Hex`
: Current radix is 16 (d 6).

`Radixn`
: Current radix is n (d r).

`Zero`
: Leading zeros (d z; see section Radix Modes).

`Big`
: Big language mode (d B; see section Normal Language Modes).

`Flat`
: One-line normal language mode (d O).

`Unform`
: Unformatted language mode (d U).

`C`
: C language mode (d C; see section C, FORTRAN, and Pascal Modes).

`Pascal`

Pascal language mode (d P).

`Fortran`
: FORTRAN language mode (d F).

`TeX`
: TeX language mode (d T; see section TeX Language Mode).

`Eqn`
: Eqn language mode (d E; see section Eqn Language Mode).

`Math`
: Mathematica language mode (d M; see section Mathematica Language Mode).

`Maple`
: Maple language mode (d W; see section Maple Language Mode).

`Normn`
: Normal float mode with n digits (d n; see section Float Formats).

`Fixn`
: Fixed point mode with n digits after the point (d f).

`Sci`
: Scientific notation mode (d s).

`Scin`
: Scientific notation with n digits (d s).

`Eng`
: Engineering notation mode (d e).

`Engn`
: Engineering notation with n digits (d e).

`Leftn`
: Left-justified display indented by n (d <; see section Justification).

`Right`
: Right-justified display (d >).

`Rightn`
: Right-justified display with width n (d >).

`Center`
: Centered display (d =).

`Centern`
: Centered display with center column n (d =).

`Widn`
: Line breaking with width n (d b; see section Normal Language Modes).

`Wide`

No line breaking (d b).

`Break`
: Selections show deep structure (j b; see section Making Selections).

`Save`
: Record modes in `` `~/.emacs' `` (m R; see section General Mode Commands).

`Local`
: Record modes in Embedded buffer (m R).

`LocEdit`
: Record modes as editing-only in Embedded buffer (m R).

`LocPerm`
: Record modes as permanent-only in Embedded buffer (m R).

`Global`
: Record modes as global in Embedded buffer (m R).

`Manual`
: Automatic recomputation turned off (m C; see section Automatic Recomputation).

`Graph`
: GNUPLOT process is alive in background (see section Graphics).

`Sel`
: Top-of-stack has a selection (Embedded only; see section Making Selections).

`Dirty`
: The stack display may not be up-to-date (see section Display Modes).

`Inv`
: "Inverse" prefix was pressed (I; see section Inverse and Hyperbolic Flags).

`Hyp`
: "Hyperbolic" prefix was pressed (H).

`Keep`
: "Keep-arguments" prefix was pressed (K).

`Narrow`
: Stack is truncated (d t; see section Truncating the Stack).

In addition, the symbols `Active` and `~Active` can appear as minor modes on an Embedded buffer's mode line. See section Embedded Mode.

Arithmetic Functions

This chapter describes the Calc commands for doing simple calculations on numbers, such as addition, absolute value, and square roots. These commands work by removing the top one or two values from the stack, performing the desired operation, and pushing the result back onto the stack. If the operation cannot be performed, the result pushed is a formula instead of a number, such as `2/0' (because division by zero is illegal) or `sqrt(x)' (because the argument `x' is a formula).

Most of the commands described here can be invoked by a single keystroke. Some of the more obscure ones are two-letter sequences beginning with the f ("functions") prefix key.

See section Numeric Prefix Arguments, for a discussion of the effect of numeric prefix arguments on commands in this chapter which do not otherwise interpret a prefix argument.

Basic Arithmetic

The + (`calc-plus`) command adds two numbers. The numbers may be any of the standard Calc data types. The resulting sum is pushed back onto the stack.

If both arguments of + are vectors or matrices (of matching dimensions), the result is a vector or matrix sum. If one argument is a vector and the other a scalar (i.e., a non-vector), the scalar is added to each of the elements of the vector to form a new vector. If the scalar is not a number, the operation is left in symbolic form: Suppose you added `x' to the vector `[1,2]'. You may want the result `[1+x,2+x]', or you may plan to substitute a 2-vector for `x' in the future. Since the Calculator can't tell which interpretation you want, it makes the safest assumption. See section Reducing and Mapping Vectors, for a way to add `x' to every element of a vector.

If either argument of + is a complex number, the result will in general be complex. If one argument is in rectangular form and the other polar, the current Polar Mode determines the form of the result. If Symbolic Mode is enabled, the sum may be left as a formula if the necessary conversions for polar addition are non-trivial.

If both arguments of + are HMS forms, the forms are added according to the usual conventions of hours-minutes-seconds notation. If one argument is an HMS form and the other is a number, that number is converted from degrees or radians (depending on the current Angular Mode) to HMS format and then the two HMS forms are added.

If one argument of + is a date form, the other can be either a real number, which advances the date by a certain number of days, or an HMS form, which advances the date by a certain amount of time. Subtracting two date forms yields the number of days between them. Adding two date forms is meaningless, but Calc interprets it as the subtraction of one date form and the negative of the other. (The negative of a date form can be understood by remembering that dates are stored as the number of days before or after Jan 1, 1 AD.)

If both arguments of + are error forms, the result is an error form with an appropriately computed standard deviation. If one argument is an error form and the other is a number, the number is taken to have zero error. Error forms may have symbolic formulas as their mean and/or error parts; adding these will produce a symbolic error form result. However, adding an error form to a plain symbolic formula (as in `(a +/- b) + c') will not work, for the same reasons just mentioned for vectors. Instead you must write `(a +/- b) + (c +/- 0)'.

If both arguments of + are modulo forms with equal values of M, or if one argument is a modulo form and the other a plain number, the result is a modulo form which represents the sum, modulo M, of the two values.

If both arguments of + are intervals, the result is an interval which describes all possible sums of the possible input values. If one argument is a plain number, it is treated as the interval `[x .. x]'.

If one argument of + is an infinity and the other is not, the result is that same infinity. If both arguments are infinite and in the same direction, the result is the same infinity, but if they are infinite in different directions the result is `nan`.

The - (`calc-minus`) command subtracts two values. The top number on the stack is subtracted from the one behind it, so that the computation 5 RET 2 - produces 3, not *-3*. All options available for + are available for - as well.

The * (`calc-times`) command multiplies two numbers. If one argument is a vector and the other a scalar, the scalar is multiplied by the elements of the vector to produce a new vector. If both arguments are vectors, the interpretation depends on the dimensions of the vectors: If both arguments are matrices, a matrix multiplication is done. If one argument is a matrix and the other a plain vector, the vector is interpreted as a row vector or column vector, whichever is dimensionally correct. If both arguments are plain vectors, the result is a single scalar number which is the dot product of the two vectors.

If one argument of * is an HMS form and the other a number, the HMS form is multiplied by that amount. It is an error to multiply two HMS forms together, or to attempt any multiplication involving date forms. Error forms, modulo forms, and intervals can be multiplied; see the comments for addition of those forms. When two error forms or intervals are multiplied they are considered to be statistically independent; thus, `[-2 .. 3] * [-2 .. 3]' is `[-6 .. 9]', whereas `[-2 .. 3] ^ 2' is `[0 .. 9]'.

The / (`calc-divide`) command divides two numbers. When dividing a scalar B by a square matrix A, the computation performed is B times the inverse of A. This also occurs if B is itself a vector or matrix, in which case the effect is to solve the set of linear equations represented by B. If B is a matrix with the same number of rows as A, or a plain vector (which is interpreted here as a column vector), then the equation A X = B is solved for the vector or matrix X. Otherwise, if B is a non-square matrix with the same number of *columns* as A, the equation X A = B is solved. If you wish a vector B to be interpreted as a row vector to be solved as X A = B, make it into a one-row matrix with C-u 1 v p first. To force a left-handed solution with a square matrix B, transpose A and B before dividing, then transpose the result.

HMS forms can be divided by real numbers or by other HMS forms. Error forms can be divided in any combination of ways. Modulo forms where both values and the modulo are integers can be divided to get an integer modulo form result. Intervals can be divided; dividing by an interval that encompasses zero or has zero as a limit will result in an infinite interval.

The ^ (`calc-power`) command raises a number to a power. If the power is an integer, an exact res computed using repeated multiplications. For non-integer powers, Calc uses Newton's method or logarithms and exponentials. Square matrices can be raised to integer powers. If either argument is an error (or interval or modulo) form, the result is also an error (or interval or modulo) form.

If you press the I (inverse) key first, the I ^ command computes an Nth root: 125 RET 3 I ^ computes the number 5. (This is entirely equivalent to 125 RET 1:3 ^.)

The \ (`calc-idiv`) command divides two numbers on the stack to produce an integer result. It is equivalent to dividing with /, then rounding down with F (`calc-floor`), only a bit more convenient and efficient. Also, since it is an all-integer operation when the arguments are integers, it avoids problems that / F would have with floating-point roundoff.

The % (`calc-mod`) command performs a "modulo" (or "remainder") operation. Mathematically, `a%b = a - (a\b)*b', and is defined for all real numbers a and b (except b=0). For positive b, the result will always be between 0 (inclusive) and b (exclusive). Modulo does not work for HMS forms and error forms. If a is a modulo form, its modulo is changed to b, which must be positive real number.

The : (`calc-fdiv`) command [`fdiv` function in a formula] divides the two integers on the top of the stack to produce a fractional result. This is a convenient shorthand for enabling Fraction Mode (with m f) temporarily and using `/'. Note that during numeric entry the : key is interpreted as a fraction separator, so to divide 8 by 6 you would have to type 8 RET 6 RET :. (Of course, in this case, it would be much easier simply to enter the fraction directly as 8:6 RET!)

The n (`calc-change-sign`) command negates the number on the top of the stack. It works on numbers, vectors and matrices, HMS forms, date forms, error forms, intervals, and modulo forms.

The A (`calc-abs`) [`abs`] command computes the absolute value of a number. The result of `abs` is always a nonnegative real number: With a complex argument, it computes the complex magnitude. With a vector or matrix argument, it computes the Frobenius norm, i.e., the square root of the sum of the squares of the absolute values of the elements. The absolute value of an error form is defined by replacing the mean part with its absolute value and leaving the error part the same. The absolute value of a modulo form is undefined. The absolute value of an interval is defined in the obvious way.

The f A (`calc-abssqr`) [`abssqr`] command computes the absolute value squared of a number, vector or matrix, or error form.

The f s (`calc-sign`) [`sign`] command returns 1 if its argument is positive, *-1* if its argument is negative, or 0 if its argument is zero. In algebraic form, you can also write `sign(a,x)' which evaluates to `x * sign(a)', i.e., either `x', `-x', or zero depending on the sign of `a'.

The & (`calc-inv`) [`inv`] command computes the reciprocal of a number, i.e., 1 / x. Operating on a square matrix, it computes the inverse of that matrix.

The Q (`calc-sqrt`) [`sqrt`] command computes the square root of a number. For a negative real argument, the result will be a complex number whose form is determined by the current Polar Mode.

The f h (`calc-hypot`) [`hypot`] command computes the square root of the sum of the squares of two numbers. That is, `hypot(a,b)' is the length of the hypotenuse of a right triangle with sides a and b. If the arguments are complex numbers, their squared magnitudes are used.

The f Q (`calc-isqrt`) [`isqrt`] command computes the integer square root of an integer. This is the true square root of the number, rounded down to an integer. For example, `isqrt(10)' produces 3. Note that, like \ [`idiv`], this uses exact integer arithmetic throughout to avoid roundoff problems. If the input is a floating-point number or other non-integer value, this is exactly the same as `floor(sqrt(x))'.

The f n (`calc-min`) [`min`] and f x (`calc-max`) [`max`] commands take the minimum or maximum of two real numbers, respectively. These commands also work on HMS forms, date forms, intervals, and infinities. (In algebraic expressions, these functions take any number of arguments and return the maximum or minimum among all the arguments.)

The f M (`calc-mant-part`) [`mant`] function extracts the "mantissa" part m of its floating-point argument; f X (`calc-xpon-part`) [`xpon`] extracts the "exponent" part e. The original number is equal to @c{$m \times 10^e$} m * 10^e, where m is in the interval `[1.0 .. 10.0)' except that m=e=0 if the original number is zero. For integers and fractions, `mant` returns the number unchanged and `xpon` returns zero. The v u (`calc-unpack`) command can also be used to "unpack" a floating-point number; this produces an integer mantissa and exponent, with the constraint that the mantissa is not a multiple of ten (again except for the m=e=0 case).

The f S (`calc-scale-float`) [`scf`] function scales a number by a given power of ten. Thus, `scf(mant(x), xpon(x)) = x' for any real `x'. The second argument must be an integer, but the first may actually be any numeric value. For example, `scf(5,-2) = 0.05' or `1:20' depending on the current Fraction Mode.

The f [(`calc-decrement`) [`decr`] and f] (`calc-increment`) [`incr`] functions decrease or increase a number by one unit. For integers, the effect is obvious. For floating-point numbers, the change is by one unit in the last place. For example, incrementing `12.3456' when the current precision is 6 digits yields `12.3457'. If the current precision had been 8 digits, the result would have been `12.345601'. Incrementing `0.0' produces @c{10^{-p}} 10^-p, where p is the current precision. These operations are defined only on integers and floats. With numeric prefix arguments, they change the number by n units.

Note that incrementing followed by decrementing, or vice-versa, will almost but not quite always cancel out. Suppose the precision is 6 digits and the number `9.99999' is on the stack. Incrementing will produce `10.0000'; decrementing will produce `9.9999'. One digit has been dropped. This is an unavoidable consequence of the way floating-point numbers work.

Incrementing a date/time form adjusts it by a certain number of seconds. Incrementing a pure date form adjusts it by a certain number of days.

Integer Truncation

There are four commands for truncating a real number to an integer, differing mainly in their treatment of negative numbers. All of these commands have the property that if the argument is an integer, the result is the same integer. An integer-valued floating-point argument is converted to integer form.

If you press H (`calc-hyperbolic`) first, the result will be expressed as an integer-valued floating-point number.

The F (`calc-floor`) [`floor` or `ffloor`] command truncates a real number to the next lower int i.e., toward minus infinity. Thus 3.6 F produces 3, but _3.6 F produces -*4*.

The I F (`calc-ceiling`) [`ceil` or `fceil`] command truncates toward positive infinity. Thus 3.6 I F produces 4, and _3.6 I F produces -*3*.

The R (`calc-round`) [`round` or `fround`] command rounds to the nearest integer. When the fractional part is .5 exactly, this command rounds away from zero. (All other rounding in the Calculator uses this convention as well.) Thus 3.5 R produces 4 but 3.4 R produces 3; _3.5 R produces -*4*.

The I R (`calc-trunc`) [`trunc` or `ftrunc`] command truncates toward zero. In other words, it "chops off" everything after the decimal point. Thus 3.6 I R produces 3 and _3.6 I R produces -*3*.

These functions may not be applied meaningfully to error forms, but they do work for intervals. As a convenience, applying `floor` to a modulo form floors the value part of the form. Applied to a vector, these functions operate on all elements of the vector one by one. Applied to a date form, they operate on the internal numerical representation of dates, converting a date/time form into a pure date.

There are two more rounding functions which can only be entered in algebraic notation. The `roundu` function is like `round` except that it rounds up, toward plus infinity, when the fractional part is .5. This distinction matters only for negative arguments. Also, `rounde` rounds to an even number in the case of a tie, rounding up or down as necessary. For example, `round(3.5)' and `round(4.5)' both return 4, but `round(5.5)' returns 6. The advantage of round-to-even is that the net error due to rounding after a long calculation tends to cancel out to zero. An important subtle point here is that the number being fed to `rounde` will already have been rounded to the current precision before `rounde` begins. For example, `round(2.500001)' with a current precision of 6 will incorrectly, or at least surprisingly, yield 2 because the argument will first have been rounded down to 2.5 (which `rounde` sees as an exact tie between 2 and 3).

Each of these functions, when written in algebraic formulas, allows a second argument which specifies the number of digits after the decimal point to keep. For example, `round(123.4567, 2)' will produce the answer 123.46, and `round(123.4567, -1)' will produce 120 (i.e., the cutoff is one digit to the *left* of the decimal point). A second argument of zero is equivalent to no second argument at all.

To compute the fractional part of a number (i.e., the amount which, when added to `floor(*N*)', will produce N) just take N modulo 1 using the % command.

Note also the \ (integer quotient), f I (integer logarithm), and f Q (integer square root) commands, which are analogous to /, B, and Q, respectively, except that they take integer arguments and return the result rounded down to an integer.

Complex Number Functions

The J (`calc-conj`) [`conj`] command computes the complex conjugate of a number. For complex number a+bi, the complex conjugate is a-bi. If the argument is a real number, this command leaves it the same. If the argument is a vector or matrix, this command replaces each element by its complex conjugate.

The G (`calc-argument`) [`arg`] command computes the "argument" or polar angle of a complex number. For a number in polar notation, this is simply the second component of the pair `(r;@c{θ} *theta*)'. The result is expressed according to the current angular mode and will be in the range *-180* degrees (exclusive) to *+180* degrees (inclusive), or the equivalent range in radians.

The `calc-imaginary` command multiplies the number on the top of the stack by the imaginary number i = (0,1). This command is not normally bound to a key in Calc, but it is available on the IMAG button in Keypad Mode.

The f r (`calc-re`) [`re`] command replaces a complex number by its real part. This command has no effect on real numbers. (As an added convenience, `re` applied to a modulo form extracts the value part.)

The f i (`calc-im`) [`im`] command replaces a complex number by its imaginary part; real numbers are converted to zero. With a vector or matrix argument, these functions operate element-wise.

The v p (`calc-pack`) command can pack the top two numbers on the the stack into a composite object such as a complex number. With a prefix argument of *-1*, it produces a rectangular complex number; with an argument of *-2*, it produces a polar complex number. (Also, see section Building Vectors.)

The v u (`calc-unpack`) command takes the complex number (or other composite object) on the top of the stack and unpacks it into its separate components.

Conversions

The commands described in this section convert numbers from one form to another; they are two-key sequences beginning with the letter c.

The c f (`calc-float`) [`pfloat`] command converts the number on the top of the stack to floating-point form. For example, 23 is converted to 23.0, 3:2 is converted to 1.5, and 2.3 is left the same. If the value is a composite object such as a complex number or vector, each of the components is converted to floating-point. If the value is a formula, all numbers in the formula are converted to floating-point. Note that depending on the current floating-point precision, conversion to floating-point format may lose information.

As a special exception, integers which appear as powers or subscripts are not floated by c f. If you really want to float a power, you can use a j s command to select the power followed by c f. Because c f cannot examine the formula outside of the selection, it does not notice that the thing being floated is a power. See section Selecting Sub-Formulas.

The normal c f command is "pervasive" in the sense that it applies to all numbers throughout the formula. The `pfloat` algebraic function never stays around in a formula; `pfloat(a + 1)' changes to `a + 1.0' as soon as it is evaluated.

With the Hyperbolic flag, H c f [`float`] operates only on the number or vector of numbers at the top level of its argument. Thus, `float(1)' is 1.0, but `float(a + 1)' is left unevaluated because its argument is not a number.

You should use H c f if you wish to guarantee that the final value, once all the variables have been

assigned, is a float; you would use c f if you wish to do the conversion on the numbers that appear r
now.

The c F (`calc-fraction`) [`pfrac`] command converts a floating-point number into a fractional approximation. By default, it produces a fraction whose decimal representation is the same as the input number, to within the current precision. You can also give a numeric prefix argument to specify a tolerance, either directly, or, if the prefix argument is zero, by using the number on top of the stack as the tolerance. If the tolerance is a positive integer, the fraction is correct to within that many significant figures. If the tolerance is a non-positive integer, it specifies how many digits fewer than the current precision to use. If the tolerance is a floating-point number, the fraction is correct to within that absolute amount.

The `pfrac` function is pervasive, like `pfloat`. There is also a non-pervasive version, H c F [`frac`], which is analogous to H c f discussed above.

The c d (`calc-to-degrees`) [`deg`] command converts a number into degrees form. The value on the top of the stack may be an HMS form (interpreted as degrees-minutes-seconds), or a real number which will be interpreted in radians regardless of the current angular mode.

The c r (`calc-to-radians`) [`rad`] command converts an HMS form or angle in degrees into an angle in radians.

The c h (`calc-to-hms`) [`hms`] command converts a real number, interpreted according to the current angular mode, to an HMS form describing the same angle. In algebraic notation, the `hms` function also accepts three arguments: `hms(h, m, s)'. (The three-argument version is independent of the current angular mode.)

The `calc-from-hms` command converts the HMS form on the top of the stack into a real number according to the current angular mode.

The c p (`calc-polar`) command converts the complex number on the top of the stack from polar to rectangular form, or from rectangular to polar form, whichever is appropriate. Real numbers are left the same. This command is equivalent to the `rect` or `polar` functions in algebraic formulas, depending on the direction of conversion. (It uses `polar`, except that if the argument is already a polar complex number, it uses `rect` instead. The I c p command always uses `rect`.)

The c c (`calc-clean`) [`pclean`] command "cleans" the number on the top of the stack. Floating point numbers are re-rounded according to the current precision. Polar numbers whose angular components have strayed from the *-180* to *+180* degree range are normalized. (Note that results will be undesirable if the current angular mode is different from the one under which the number was produced!) Integers and fractions are generally unaffected by this operation. Vectors and formulas are cleaned by cleaning each component number (i.e., pervasively).

If the simplification mode is set below the default level, it is raised to the default level for the purposes of this command. Thus, c c applies the default simplifications even if their automatic application is disabled. See section Simplification Modes.

A numeric prefix argument to c c sets the floating-point precision to that value for the duration of the command. A positive prefix (of at least 3) sets the precision to the specified value; a negative or zero

prefix decreases the precision by the specified amount.

The keystroke sequences c 0 through c 9 are equivalent to c c with the corresponding negative prefix argument. If roundoff errors have changed 2.0 into 1.999999, typing c 1 to clip off one decimal place often conveniently does the trick.

The c c command with a numeric prefix argument, and the c 0 through c 9 commands, also "clip" very small floating-point numbers to zero. If the exponent is less than or equal to the negative of the specified precision, the number is changed to 0.0. For example, if the current precision is 12, then c 2 changes the vector `[1e-8, 1e-9, 1e-10, 1e-11]' to `[1e-8, 1e-9, 0, 0]'. Numbers this small generally arise from roundoff noise.

If the numbers you are using really are legitimately this small, you should avoid using the c 0 through c 9 commands. (The plain c c command rounds to the current precision but does not clip small numbers.)

One more property of c 0 through c 9, and of c c with a prefix argument, is that integer-valued floats are converted to plain integers, so that c 1 on `[1., 1.5, 2., 2.5, 3.]' produces `[1, 1.5, 2, 2.5, 3]'. This is not done for huge numbers (`1e100' is technically an integer-valued float, but you wouldn't want it automatically converted to a 100-digit integer).

With the Hyperbolic flag, H c c and H c 0 through H c 9 operate non-pervasively [`clean`].

Date Arithmetic

The commands described in this section perform various conversions and calculations involving date forms (see section Date Forms). They use the t (for time/date) prefix key followed by shifted letters.

The simplest date arithmetic is done using the regular + and - commands. In particular, adding a number to a date form advances the date form by a certain number of days; adding an HMS form to a date form advances the date by a certain amount of time; and subtracting two date forms produces a difference measured in days. The commands described here provide additional, more specialized operations on dates.

Many of these commands accept a numeric prefix argument; if you give plain C-u as the prefix, these commands will instead take the additional argument from the top of the stack.

Date Conversions

The t D (`calc-date`) [`date`] command converts a date form into a number, measured in days since Jan 1, 1 AD. The result will be an integer if date is a pure date form, or a fraction or float if date is a date/time form. Or, if its argument is a number, it converts this number into a date form.

With a numeric prefix argument, t D takes that many objects (up to six) from the top of the stack and interprets them in one of the following ways:

The `date(year, month, day)' function builds a pure date form out of the specified year, month, and day, which must all be integers. Year is a year number, such as 1991 (*not* the same as 91!). Month must be an integer in the range 1 to 12; day must be in the range 1 to 31. If the specified month has fewer than 31

days and day is too large, the equivalent day in the following month will be used.

The `date(month, day)' function builds a pure date form using the current year, as determined by the real-time clock.

The `date(year, month, day, hms)' function builds a date/time form using an hms form.

The `date(year, month, day, hour, minute, second)' function builds a date/time form. hour should be an integer in the range 0 to 23; minute should be an integer in the range 0 to 59; second should be any real number in the range `[0 .. 60)'. The last two arguments default to zero if omitted.

The t J (`calc-julian') [`julian'] command converts a date form into a Julian day count, which is the number of days since noon on Jan 1, 4713 BC. A pure date is converted to an integer Julian count representing noon of that day. A date/time form is converted to an exact floating-point Julian count, adjusted to interpret the date form in the current time zone but the Julian day count in Greenwich Mean Time. A numeric prefix argument allows you to specify the time zone; see section Time Zones. Use a prefix of zero to suppress the time zone adjustment. Note that pure date forms are never time-zone adjusted.

This command can also do the opposite conversion, from a Julian day count (either an integer day, or a floating-point day and time in the GMT zone), into a pure date form or a date/time form in the current or specified time zone.

The t U (`calc-unix-time') [`unixtime'] command converts a date form into a Unix time value, which is the number of seconds since midnight on Jan 1, 1970, or vice-versa. The numeric result will be an integer if the current precision is 12 or less; for higher precisions, the result may be a float with (precision-12) digits after the decimal. Just as for t J, the numeric time is interpreted in the GMT time zone and the date form is interpreted in the current or specified zone. Some systems use Unix-like numbering but with the local time zone; give a prefix of zero to suppress the adjustment if so.

The t C (`calc-convert-time-zones') [`tzconv'] command converts a date form from one time zone to another. You are prompted for each time zone name in turn; you can answer with any suitable Calc time zone expression (see section Time Zones). If you answer either prompt with a blank line, the local time zone is used for that prompt. You can also answer the first prompt with $ to take the two time zone names from the stack (and the date to be converted from the third stack level).

Date Functions

The t N (`calc-now') [`now'] command pushes the current date and time on the stack as a date form. The time is reported in terms of the specified time zone; with no numeric prefix argument, t N reports for the current time zone.

The t P (`calc-date-part') command extracts one part of a date form. The prefix argument specifies the part; with no argument, this command prompts for a part code from 1 to 9. The various part codes are described in the following paragraphs.

The M-1 t P [`year'] function extracts the year number from a date form as an integer, e.g., 1991. This and the following functions will also accept a real number for an argument, which is interpreted as a

standard Calc day number. Note that this function will never return zero, since the year 1 BC immediately precedes the year 1 AD.

The M-2 t P [`month`] function extracts the month number from a date form as an integer in the range 1 to 12.

The M-3 t P [`day`] function extracts the day number from a date form as an integer in the range 1 to 31.

The M-4 t P [`hour`] function extracts the hour from a date form as an integer in the range 0 (midnight) to 23. Note that 24-hour time is always used. This returns zero for a pure date form. This function (and the following two) also accept HMS forms as input.

The M-5 t P [`minute`] function extracts the minute from a date form as an integer in the range 0 to 59.

The M-6 t P [`second`] function extracts the second from a date form. If the current precision is 12 or less, the result is an integer in the range 0 to 59. For higher precisions, the result may instead be a floating-point number.

The M-7 t P [`weekday`] function extracts the weekday number from a date form as an integer in the range 0 (Sunday) to 6 (Saturday).

The M-8 t P [`yearday`] function extracts the day-of-year number from a date form as an integer in the range 1 (January 1) to 366 (December 31 of a leap year).

The M-9 t P [`time`] function extracts the time portion of a date form as an HMS form. This returns `0@ 0' 0"' for a pure date form.

The t M (`calc-new-month`) [`newmonth`] command computes a new date form that represents the first day of the month specified by the input date. The result is always a pure date form; only the year and month numbers of the input are retained. With a numeric prefix argument n in the range from 1 to 31, t M computes the nth day of the month. (If n is greater than the actual number of days in the month, or if n is zero, the last day of the month is used.)

The t Y (`calc-new-year`) [`newyear`] command computes a new pure date form that represents the first day of the year specified by the input. The month, day, and time of the input date form are lost. With a numeric prefix argument n in the range from 1 to 366, t Y computes the nth day of the year (366 is treated as 365 in non-leap years). A prefix argument of 0 computes the last day of the year (December 31). A negative prefix argument from *-1* to *-12* computes the first day of the nth month of the year.

The t W (`calc-new-week`) [`newweek`] command computes a new pure date form that represents the Sunday on or before the input date. With a numeric prefix argument, it can be made to use any day of the week as the starting day; the argument must be in the range from 0 (Sunday) to 6 (Saturday). This function always subtracts between 0 and 6 days from the input date.

Here's an example use of `newweek`: Find the date of the next Wednesday after a given date. Using M-3 t W or `newweek(d, 3)' will give you the *preceding* Wednesday, so `newweek(d+7, 3)' will give you the following Wednesday. A further look at the definition of `newweek` shows that if the input date is itself a Wednesday, this formula will return the Wednesday one week in the future. An exercise for the reader is to modify this formula to yield the same day if the input is already a Wednesday. Another interesting exercise is to preserve the time-of-day portion of the input (`newweek` resets the time to midnight; hint:

how can `newweek` be defined in terms of the `weekday` function?).

The `pwday(date)' function (not on any key) computes the day-of-month number of the Sunday on or before date. With two arguments, `pwday(date, day)' computes the day number of the Sunday on or before day number day of the month specified by date. The day must be in the range from 7 to 31; if the day number is greater than the actual number of days in the month, the true number of days is used instead. Thus `pwday(date, 7)' finds the first Sunday of the month, and `pwday(date, 31)' finds the last Sunday of the month. With a third weekday argument, `pwday` can be made to look for any day of the week instead of Sunday.

The t I (`calc-inc-month`) [`incmonth`] command increases a date form by one month, or by an arbitrary number of months specified by a numeric prefix argument. The time portion, if any, of the date form stays the same. The day also stays the same, except that if the new month has fewer days the day number may be reduced to lie in the valid range. For example, `incmonth(<Jan 31, 1991>)' produces `<Feb 28, 1991>'. Because of this, t I t I and M-2 t I do not always give the same results (`<Mar 28, 1991>' versus `<Mar 31, 1991>' in this case).

The `incyear(date, step)' function increases a date form by the specified number of years, which may be any positive or negative integer. Note that `incyear(d, n)' is equivalent to `incmonth(d, 12*n)', but these do not have simple equivalents in terms of day arithmetic because months and years have varying lengths. If the step argument is omitted, 1 year is assumed. There is no keyboard command for this function; use C-u 12 t I instead.

There is no `newday` function at all because F [`floor`] serves this purpose. Similarly, instead of `incday` and `incweek` simply use d + n or d + 7 n.

See section Basic Arithmetic, for the f] [`incr`] command which can adjust a date/time form by a certain number of seconds.

Business Days

Often time is measured in "business days" or "working days," where weekends and holidays are skipped. Calc's normal date arithmetic functions use calendar days, so that subtracting two consecutive Mondays will yield a difference of 7 days. By contrast, subtracting two consecutive Mondays would yield 5 business days (assuming two-day weekends and the absence of holidays).

The t + (`calc-business-days-plus`) [`badd`] and t - (`calc-business-days-minus`) [`bsub`] commands perform arithmetic using business days. For t +, one argument must be a date form and the other must be a real number (positive or negative). If the number is not an integer, then a certain amount of time is added as well as a number of days; for example, adding 0.5 business days to a time in Friday evening will produce a time in Monday morning. It is also possible to add an HMS form; adding `12@ 0' 0"' also adds half a business day. For t -, the arguments are either a date form and a number or HMS form, or two date forms, in which case the result is the number of business days between the two dates.

By default, Calc considers any day that is not a Saturday or Sunday to be a business day. You can define any number of additional holidays by editing the variable `Holidays`. (There is an s H convenience command for editing this variable.) Initially, `Holidays` contains the vector `[sat, sun]'. Entries in the

`Holidays` vector may be any of the following kinds of objects:

- Date forms (pure dates, not date/time forms). These specify particular days which are to be treated as holidays.
- Intervals of date forms. These specify a range of days, all of which are holidays (e.g., Christmas week). See section Interval Forms.
- Nested vectors of date forms. Each date form in the vector is considered to be a holiday.
- Any Calc formula which evaluates to one of the above three things. If the formula involves the variable y, it stands for a yearly repeating holiday; y will take on various year numbers like 1992. For example, `date(y, 12, 25)' specifies Christmas day, and `newweek(date(y, 11, 7), 4) + 21' specifies Thanksgiving (which is held on the fourth Thursday of November). If the formula involves the variable m, that variable takes on month numbers from 1 to 12: `date(y, m, 15)' is a holiday that takes place on the 15th of every month.
- A weekday name, such as `sat` or `sun`. This is really a variable whose name is a three-letter, lower-case day name.
- An interval of year numbers (integers). This specifies the span of years over which this holiday list is to be considered valid. Any business-day arithmetic that goes outside this range will result in an error message. Use this if you are including an explicit list of holidays, rather than a formula to generate them, and you want to make sure you don't accidentally go beyond the last point where the holidays you entered are complete. If there is no limiting interval in the `Holidays` vector, the default `[1 .. 2737]' is used. (This is the absolute range of years for which Calc's business-day algorithms will operate.)
- An interval of HMS forms. This specifies the span of hours that are to be considered one business day. For example, if this range is `[9@ 0' 0" .. 17@ 0' 0"]' (i.e., 9am to 5pm), then the business day is only eight hours long, so that 1.5 t + on `<4:00pm Fri Dec 13, 1991>' will add one business day and four business hours to produce `<12:00pm Tue Dec 17, 1991>'. Likewise, t - will now express differences in time as fractions of an eight-hour day. Times before 9am will be treated as 9am by business date arithmetic, and times at or after 5pm will be treated as 4:59:59pm. If there is no HMS interval in `Holidays`, the full 24-hour day `[0 0' 0" .. 24 0' 0"]' is assumed. (Regardless of the type of bounds you specify, the interval is treated as inclusive on the low end and exclusive on the high end, so that the work day goes from 9am up to, but not including, 5pm.)

If the `Holidays` vector is empty, then t + and t - will act just like + and - because there will then be no difference between business days and calendar days.

Calc expands the intervals and formulas you give into a complete list of holidays for internal use. This is done mainly to make sure it can detect multiple holidays. (For example, `<Jan 1, 1989>' is both New Year's Day and a Sunday, but Calc's algorithms take care to count it only once when figuring the number of holidays between two dates.)

Since the complete list of holidays for all the years from 1 to 2737 would be huge, Calc actually computes only the part of the list between the smallest and largest years that have been involved in business-day calculations so far. Normally, you won't have to worry about this. Keep in mind, however, that if you do one calculation for 1992, and another for 1792, even if both involve only a small range of years, Calc will still work out all the holidays that fall in that 200-year span.

If you add a (positive) number of days to a date form that falls on a weekend or holiday, the date form is treated as if it were the most recent business day. (Thus adding one business day to a Friday, Saturday, or Sunday will all yield the following Monday.) If you subtract a number of days from a weekend or holiday, the date is effectively on the following business day. (So subtracting one business day from Saturday, Sunday, or Monday yields the preceding Friday.) The difference between two dates one or both of which fall on holidays equals the number of actual business days between them. These conventions are consistent in the sense that, if you add n business days to any date, the difference between the result and the original date will come out to n business days. (It can't be completely consistent though; a subtraction followed by an addition might come out a bit differently, since t + is incapable of producing a date that falls on a weekend or holiday.)

There is a `holiday` function, not on any keys, that takes any date form and returns 1 if that date falls on a weekend or holiday, as defined in `Holidays`, or 0 if the date is a business day.

Time Zones

Time zones and daylight savings time are a complicated business. The conversions to and from Julian and Unix-style dates automatically compute the correct time zone and daylight savings adjustment to use, provided they can figure out this information. This section describes Calc's time zone adjustment algorithm in detail, in case you want to do conversions in different time zones or in case Calc's algorithms can't determine the right correction to use.

Adjustments for time zones and daylight savings time are done by t U, t J, t N, and t C, but not by any other commands. In particular, `<may 1 1991> - <apr 1 1991>' evaluates to exactly 30 days even though there is a daylight-savings transition in between. This is also true for Julian pure dates: `julian(<may 1 1991>) - julian(<apr 1 1991>)'. But Julian and Unix date/times will adjust for daylight savings time: `julian(<12am may 1 1991>) - julian(<12am apr 1 1991>)' evaluates to `29.95834' (that's 29 days and 23 hours) because one hour was lost when daylight savings commenced on April 7, 1991.

In brief, the idiom `julian(date1) - julian(date2)' computes the actual number of 24-hour periods between two dates, whereas `date1 - date2' computes the number of calendar days between two dates without taking daylight savings into account.

The `calc-time-zone` [`tzone`] command converts the time zone specified by its numeric prefix argument into a number of seconds difference from Greenwich mean time (GMT). If the argument is a number, the result is simply that value multiplied by 3600. Typical arguments for North America are 5 (Eastern) or 8 (Pacific). If Daylight Savings time is in effect, one hour should be subtracted from the normal difference.

If you give a prefix of plain C-u, `calc-time-zone` (like other date arithmetic commands that include a time zone argument) takes the zone argument from the top of the stack. (In the case of t J and t U, the normal argument is then taken from the second-to-top stack position.) This allows you to give a non-integer time zone adjustment. The time-zone argument can also be an HMS form, or it can be a variable which is a time zone name in upper- or lower-case. For example `tzone(PST) = tzone(8)' and `tzone(pdt) = tzone(7)' (for Pacific standard and daylight savings times, respectively).

North American and European time zone names are defined as follows; note that for each time zone there is one name for standard time, another for daylight savings time, and a third for "generalized" time in

which the daylight savings adjustment is computed from context.

```
YST   PST   MST   CST   EST   AST     NST     GMT   WET     MET     MEZ
 9     8     7     6     5     4       3.5     0     -1      -2      -2

YDT   PDT   MDT   CDT   EDT   ADT     NDT     BST   WETDST  METDST  MESZ
 8     7     6     5     4     3       2.5     -1    -2      -3      -3

YGT   PGT   MGT   CGT   EGT   AGT     NGT     BGT   WEGT    MEGT    MEGZ
9/8   8/7   7/6   6/5   5/4   4/3   3.5/2.5   0/-1 -1/-2   -2/-3   -2/-3
```

To define time zone names that do not appear in the above table, you must modify the Lisp variable `math-tzone-names`. This is a list of lists describing the different time zone names; its structure is best explained by an example. The three entries for Pacific Time look like this:

```
( ( "PST" 8 0 )    ; Name as an upper-case string, then standard
  ( "PDT" 8 -1 )   ; adjustment, then daylight savings adjustment.
  ( "PGT" 8 "PST" "PDT" ) )   ; Generalized time zone.
```

With no arguments, `calc-time-zone` or `tzone()' obtains an argument from the Calc variable `TimeZone` if a value has been stored for that variable. If not, Calc runs the Unix `date' command and looks for one of the above time zone names in the output; if this does not succeed, `tzone()' leaves itself unevaluated. The time zone name in the `date' output may be followed by a signed adjustment, e.g., `GMT+5' or `GMT+0500' which specifies a number of hours and minutes to be added to the base time zone. Calc stores the time zone it finds into `TimeZone` to speed later calls to `tzone()'.

The special time zone name `local` is equivalent to no argument, i.e., it uses the local time zone as obtained from the `date` command.

If the time zone name found is one of the standard or daylight savings zone names from the above table, and Calc's internal daylight savings algorithm says that time and zone are consistent (e.g., `PDT` accompanies a date that Calc's algorithm would also consider to be daylight savings, or `PST` accompanies a date that Calc would consider to be standard time), then Calc substitutes the corresponding generalized time zone (like `PGT`).

If your system does not have a suitable `date' command, you may wish to put a `(setq var-TimeZone ...)' in your Emacs initialization file to set the time zone. The easiest way to do this is to edit the `TimeZone` variable using Calc's s T command, then use the s p (`calc-permanent-variable`) command to save the value of `TimeZone` permanently.

The t J and `t U` commands with no numeric prefix arguments do the same thing as `tzone()'. If the current time zone is a generalized time zone, e.g., `EGT`, Calc examines the date being converted to tell whether to use standard or daylight savings time. But if the current time zone is explicit, e.g., `EST` or `EDT`, then that adjustment is used exactly and Calc's daylight savings algorithm is not consulted.

Some places don't follow the usual rules for daylight savings time. The state of Arizona, for example, does not observe daylight savings time. If you run Calc during the winter season in Arizona, the Unix `date` command will report `MST` time zone, which Calc will change to `MGT`. If you then convert a time

that lies in the summer months, Calc will apply an incorrect daylight savings time adjustment. To av this, set your `TimeZone` variable explicitly to `MST` to force the use of standard, non-daylight-savings time.

By default Calc always considers daylight savings time to begin at 2 a.m. on the first Sunday of April, and to end at 2 a.m. on the last Sunday of October. This is the rule that has been in effect in North America since 1987. If you are in a country that uses different rules for computing daylight savings time, you have two choices: Write your own daylight savings hook, or control time zones explicitly by setting the `TimeZone` variable and/or always giving a time-zone argument for the conversion functions.

The Lisp variable `math-daylight-savings-hook` holds the name of a function that is used to compute the daylight savings adjustment for a given date. The default is `math-std-daylight-savings`, which computes an adjustment (either 0 or *-1*) using the North American rules given above.

The daylight savings hook function is called with four arguments: The date, as a floating-point number in standard Calc format; a six-element list of the date decomposed into year, month, day, hour, minute, and second, respectively; a string which contains the generalized time zone name in upper-case, e.g., `"WEGT"`; and a special adjustment to be applied to the hour value when converting into a generalized time zone (see below).

The Lisp function `math-prev-weekday-in-month` is useful for daylight savings computations. This is an internal version of the user-level `pwday` function described in the previous section. It takes four arguments: The floating-point date value, the corresponding six-element date list, the day-of-month number, and the weekday number (0-6).

The default daylight savings hook ignores the time zone name, but a more sophisticated hook could use different algorithms for different time zones. It would also be possible to use different algorithms depending on the year number, but the default hook always uses the algorithm for 1987 and later. Here is a listing of the default daylight savings hook:

```
(defun math-std-daylight-savings (date dt zone bump)
  (cond ((< (nth 1 dt) 4) 0)
        ((= (nth 1 dt) 4)
         (let ((sunday (math-prev-weekday-in-month date dt 7 0)))
           (cond ((< (nth 2 dt) sunday) 0)
                 ((= (nth 2 dt) sunday)
                  (if (>= (nth 3 dt) (+ 3 bump)) -1 0))
                 (t -1))))
        ((< (nth 1 dt) 10) -1)
        ((= (nth 1 dt) 10)
         (let ((sunday (math-prev-weekday-in-month date dt 31 0)))
           (cond ((< (nth 2 dt) sunday) -1)
                 ((= (nth 2 dt) sunday)
                  (if (>= (nth 3 dt) (+ 2 bump)) 0 -1))
                 (t 0))))
        (t 0))
```

)

The `bump` parameter is equal to zero when Calc is converting from a date form in a generalized time zone into a GMT date value. It is *-1* when Calc is converting in the other direction. The adjustments shown above ensure that the conversion behaves correctly and reasonably around the 2 a.m. transition in each direction.

There is a "missing" hour between 2 a.m. and 3 a.m. at the beginning of daylight savings time; converting a date/time form that falls in this hour results in a time value for the following hour, from 3 a.m. to 4 a.m. At the end of daylight savings time, the hour from 1 a.m. to 2 a.m. repeats itself; converting a date/time form that falls in in this hour results in a time value for the first manifestion of that time (*not* the one that occurs one hour later).

If `math-daylight-savings-hook` is `nil`, then the daylight savings adjustment is always taken to be zero.

In algebraic formulas, `tzone(zone, date)' computes the time zone adjustment for a given zone name at a given date. The date is ignored unless zone is a generalized time zone. If date is a date form, the daylight savings computation is applied to it as it appears. If date is a numeric date value, it is adjusted for the daylight-savings version of zone before being given to the daylight savings hook. This odd-sounding rule ensures that the daylight-savings computation is always done in local time, not in the GMT time that a numeric date is typically represented in.

The `dsadj(date, zone)' function computes the daylight savings adjustment that is appropriate for date in time zone zone. If zone is explicitly in or not in daylight savings time (e.g., `PDT` or `PST`) the date is ignored. If zone is a generalized time zone, the algorithms described above are used. If zone is omitted, the computation is done for the current time zone.

See section Reporting Bugs, for the address of Calc's author, if you should wish to contribute your improved versions of `math-tzone-names` and `math-daylight-savings-hook` to the Calc distribution.

Financial Functions

Calc's financial or business functions use the b prefix key followed by a shifted letter. (The b prefix followed by a lower-case letter is used for operations on binary numbers.)

Note that the rate and the number of intervals given to these functions must be on the same time scale, e.g., both months or both years. Mixing an annual interest rate with a time expressed in months will give you very wrong answers!

It is wise to compute these functions to a higher precision than you really need, just to make sure your answer is correct to the last penny; also, you may wish to check the definitions at the end of this section to make sure the functions have the meaning you expect.

Percentages

The M-% (`calc-percent`) command takes a percentage value, say 5.4, and converts it to an equivalent actual number. For example, 5.4 M-% enters 0.054 on the stack. (That's the META or ESC key combined with %.)

Actually, M-% creates a formula of the form `5.4%'. You can enter `5.4%' yourself during algebraic entry. The `%' operator simply means, "the preceding value divided by 100." The `%' operator has very high precedence, so that `1+8%' is interpreted as `1+(8%)', not as `(1+8)%'. (The `%' operator is just a postfix notation for the `percent` function, just like `20!' is the notation for `fact(20)', or twenty-factorial.)

The formula `5.4%' would normally evaluate immediately to 0.054, but the M-% command suppresses evaluation as it puts the formula onto the stack. However, the next Calc command that uses the formula `5.4%' will evaluate it as its first step. The net effect is that you get to look at `5.4%' on the stack, but Calc commands see it as `0.054', which is what they expect.

In particular, `5.4%' and `0.054' are suitable values for the rate arguments of the various financial functions, but the number `5.4' is probably *not* suitable--it represents a rate of 540 percent!

The key sequence M-% * effectively means "percent-of." For example, 68 RET 25 M-% * computes 17, which is 25% of 68 (and also 68% of 25, which comes out to the same thing).

The c % (`calc-convert-percent`) command converts the value on the top of the stack from numeric to percentage form. For example, if 0.08 is on the stack, c % converts it to `8%'. The quantity is the same, it's just represented differently. (Contrast this with M-%, which would convert this number to `0.08%'.) The = key is a convenient way to convert a formula like `8%' back to numeric form, 0.08.

To compute what percentage one quantity is of another quantity, use / c %. For example, 17 RET 68 / c % displays `25%'.

The b % (`calc-percent-change`) [`relch`] command calculates the percentage change from one number to another. For example, 40 RET 50 b % produces the answer `25%', since 50 is 25% larger than 40. A negative result represents a decrease: 50 RET 40 b % produces `-20%', since 40 is 20% smaller than 50. (The answers are different in magnitude because, in the first case, we're increasing by 25% of 40, but in the second case, we're decreasing by 20% of 50.) The effect of 40 RET 50 b % is to compute (50-40)/40, converting the answer to percentage form as if by c %.

Future Value

The b F (`calc-fin-fv`) [`fv`] command computes the future value of an investment. It takes three arguments from the stack: `fv(rate, n, payment)'. If you give payments of payment every year for n years, and the money you have paid earns interest at rate per year, then this function tells you what your investment would be worth at the end of the period. (The actual interval doesn't have to be years, as long as n and rate are expressed in terms of the same intervals.) This function assumes payments occur at the *end* of each interval.

The I b F [`fvb`] command does the same computation, but assuming your payments are at the beginning

of each interval. Suppose you plan to deposit $1000 per year in a savings account earning 5.4% inter starting right now. How much will be in the account after five years? `fvb(5.4%, 5, 1000) = 5870.73`. Thus you will have earned $870 worth of interest over the years. Using the stack, this calculation would have been 5.4 M-% 5 RET 1000 I b F. Note that the rate is expressed as a number between 0 and 1, *not* as a percentage.

The H b F [`fvl`] command computes the future value of an initial lump sum investment. Suppose you could deposit those five thousand dollars in the bank right now; how much would they be worth in five years? `fvl(5.4%, 5, 5000) = 6503.89`.

The algebraic functions `fv` and `fvb` accept an optional fourth argument, which is used as an initial lump sum in the sense of `fvl`. In other words, `fv(rate, n, payment, initial) = fv(rate, n, payment) + fvl(rate, n, initial)`.

To illustrate the relationships between these functions, we could do the `fvb` calculation "by hand" using `fvl`. The final balance will be the sum of the contributions of our five deposits at various times. The first deposit earns interest for five years: `fvl(5.4%, 5, 1000) = 1300.78`. The second deposit only earns interest for four years: `fvl(5.4%, 4, 1000) = 1234.13`. And so on down to the last deposit, which earns one year's interest: `fvl(5.4%, 1, 1000) = 1054.00`. The sum of these five values is, sure enough, $5870.73, just as was computed by `fvb` directly.

What does `fv(5.4%, 5, 1000) = 5569.96` mean? The payments are now at the ends of the periods. The end of one year is the same as the beginning of the next, so what this really means is that we've lost the payment at year zero (which contributed $1300.78), but we're now counting the payment at year five (which, since it didn't have a chance to earn interest, counts as $1000). Indeed, 5569.96 = 5870.73 - 1300.78 + 1000 (give or take a bit of roundoff error).

Present Value

The b P (`calc-fin-pv`) [`pv`] command computes the present value of an investment. Like `fv`, it takes three arguments: `pv(rate, n, payment)`. It computes the present value of a series of regular payments. Suppose you have the chance to make an investment that will pay $2000 per year over the next four years; as you receive these payments you can put them in the bank at 9% interest. You want to know whether it is better to make the investment, or to keep the money in the bank where it earns 9% interest right from the start. The calculation `pv(9%, 4, 2000)` gives the result 6479.44. If your initial investment must be less than this, say, $6000, then the investment is worthwhile. But if you had to put up $7000, then it would be better just to leave it in the bank.

Here is the interpretation of the result of `pv`: You are trying to compare the return from the investment you are considering, which is `fv(9%, 4, 2000) = 9146.26`, with the return from leaving the money in the bank, which is `fvl(9%, 4, x)` where x is the amount of money you would have to put up in advance. The `pv` function finds the break-even point, x = 6479.44, at which `fvl(9%, 4, 6479.44)` is also equal to 9146.26. This is the largest amount you should be willing to invest.

The I b P [`pvb`] command solves the same problem, but with payments occurring at the beginning of each interval. It has the same relationship to `fvb` as `pv` has to `fv`. For example `pvb(9%, 4, 2000) = 7062.59`, a larger number than `pv` produced because we get to start earning interest on the return from our investment sooner.

The H b P [pvl] command computes the present value of an investment that will pay off in one lump sum at the end of the period. For example, if we get our $8000 all at the end of the four years, `pvl(9%, 4, 8000) = 5667.40`. This is much less than pv reported, because we don't earn any interest on the return from this investment. Note that pvl and fvl are simple inverses: `fvl(9%, 4, 5667.40) = 8000`.

You can give an optional fourth lump-sum argument to pv and pvb; this is handled in exactly the same way as the fourth argument for fv and fvb.

The b N (`calc-fin-npv`) [npv] command computes the net present value of a series of irregular investments. The first argument is the interest rate. The second argument is a vector which represents the expected return from the investment at the end of each interval. For example, if the rate represents a yearly interest rate, then the vector elements are the return from the first year, second year, and so on.

Thus, `npv(9%, [2000,2000,2000,2000]) = pv(9%, 4, 2000) = 6479.44`. Obviously this function is more interesting when the payments are not all the same!

The npv function can actually have two or more arguments. Multiple arguments are interpreted in the same way as for the vector statistical functions like vsum. See section Single-Variable Statistics. Basically, if there are several payment arguments, each either a vector or a plain number, all these values are collected left-to-right into the complete list of payments. A numeric prefix argument on the b N command says how many payment values or vectors to take from the stack.

The I b N [npvb] command computes the net present value where payments occur at the beginning of each interval rather than at the end.

Related Financial Functions

The functions in this section are basically inverses of the present value functions with respect to the various arguments.

The b M (`calc-fin-pmt`) [pmt] command computes the amount of periodic payment necessary to amortize a loan. Thus `pmt(rate, n, amount)` equals the value of payment such that `pv(rate, n, payment) = amount`.

The I b M [pmtb] command does the same computation but using pvb instead of pv. Like pv and pvb, these functions can also take a fourth argument which represents an initial lump-sum investment.

The H b M key just invokes the fvl function, which is the inverse of pvl. There is no explicit pmtl function.

The b # (`calc-fin-nper`) [nper] command computes the number of regular payments necessary to amortize a loan. Thus `nper(rate, payment, amount)` equals the value of n such that `pv(rate, n, payment) = amount`. If payment is too small ever to amortize a loan for amount at interest rate rate, the nper function is left in symbolic form.

The I b # [nperb] command does the same computation but using pvb instead of pv. You can give a fourth lump-sum argument to these functions, but the computation will be rather slow in the

four-argument case.

The H b # [`nperl`] command does the same computation using `pvl`. By exchanging payment and amount you can also get the solution for `fvl`. For example, `nperl(8%, 2000, 1000) = 9.006`, so if you place $1000 in a bank account earning 8%, it will take nine years to grow to $2000.

The b T (`calc-fin-rate`) [`rate`] command computes the rate of return on an investment. This is also an inverse of `pv`: `rate(n, payment, amount)` computes the value of rate such that `pv(rate, n, payment) = amount`. The result is expressed as a formula like `6.3%'.

The I b T [`rateb`] and H b T [`ratel`] commands solve the analogous equations with `pvb` or `pvl` in place of `pv`. Also, `rate` and `rateb` can accept an optional fourth argument just like `pv` and `pvb`. To redo the above example from a different perspective, `ratel(9, 2000, 1000) = 8.00597%`, which says you will need an interest rate of 8% in order to double your account in nine years.

The b I (`calc-fin-irr`) [`irr`] command is the analogous function to `rate` but for net present value. Its argument is a vector of payments. Thus `irr(payments)` computes the rate such that `npv(rate, payments) = 0`; this rate is known as the internal rate of return.

The I b I [`irrb`] command computes the internal rate of return assuming payments occur at the beginning of each period.

Depreciation Functions

The functions in this section calculate depreciation, which is the amount of value that a possession loses over time. These functions are characterized by three parameters: cost, the original cost of the asset; salvage, the value the asset will have at the end of its expected "useful life"; and life, the number of years (or other periods) of the expected useful life.

There are several methods for calculating depreciation that differ in the way they spread the depreciation over the lifetime of the asset.

The b S (`calc-fin-sln`) [`sln`] command computes the "straight-line" depreciation. In this method, the asset depreciates by the same amount every year (or period). For example, `sln(12000, 2000, 5)' returns 2000. The asset costs $12000 initially and will be worth $2000 after five years; it loses $2000 per year.

The b Y (`calc-fin-syd`) [`syd`] command computes the accelerated "sum-of-years'-digits" depreciation. Here the depreciation is higher during the early years of the asset's life. Since the depreciation is different each year, b Y takes a fourth period parameter which specifies which year is requested, from 1 to life. If period is outside this range, the `syd` function will return zero.

The b D (`calc-fin-ddb`) [`ddb`] command computes an accelerated depreciation using the double-declining balance method. It also takes a fourth period parameter.

For symmetry, the `sln` function will accept a period parameter as well, although it will ignore its value except that the return value will as usual be zero if period is out of range.

For example, pushing the vector [1,2,3,4,5] (perhaps with v x 5) and then mapping V M '

[sln(12000,2000,5,$), syd(12000,2000,5,$), ddb(12000,2000,5,$)] RET produces a matrix that allows to compare the three depreciation methods:

```
[ [ 2000, 3333, 4800 ]
  [ 2000, 2667, 2880 ]
  [ 2000, 2000, 1728 ]
  [ 2000, 1333,  592 ]
  [ 2000,  667,   0  ] ]
```

(Values have been rounded to nearest integers in this figure.) We see that `sln` depreciates by the same amount each year, syd depreciates more at the beginning and less at the end, and ddb weights the depreciation even more toward the beginning.

Summing columns with V R : + yields [10000, 10000, 10000]; the total depreciation in any method is (by definition) the difference between the cost and the salvage value.

Definitions

For your reference, here are the actual formulas used to compute Calc's financial functions.

Calc will not evaluate a financial function unless the rate or n argument is known. However, payment or amount can be a variable. Calc expands these functions according to the formulas below for symbolic arguments only when you use the a " (`calc-expand-formula`) command, or when taking derivatives or integrals or solving equations involving the functions.

In `pmt` and `pmtb`, x=0 if omitted.

These functions accept any numeric objects, including error forms, intervals, and even (though not very usefully) complex numbers. The above formulas specify exactly the behavior of these functions with all sorts of inputs.

Note that if the first argument to the `log` in `nper` is negative, `nper` leaves itself in symbolic form rather than returning a (financially meaningless) complex number.

`rate(num, pmt, amt)' solves the equation `pv(rate, num, pmt) = amt' for `rate' using H a R (`calc-find-root`), with the interval `[.01% .. 100%]' for an initial guess. The `rateb` function is the same except that it uses `pvb`. Note that `ratel` can be solved directly; its formula is shown in the above list.

Similarly, `irr(pmts)' solves the equation `npv(rate, pmts) = 0' for `rate'.

If you give a fourth argument to `nper` or `nperb`, Calc will also use H a R to solve the equation using an initial guess interval of `[0 .. 100]'.

A fourth argument to `fv` simply sums the two components calculated from the above formulas for `fv` and `fvl`. The same is true of `fvb`, `pv`, and `pvb`.

The ddb function is computed iteratively; the "book" value starts out equal to cost, and decreases according to the above formula for the specified number of periods. If the book value would decrease

below salvage, it only decreases to salvage and the depreciation is zero for all subsequent periods. Th `ddb` function returns the amount the book value decreased in the specified period.

The Calc financial function names were borrowed mostly from Microsoft Excel and Borland's Quattro. The `ratel` function corresponds to `@CGR' in Borland's Reflex. The `nper` and `nperl` functions correspond to `@TERM' and `@CTERM' in Quattro, respectively. Beware that the Calc functions may take their arguments in a different order than the corresponding functions in your favorite spreadsheet.

Binary Number Functions

The commands in this chapter all use two-letter sequences beginning with the b prefix.

The "binary" operations actually work regardless of the currently displayed radix, although their results make the most sense in a radix like 2, 8, or 16 (as obtained by the d 2, d 8, or d 6 commands, respectively). You may also wish to enable display of leading zeros with d z. See section Radix Modes.

The Calculator maintains a current word size w, an arbitrary positive or negative integer. For a positive word size, all of the binary operations described here operate modulo 2^w. In particular, negative arguments are converted to positive integers modulo 2^w by all binary functions.

If the word size is negative, binary operations produce 2's complement integers from @c{-2^{-w-1}} -(2^(-w-1)) to @c{$2^{-w-1}-1$} 2^(-w-1)-1 inclusive. Either mode accepts inputs in any range; the sign of w affects only the results produced.

The b c (`calc-clip`) [`clip`] command can be used to clip a number by reducing it modulo 2^w. The commands described in this chapter automatically clip their results to the current word size. Note that other operations like addition do not use the current word size, since integer addition generally is not "binary." (However, see section Simplification Modes, `calc-bin-simplify-mode`.) For example, with a word size of 8 bits b c converts a number to the range 0 to 255; with a word size of *-8* b c converts to the range *-128* to 127.

The default word size is 32 bits. All operations except the shifts and rotates allow you to specify a different word size for that one operation by giving a numeric prefix argument: C-u 8 b c clips the top of stack to the range 0 to 255 regardless of the current word size. To set the word size permanently, use b w (`calc-word-size`). This command displays a prompt with the current word size; press RET immediately to keep this word size, or type a new word size at the prompt.

When the binary operations are written in symbolic form, they take an optional second (or third) word-size parameter. When a formula like `and(a,b)' is finally evaluated, the word size current at that time will be used, but when `and(a,b,-8)' is evaluated, a word size of *-8* will always be used. A symbolic binary function will be left in symbolic form unless the all of its argument(s) are integers or integer-valued floats.

If either or both arguments are modulo forms for which M is a power of two, that power of two is taken as the word size unless a numeric prefix argument overrides it. The current word size is never consulted when modulo-power-of-two forms are involved.

The b a (`calc-and`) [`and`] command computes the bitwise AND of the two numbers on the top of the

stack. In other words, for each of the w binary digits of the two numbers (pairwise), the correspondi of the result is 1 if and only if both input bits are 1: `and(2#1100, 2#1010) = 2#1000'.

The b o (`calc-or`) [`or`] command computes the bitwise inclusive OR of two numbers. A bit is 1 if either of the input bits, or both, are 1: `or(2#1100, 2#1010) = 2#1110'.

The b x (`calc-xor`) [`xor`] command computes the bitwise exclusive OR of two numbers. A bit is 1 if exactly one of the input bits is 1: `xor(2#1100, 2#1010) = 2#0110'.

The b d (`calc-diff`) [`diff`] command computes the bitwise difference of two numbers; this is defined by `diff(a,b) = and(a,not(b))', so that `diff(2#1100, 2#1010) = 2#0100'.

The b n (`calc-not`) [`not`] command computes the bitwise NOT of a number. A bit is 1 if the input bit is 0 and vice-versa.

The b l (`calc-lshift-binary`) [`lsh`] command shifts a number left by one bit, or by the number of bits specified in the numeric prefix argument. A negative prefix argument performs a logical right shift, in which zeros are shifted in on the left. In symbolic form, `lsh(a)' is short for `lsh(a,1)', which in turn is short for `lsh(a,n,w)'. Bits shifted "off the end," according to the current word size, are lost.

The H b l command also does a left shift, but it takes two arguments from the stack (the value to shift, and, at top-of-stack, the number of bits to shift). This version interprets the prefix argument just like the regular binary operations, i.e., as a word size. The Hyperbolic flag has a similar effect on the rest of the binary shift and rotate commands.

The b r (`calc-rshift-binary`) [`rsh`] command shifts a number right by one bit, or by the number of bits specified in the numeric prefix argument: `rsh(a,n) = lsh(a,-n)'.

The b L (`calc-lshift-arith`) [`ash`] command shifts a number left. It is analogous to `lsh`, except that if the shift is rightward (the prefix argument is negative), an arithmetic shift is performed as described below.

The b R (`calc-rshift-arith`) [`rash`] command performs an "arithmetic" shift to the right, in which the leftmost bit (according to the current word size) is duplicated rather than shifting in zeros. This corresponds to dividing by a power of two where the input is interpreted as a signed, twos-complement number. (The distinction between the `rsh' and `rash' operations is totally independent from whether the word size is positive or negative.) With a negative prefix argument, this performs a standard left shift.

The b t (`calc-rotate-binary`) [`rot`] command rotates a number one bit to the left. The leftmost bit (according to the current word size) is dropped off the left and shifted in on the right. With a numeric prefix argument, the number is rotated that many bits to the left or right.

See section Set Operations using Vectors, for the b p and b u commands that pack and unpack binary integers into sets. (For example, b u unpacks the number `2#11001' to the set of bit-numbers `[0, 3, 4]'.) Type b u V # to count the number of "1" bits in a binary integer.

Another interesting use of the set representation of binary integers is to reverse the bits in, say, a 32-bit integer. Type b u to unpack; type 31 TAB - to replace each bit-number in the set with 31 minus that bit-number; type b p to pack the set back into a binary integer.

Scientific Functions

The functions described here perform trigonometric and other transcendental calculations. They generally produce floating-point answers correct to the full current precision. The H (Hyperbolic) and I (Inverse) flag keys must be used to get some of these functions from the keyboard.

One miscellanous command is shift-P (`calc-pi`), which pushes the value of @c{π} pi (at the current precision) onto the stack. With the Hyperbolic flag, it pushes the value e, the base of natural logarithms. With the Inverse flag, it pushes Euler's constant @c{γ} gamma (about 0.5772). With both Inverse and Hyperbolic, it pushes the "golden ratio" @c{ϕ} phi (about 1.618). (At present, Euler's constant is not available to unlimited precision; Calc knows only the first 100 digits.) In Symbolic mode, these commands push the actual variables `pi', `e', `gamma', and `phi', respectively, instead of their values; see section Symbolic Mode.

The Q (`calc-sqrt`) [`sqrt`] function is described elsewhere; see section Basic Arithmetic. With the Inverse flag [`sqr`], this command computes the square of the argument.

See section Numeric Prefix Arguments, for a discussion of the effect of numeric prefix arguments on commands in this chapter which do not otherwise interpret a prefix argument.

Logarithmic Functions

The shift-L (`calc-ln`) [`ln`] command computes the natural logarithm of the real or complex number on the top of the stack. With the Inverse flag it computes the exponential function instead, although this is redundant with the E command.

The shift-E (`calc-exp`) [`exp`] command computes the exponential, i.e., e raised to the power of the number on the stack. The meanings of the Inverse and Hyperbolic flags follow from those for the `calc-ln` command.

The H L (`calc-log10`) [`log10`] command computes the common (base-10) logarithm of a number. (With the Inverse flag [`exp10`], it raises ten to a given power.) Note that the common logarithm of a complex number is computed by taking the natural logarithm and dividing by @c{$\ln10$} ln(10).

The B (`calc-log`) [`log`] command computes a logarithm to any base. For example, 1024 RET 2 B produces 10, since 2^10 = 1024. In certain cases like `log(3,9)', the result will be either 1:2 or 0.5 depending on the current Fraction Mode setting. With the Inverse flag [`alog`], this command is similar to ^ except that the order of the arguments is reversed.

The f I (`calc-ilog`) [`ilog`] command computes the integer logarithm of a number to any base. The number and the base must themselves be positive integers. This is the true logarithm, rounded down to an integer. Thus ilog(x,10) is 3 for all x in the range from 1000 to 9999. If both arguments are positive integers, exact integer arithmetic is used; otherwise, this is equivalent to `floor(log(x,b))'.

The f E (`calc-expm1`) [`expm1`] command computes exp(x)-1, but using an algorithm that produces more accurate answer when the result is close to zero, i.e., when @c{e^x} exp(x) is close to one.

The f L (`calc-lnp1`) [`lnp1`] command computes ln(x+1), producing a more accurate answer when x is close to zero.

Trigonometric/Hyperbolic Functions

The shift-S (`calc-sin`) [`sin`] command computes the sine of an angle or complex number. If the input is an HMS form, it is interpreted as degrees-minutes-seconds; otherwise, the input is interpreted according to the current angular mode. It is best to use Radians mode when operating on complex numbers.

Calc's "units" mechanism includes angular units like `deg`, `rad`, and `grad`. While `sin(45 deg)' is not evaluated all the time, the u s (`calc-simplify-units`) command will simplify `sin(45 deg)' by taking the sine of 45 degrees, regardless of the current angular mode. See section Basic Operations on Units.

Also, the symbolic variable `pi` is not ordinarily recognized in arguments to trigonometric functions, as in `sin(3 pi / 4)', but the a s (`calc-simplify`) command recognizes many such formulas when the current angular mode is radians *and* symbolic mode is enabled; this example would be replaced by `sqrt(2) / 2'. See section Symbolic Mode. Beware, this simplification occurs even if you have stored a different value in the variable `pi'; this is one reason why changing built-in variables is a bad idea. Arguments of the form x plus a multiple of @c{$\pi/2$} pi/2 are also simplified. Calc includes similar formulas for `cos` and `tan`.

The a s command knows all angles which are integer multiples of pi/12, @c{$\pi/10$} pi/10, or @c{$\pi/8$} pi/8 radians. In degrees mode, analogous simplifications occur for integer multiples of 15 or 18 degrees, and for arguments plus multiples of 90 degrees.

With the Inverse flag, `calc-sin` computes an arcsine. This is also available as the `calc-arcsin` command or `arcsin` algebraic function. The returned argument is converted to degrees, radians, or HMS notation depending on the current angular mode.

With the Hyperbolic flag, `calc-sin` computes the hyperbolic sine, also available as `calc-sinh` [`sinh`]. With the Hyperbolic and Inverse flags, it computes the hyperbolic arcsine (`calc-arcsinh`) [`arcsinh`].

The shift-C (`calc-cos`) [`cos`] command computes the cosine of an angle or complex number, and shift-T (`calc-tan`) [`tan`] computes the tangent, along with all the various inverse and hyperbolic variants of these functions.

The f T (`calc-arctan2`) [`arctan2`] command takes two numbers from the stack and computes the arc tangent of their ratio. The result is in the full range from *-180* (exclusive) to *+180* (inclusive) degrees, or the analogous range in radians. A similar result would be obtained with / followed by I T, but the value would only be in the range from *-90* to *+90* degrees since the division loses information about the signs of the two components, and an error might result from an explicit division by zero which

`arctan2` would avoid. By (arbitrary) definition, `arctan2(0,0)=0'.

The `calc-sincos` [`sincos`] command computes the sine and cosine of a number, returning them as a vector of the form `[cos, sin]'. With the Inverse flag [`arcsincos`], this command takes a two-element vector as an argument and computes `arctan2` of the elements. (This command does not accept the Hyperbolic flag.)

Advanced Mathematical Functions

Calc can compute a variety of less common functions that arise in various branches of mathematics. All of the functions described in this section allow arbitrary complex arguments and, except as noted, will work to arbitrarily large precisions. They can not at present handle error forms or intervals as arguments.

NOTE: These functions are still experimental. In particular, their accuracy is not guaranteed in all domains. It is advisable to set the current precision comfortably higher than you actually need when using these functions. Also, these functions may be impractically slow for some values of the arguments.

The f g (`calc-gamma`) [`gamma`] command computes the Euler gamma function. For positive integer arguments, this is related to the factorial function: `gamma(n+1) = fact(n)'. For general complex arguments the gamma function can be defined by the following definite integral: @c{$\Gamma(a) = \int_0^\infty t^{a-1} e^t dt$} gamma(a) = integ(t^(a-1) exp(t), t, 0, inf). (The actual implementation uses far more efficient computational methods.)

The f G (`calc-inc-gamma`) [`gammaP`] command computes the incomplete gamma function, denoted `P(a,x)'. This is defined by the integral, @c{$P(a,x) = \left( \int_0^x t^{a-1} e^t dt \right) / \Gamma(a)$} gammaP(a,x) = integ(t^(a-1) exp(t), t, 0, x) / gamma(a). This implies that `gammaP(a,inf) = 1' for any a (see the definition of the normal gamma function).

Several other varieties of incomplete gamma function are defined. The complement of P(a,x), called Q(a,x) = 1-P(a,x) by some authors, is computed by the I f G [`gammaQ`] command. You can think of this as taking the other half of the integral, from x to infinity.

The f b (`calc-beta`) [`beta`] command computes the Euler beta function, which is defined in terms of the gamma function as beta(a,b) = gamma(a) gamma(b) / gamma(a+b), or by beta(a,b) = integ(t^(a-1) (1-t)^(b-1), t, 0, 1).

The f B (`calc-inc-beta`) [`betaI`] command computes the incomplete beta function I(x,a,b). It is defined by betaI(x,a,b) = integ(t^(a-1) (1-t)^(b-1), t, 0, x) / beta(a,b). Once again, the H (hyperbolic) prefix gives the corresponding un-normalized version [`betaB`].

The f e (`calc-erf`) [`erf`] command computes the error function @c{$\hbox{erf}(x) = {2 \over \sqrt{\pi}} \int_0^x e^{-t^2} dt$} erf(x) = 2 integ(exp(-(t^2)), t, 0, x) / sqrt(pi). The complementary error function I f e (`calc-erfc`) [`erfc`] is the corresponding integral from `x' to infinity; the sum erf(x) + erfc(x) = 1.

The f j (`calc-bessel-J`) [`besJ`] and f y (`calc-bessel-Y`) [`besY`] commands compute the Bessel functions of the first and second kinds, respectively. In `besJ(n,x)' and `besY(n,x)' the "order" parameter n is often an integer, but is not required to be one. Calc's implementation of the Bessel

functions currently limits the precision to 8 digits, and may not be exact even to that precision. Use with care!

Branch Cuts and Principal Values

All of the logarithmic, trigonometric, and other scientific functions are defined for complex numbers as well as for reals. This section describes the values returned in cases where the general result is a family of possible values. Calc follows section 12.5.3 of Steele's Common Lisp, the Language, second edition, in these matters. This section will describe each function briefly; for a more detailed discussion (including some nifty diagrams), consult Steele's book.

Note that the branch cuts for `arctan` and `arctanh` were changed between the first and second editions of Steele. Versions of Calc starting with 2.00 follow the second edition.

The new branch cuts exactly match those of the HP-28/48 calculators. They also match those of Mathematica 1.2, except that Mathematica's `arctan` cut is always in the right half of the complex plane, and its `arctanh` cut is always in the top half of the plane. Calc's cuts are continuous with quadrants I and III for `arctan`, or II and IV for `arctanh`.

Note: The current implementations of these functions with complex arguments are designed with proper behavior around the branch cuts in mind, *not* efficiency or accuracy. You may need to increase the floating precision and wait a while to get suitable answers from them.

For `sqrt(a+bi)': When a<0 and b is small but positive or zero, the result is close to the +i axis. For b small and negative, the result is close to the -i axis. The result always lies in the right half of the complex plane.

For `ln(a+bi)': The real part is defined as `ln(abs(a+bi))'. The imaginary part is defined as `arg(a+bi) = arctan2(b,a)'. Thus the branch cuts for `sqrt` and `ln` both lie on the negative real axis.

The following table describes these branch cuts in another way. If the real and imaginary parts of z are as shown, then the real and imaginary parts of f(z) will be as shown. Here `eps` stands for a small positive value; each occurrence of `eps` may stand for a different small value.

```
     z           sqrt(z)       ln(z)
-----------------------------------------
   +,   0         +,  0       any, 0
   -,   0         0,  +       any, pi
   -, +eps      +eps, +      +eps, +
   -, -eps      +eps, -      +eps, -
```

For `z1^z2': This is defined by `exp(ln(z1)*z2)'. One interesting consequence of this is that `(-8)^1:3' does not evaluate to *-2* as you might expect, but to the complex number (1., 1.732). Both of these are valid cube roots of *-8* (as is (1., -1.732)); Calc chooses a perhaps less-obvious root for the sake of mathematical consistency.

For `arcsin(z)': This is defined by `-i*ln(i*z + sqrt(1-z^2))'. The branch cuts are on the real axis, less than

-1 and greater than 1.

For `arccos(z)': This is defined by `-i*ln(z + i*sqrt(1-z^2))', or equivalently by `pi/2 - arcsin(z)'. The branch cuts are on the real axis, less than *-1* and greater than 1.

For `arctan(z)': This is defined by `(ln(1+i*z) - ln(1-i*z)) / (2*i)'. The branch cuts are on the imaginary axis, below -i and above i.

For `arcsinh(z)': This is defined by `ln(z + sqrt(1+z^2))'. The branch cuts are on the imaginary axis, below -i and above i.

For `arccosh(z)': This is defined by `ln(z + (z+1)*sqrt((z-1)/(z+1)))'. The branch cut is on the real axis less than 1.

For `arctanh(z)': This is defined by `(ln(1+z) - ln(1-z)) / 2'. The branch cuts are on the real axis, less than *-1* and greater than 1.

The following tables for `arcsin`, `arccos`, and `arctan` assume the current angular mode is radians. The hyperbolic functions operate independently of the angular mode.

z	arcsin(z)	arccos(z)
(-1..1), 0	(-pi/2..pi/2), 0	(0..pi), 0
(-1..1), +eps	(-pi/2..pi/2), +eps	(0..pi), -eps
(-1..1), -eps	(-pi/2..pi/2), -eps	(0..pi), +eps
<-1, 0	-pi/2, +	pi, -
<-1, +eps	-pi/2 + eps, +	pi - eps, -
<-1, -eps	-pi/2 + eps, -	pi - eps, +
>1, 0	pi/2, -	0, +
>1, +eps	pi/2 - eps, +	+eps, -
>1, -eps	pi/2 - eps, -	+eps, +

z	arccosh(z)	arctanh(z)
(-1..1), 0	0, (0..pi)	any, 0
(-1..1), +eps	+eps, (0..pi)	any, +eps
(-1..1), -eps	+eps, (-pi..0)	any, -eps
<-1, 0	+, pi	-, pi/2
<-1, +eps	+, pi - eps	-, pi/2 - eps
<-1, -eps	+, -pi + eps	-, -pi/2 + eps
>1, 0	+, 0	+, -pi/2
>1, +eps	+, +eps	+, pi/2 - eps
>1, -eps	+, -eps	+, -pi/2 + eps

z	arcsinh(z)	arctan(z)
0, (-1..1)	0, (-pi/2..pi/2)	0, any

```
  0,   <-1      -,    -pi/2          -pi/2,    -
+eps,  <-1      +, -pi/2 + eps      pi/2 - eps, -
-eps,  <-1      -, -pi/2 + eps     -pi/2 + eps, -
  0,    >1      +,     pi/2           pi/2,    +
+eps,   >1      +,  pi/2 - eps      pi/2 - eps, +
-eps,   >1      -,  pi/2 - eps     -pi/2 + eps, +
```

Finally, the following identities help to illustrate the relationship between the complex trigonometric and hyperbolic functions. They are valid everywhere, including on the branch cuts.

```
sin(i*z)  = i*sinh(z)       arcsin(i*z)  = i*arcsinh(z)
cos(i*z)  =   cosh(z)       arcsinh(i*z) = i*arcsin(z)
tan(i*z)  = i*tanh(z)       arctan(i*z)  = i*arctanh(z)
sinh(i*z) = i*sin(z)        cosh(i*z)    =   cos(z)
```

The "advanced math" functions (gamma, Bessel, etc.) are also defined for general complex arguments, but their branch cuts and principal values are not rigorously specified at present.

Random Numbers

The k r (`calc-random`) [`random`] command produces random numbers of various sorts.

Given a positive numeric prefix argument M, it produces a random integer N in the range @c{$0 \le N < M$} 0 <= N < M. Each of the M values appears with equal probability.

With no numeric prefix argument, the k r command takes its argument from the stack instead. Once again, if this is a positive integer M the result is a random integer less than M. However, note that while numeric prefix arguments are limited to six digits or so, an M taken from the stack can be arbitrarily large. If M is negative, the result is a random integer in the range @c{$M < N \le 0$} M < N <= 0.

If the value on the stack is a floating-point number M, the result is a random floating-point number N in the range @c{$0 \le N < M$} 0 <= N < M or @c{$M < N \le 0$} M < N <= 0, according to the sign of M.

If M is zero, the result is a Gaussian-distributed random real number; the distribution has a mean of zero and a standard deviation of one. The algorithm used generates random numbers in pairs; thus, every other call to this function will be especially fast.

If M is an error form @c{m +/- σ} `m +/- s' where *m* and @c{σ} *s* are both real numbers, the result uses a Gaussian distribution with mean *m* and standard deviation @c{σ} *s*.

If M is an interval form, the lower and upper bounds specify the acceptable limits of the random numbers. If both bounds are integers, the result is a random integer in the specified range. If either bound is floating-point, the result is a random real number in the specified range. If the interval is open at either end, the result will be sure not to equal that end value. (This makes a big difference for integer intervals, but for floating-point intervals it's relatively minor: with a precision of 6, `random([1.0..2.0))' will return any of one million numbers from 1.00000 to 1.99999; `random([1.0..2.0])' may additionally return

2.00000, but the probability of this happening is extremely small.)

If M is a vector, the result is one element taken at random from the vector. All elements of the vector are given equal probabilities.

The sequence of numbers produced by k r is completely random by default, i.e., the sequence is seeded each time you start Calc using the current time and other information. You can get a reproducible sequence by storing a particular "seed value" in the Calc variable `RandSeed`. Any integer will do for a seed; integers of from 1 to 12 digits are good. If you later store a different integer into `RandSeed`, Calc will switch to a different pseudo-random sequence. If you "unstore" `RandSeed`, Calc will re-seed itself from the current time. If you store the same integer that you used before back into `RandSeed`, you will get the exact same sequence of random numbers as before.

The `calc-rrandom` command (not on any key) produces a random real number between zero and one. It is equivalent to `random(1.0)'.

The k a (`calc-random-again`) command produces another random number, re-using the most recent value of M. With a numeric prefix argument n, it produces n more random numbers using that value of M.

The k h (`calc-shuffle`) command produces a vector of several random values with no duplicates. The value on the top of the stack specifies the set from which the random values are drawn, and may be any of the M formats described above. The numeric prefix argument gives the length of the desired list. (If you do not provide a numeric prefix argument, the length of the list is taken from the top of the stack, and M from second-to-top.)

If M is a floating-point number, zero, or an error form (so that the random values are being drawn from the set of real numbers) there is little practical difference between using k h and using k r several times. But if the set of possible values consists of just a few integers, or the elements of a vector, then there is a very real chance that multiple k r's will produce the same number more than once. The k h command produces a vector whose elements are always distinct. (Actually, there is a slight exception: If M is a vector, no given vector element will be drawn more than once, but if several elements of M are equal, they may each make it into the result vector.)

One use of k h is to rearrange a list at random. This happens if the prefix argument is equal to the number of values in the list: [1, 1.5, 2, 2.5, 3] 5 k h might produce the permuted list `[2.5, 1, 1.5, 3, 2]'. As a convenient feature, if the argument n is negative it is replaced by the size of the set represented by M. Naturally, this is allowed only when M specifies a small discrete set of possibilities.

To do the equivalent of k h but with duplications allowed, given M on the stack and with n just entered as a numeric prefix, use v b to build a vector of copies of M, then use V M k r to "map" the normal k r function over the elements of this vector. See section Vector/Matrix Functions.

Random Number Generator

Calc's random number generator uses several methods to ensure that the numbers it produces are highly random. Knuth's *Art of Computer Programming*, Volume II, contains a thorough description of the theory of random number generators and their measurement and characterization.

If `RandSeed` has no stored value, Calc calls Emacs' built-in `random` function to get a stream of random numbers, which it then treats in various ways to avoid problems inherent in the simple random number generators that many systems use to implement `random`.

When Calc's random number generator is first invoked, it "seeds" the low-level random sequence using the time of day, so that the random number sequence will be different every time you use Calc.

Since Emacs Lisp doesn't specify the range of values that will be returned by its `random` function, Calc exercises the function several times to estimate the range. When Calc subsequently uses the `random` function, it takes only 10 bits of the result near the most-significant end. (It avoids at least the bottom four bits, preferably more, and also tries to avoid the top two bits.) This strategy works well with the linear congruential generators that are typically used to implement `random`.

If `RandSeed` contains an integer, Calc uses this integer to seed an "additive congruential" method (Knuth's algorithm 3.2.2A, computing @c{$X_{n-55} - X_{n-24}$} X_n-55 - X_n-24). This method expands the seed value into a large table which is maintained internally; the variable `RandSeed` is changed from, e.g., 42 to the vector [42] to indicate that the seed has been absorbed into this table. When `RandSeed` contains a vector, k r and related commands continue to use the same internal table as last time. There is no way to extract the complete state of the random number generator so that you can restart it from any point; you can only restart it from the same initial seed value. A simple way to restart from the same seed is to type s r RandSeed to get the seed vector, v u to unpack it back into a number, then s t RandSeed to reseed the generator with that number.

Calc uses a "shuffling" method as described in algorithm 3.2.2B of Knuth. It fills a table with 13 random 10-bit numbers. Then, to generate a new random number, it uses the previous number to index into the table, picks the value it finds there as the new random number, then replaces that table entry with a new value obtained from a call to the base random number generator (either the additive congruential generator or the `random` function supplied by the system). If there are any flaws in the base generator, shuffling will tend to even them out. But if the system provides an excellent `random` function, shuffling will not damage its randomness.

To create a random integer of a certain number of digits, Calc builds the integer three decimal digits at a time. For each group of three digits, Calc calls its 10-bit shuffling random number generator (which returns a value from 0 to 1023); if the random value is 1000 or more, Calc throws it out and tries again until it gets a suitable value.

To create a random floating-point number with precision p, Calc simply creates a random p-digit integer and multiplies by 10^-p. The resulting random numbers should be very clean, but note that relatively small numbers will have few significant random digits. In other words, with a precision of 12, you will occasionally get numbers on the order of @c{10^{-9}} 10^-9 or @c{10^{-10}} 10^-10, but those numbers will only have two or three random digits since they correspond to small integers times @c{10^{-12}} 10^-12.

To create a random integer in the interval `[0 .. m)', Calc counts the digits in m, creates a random integer with three additional digits, then reduces modulo m. Unless m is a power of ten the resulting values will be very slightly biased toward the lower numbers, but this bias will be less than 0.1%. (For example, if m is 42, Calc will reduce a random integer less than 100000 modulo 42 to get a result less than 42. It is easy to show that the numbers 40 and 41 will be only 2380/2381 as likely to result from this modulo operation

as numbers 39 and below.) If m is a power of ten, however, the numbers should be completely unbia

The Gaussian random numbers generated by `random(0.0)' use the "polar" method described in Knuth section 3.4.1C. This method generates a pair of Gaussian random numbers at a time, so only every other call to `random(0.0)' will require significant calculations.

Combinatorial Functions

Commands relating to combinatorics and number theory begin with the k key prefix.

The k g (`calc-gcd`) [`gcd`] command computes the Greatest Common Divisor of two integers. It also accepts fractions; the GCD of two fractions is defined by taking the GCD of the numerators, and the LCM of the denominators. This definition is consistent with the idea that `a / gcd(a,x)' should yield an integer for any `a' and `x'. For other types of arguments, the operation is left in symbolic form.

The k l (`calc-lcm`) [`lcm`] command computes the Least Common Multiple of two integers or fractions. The product of the LCM and GCD of two numbers is equal to the product of the numbers.

The k E (`calc-extended-gcd`) [`egcd`] command computes the GCD of two integers x and y and returns a vector [g, a, b] where @c{$g = \gcd(x,y) = a x + b y$} g = gcd(x,y) = a x + b y.

The ! (`calc-factorial`) [`fact`] command computes the factorial of the number at the top of the stack. If the number is an integer, the result is an exact integer. If the number is an integer-valued float, the result is a floating-point approximation. If the number is a non-integral real number, the generalized factorial is used, as defined by the Euler Gamma function. Please note that computation of large factorials can be slow; using floating-point format will help since fewer digits must be maintained. The same is true of many of the commands in this section.

The k d (`calc-double-factorial`) [`dfact`] command computes the "double factorial" of an integer. For an even integer, this is the product of even integers from 2 to N. For an odd integer, this is the product of odd integers from 3 to N. If the argument is an integer-valued float, the result is a floating-point approximation. This function is undefined for negative even integers. The notation N!! is also recognized for double factorials.

The k c (`calc-choose`) [`choose`] command computes the binomial coefficient N-choose-M, where M is the number on the top of the stack and N is second-to-top. If both arguments are integers, the result is an exact integer. Otherwise, the result is a floating-point approximation. The binomial coefficient is defined for all real numbers by @c{$N! \over M! (N-M)!\,$} N! / M! (N-M)!.

The k b (`calc-bernoulli-number`) [`bern`] command computes a given Bernoulli number. The value at the top of the stack is a nonnegative integer n that specifies which Bernoulli number is desired. The H k b command computes a Bernoulli polynomial, taking n from the second-to-top position and x from the top of the stack. If x is a variable or formula the result is a polynomial in x; if x is a number the result is a number.

The k e (`calc-euler-number`) [`euler`] command similarly computes an Euler number, and H k e computes an Euler polynomial. Bernoulli and Euler numbers occur in the Taylor expansions of several functions.

The k s (`calc-stirling-number`) [`stir1`] command computes a Stirling number of the first kind@c{ $n \brack m$} , given two integers n and m on the stack. The H k s [`stir2`] command computes a Stirling number of the second kind@c{ $n \brace m$} . These are the number of m-cycle permutations of n objects, and the number of ways to partition n objects into m non-empty sets, respectively.

The k p (`calc-prime-test`) command checks if the integer on the top of the stack is prime. For integers less than eight million, the answer is always exact and reasonably fast. For larger integers, a probabilistic method is used (see Knuth vol. II, section 4.5.4, algorithm P). The number is first checked against small prime factors (up to 13). Then, any number of iterations of the algorithm are performed. Each step either discovers that the number is non-prime, or substantially increases the certainty that the number is prime. After a few steps, the chance that a number was mistakenly described as prime will be less than one percent. (Indeed, this is a worst-case estimate of the probability; in practice even a single iteration is quite reliable.) After the k p command, the number will be reported as definitely prime or non-prime if possible, or otherwise "probably" prime with a certain probability of error.

The normal k p command performs one iteration of the primality test. Pressing k p repeatedly for the same integer will perform additional iterations. Also, k p with a numeric prefix performs the specified number of iterations. There is also an algebraic function `prime(n)' or `prime(n,iters)' which returns 1 if n is (probably) prime and 0 if not.

The k f (`calc-prime-factors`) [`prfac`] command attempts to decompose an integer into its prime factors. For numbers up to 25 million, the answer is exact although it may take some time. The result is a vector of the prime factors in increasing order. For larger inputs, prime factors above 5000 may not be found, in which case the last number in the vector will be an unfactored integer greater than 25 million (with a warning message). For negative integers, the first element of the list will be *-1*. For inputs *-1*, *0*, and *1*, the result is a list of the same number.

The k n (`calc-next-prime`) [`nextprime`] command finds the next prime above a given number. Essentially, it searches by calling `calc-prime-test` on successive integers until it finds one that passes the test. This is quite fast for integers less than eight million, but once the probabilistic test comes into play the search may be rather slow. Ordinarily this command stops for any prime that passes one iteration of the primality test. With a numeric prefix argument, a number must pass the specified number of iterations before the search stops. (This only matters when searching above eight million.) You can always use additional k p commands to increase your certainty that the number is indeed prime.

The I k n (`calc-prev-prime`) [`prevprime`] command analogously finds the next prime less than a given number.

The k t (`calc-totient`) [`totient`] command computes the Euler "totient" function@c{ $\phi(n)$} , the number of integers less than n which are relatively prime to n.

The k m (`calc-moebius`) [`moebius`] command computes the Moebius "mu" function. If the input number is a product of k distinct factors, this is (-1)^k. If the input number has any duplicate factors (i.e., can be divided by the same prime more than once), the result is zero.

Probability Distribution Functions

The functions in this section compute various probability distributions. For continuous distributions, this is the integral of the probability density function from x to infinity. (These are the "upper tail" distribution functions; there are also corresponding "lower tail" functions which integrate from minus infinity to x.) For discrete distributions, the upper tail function gives the sum from x to infinity; the lower tail function gives the sum from minus infinity up to, but not including, x.

To integrate from x to y, just use the distribution function twice and subtract. For example, the probability that a Gaussian random variable with mean 2 and standard deviation 1 will lie in the range from 2.5 to 2.8 is `utpn(2.5,2,1) - utpn(2.8,2,1)' ("the probability that it is greater than 2.5, but not greater than 2.8"), or equivalently `ltpn(2.8,2,1) - ltpn(2.5,2,1)'.

The k B (`calc-utpb`) [`utpb`] function uses the binomial distribution. Push the parameters n, p, and then x onto the stack; the result (`utpb(x,n,p)') is the probability that an event will occur x or more times out of n trials, if its probability of occurring in any given trial is p. The I k B [`ltpb`] function is the probability that the event will occur fewer than x times.

The other probability distribution functions similarly take the form k X (`calc-utpx`) [`utpx`] and I k X [`ltpx`], for various letters x. The arguments to the algebraic functions are the value of the random variable first, then whatever other parameters define the distribution. Note these are among the few Calc functions where the order of the arguments in algebraic form differs from the order of arguments as found on the stack. (The random variable comes last on the stack, so that you can type, e.g., 2 RET 1 RET 2.5 k N M-RET DEL 2.8 k N -, using M-RET DEL to recover the original arguments but substitute a new value for x.)

The `utpc(x,v)' function uses the chi-square distribution with v degrees of freedom. It is the probability that a model is correct if its chi-square statistic is x.

The `utpf(F,v1,v2)' function uses the F distribution, used in various statistical tests. The parameters @c{ν_1} v1 and @c{ν_2} v2 are the degrees of freedom in the numerator and denominator, respectively, used in computing the statistic F.

The `utpn(x,m,s)' function uses a normal (Gaussian) distribution with mean m and standard deviation @c{σ} s. It is the probability that such a normal-distributed random variable would exceed x.

The `utpp(n,x)' function uses a Poisson distribution with mean x. It is the probability that n or more such Poisson random events will occur.

The `utpt(t,v)' function uses the Student's "t" distribution with @c{ν} v degrees of freedom. It is the probability that a t-distributed random variable will be greater than t. (Note: This computes the distribution function @c{$A(t|\nu)$} A(t|v) where @c{$A(0|\nu) = 1$} A(0|v) = 1 and @c{$A(\infty|\nu) \to 0$} A(inf|v) -> 0. The `UTPT` operation on the HP-48 uses a different definition which returns half of Calc's value: `UTPT(t,v) = .5*utpt(t,v)'.)

While Calc does not provide inverses of the probability distribution functions, the a R command can be used to solve for the inverse. Since the distribution functions are monotonic, a R is guaranteed to be able to find a solution given any initial guess. See section Numerical Solutions.

Go to the previous, next section.

Vector/Matrix Functions

Many of the commands described here begin with the v prefix. (For convenience, the shift-V prefix is equivalent to v.) The commands usually apply to both plain vectors and matrices; some apply only to matrices or only to square matrices. If the argument has the wrong dimensions the operation is left in symbolic form.

Vectors are entered and displayed using `[a,b,c]' notation. Matrices are vectors of which all elements are vectors of equal length. (Though none of the standard Calc commands use this concept, a three-dimensional matrix or rank-3 tensor could be defined as a vector of matrices, and so on.)

Packing and Unpacking

Calc's "pack" and "unpack" commands collect stack entries to build composite objects such as vectors and complex numbers. They are described in this chapter because they are most often used to build vectors.

The v p (`calc-pack`) [`pack`] command collects several elements from the stack into a matrix, complex number, HMS form, error form, etc. It uses a numeric prefix argument to specify the kind of object to be built; this argument is referred to as the "packing mode." If the packing mode is a nonnegative integer, a vector of that length is created. For example, C-u 5 v p will pop the top five stack elements and push back a single vector of those five elements. (C-u 0 v p simply creates an empty vector.)

The same effect can be had by pressing [to push an incomplete vector on the stack, using TAB (`calc-roll-down`) to sneak the incomplete object up past a certain number of elements, and then pressing] to complete the vector.

Negative packing modes create other kinds of composite objects:

-1

Two values are collected to build a complex number. For example, 5 RET 7 C-u -1 v p creates the complex number (5, 7). The result is always a rectangular complex number. The two input values must both be real numbers, i.e., integers, fractions, or floats. If they are not, Calc will instead build a formula like `a + (0, 1) b'. (The other packing modes also create a symbolic answer if the components are not suitable.)

-2

Two values are collected to build a polar complex number. The first is the magnitude; the second is the phase expressed in either degrees or radians according to the current angular mode.

-3

Three values are collected into an HMS form. The first two values (hours and minutes) must be integers or integer-valued floats. The third value may be any real number.

-4

Two values are collected into an error form. The inputs may be real numbers or formulas.

-5

Two values are collected into a modulo form. The inputs must be real numbers.

-6

Two values are collected into the interval `[a .. b]'. The inputs may be real numbers, HMS or date forms, or formulas.

-7

Two values are collected into the interval `[a .. b)'.

-8

Two values are collected into the interval `(a .. b]'.

-9

Two values are collected into the interval `(a .. b)'.

-10

Two integer values are collected into a fraction.

-11

Two values are collected into a floating-point number. The first is the mantissa; the second, which must be an integer, is the exponent. The result is the mantissa times ten to the power of the exponent.

-12

This is treated the same as *-11* by the v p command. When unpacking, *-12* specifies that a floating-point mantissa is desired.

-13

A real number is converted into a date form.

-14

Three numbers (year, month, day) are packed into a pure date form.

-15

Six numbers are packed into a date/time form.

With any of the two-input negative packing modes, either or both of the inputs may be vectors. If both are vectors of the same length, the result is another vector made by packing corresponding elements of the input vectors. If one input is a vector and the other is a plain number, the number is packed along with each vector element to produce a new vector. For example, C-u -4 v p could be used to convert a vector of numbers and a vector of errors into a single vector of error forms; C-u -5 v p could convert a vector of numbers and a single number M into a vector of numbers modulo M.

If you don't give a prefix argument to v p, it takes the packing mode from the top of the stack. The elements to be packed then begin at stack level 2. Thus 1 RET 2 RET 4 n v p is another way to enter the error form `1 +/- 2'.

If the packing mode taken from the stack is a vector, the result is a matrix with the dimensions specified

by the elements of the vector, which must each be integers. For example, if the packing mode is `[2, 3]' then six numbers will be taken from the stack and returned in the form `[[a, b, c], [d, e, f]]'.

If any elements of the vector are negative, other kinds of packing are done at that level as described above. For example, `[2, 3, -4]' takes 12 objects and creates a 2x3 matrix of error forms: `[[a +/- b, c +/- d ...]]'. Also, `[-4, -10]' will convert four integers into an error form consisting of two fractions: `a:b +/- c:d'.

There is an equivalent algebraic function, `pack(mode, items)' where mode is a packing mode (an integer or a vector of integers) and items is a vector of objects to be packed (re-packed, really) according to that mode. For example, `pack([3, -4], [a,b,c,d,e,f])' yields `[a +/- b, c +/- d, e +/- f]'. The function is left in symbolic form if the packing mode is illegal, or if the number of data items does not match the number of items required by the mode.

The v u (`calc-unpack`) command takes the vector, complex number, HMS form, or other composite object on the top of the stack and "unpacks" it, pushing each of its elements onto the stack as separate objects. Thus, it is the "inverse" of v p. If the value at the top of the stack is a formula, v u unpacks it by pushing each of the arguments of the top-level operator onto the stack.

You can optionally give a numeric prefix argument to v u to specify an explicit (un)packing mode. If the packing mode is negative and the input is actually a vector or matrix, the result will be two or more similar vectors or matrices of the elements. For example, given the vector `[a +/- b, c^2, d +/- 7]', the result of C-u -4 v u will be the two vectors `[a, c^2, d]' and `[b, 0, 7]'.

Note that the prefix argument can have an effect even when the input is not a vector. For example, if the input is the number *-5*, then c-u -1 v u yields *-5* and 0 (the components of *-5* when viewed as a rectangular complex number); C-u -2 v u yields 5 and 180 (assuming degrees mode); and C-u -10 v u yields *-5* and 1 (the numerator and denominator of *-5*, viewed as a rational number). Plain v u with this input would complain that the input is not a composite object.

Unpacking mode *-11* converts a float into an integer mantissa and an integer exponent, where the mantissa is not divisible by 10 (except that 0.0 is represented by a mantissa and exponent of 0). Unpacking mode *-12* converts a float into a floating-point mantissa and integer exponent, where the mantissa (for non-zero numbers) is guaranteed to lie in the range [1 .. 10). In both cases, the mantissa is shifted left or right (and the exponent adjusted to compensate) in order to satisfy these constraints.

Positive unpacking modes are treated differently than for v p. A mode of 1 is much like plain v u with no prefix argument, except that in addition to the components of the input object, a suitable packing mode to re-pack the object is also pushed. Thus, C-u 1 v u followed by v p will re-build the original object.

A mode of 2 unpacks two levels of the object; the resulting re-packing mode will be a vector of length 2. This might be used to unpack a matrix, say, or a vector of error forms. Higher unpacking modes unpack the input even more deeply.

There are two algebraic functions analogous to v u. The `unpack(mode, item)' function unpacks the item using the given mode, returning the result as a vector of components. Here the mode must be an integer, not a vector. For example, `unpack(-4, a +/- b)' returns `[a, b]', as does `unpack(1, a +/- b)'.

The `unpackt` function is like `unpack` but instead of returning a simple vector of items, it returns a

vector of two things: The mode, and the vector of items. For example, `unpackt(1, 2:3 +/- 1:4)' returns `[-4, [2:3, 1:4]]', and `unpackt(2, 2:3 +/- 1:4)' returns `[[-4, -10], [2, 3, 1, 4]]'. The identity for re-building the original object is `apply(pack, unpackt(n, x)) = x'. (The `apply` function builds a function call given the function name and a vector of arguments.)

Subscript notation is a useful way to extract a particular part of an object. For example, to get the numerator of a rational number, you can use `unpack(-10, x)_1'.

Building Vectors

Vectors and matrices can be added, subtracted, multiplied, and divided; see section Basic Arithmetic.

The | (`calc-concat`) command "concatenates" two vectors into one. For example, after [1 , 2] [3 , 4] |, the stack will contain the single vector `[1, 2, 3, 4]'. If the arguments are matrices, the rows of the first matrix are concatenated with the rows of the second. (In other words, two matrices are just two vectors of row-vectors as far as | is concerned.)

If either argument to | is a scalar (a non-vector), it is treated like a one-element vector for purposes of concatenation: 1 [2 , 3] | produces the vector `[1, 2, 3]'. Likewise, if one argument is a matrix and the other is a plain vector, the vector is treated as a one-row matrix.

The H | (`calc-append`) [`append`] command concatenates two vectors without any special cases. Both inputs must be vectors. Whether or not they are matrices is not taken into account. If either argument is a scalar, the `append` function is left in symbolic form. See also `cons` and `rcons` below.

The I | and H I | commands are similar, but they use their two stack arguments in the opposite order. Thus I | is equivalent to TAB |, but possibly more convenient and also a bit faster.

The v d (`calc-diag`) [`diag`] function builds a diagonal square matrix. The optional numeric prefix gives the number of rows and columns in the matrix. If the value at the top of the stack is a vector, the elements of the vector are used as the diagonal elements; the prefix, if specified, must match the size of the vector. If the value on the stack is a scalar, it is used for each element on the diagonal, and the prefix argument is required.

To build a constant square matrix, e.g., a @c{3×3} 3x3 matrix filled with ones, use 0 M-3 v d 1 +, i.e., build a zero matrix first and then add a constant value to that matrix. (Another alternative would be to use v b and v a; see below.)

The v i (`calc-ident`) [`idn`] function builds an identity matrix of the specified size. It is a convenient form of v d where the diagonal element is always one. If no prefix argument is given, this command prompts for one.

In algebraic notation, `idn(a,n)' acts much like `diag(a,n)', except that a is required to be a scalar (non-vector) quantity. If n is omitted, `idn(a)' represents a times an identity matrix of unknown size. Calc can operate algebraically on such generic identity matrices, and if one is combined with a matrix whose size is known, it is converted automatically to an identity matrix of a suitable matching size. The v i command with an argument of zero creates a generic identity matrix, `idn(1)'. Note that in dimensioned matrix mode (see section Matrix and Scalar Modes), generic identity matrices are immediately expanded

to the current default dimensions.

The v x (`calc-index`) [`index`] function builds a vector of consecutive integers from 1 to n, where n is the numeric prefix argument. If you do not provide a prefix argument, you will be prompted to enter a suitable number. If n is negative, the result is a vector of negative integers from n to *-1*.

With a prefix argument of just C-u, the v x command takes three values from the stack: n, start, and incr (with incr at top-of-stack). Counting starts at start and increases by incr for successive vector elements. If start or n is in floating-point format, the resulting vector elements will also be floats. Note that start and incr may in fact be any kind of numbers or formulas.

When start and incr are specified, a negative n has a different interpretation: It causes a geometric instead of arithmetic sequence to be generated. For example, `index(-3, a, b)' produces `[a, a b, a b^2]'. If you omit incr in the algebraic form, `index(n, start)', the default value for incr is one for positive n or two for negative n.

The v b (`calc-build-vector`) [`cvec`] function builds a vector of n copies of the value on the top of the stack, where n is the numeric prefix argument. In algebraic formulas, `cvec(x,n,m)' can also be used to build an n-by-m matrix of copies of x. (Interactively, just use v b twice: once to build a row, then again to build a matrix of copies of that row.)

The v h (`calc-head`) [`head`] function returns the first element of a vector. The I v h (`calc-tail`) [`tail`] function returns the vector with its first element removed. In both cases, the argument must be a non-empty vector.

The v k (`calc-cons`) [`cons`] function takes a value h and a vector t from the stack, and produces the vector whose head is h and whose tail is t. This is similar to |, except if h is itself a vector, | will concatenate the two vectors whereas `cons` will insert h at the front of the vector t.

Each of these three functions also accepts the Hyperbolic flag [`rhead`, `rtail`, `rcons`] in which case t instead represents the *last* single element of the vector, with h representing the remainder of the vector. Thus the vector `[a, b, c, d] = cons(a, [b, c, d]) = rcons([a, b, c], d)'. Also, `head([a, b, c, d]) = a', `tail([a, b, c, d]) = [b, c, d]', `rhead([a, b, c, d]) = [a, b, c]', and `rtail([a, b, c, d]) = d'.

Extracting Vector Elements

The v r (`calc-mrow`) [`mrow`] command extracts one row of the matrix on the top of the stack, or one element of the plain vector on the top of the stack. The row or element is specified by the numeric prefix argument; the default is to prompt for the row or element number. The matrix or vector is replaced by the specified row or element in the form of a vector or scalar, respectively.

With a prefix argument of C-u only, v r takes the index of the element or row from the top of the stack, and the vector or matrix from the second-to-top position. If the index is itself a vector of integers, the result is a vector of the corresponding elements of the input vector, or a matrix of the corresponding rows of the input matrix. This command can be used to obtain any permutation of a vector.

With C-u, if the index is an interval form with integer components, it is interpreted as a range of indices and the corresponding subvector or submatrix is returned.

Subscript notation in algebraic formulas (`a_b') stands for the Calc function `subscr`, which is synonymous with `mrow`. Thus, `[x, y, z]_k' produces x, y, or z if k is one, two, or three, respectively. A double subscript (`M_i_j', equivalent to `subscr(subscr(M, i), j)') will access the element at row i, column j of a matrix. The a _ (`calc-subscript`) command creates a subscript formula `a_b' out of two stack entries. (It is on the a "algebra" prefix because subscripted variables are often used purely as an algebraic notation.)

Given a negative prefix argument, v r instead deletes one row or element from the matrix or vector on the top of the stack. Thus C-u 2 v r replaces a matrix with its second row, but C-u -2 v r replaces the matrix with the same matrix with its second row removed. In algebraic form this function is called `mrrow`.

Given a prefix argument of zero, v r extracts the diagonal elements of a square matrix in the form of a vector. In algebraic form this function is called `getdiag`.

The v c (`calc-mcol`) [`mcol` or `mrcol`] command is the analogous operation on columns of a matrix. Given a plain vector it extracts (or removes) one element, just like v r. If the index in C-u v c is an interval or vector and the argument is a matrix, the result is a submatrix with only the specified columns retained (and possibly permuted in the case of a vector index).

To extract a matrix element at a given row and column, use v r to extract the row as a vector, then v c to extract the column element from that vector. In algebraic formulas, it is often more convenient to use subscript notation: `m_i_j' gives row i, column j of matrix m.

The v s (`calc-subvector`) [`subvec`] command extracts a subvector of a vector. The arguments are the vector, the starting index, and the ending index, with the ending index in the top-of-stack position. The starting index indicates the first element of the vector to take. The ending index indicates the first element *past* the range to be taken. Thus, `subvec([a, b, c, d, e], 2, 4)' produces the subvector `[b, c]'. You could get the same result using `mrow([a, b, c, d, e], [2 .. 4))'.

If either the start or the end index is zero or negative, it is interpreted as relative to the end of the vector. Thus `subvec([a, b, c, d, e], 2, -2)' also produces `[b, c]'. In the algebraic form, the end index can be omitted in which case it is taken as zero, i.e., elements from the starting element to the end of the vector are used. The infinity symbol, `inf`, also has this effect when used as the ending index.

With the Inverse flag, I v s [`rsubvec`] removes a subvector from a vector. The arguments are interpreted the same as for the normal v s command. Thus, `rsubvec([a, b, c, d, e], 2, 4)' produces `[a, d, e]'. It is always true that `subvec` and `rsubvec` return complementary parts of the input vector.

See section Selecting Sub-Formulas, for an alternative way to operate on vectors one element at a time.

Manipulating Vectors

The v l (`calc-vlength`) [`vlen`] command computes the length of a vector. The length of a non-vector is considered to be zero. Note that matrices are just vectors of vectors for the purposes of this command.

With the Hyperbolic flag, H v l [`mdims`] computes a vector of the dimensions of a vector, matrix, or higher-order object. For example, `mdims([[a,b,c],[d,e,f]])' returns `[2, 3]' since its argument is a

@c{2×3} 2x3 matrix.

The v f (`calc-vector-find`) [`find`] command searches along a vector for the first element equal to a given target. The target is on the top of the stack; the vector is in the second-to-top position. If a match is found, the result is the index of the matching element. Otherwise, the result is zero. The numeric prefix argument, if given, allows you to select any starting index for the search.

The v a (`calc-arrange-vector`) [`arrange`] command rearranges a vector to have a certain number of columns and rows. The numeric prefix argument specifies the number of columns; if you do not provide an argument, you will be prompted for the number of columns. The vector or matrix on the top of the stack is flattened into a plain vector. If the number of columns is nonzero, this vector is then formed into a matrix by taking successive groups of n elements. If the number of columns does not evenly divide the number of elements in the vector, the last row will be short and the result will not be suitable for use as a matrix. For example, with the matrix `[[1, 2], [3, 4]]' on the stack, v a 4 produces `[[1, 2, 3, 4]]' (a @c{1×4} 1x4 matrix), v a 1 produces `[[1], [2], [3], [4]]' (a @c{$4\times1$} 4x1 matrix), v a 2 produces `[[1, 2], [3, 4]]' (the original @c{2×2} 2x2 matrix), v a 3 produces `[[1, 2, 3], [4]]' (not a matrix), and v a 0 produces the flattened list `[1, 2, 3, 4]'.

The V S (`calc-sort`) [`sort`] command sorts the elements of a vector into increasing order. Real numbers, real infinities, and constant interval forms come first in this ordering; next come other kinds of numbers, then variables (in alphabetical order), then finally come formulas and other kinds of objects; these are sorted according to a kind of lexicographic ordering with the useful property that one vector is less or greater than another if the first corresponding unequal elements are less or greater, respectively. Since quoted strings are stored by Calc internally as vectors of ASCII character codes (see section Strings), this means vectors of strings are also sorted into alphabetical order by this command.

The I V S [`rsort`] command sorts a vector into decreasing order.

The V G (`calc-grade`) [`grade`, `rgrade`] command produces an index table or permutation vector which, if applied to the input vector (as the index of C-u v r, say), would sort the vector. A permutation vector is just a vector of integers from 1 to n, where each integer occurs exactly once. One application of this is to sort a matrix of data rows using one column as the sort key; extract that column, grade it with V G, then use the result to reorder the original matrix with C-u v r. Another interesting property of the `V G` command is that, if the input is itself a permutation vector, the result will be the inverse of the permutation. The inverse of an index table is a rank table, whose kth element says where the kth original vector element will rest when the vector is sorted. To get a rank table, just use V G V G.

With the Inverse flag, I V G produces an index table that would sort the input into decreasing order. Note that V S and V G use a "stable" sorting algorithm, i.e., any two elements which are equal will not be moved out of their original order. Generally there is no way to tell with V S, since two elements which are equal look the same, but with V G this can be an important issue. In the matrix-of-rows example, suppose you have names and telephone numbers as two columns and you wish to sort by phone number primarily, and by name when the numbers are equal. You can sort the data matrix by names first, and then again by phone numbers. Because the sort is stable, any two rows with equal phone numbers will remain sorted by name even after the second sort.

The V H (`calc-histogram`) [`histogram`] command builds a histogram of a vector of numbers. Vector elements are assumed to be integers or real numbers in the range [0..n) for some "number of bins"

n, which is the numeric prefix argument given to the command. The result is a vector of n counts of h many times each value appeared in the original vector. Non-integers in the input are rounded down t integers. Any vector elements outside the specified range are ignored. (You can tell if elements have been ignored by noting that the counts in the result vector don't add up to the length of the input vector.)

With the Hyperbolic flag, H V H pulls two vectors from the stack. The second-to-top vector is the list of numbers as before. The top vector is an equal-sized list of "weights" to attach to the elements of the data vector. For example, if the first data element is 4.2 and the first weight is 10, then 10 will be added to bin 4 of the result vector. Without the hyperbolic flag, every element has a weight of one.

The v t (`calc-transpose`) [`trn`] command computes the transpose of the matrix at the top of the stack. If the argument is a plain vector, it is treated as a row vector and transposed into a one-column matrix.

The v v (`calc-reverse-vector`) [`vec`] command reverses a vector end-for-end. Given a matrix, it reverses the order of the rows. (To reverse the columns instead, just use v t v v v t. The same principle can be used to apply other vector commands to the columns of a matrix.)

The v m (`calc-mask-vector`) [`vmask`] command uses one vector as a mask to extract elements of another vector. The mask is in the second-to-top position; the target vector is on the top of the stack. These vectors must have the same length. The result is the same as the target vector, but with all elements which correspond to zeros in the mask vector deleted. Thus, for example, `vmask([1, 0, 1, 0, 1], [a, b, c, d, e])' produces `[a, c, e]'. See section Logical Operations.

The v e (`calc-expand-vector`) [`vexp`] command expands a vector according to another mask vector. The result is a vector the same length as the mask, but with nonzero elements replaced by successive elements from the target vector. The length of the target vector is normally the number of nonzero elements in the mask. If the target vector is longer, its last few elements are lost. If the target vector is shorter, the last few nonzero mask elements are left unreplaced in the result. Thus `vexp([2, 0, 3, 0, 7], [a, b])' produces `[a, 0, b, 0, 7]'.

With the Hyperbolic flag, H v e takes a filler value from the top of the stack; the mask and target vectors come from the third and second elements of the stack. This filler is used where the mask is zero: `vexp([2, 0, 3, 0, 7], [a, b], z)' produces `[a, z, c, z, 7]'. If the filler value is itself a vector, then successive values are taken from it, so that the effect is to interleave two vectors according to the mask: `vexp([2, 0, 3, 7, 0, 0], [a, b], [x, y])' produces `[a, x, b, 7, y, 0]'.

Another variation on the masking idea is to combine `[a, b, c, d, e]' with the mask `[1, 0, 1, 0, 1]' to produce `[a, 0, c, 0, e]'. You can accomplish this with V M a &, mapping the logical "and" operation across the two vectors. See section Logical Operations. Note that the `? :` operation also discussed there allows other types of masking using vectors.

Vector and Matrix Arithmetic

Basic arithmetic operations like addition and multiplication are defined for vectors and matrices as well as for numbers. Division of matrices, in the sense of multiplying by the inverse, is supported. (Division by a matrix actually uses LU-decomposition for greater accuracy and speed.) See section Basic

Arithmetic.

The following functions are applied element-wise if their arguments are vectors or matrices: `change-sign`, `conj`, `arg`, `re`, `im`, `polar`, `rect`, `clean`, `float`, `frac`. See section Index of Algebraic Functions.

The V J (`calc-conj-transpose`) [`ctrn`] command computes the conjugate transpose of its argument, i.e., `conj(trn(x))'.

The A (`calc-abs`) [`abs`] command computes the Frobenius norm of a vector or matrix argument. This is the square root of the sum of the squares of the absolute values of the elements of the vector or matrix. If the vector is interpreted as a point in two- or three-dimensional space, this is the distance from that point to the origin.

The v n (`calc-rnorm`) [`rnorm`] command computes the row norm, or infinity-norm, of a vector or matrix. For a plain vector, this is the maximum of the absolute values of the elements. For a matrix, this is the maximum of the row-absolute-value-sums, i.e., of the sums of the absolute values of the elements along the various rows.

The V N (`calc-cnorm`) [`cnorm`] command computes the column norm, or one-norm, of a vector or matrix. For a plain vector, this is the sum of the absolute values of the elements. For a matrix, this is the maximum of the column-absolute-value-sums. General k-norms for k other than one or infinity are not provided.

The V C (`calc-cross`) [`cross`] command computes the right-handed cross product of two vectors, each of which must have exactly three elements.

The & (`calc-inv`) [`inv`] command computes the inverse of a square matrix. If the matrix is singular, the inverse operation is left in symbolic form. Matrix inverses are recorded so that once an inverse (or determinant) of a particular matrix has been computed, the inverse and determinant of the matrix can be recomputed quickly in the future.

If the argument to & is a plain number x, this command simply computes 1/x. This is okay, because the `/' operator also does a matrix inversion when dividing one by a matrix.

The V D (`calc-mdet`) [`det`] command computes the determinant of a square matrix.

The V L (`calc-mlud`) [`lud`] command computes the LU decomposition of a matrix. The result is a list of three matrices which, when multiplied together left-to-right, form the original matrix. The first is a permutation matrix that arises from pivoting in the algorithm, the second is lower-triangular with ones on the diagonal, and the third is upper-triangular.

The V T (`calc-mtrace`) [`tr`] command computes the trace of a square matrix. This is defined as the sum of the diagonal elements of the matrix.

Set Operations using Vectors

Calc includes several commands which interpret vectors as sets of objects. A set is a collection of objects; any given object can appear only once in the set. Calc stores sets as vectors of objects in sorted order. Objects in a Calc set can be any of the usual things, such as numbers, variables, or formulas. Two set elements are considered equal if they are identical, except that numerically equal numbers like the integer 4 and the float 4.0 are considered equal even though they are not "identical." Variables are treated like plain symbols without attached values by the set operations; subtracting the set `[b]' from `[a, b]' always yields the set `[a]' even though if the variables `a' and `b' both equalled 17, you might expect the answer `[]'.

If a set contains interval forms, then it is assumed to be a set of real numbers. In this case, all set operations require the elements of the set to be only things that are allowed in intervals: Real numbers, plus and minus infinity, HMS forms, and date forms. If there are variables or other non-real objects present in a real set, all set operations on it will be left in unevaluated form.

If the input to a set operation is a plain number or interval form a, it is treated like the one-element vector `[a]'. The result is always a vector, except that if the set consists of a single interval, the interval itself is returned instead.

See section Logical Operations, for the `in` function which tests if a certain value is a member of a given set. To test if the set A is a subset of the set B, use `vdiff(A, B) = []'.

The V + (`calc-remove-duplicates`) [`rdup`] command converts an arbitrary vector into set notation. It works by sorting the vector as if by V S, then removing duplicates. (For example, [a, 5, 4, a, 4.0] is sorted to `[4, 4.0, 5, a, a]' and then reduced to `[4, 5, a]'). Overlapping intervals are merged as necessary. You rarely need to use V + explicitly, since all the other set-based commands apply V + to their inputs before using them.

The V V (`calc-set-union`) [`vunion`] command computes the union of two sets. An object is in the union of two sets if and only if it is in either (or both) of the input sets. (You could accomplish the same thing by concatenating the sets with |, then using V +.)

The V ^ (`calc-set-intersect`) [`vint`] command computes the intersection of two sets. An object is in the intersection if and only if it is in both of the input sets. Thus if the input sets are disjoint, i.e., if they share no common elements, the result will be the empty vector `[]'. Note that the characters V and ^ were chosen to be close to the conventional mathematical notation for set union@c{ ($A \cup B$)} and intersection@c{ ($A \cap B$)} .

The V - (`calc-set-difference`) [`vdiff`] command computes the difference between two sets. An object is in the difference A - B if and only if it is in A but not in B. Thus subtracting `[y,z]' from a set will remove the elements `y' and `z' if they are present. You can also think of this as a general set complement operator; if A is the set of all possible values, then A - B is the "complement" of B. Obviously this is only practical if the set of all possible values in your problem is small enough to list in a Calc vector (or simple enough to express in a few intervals).

The V X (`calc-set-xor`) [`vxor`] command computes the "exclusive-or," or "symmetric difference" of two sets. An object is in the symmetric difference of two sets if and only if it is in one, but *not* both, of

the sets. Objects that occur in both sets "cancel out."

The V ~ (`calc-set-complement`) [`vcompl`] command computes the complement of a set with respect to the real numbers. Thus `vcompl(x)' is equivalent to `vdiff([-inf .. inf], x)'. For example, `vcompl([2, (3 .. 4]])' evaluates to `[[-inf .. 2), (2 .. 3], (4 .. inf]]'.

The V F (`calc-set-floor`) [`vfloor`] command reinterprets a set as a set of integers. Any non-integer values, and intervals that do not enclose any integers, are removed. Open intervals are converted to equivalent closed intervals. Successive integers are converted into intervals of integers. For example, the complement of the set `[2, 6, 7, 8]' is messy, but if you wanted the complement with respect to the set of integers you could type V ~ V F to get `[[-inf .. 1], [3 .. 5], [9 .. inf]]'.

The V E (`calc-set-enumerate`) [`venum`] command converts a set of integers into an explicit vector. Intervals in the set are expanded out to lists of all integers encompassed by the intervals. This only works for finite sets (i.e., sets which do not involve `-inf' or `inf').

The V : (`calc-set-span`) [`vspan`] command converts any set of reals into an interval form that encompasses all its elements. The lower limit will be the smallest element in the set; the upper limit will be the largest element. For an empty set, `vspan([])' returns the empty interval `[0 .. 0)'.

The V # (`calc-set-cardinality`) [`vcard`] command counts the number of integers in a set. The result is the length of the vector that would be produced by V E, although the computation is much more efficient than actually producing that vector.

Another representation for sets that may be more appropriate in some cases is binary numbers. If you are dealing with sets of integers in the range 0 to 49, you can use a 50-bit binary number where a particular bit is 1 if the corresponding element is in the set. See section Binary Number Functions, for a list of commands that operate on binary numbers. Note that many of the above set operations have direct equivalents in binary arithmetic: b o (`calc-or`), b a (`calc-and`), b d (`calc-diff`), b x (`calc-xor`), and b n (`calc-not`), respectively. You can use whatever representation for sets is most convenient to you.

The b u (`calc-unpack-bits`) [`vunpack`] command converts an integer that represents a set in binary into a set in vector/interval notation. For example, `vunpack(67)' returns `[[0 .. 1], 6]'. If the input is negative, the set it represents is semi-infinite: `vunpack(-4) = [2 .. inf)'. Use V E afterwards to expand intervals to individual values if you wish. Note that this command uses the b (binary) prefix key.

The b p (`calc-pack-bits`) [`vpack`] command converts the other way, from a vector or interval representing a set of nonnegative integers into a binary integer describing the same set. The set may include positive infinity, but must not include any negative numbers. The input is interpreted as a set of integers in the sense of V F (`vfloor`). Beware that a simple input like `[100]' can result in a huge integer representation (@c{2^{100}} 2^100, a 31-digit integer, in this case).

Statistical Operations on Vectors

The commands in this section take vectors as arguments and compute various statistical measures on the data stored in the vectors. The references used in the definitions of these functions are Bevington's *Data Reduction and Error Analysis for the Physical Sciences*, and *Numerical Recipes* by Press, Flannery,

Teukolsky and Vetterling.

The statistical commands use the u prefix key followed by a shifted letter or other character.

See section Manipulating Vectors, for a description of V H (`calc-histogram`).

See section Curve Fitting, for the a F command for doing least-squares fits to statistical data.

See section Probability Distribution Functions, for several common probability distribution functions.

Single-Variable Statistics

These functions do various statistical computations on single vectors. Given a numeric prefix argument, they actually pop n objects from the stack and combine them into a data vector. Each object may be either a number or a vector; if a vector, any sub-vectors inside it are "flattened" as if by v a 0; see section Manipulating Vectors. By default one object is popped, which (in order to be useful) is usually a vector.

If an argument is a variable name, and the value stored in that variable is a vector, then the stored vector is used. This method has the advantage that if your data vector is large, you can avoid the slow process of manipulating it directly on the stack.

These functions are left in symbolic form if any of their arguments are not numbers or vectors, e.g., if an argument is a formula, or a non-vector variable. However, formulas embedded within vector arguments are accepted; the result is a symbolic representation of the computation, based on the assumption that the formula does not itself represent a vector. All varieties of numbers such as error forms and interval forms are acceptable.

Some of the functions in this section also accept a single error form or interval as an argument. They then describe a property of the normal or uniform (respectively) statistical distribution described by the argument. The arguments are interpreted in the same way as the M argument of the random number function k r. In particular, an interval with integer limits is considered an integer distribution, so that `[2 .. 6)' is the same as `[2 .. 5]'. An interval with at least one floating-point limit is a continuous distribution: `[2.0 .. 6.0)' is *not* the same as `[2.0 .. 5.0]'!

The u # (`calc-vector-count`) [`vcount`] command computes the number of data values represented by the inputs. For example, `vcount(1, [2, 3], [[4, 5], [], x, y])' returns 7. If the argument is a single vector with no sub-vectors, this simply computes the length of the vector.

The u + (`calc-vector-sum`) [`vsum`] command computes the sum of the data values. The u * (`calc-vector-prod`) [`vprod`] command computes the product of the data values. If the input is a single flat vector, these are the same as V R + and V R * (see section Reducing and Mapping Vectors).

The u X (`calc-vector-max`) [`vmax`] command computes the maximum of the data values, and the u N (`calc-vector-min`) [`vmin`] command computes the minimum. If the argument is an interval, this finds the minimum or maximum value in the interval. (Note that `vmax([2..6)) = 5' as described above.) If the argument is an error form, this returns plus or minus infinity.

The u M (`calc-vector-mean`) [`vmean`] command computes the average (arithmetic mean) of the data values. If the inputs are error forms @c{x +/- σ} `x +/- s', this is the weighted mean of

the x values with weights @c{$1 / \sigma^2$} 1 / s^2. If the inputs are not error forms, this is simply the sum of the values divided by the count of the values.

Note that a plain number can be considered an error form with error @c{$\sigma = 0$} s = 0. If the input to u M is a mixture of plain numbers and error forms, the result is the mean of the plain numbers, ignoring all values with non-zero errors. (By the above definitions it's clear that a plain number effectively has an infinite weight, next to which an error form with a finite weight is completely negligible.)

This function also works for distributions (error forms or intervals). The mean of an error form `*a* `+/-` *b*' is simply a. The mean of an interval is the mean of the minimum and maximum values of the interval.

The I u M (`calc-vector-mean-error`) [`vmeane`] command computes the mean of the data points expressed as an error form. This includes the estimated error associated with the mean. If the inputs are error forms, the error is the square root of the reciprocal of the sum of the reciprocals of the squares of the input errors. (I.e., the variance is the reciprocal of the sum of the reciprocals of the variances.) If the inputs are plain numbers, the error is equal to the standard deviation of the values divided by the square root of the number of values. (This works out to be equivalent to calculating the standard deviation and then assuming each value's error is equal to this standard deviation.)

The H u M (`calc-vector-median`) [`vmedian`] command computes the median of the data values. The values are first sorted into numerical order; the median is the middle value after sorting. (If the number of data values is even, the median is taken to be the average of the two middle values.) The median function is different from the other functions in this section in that the arguments must all be real numbers; variables are not accepted even when nested inside vectors. (Otherwise it is not possible to sort the data values.) If any of the input values are error forms, their error parts are ignored.

The median function also accepts distributions. For both normal (error form) and uniform (interval) distributions, the median is the same as the mean.

The H I u M (`calc-vector-harmonic-mean`) [`vhmean`] command computes the harmonic mean of the data values. This is defined as the reciprocal of the arithmetic mean of the reciprocals of the values.

The u G (`calc-vector-geometric-mean`) [`vgmean`] command computes the geometric mean of the data values. This is the *N*th root of the product of the values. This is also equal to the `exp` of the arithmetic mean of the logarithms of the data values.

The H u G [`agmean`] command computes the "arithmetic-geometric mean" of two numbers taken from the stack. This is computed by replacing the two numbers with their arithmetic mean and geometric mean, then repeating until the two values converge.

Another commonly used mean, the RMS (root-mean-square), can be computed for a vector of numbers simply by using the A command.

The u S (`calc-vector-sdev`) [`vsdev`] command computes the standard deviation@c{ σ} of the data values. If the values are error forms, the errors are used as weights just as for u M. This is the *sample* standard deviation, whose value is the square root of the sum of the squares of the differences between the values and the mean of the N values, divided by N-1.

This function also applies to distributions. The standard deviation of a single error form is simply the error part. The standard deviation of a continuous interval happens to equal the difference between the limits, divided by @c{$\sqrt{12}$} sqrt(12). The standard deviation of an integer interval is the same as the standard deviation of a vector of those integers.

The I u S (`calc-vector-pop-sdev`) [`vpsdev`] command computes the *population* standard deviation. It is defined by the same formula as above but dividing by N instead of by N-1. The population standard deviation is used when the input represents the entire set of data values in the distribution; the sample standard deviation is used when the input represents a sample of the set of all data values, so that the mean computed from the input is itself only an estimate of the true mean.

For error forms and continuous intervals, `vpsdev` works exactly like `vsdev`. For integer intervals, it computes the population standard deviation of the equivalent vector of integers.

The H u S (`calc-vector-variance`) [`vvar`] and H I u S (`calc-vector-pop-variance`) [`vpvar`] commands compute the variance of the data values. The variance is the square@c{ σ^2} of the standard deviation, i.e., the sum of the squares of the deviations of the data values from the mean. (This definition also applies when the argument is a distribution.)

The `vflat` algebraic function returns a vector of its arguments, interpreted in the same way as the other functions in this section. For example, `vflat(1, [2, [3, 4]], 5)' returns `[1, 2, 3, 4, 5]'.

Paired-Sample Statistics

The functions in this section take two arguments, which must be vectors of equal size. The vectors are each flattened in the same way as by the single-variable statistical functions. Given a numeric prefix argument of 1, these functions instead take one object from the stack, which must be an @c{$N\times2$} Nx2 matrix of data values. Once again, variable names can be used in place of actual vectors and matrices.

The u C (`calc-vector-covariance`) [`vcov`] command computes the sample covariance of two vectors. The covariance of vectors x and y is the sum of the products of the differences between the elements of x and the mean of x times the differences between the corresponding elements of y and the mean of y, all divided by N-1. Note that the variance of a vector is just the covariance of the vector with itself. Once again, if the inputs are error forms the errors are used as weight factors. If both x and y are composed of error forms, the error for a given data point is taken as the square root of the sum of the squares of the two input errors.

The I u C (`calc-vector-pop-covariance`) [`vpcov`] command computes the population covariance, which is the same as the sample covariance computed by u C except dividing by N instead of N-1.

The H u C (`calc-vector-correlation`) [`vcorr`] command computes the linear correlation coefficient of two vectors. This is defined by the covariance of the vectors divided by the product of their standard deviations. (There is no difference between sample or population statistics here.)

Reducing and Mapping Vectors

The commands in this section allow for more general operations on the elements of vectors.

The simplest of these operations is V A (`calc-apply`) [`apply`], which applies a given operator to the elements of a vector. For example, applying the hypothetical function `f` to the vector `[1, 2, 3]' would produce the function call `f(1, 2, 3)'. Applying the + function to the vector `[a, b]' gives `a + b'. Applying + to the vector `[a, b, c]' is an error, since the + function expects exactly two arguments.

While V A is useful in some cases, you will usually find that either V R or V M, described below, is closer to what you want.

Specifying Operators

Commands in this section (like V A) prompt you to press the key corresponding to the desired operator. Press ? for a partial list of the available operators. Generally, an operator is any key or sequence of keys that would normally take one or more arguments from the stack and replace them with a result. For example, V A H C uses the hyperbolic cosine operator, `cosh`. (Since `cosh` expects one argument, V A H C requires a vector with a single element as its argument.)

You can press x at the operator prompt to select any algebraic function by name to use as the operator. This includes functions you have defined yourself using the Z F command. (See section Programming with Formulas.) If you give a name for which no function has been defined, the result is left in symbolic form, as in `f(1, 2, 3)'. Calc will prompt for the number of arguments the function takes if it can't figure it out on its own (say, because you named a function that is currently undefined). It is also possible to type a digit key before the function name to specify the number of arguments, e.g., V M 3 x f RET calls `f` with three arguments even if it looks like it ought to have only two. This technique may be necessary if the function allows a variable number of arguments. For example, the v e [`vexp`] function accepts two or three arguments; if you want to map with the three-argument version, you will have to type V M 3 v e.

It is also possible to apply any formula to a vector by treating that formula as a function. When prompted for the operator to use, press ' (the apostrophe) and type your formula as an algebraic entry. You will then be prompted for the argument list, which defaults to a list of all variables that appear in the formula, sorted into alphabetic order. For example, suppose you enter the formula `x + 2y^x'. The default argument list would be `(x y)', which means that if this function is applied to the arguments `[3, 10]' the result will be `3 + 2*10^3'. (If you plan to use a certain formula in this way often, you might consider defining it as a function with Z F.)

Another way to specify the arguments to the formula you enter is with $, $$, and so on. For example, V A ' $$ + 2$^$$ has the same effect as the previous example. The argument list is automatically taken to be `($$ $)'. (The order of the arguments may seem backwards, but it is analogous to the way normal algebraic entry interacts with the stack.)

If you press $ at the operator prompt, the effect is similar to the apostrophe except that the relevant formula is taken from top-of-stack instead. The actual vector arguments of the V A $ or related command then start at the second-to-top stack position. You will still be prompted for an argument list.

A function can be written without a name using the notation `<#1 - #2>', which means "a function of arguments that computes the first argument minus the second argument." The symbols `#1' and `#2' are placeholders for the arguments. You can use any names for these placeholders if you wish, by including an argument list followed by a colon: `<x, y : x - y>'. When you type V A ' $$ + 2$^$$ RET, Calc builds the nameless function `<#1 + 2 #2^#1>' as the function to map across the vectors. When you type V A ' x + 2y^x RET RET, Calc builds the nameless function `<x, y : x + 2 y^x>'. In both cases, Calc also writes the nameless function to the Trail so that you can get it back later if you wish.

If there is only one argument, you can write `#' in place of `#1'. (Note that `< >' notation is also used for date forms. Calc tells that `<stuff>' is a nameless function by the presence of `#' signs inside stuff, or by the fact that stuff begins with a list of variables followed by a colon.)

You can type a nameless function directly to V A ', or put one on the stack and use it with V A $. Calc will not prompt for an argument list in this case, since the nameless function specifies the argument list as well as the function itself. In V A ', you can omit the `< >' marks if you use `#' notation for the arguments, so that V A ' #1+#2 RET is the same as V A ' <#1+#2> RET, which in turn is the same as V A ' $$+$ RET.

The internal format for `<x, y : x + y>' is `lambda(x, y, x + y)'. (The word `lambda` derives from Lisp notation and the theory of functions.) The internal format for `<#1 + #2>' is `lambda(ArgA, ArgB, ArgA + ArgB)'. Note that there is no actual Calc function called `lambda`; the whole point is that the `lambda` expression is used in its symbolic form, not evaluated for an answer until it is applied to specific arguments by a command like V A or V M.

(Actually, `lambda` does have one special property: Its arguments are never evaluated; for example, putting `<(2/3) #>' on the stack will not simplify the `2/3' until the nameless function is actually called.)

As usual, commands like V A have algebraic function name equivalents. For example, V A k g with an argument of `v' is equivalent to `apply(gcd, v)'. The first argument specifies the operator name, and is either a variable whose name is the same as the function name, or a nameless function like `<#^3+1>'. Operators that are normally written as algebraic symbols have the names `add`, `sub`, `mul`, `div`, `pow`, `neg`, `mod`, and `vconcat`.

The `call` function builds a function call out of several arguments: `call(gcd, x, y)' is the same as `apply(gcd, [x, y])', which in turn is the same as `gcd(x, y)'. The first argument of `call`, like the other functions described here, may be either a variable naming a function, or a nameless function (`call(<#1+2#2>, x, y)' is the same as `x + 2y').

(Experts will notice that it's not quite proper to use a variable to name a function, since the name `gcd` corresponds to the Lisp variable `var-gcd` but to the Lisp function `calcFunc-gcd`. Calc automatically makes this translation, so you don't have to worry about it.)

Mapping

The V M (`calc-map`) [`map`] command applies a given operator elementwise to one or more vectors. For example, mapping `A` [`abs`] produces a vector of the absolute values of the elements in the input vector. Mapping `+` pops two vectors from the stack, which must be of equal length, and produces a vector of the pairwise sums of the elements. If either argument is a non-vector, it is duplicated for each

element of the other vector. For example, [1,2,3] 2 V M ^ squares the elements of the specified vector. With the 2 listed first, it would have computed a vector of powers of two. Mapping a user-defined function pops as many arguments from the stack as the function requires. If you give an undefined name, you will be prompted for the number of arguments to use.

If any argument to V M is a matrix, the operator is normally mapped across all elements of the matrix. For example, given the matrix [[1, -2, 3], [-4, 5, -6]], V M A takes six absolute values to produce another @c{3×2} 3x2 matrix, [[1, 2, 3], [4, 5, 6]].

The command V M _ [`mapr`] (i.e., type an underscore at the operator prompt) maps by rows instead. For example, V M _ A views the above matrix as a vector of two 3-element row vectors. It produces a new vector which contains the absolute values of those row vectors, namely [3.74, 8.77]. (Recall, the absolute value of a vector is defined as the square root of the sum of the squares of the elements.) Some operators accept vectors and return new vectors; for example, v v reverses a vector, so V M _ v v would reverse each row of the matrix to get a new matrix, [[3, -2, 1], [-6, 5, -4]].

Sometimes a vector of vectors (representing, say, strings, sets, or lists) happens to look like a matrix. If so, remember to use V M _ if you want to map a function across the whole strings or sets rather than across their individual elements.

The command V M : [`mapc`] maps by columns. Basically, it transposes the input matrix, maps by rows, and then, if the result is a matrix, transposes again. For example, V M : A takes the absolute values of the three columns of the matrix, treating each as a 2-vector, and V M : v v reverses the columns to get the matrix [[-4, 5, -6], [1, -2, 3]].

(The symbols _ and : were chosen because they had row-like and column-like appearances, and were not already taken by useful operators. Also, they appear shifted on most keyboards so they are easy to type after V M.)

The _ and : modifiers have no effect on arguments that are not matrices (so if none of the arguments are matrices, they have no effect at all). If some of the arguments are matrices and others are plain numbers, the plain numbers are held constant for all rows of the matrix (so that 2 V M _ ^ squares every row of a matrix; squaring a vector takes a dot product of the vector with itself).

If some of the arguments are vectors with the same lengths as the rows (for V M _) or columns (for V M :) of the matrix arguments, those vectors are also held constant for every row or column.

Sometimes it is useful to specify another mapping command as the operator to use with V M. For example, V M _ V A + applies V A + to each row of the input matrix, which in turn adds the two values on that row. If you give another vector-operator command as the operator for V M, it automatically uses map-by-rows mode if you don't specify otherwise; thus V M V A + is equivalent to V M _ V A +. (If you really want to map-by-elements another mapping command, you can use a triple-nested mapping command: V M V M V A + means to map V M V A + over the rows of the matrix; in turn, V A + is mapped over the elements of each row.)

Previous versions of Calc had "map across" and "map down" modes that are now considered obsolete; the old "map across" is now simply V M V A, and "map down" is now V M : V A. The algebraic functions `mapa` and `mapd` are still supported, though. Note also that, while the old mapping modes were persistent (once you set the mode, it would apply to later mapping commands until you reset it), the new

: and _ modifiers apply only to the current mapping command. The default V M always means map-by-elements.

See section Algebraic Manipulation, for the a M command, which is like V M but for equations and inequalities instead of vectors. See section Storing Variables, for the s m command which modifies a variable's stored value using a V M-like operator.

Reducing

The V R (`calc-reduce`) [`reduce`] command applies a given binary operator across all the elements of a vector. A binary operator is a function such as `+` or `max` which takes two arguments. For example, reducing `+` over a vector computes the sum of the elements of the vector. Reducing `-` computes the first element minus each of the remaining elements. Reducing `max` computes the maximum element and so on. In general, reducing `f` over the vector `[a, b, c, d]' produces `f(f(f(a, b), c), d)'.

The I V R [`rreduce`] command is similar to V R except that works from right to left through the vector. For example, plain V R - on the vector `[a, b, c, d]' produces `a - b - c - d' but I V R - on the same vector produces `a - (b - (c - d))', or `a - b + c - d'. This "alternating sum" occurs frequently in power series expansions.

The V U (`calc-accumulate`) [`accum`] command does an accumulation operation. Here Calc does the corresponding reduction operation, but instead of producing only the final result, it produces a vector of all the intermediate results. Accumulating `+` over the vector `[a, b, c, d]' produces the vector `[a, a + b, a + b + c, a + b + c + d]'.

The I V U [`raccum`] command does a right-to-left accumulation. For example, I V U - on the vector `[a, b, c, d]' produces the vector `[a - b + c - d, b - c + d, c - d, d]'.

As for V M, V R normally reduces a matrix elementwise. For example, given the matrix [[a, b, c], [d, e, f]], V R + will compute a + b + c + d + e + f. You can type V R _ or V R : to modify this behavior. The V R _ [`reducea`] command reduces "across" the matrix; it reduces each row of the matrix as a vector, then collects the results. Thus V R _ + of this matrix would produce [a + b + c, d + e + f]. Similarly, V R : [`reduced`] reduces down; V R : + would produce [a + d, b + e, c + f].

There is a third "by rows" mode for reduction that is occasionally useful; V R = [`reducer`] simply reduces the operator over the rows of the matrix themselves. Thus V R = + on the above matrix would get the same result as V R : +, since adding two row vectors is equivalent to adding their elements. But V R = * would multiply the two rows (to get a single number, their dot product), while V R : * would produce a vector of the products of the columns.

These three matrix reduction modes work with V R and I V R, but they are not currently supported with V U or I V U.

The obsolete reduce-by-columns function, `reducec`, is still supported but there is no way to get it through the V R command.

The commands M-# : and M-# _ are equivalent to typing M-# r to grab a rectangle of data into Calc, and then typing V R : + or V R _ +, respectively, to sum the columns or rows of the matrix. See section

Grabbing from Other Buffers.

Nesting and Fixed Points

The H V R [`nest`] command applies a function to a given argument repeatedly. It takes two values, `a' and `n', from the stack, where `n' must be an integer. It then applies the function nested `n' times; if the function is `f' and `n' is 3, the result is `f(f(f(a)))'. The number `n' may be negative if Calc knows an inverse for the function `f'; for example, `nest(sin, a, -2)' returns `arcsin(arcsin(a))'.

The H V U [`anest`] command is an accumulating version of `nest`: It returns a vector of `n+1' values, e.g., `[a, f(a), f(f(a)), f(f(f(a)))]'. If `n' is negative and `F' is the inverse of `f', then the result is of the form `[a, F(a), F(F(a)), F(F(F(a)))]'.

The H I V R [`fixp`] command is like H V R, except that it takes only an `a' value from the stack; the function is applied until it reaches a "fixed point," i.e., until the result no longer changes.

The H I V U [`afixp`] command is an accumulating `fixp`. The first element of the return vector will be the initial value `a'; the last element will be the final result that would have been returned by `fixp`.

For example, 0.739085 is a fixed point of the cosine function (in radians): `cos(0.739085) = 0.739085'. You can find this value by putting, say, 1.0 on the stack and typing H I V U C. (We use the accumulating version so we can see the intermediate results: `[1, 0.540302, 0.857553, 0.65329, ...]'. With a precision of six, this command will take 36 steps to converge to 0.739085.)

Newton's method for finding roots is a classic example of iteration to a fixed point. To find the square root of five starting with an initial guess, Newton's method would look for a fixed point of the function `(x + 5/x) / 2'. Putting a guess of 1 on the stack and typing H I V R ' ($ + 5/$)/2 RET quickly yields the result 2.23607. This is equivalent to using the a R (`calc-find-root`) command to find a root of the equation `x^2 = 5'.

These examples used numbers for `a' values. Calc keeps applying the function until two successive results are equal to within the current precision. For complex numbers, both the real parts and the imaginary parts must be equal to within the current precision. If `a' is a formula (say, a variable name), then the function is applied until two successive results are exactly the same formula. It is up to you to ensure that the function will eventually converge; if it doesn't, you may have to press C-g to stop the Calculator.

The algebraic `fixp` function takes two optional arguments, `n' and `tol'. The first is the maximum number of steps to be allowed, and must be either an integer or the symbol `inf' (infinity, the default). The second is a convergence tolerance. If a tolerance is specified, all results during the calculation must be numbers, not formulas, and the iteration stops when the magnitude of the difference between two successive results is less than or equal to the tolerance. (This implies that a tolerance of zero iterates until the results are exactly equal.)

Putting it all together, `fixp(<(# + A/#)/2>, B, 20, 1e-10)' computes the square root of `A' given the initial guess `B', stopping when the result is correct within the specified tolerance, or when 20 steps have been taken, whichever is sooner.

Generalized Products

The V O (`calc-outer-product`) [`outer`] command applies a given binary operator to all possible pairs of elements from two vectors, to produce a matrix. For example, V O * with `[a, b]' and `[x, y, z]' on the stack produces a multiplication table: `[[a x, a y, a z], [b x, b y, b z]]'. Element r,c of the result matrix is obtained by applying the operator to element r of the lefthand vector and element c of the righthand vector.

The V I (`calc-inner-product`) [`inner`] command computes the generalized inner product of two vectors or matrices, given a "multiplicative" operator and an "additive" operator. These can each actually be any binary operators; if they are `*' and `+', respectively, the result is a standard matrix multiplication. Element r,c of the result matrix is obtained by mapping the multiplicative operator across row r of the lefthand matrix and column c of the righthand matrix, and then reducing with the additive operator. Just as for the standard * command, this can also do a vector-matrix or matrix-vector inner product, or a vector-vector generalized dot product.

Since V I requires two operators, it prompts twice. In each case, you can use any of the usual methods for entering the operator. If you use $ twice to take both operator formulas from the stack, the first (multiplicative) operator is taken from the top of the stack and the second (additive) operator is taken from second-to-top.

Vector and Matrix Display Formats

Commands for controlling vector and matrix display use the v prefix instead of the usual d prefix. But they are display modes; in particular, they are influenced by the I and H prefix keys in the same way (see section Display Modes). Matrix display is also influenced by the d O (`calc-flat-language`) mode; see section Normal Language Modes.

The commands v < (`calc-matrix-left-justify`), v > (`calc-matrix-right-justify`), and v = (`calc-matrix-center-justify`) control whether matrix elements are justified to the left, right, or center of their columns.

The v [(`calc-vector-brackets`) command turns the square brackets that surround vectors and matrices displayed in the stack on and off. The v { (`calc-vector-braces`) and v ((`calc-vector-parens`) commands use curly braces or parentheses, respectively, instead of square brackets. For example, v { might be used in preparation for yanking a matrix into a buffer running Mathematica. (In fact, the Mathematica language mode uses this mode; see section Mathematica Language Mode.) Note that, regardless of the display mode, either brackets or braces may be used to enter vectors, and parentheses may never be used for this purpose.

The v] (`calc-matrix-brackets`) command controls the "big" style display of matrices. It prompts for a string of code letters; currently implemented letters are `R`, which enables brackets on each row of the matrix; `O`, which enables outer brackets in opposite corners of the matrix; and `C`, which enables commas or semicolons at the ends of all rows but the last. The default format is `RO'. (Before Calc 2.00, the format was fixed at `ROC'.) Here are some example matrices:

```
[ [ 123,  0,   0  ]       [ [ 123,  0,   0  ],
  [  0,  123,  0  ]         [  0,  123,  0  ],
  [  0,   0,  123 ] ]       [  0,   0,  123 ] ]

        RO                        ROC

  [ 123,  0,   0            [ 123,  0,   0 ;
    0,  123,  0               0,  123,  0 ;
    0,   0,  123 ]            0,   0,  123 ]

        O                         OC

  [ 123,  0,   0  ]           123,  0,   0
  [  0,  123,  0  ]            0,  123,  0
  [  0,   0,  123 ]            0,   0,  123

        R                        blank
```

Note that of the formats shown here, `RO', `ROC', and `OC' are all recognized as matrices during reading, while the others are useful for display only.

The v , (`calc-vector-commas`) command turns commas on and off in vector and matrix display.

In vectors of length one, and in all vectors when commas have been turned off, Calc adds extra parentheses around formulas that might otherwise be ambiguous. For example, `[a b]' could be a vector of the one formula `a b', or it could be a vector of two variables with commas turned off. Calc will display the former case as `[(a b)]'. You can disable these extra parentheses (to make the output less cluttered at the expense of allowing some ambiguity) by adding the letter `P` to the control string you give to v] (as described above).

The v . (`calc-full-vectors`) command turns abbreviated display of long vectors on and off. In this mode, vectors of six or more elements, or matrices of six or more rows or columns, will be displayed in an abbreviated form that displays only the first three elements and the last element: `[a, b, c, ..., z]'. When very large vectors are involved this will substantially improve Calc's display speed.

The t . (`calc-full-trail-vectors`) command controls a similar mode for recording vectors in the Trail. If you turn on this mode, vectors of six or more elements and matrices of six or more rows or columns will be abbreviated when they are put in the Trail. The t y (`calc-trail-yank`) command will be unable to recover those vectors. If you are working with very large vectors, this mode will improve the speed of all operations that involve the trail.

The v / (`calc-break-vectors`) command turns multi-line vector display on and off. Normally, matrices are displayed with one row per line but all other types of vectors are displayed in a single line. This mode causes all vectors, whether matrices or not, to be displayed with a single element per line. Sub-vectors within the vectors will still use the normal linear form.

Go to the previous, next section.

Go to the previous, next section.

Algebra

This section covers the Calc features that help you work with algebraic formulas. First, the general sub-formula selection mechanism is described; this works in conjunction with any Calc commands. Then, commands for specific algebraic operations are described. Finally, the flexible rewrite rule mechanism is discussed.

The algebraic commands use the a key prefix; selection commands use the j (for "just a letter that wasn't used for anything else") prefix.

See section Editing Stack Entries, to see how to manipulate formulas using regular Emacs editing commands.

When doing algebraic work, you may find several of the Calculator's modes to be helpful, including algebraic-simplification mode (m A) or no-simplification mode (m O), algebraic-entry mode (m a), fraction mode (m f), and symbolic mode (m s). See section Mode Settings, for discussions of these modes. You may also wish to select "big" display mode (d B). See section Normal Language Modes.

Selecting Sub-Formulas

When working with an algebraic formula it is often necessary to manipulate a portion of the formula rather than the formula as a whole. Calc allows you to "select" a portion of any formula on the stack. Commands which would normally operate on that stack entry will now operate only on the sub-formula, leaving the surrounding part of the stack entry alone.

One common non-algebraic use for selection involves vectors. To work on one element of a vector in-place, simply select that element as a "sub-formula" of the vector.

Making Selections

To select a sub-formula, move the Emacs cursor to any character in that sub-formula, and press j s (`calc-select-here`). Calc will highlight the smallest portion of the formula that contains that character. By default the sub-formula is highlighted by blanking out all of the rest of the formula with dots. Selection works in any display mode but is perhaps easiest in "big" (d B) mode. Suppose you enter the following formula:

```
                3    ___
    (a + b)    + V c
1:  ---------------
        2 x + 1
```

(by typing ' ((a+b)^3 + sqrt(c)) / (2x+1)). If you move the cursor to the letter `b' and press j s, the display changes to

```
          .    ...
    .. . b.  . . .
1*  ..............
        . . . .
```

Every character not part of the sub-formula `b' has been changed to a dot. The `*' next to the line number is to remind you that the formula has a portion of it selected. (In this case, it's very obvious, but it might not always be. If Embedded Mode is enabled, the word `Sel' also appears in the mode line because the stack may not be visible. see section Embedded Mode.)

If you had instead placed the cursor on the parenthesis immediately to the right of the `b', the selection would have been:

```
          .    ...
    (a + b)  . . .
1*  ..............
        . . . .
```

The portion selected is always large enough to be considered a complete formula all by itself, so selecting the parenthesis selects the whole formula that it encloses. Putting the cursor on the the `+' sign would have had the same effect.

(Strictly speaking, the Emacs cursor is really the manifestation of the Emacs "point," which is a position *between* two characters in the buffer. So purists would say that Calc selects the smallest sub-formula which contains the character to the right of "point.")

If you supply a numeric prefix argument n, the selection is expanded to the nth enclosing sub-formula. Thus, positioning the cursor on the `b' and typing C-u 1 j s will select `a + b'; typing C-u 2 j s will select `(a + b)^3', and so on.

If the cursor is not on any part of the formula, or if you give a numeric prefix that is too large, the entire formula is selected.

If the cursor is on the `.' line that marks the top of the stack (i.e., its normal "rest position"), this command selects the entire formula at stack level 1. Most selection commands similarly operate on the formula at the top of the stack if you haven't positioned the cursor on any stack entry.

The j a (`calc-select-additional`) command enlarges the current selection to encompass the cursor. To select the smallest sub-formula defined by two different points, move to the first and press j s, then move to the other and press j a. This is roughly analogous to using C-@ (`set-mark-command`) to select the two ends of a region of text during normal Emacs editing.

The j o (`calc-select-once`) command selects a formula in exactly the same way as j s, except that the selection will last only as long as the next command that uses it. For example, j o 1 + is a handy way to add one to the sub-formula indicated by the cursor.

(A somewhat more precise definition: The j o command sets a flag such that the next command involving selected stack entries will clear the selections on those stack entries afterwards. All other selection commands except j a and j O clear this flag.)

The j S (`calc-select-here-maybe`) and j O (`calc-select-once-maybe`) commands are equivalent to j s and j o, respectively, except that if the formula already has a selection they have no effect. This is analogous to the behavior of some commands such as j r (`calc-rewrite-selection`; see section Selections with Rewrite Rules) and is mainly intended to be used in keyboard macros that implement your own selection-oriented commands.

Selection of sub-formulas normally treats associative terms like `a + b - c + d' and `x * y * z' as single levels of the formula. If you place the cursor anywhere inside `a + b - c + d' except on one of the variable names and use j s, you will select the entire four-term sum.

The j b (`calc-break-selections`) command controls a mode in which the "deep structure" of these associative formulas shows through. Calc actually stores the above formulas as `((a + b) - c) + d' and `x * (y * z)'. (Note that for certain obscure reasons, Calc treats multiplication as right-associative.) Once you have enabled j b mode, selecting with the cursor on the `-' sign would only select the `a + b - c' portion, which makes sense when the deep structure of the sum is considered. There is no way to select the `b - c + d' portion; although this might initially look like just as legitimate a sub-formula as `a + b - c', the deep structure shows that it isn't. The d U command can be used to view the deep structure of any formula (see section Normal Language Modes).

When j b mode has not been enabled, the deep structure is generally hidden by the selection commands--what you see is what you get.

The j u (`calc-unselect`) command unselects the formula that the cursor is on. If there was no selection in the formula, this command has no effect. With a numeric prefix argument, it unselects the nth stack element rather than using the cursor position.

The j c (`calc-clear-selections`) command unselects all stack elements.

Changing Selections

Once you have selected a sub-formula, you can expand it using the j m (`calc-select-more`) command. If `a + b' is selected, pressing j m repeatedly works as follows:

```
           3    ...                3   ___                3   ___
    (a + b)   . . .         (a + b)  + V c         (a + b)  + V c
1*  ...............     1*  ...............     1*  ---------------
        . . . .                 . . . .                 2 x + 1
```

In the last example, the entire formula is selected. This is roughly the same as having no selection at all, but because there are subtle differences the `*' character is still there on the line number.

With a numeric prefix argument n, j m expands n times (or until the entire formula is selected). Note that j s with argument n is equivalent to plain j s followed by j m with argument n. If j m is used when there is no current selection, it is equivalent to j s.

Even though j m does not explicitly use the location of the cursor within the formula, it nevertheless uses the cursor to determine which stack element to operate on. As usual, j m when the cursor is not on any stack element operates on the top stack element.

The j l (`calc-select-less`) command reduces the current selection around the cursor position. That is, it selects the immediate sub-formula of the current selection which contains the cursor, the opposite of m. If the cursor is not inside the current selection, the command de-selects the formula.

The j 1 through j 9 (`calc-select-part`) commands select the nth sub-formula of the current selection. They are like j l (`calc-select-less`) except they use counting rather than the cursor position to decide which sub-formula to select. For example, if the current selection is a + b + c or f(a, b, c) or [a, b, c], then j 1 selects `a', j 2 selects `b', and j 3 selects `c'; in each of these cases, j 4 through j 9 would be errors.

If there is no current selection, j 1 through j 9 select the nth top-level sub-formula. (In other words, they act as if the entire stack entry were selected first.) To select the nth sub-formula where n is greater than nine, you must instead invoke j 1 with n as a numeric prefix argument.

The j n (`calc-select-next`) and j p (`calc-select-previous`) commands change the current selection to the next or previous sub-formula at the same level. For example, if `b' is selected in `2 + a*b*c + x', then j n selects `c'. Further j n commands would be in error because, even though there is something to the right of `c' (namely, `x'), it is not at the same level; in this case, it is not a term of the same product as `b' and `c'. However, j m (to select the whole product `a*b*c' as a term of the sum) followed by j n would successfully select the `x'.

Similarly, j p moves the selection from the `b' in this sample formula to the `a'. Both commands accept numeric prefix arguments to move several steps at a time.

It is interesting to compare Calc's selection commands with the Emacs Info system's commands for navigating through hierarchically organized documentation. Calc's j n command is completely analogous to Info's n command. Likewise, j p maps to p, j 2 maps to 2, and Info's u is like j m. (Note that j u stands for `calc-unselect`, not "up".) The Info m command is somewhat similar to Calc's j s and j l; in each case, you can jump directly to a sub-component of the hierarchy simply by pointing to it with the cursor.

Displaying Selections

The j d (`calc-show-selections`) command controls how selected sub-formulas are displayed. One of the alternatives is illustrated in the above examples; if we press j d we switch to the other style in which the selected portion itself is obscured by `#' signs:

```
          3    ...                    #    ___
    (a + b)  . . .              ## # ##  + V c
1*  ..............          1*  ---------------
       . . . .                      2 x + 1
```

Operating on Selections

Once a selection is made, all Calc commands that manipulate items on the stack will operate on the selected portions of the items instead. (Note that several stack elements may have selections at once, though there can be only one selection at a time in any given stack element.)

The j e (`calc-enable-selections`) command disables the effect that selections have on Calc commands. The current selections still exist, but Calc commands operate on whole stack elements anyway.

This mode can be identified by the fact that the `*' markers on the line numbers are gone, even though selections are visible. To reactivate the selections, press j e again.

To extract a sub-formula as a new formula, simply select the sub-formula and press RET. This normally duplicates the top stack element; here it duplicates only the selected portion of that element.

To replace a sub-formula with something different, you can enter the new value onto the stack and press TAB. This normally exchanges the top two stack elements; here it swaps the value you entered into the selected portion of the formula, returning the old selected portion to the top of the stack.

```
             3    ...                      ...                          ___
    (a + b)  . . .           17 x y . . .          17 x y + V c
2*  ..............      2*   ............      2:  -------------
       . . . .                  . . . .                2 x + 1

                                    3                        3
1:  17 x y                  1:  (a + b)              1:  (a + b)
```

In this example we select a sub-formula of our original example, enter a new formula, TAB it into place, then deselect to see the complete, edited formula.

If you want to swap whole formulas around even though they contain selections, just use j e before and after.

The j ' (`calc-enter-selection`) command is another way to replace a selected sub-formula. This command does an algebraic entry just like the regular ' key. When you press RET, the formula you type replaces the original selection. You can use the `$' symbol in the formula to refer to the original selection. If there is no selection in the formula under the cursor, the cursor is used to make a temporary selection for the purposes of the command. Thus, to change a term of a formula, all you have to do is move the Emacs cursor to that term and press j '.

The j ` (`calc-edit-selection`) command is a similar analogue of the ` (`calc-edit`) command. It edits the selected sub-formula in a separate buffer. If there is no selection, it edits the sub-formula indicated by the cursor.

To delete a sub-formula, press DEL. This generally replaces the sub-formula with the constant zero, but in a few suitable contexts it uses the constant one instead. The DEL key automatically deselects and re-simplifies the entire formula afterwards. Thus:

```
               ###
    17 x y + # #              17 x y              17 # y              17 y
1*  -------------      1:   -------      1*    -------      1:    -------
       2 x + 1               2 x + 1             2 x + 1             2 x + 1
```

In this example, we first delete the `sqrt(c)' term; Calc accomplishes this by replacing `sqrt(c)' with zero and resimplifying. We then delete the x in the numerator; since this is part of a product, Calc replaces it with `1' and resimplifies.

If you select an element of a vector and press DEL, that element is deleted from the vector. If you delete

one side of an equation or inequality, only the opposite side remains.

The j DEL (`calc-del-selection`) command is like DEL but with the auto-selecting behavior of j ' and j `. It deletes the selected portion of the formula indicated by the cursor, or, in the absence of a selection, it deletes the sub-formula indicated by the cursor position.

(There is also an auto-selecting j RET (`calc-copy-selection`) command.)

Normal arithmetic operations also apply to sub-formulas. Here we select the denominator, press 5 - to subtract five from the denominator, press n to negate the denominator, then press Q to take the square root.

```
     .. .          .. .          .. .          .. .
1*  .......   1*  .......   1*  .......   1*  .........
    2 x + 1       2 x - 4       4 - 2 x      _________
                                             V 4 - 2 x
```

Certain types of operations on selections are not allowed. For example, for an arithmetic function like - no more than one of the arguments may be a selected sub-formula. (As the above example shows, the result of the subtraction is spliced back into the argument which had the selection; if there were more than one selection involved, this would not be well-defined.) If you try to subtract two selections, the command will abort with an error message.

Operations on sub-formulas sometimes leave the formula as a whole in an "un-natural" state. Consider negating the `2 x' term of our sample formula by selecting it and pressing n (`calc-change-sign`).

```
      .. .            .. .
1*  .........   1*  ..........
     .......         .........
    . . . 2 x       . . . -2 x
```

Unselecting the sub-formula reveals that the minus sign, which would normally have cancelled out with the subtraction automatically, has not been able to do so because the subtraction was not part of the selected portion. Pressing = (`calc-evaluate`) or doing any other mathematical operation on the whole formula will cause it to be simplified.

```
       17 y            17 y
1:  ----------  1:  ----------
     _________       _________
    V 4 - -2 x      V 4 + 2 x
```

Rearranging Formulas using Selections

The j R (`calc-commute-right`) command moves the selected sub-formula to the right in its surrounding formula. Generally the selection is one term of a sum or product; the sum or product is rearranged according to the commutative laws of algebra.

As with j ' and j DEL, the term under the cursor is used if there is no selection in the current formula. All commands described in this section share this property. In this example, we place the cursor on the `a' and

type j R, then repeat.

```
1:  a + b - c          1:  b + a - c          1:  b - c + a
```

Note that in the final step above, the `a' is switched with the `c' but the signs are adjusted accordingly. When moving terms of sums and products, j R will never change the mathematical meaning of the formula.

The selected term may also be an element of a vector or an argument of a function. The term is exchanged with the one to its right. In this case, the "meaning" of the vector or function may of course be drastically changed.

```
1:  [a, b, c]          1:  [b, a, c]          1:  [b, c, a]

1:  f(a, b, c)         1:  f(b, a, c)         1:  f(b, c, a)
```

The j L (`calc-commute-left`) command is like j R except that it swaps the selected term with the one to its left.

With numeric prefix arguments, these commands move the selected term several steps at a time. It is an error to try to move a term left or right past the end of its enclosing formula. With numeric prefix arguments of zero, these commands move the selected term as far as possible in the given direction.

The j D (`calc-sel-distribute`) command mixes the selected sum or product into the surrounding formula using the distributive law. For example, in `a * (b - c)' with the `b - c' selected, the result is `a b - a c'. This also distributes products or quotients into surrounding powers, and can also do transformations like `exp(a + b)' to `exp(a) exp(b)', where `a + b' is the selected term, and `ln(a ^ b)' to `ln(a) b', where `a ^ b' is the selected term.

For multiple-term sums or products, j D takes off one term at a time: `a * (b + c - d)' goes to `a * (c - d) + a b' with the `c - d' selected so that you can type j D repeatedly to expand completely. The j D command allows a numeric prefix argument which specifies the maximum number of times to expand at once; the default is one time only.

The j D command is implemented using rewrite rules. See section Selections with Rewrite Rules. The rules are stored in the Calc variable `DistribRules`. A convenient way to view these rules is to use s e (`calc-edit-variable`) which displays and edits the stored value of a variable. Press M-# M-# to return from editing mode; be careful not to make any actual changes or else you will affect the behavior of future j D commands!

To extend j D to handle new cases, just edit `DistribRules` as described above. You can then use the s p command to save this variable's value permanently for future Calc sessions. See section Other Operations on Variables.

The j M (`calc-sel-merge`) command is the complement of j D; given `a b - a c' with either `a b' or `a c' selected, the result is `a * (b - c)'. Once again, j M can also merge calls to functions like `exp` and `ln`; examine the variable `MergeRules` to see all the relevant rules.

The j C (`calc-sel-commute`) command swaps the arguments of the selected sum, product, or equation. It always behaves as if j b mode were in effect, i.e., the sum `a + b + c' is treated as the nested sums `(a + b)

+ c' by this command. If you put the cursor on the first `+', the result is `(b + a) + c'; if you put the cursor on the second `+', the result is `c + (a + b)' (which the default simplifications will rearrange to `(c + a) + b'). The relevant rules are stored in the variable `CommuteRules`.

You may need to turn default simplifications off (with the m O command) in order to get the full benefit of j C. For example, commuting `a - b' produces `-b + a', but the default simplifications will "simplify" this right back to `a - b' if you don't turn them off. The same is true of some of the other manipulations described in this section.

The j N (`calc-sel-negate`) command replaces the selected term with the negative of that term, then adjusts the surrounding formula in order to preserve the meaning. For example, given `exp(a - b)' where `a - b' is selected, the result is `1 / exp(b - a)'. By contrast, selecting a term and using the regular n (`calc-change-sign`) command negates the term without adjusting the surroundings, thus changing the meaning of the formula as a whole. The rules variable is `NegateRules`.

The j & (`calc-sel-invert`) command is similar to j N except it takes the reciprocal of the selected term. For example, given `a - ln(b)' with `b' selected, the result is `a + ln(1/b)'. The rules variable is `InvertRules`.

The j E (`calc-sel-jump-equals`) command moves the selected term from one side of an equation to the other. Given `a + b = c + d' with `c' selected, the result is `a + b - c = d'. This command also works if the selected term is part of a `*', `/', or `^' formula. The relevant rules variable is `JumpRules`.

The j I (`calc-sel-isolate`) command isolates the selected term on its side of an equation. It uses the a S (`calc-solve-for`) command to solve the equation, and the Hyperbolic flag affects it in the same way. See section Solving Equations. When it applies, j I is often easier to use than j E. It understands more rules of algebra, and works for inequalities as well as equations.

The j * (`calc-sel-mult-both-sides`) command prompts for a formula using algebraic entry, then multiplies both sides of the selected quotient or equation by that formula. It simplifies each side with a s (`calc-simplify`) before re-forming the quotient or equation. You can suppress this simplification by providing any numeric prefix argument. There is also a j / (`calc-sel-div-both-sides`) which is similar to j * but dividing instead of multiplying by the factor you enter.

As a special feature, if the numerator of the quotient is 1, then the denominator is expanded at the top level using the distributive law (i.e., using the C-u -1 a x command). Suppose the formula on the stack is `1 / (sqrt(a) + 1)', and you wish to eliminate the square root in the denominator by multiplying both sides by `sqrt(a) - 1'. Calc's default simplifications would change the result `(sqrt(a) - 1) / (sqrt(a) - 1) (sqrt(a) + 1)' right back to the original form by cancellation; Calc expands the denominator to `sqrt(a) (sqrt(a) - 1) + sqrt(a) - 1' to prevent this. (You would now want to use an a x command to expand the rest of the way, whereupon the denominator would cancel out to the desired form, `a - 1'.) When the numerator is not 1, this initial expansion is not necessary because Calc's default simplifications will not notice the potential cancellation.

If the selection is an inequality, j * and j / will accept any factor, but will warn unless they can prove the factor is either positive or negative. (In the latter case the direction of the inequality will be switched appropriately.) See section Declarations, for ways to inform Calc that a given variable is positive or negative. If Calc can't tell for sure what the sign of the factor will be, it will assume it is positive and display a warning message.

For selections that are not quotients, equations, or inequalities, these commands pull out a multiplicative factor: They divide (or multiply) by the entered formula, simplify, then multiply (or divide) back by the formula.

The j + (`calc-sel-add-both-sides`) and j - (`calc-sel-sub-both-sides`) commands analogously add to or subtract from both sides of an equation or inequality. For other types of selections, they extract an additive factor. A numeric prefix argument suppresses simplification of the intermediate results.

The j U (`calc-sel-unpack`) command replaces the selected function call with its argument. For example, given `a + sin(x^2)' with `sin(x^2)' selected, the result is `a + x^2'. (The `x^2' will remain selected; if you wanted to change the `sin` to `cos`, just press C now to take the cosine of the selected part.)

The j v (`calc-sel-evaluate`) command performs the normal default simplifications on the selected sub-formula. These are the simplifications that are normally done automatically on all results, but which may have been partially inhibited by previous selection-related operations, or turned off altogether by the m O command. This command is just an auto-selecting version of the a v command (see section Algebraic Manipulation).

With a numeric prefix argument of 2, C-u 2 j v applies the a s (`calc-simplify`) command to the selected sub-formula. With a prefix argument of 3 or more, e.g., C-u j v applies the a e (`calc-simplify-extended`) command. See section Simplifying Formulas. With a negative prefix argument it simplifies at the top level only, just as with a v. Here the "top" level refers to the top level of the selected sub-formula.

The j " (`calc-sel-expand-formula`) command is to a " (see section Algebraic Manipulation) what j v is to a v.

You can use the j r (`calc-rewrite-selection`) command to define other algebraic operations on sub-formulas. See section Rewrite Rules.

Algebraic Manipulation

The commands in this section perform general-purpose algebraic manipulations. They work on the whole formula at the top of the stack (unless, of course, you have made a selection in that formula).

Many algebra commands prompt for a variable name or formula. If you answer the prompt with a blank line, the variable or formula is taken from top-of-stack, and the normal argument for the command is taken from the second-to-top stack level.

The a v (`calc-alg-evaluate`) command performs the normal default simplifications on a formula; for example, `a - -b' is changed to `a + b'. These simplifications are normally done automatically on all Calc results, so this command is useful only if you have turned default simplifications off with an m O command. See section Simplification Modes.

It is often more convenient to type =, which is like a v but which also substitutes stored values for variables in the formula. Use a v if you want the variables to ignore their stored values.

If you give a numeric prefix argument of 2 to a v, it simplifies as if in algebraic simplification mode. This is

equivalent to typing a s; see section Simplifying Formulas. If you give a numeric prefix of 3 or more, it uses extended simplification mode (a e).

If you give a negative prefix argument *-1*, *-2*, or *-3*, it simplifies in the corresponding mode but only works on the top-level function call of the formula. For example, `(2 + 3) * (2 + 3)' will simplify to `(2 + 3)^2', without simplifying the sub-formulas `2 + 3'. As another example, typing V R + to sum the vector `[1, 2, 3, 4]' produces the formula `reduce(add, [1, 2, 3, 4])' in no-simplify mode. Using a v will evaluate this all the way to 10; using C-u - a v will evaluate it only to `1 + 2 + 3 + 4'. (See section Reducing and Mapping Vectors.)

The = command corresponds to the `evalv` function, and the related N command, which is like = but temporarily disables symbolic (m s) mode during the evaluation, corresponds to the `evalvn` function. (These commands interpret their prefix arguments differently than a v; = treats the prefix as the number of stack elements to evaluate at once, and N treats it as a temporary different working precision.)

The `evalvn` function can take an alternate working precision as an optional second argument. This argument can be either an integer, to set the precision absolutely, or a vector containing a single integer, to adjust the precision relative to the current precision. Note that `evalvn` with a larger than current precision will do the calculation at this higher precision, but the result will as usual be rounded back down to the current precision afterward. For example, `evalvn(pi - 3.1415)' at a precision of 12 will return `9.265359e-5'; `evalvn(pi - 3.1415, 30)' will return `9.26535897932e-5' (computing a 25-digit result which is then rounded down to 12); and `evalvn(pi - 3.1415, [-2])' will return `9.2654e-5'.

The a " (`calc-expand-formula`) command expands functions into their defining formulas wherever possible. For example, `deg(x^2)' is changed to `180 x^2 / pi'. Most functions, like `sin` and `gcd`, are not defined by simple formulas and so are unaffected by this command. One important class of functions which *can* be expanded is the user-defined functions created by the Z F command. See section Programming with Formulas. Other functions which a " can expand include the probability distribution functions, most of the financial functions, and the hyperbolic and inverse hyperbolic functions. A numeric prefix argument affects a " in the same way as it does a v: A positive argument expands all functions in the formula and then simplifies in various ways; a negative argument expands and simplifies only the top-level function call.

The a M (`calc-map-equation`) [`mapeq`] command applies a given function or operator to one or more equations. It is analogous to V M, which operates on vectors instead of equations. see section Reducing and Mapping Vectors. For example, a M S changes `x = y+1' to `sin(x) = sin(y+1)', and a M + with `x = y+1' and 6 on the stack produces `x+6 = y+7'. With two equations on the stack, a M + would add the lefthand sides together and the righthand sides together to get the two respective sides of a new equation.

Mapping also works on inequalities. Mapping two similar inequalities produces another inequality of the same type. Mapping an inequality with an equation produces an inequality of the same type. Mapping a `<=' with a `<' or `!=' (not-equal) produces a `<'. If inequalities with opposite direction (e.g., `<' and `>') are mapped, the direction of the second inequality is reversed to match the first: Using a M + on `a < b' and `a > 2' reverses the latter to get `2 < a', which then allows the combination `a + 2 < b + a', which the a s command can then simplify to get `2 < b'.

Using a M *, a M /, a M n, or a M & to negate or invert an inequality will reverse the direction of the inequality. Other adjustments to inequalities are *not* done automatically; a M S will change `x < y' to `sin(x)

< sin(y)' even though this is not true for all values of the variables.

With the Hyperbolic flag, H a M [`mapeqp`] does a plain mapping operation without reversing the direction of any inequalities. Thus, H a M & would change x > 2 to 1/x > 0.5. (This change is mathematically incorrect, but perhaps you were fixing an inequality which was already incorrect.)

With the Inverse flag, I a M [`mapeqr`] always reverses the direction of the inequality. You might use I a M C to change `x < y' to `cos(x) > cos(y)' if you know you are working with small positive angles.

The a b (`calc-substitute`) [`subst`] command substitutes all occurrences of some variable or sub-expression of an expression with a new sub-expression. For example, substituting `sin(x)' with `cos(y)' in `2 sin(x)^2 + x sin(x) + sin(2 x)' produces `2 cos(y)^2 + x cos(y) + sin(2 x)'. Note that this is a purely structural substitution; the lone `x' and the `sin(2 x)' stayed the same because they did not look like `sin(x)'. See section Rewrite Rules, for a more general method for doing substitutions.

The a b command normally prompts for two formulas, the old one and the new one. If you enter a blank line for the first prompt, all three arguments are taken from the stack (new, then old, then target expression). If you type an old formula but then enter a blank line for the new one, the new formula is taken from top-of-stack and the target from second-to-top. If you answer both prompts, the target is taken from top-of-stack as usual.

Note that a b has no understanding of commutativity or associativity. The pattern `x+y' will not match the formula `y+x'. Also, `y+z' will not match inside the formula `x+y+z' because the `+' operator is left-associative, so the "deep structure" of that formula is `(x+y) + z'. Use d U (`calc-unformatted-language`) mode to see the true structure of a formula. The rewrite rule mechanism, discussed later, does not have these limitations.

As an algebraic function, `subst` takes three arguments: Target expression, old, new. Note that `subst` is always evaluated immediately, even if its arguments are variables, so if you wish to put a call to `subst` onto the stack you must turn the default simplifications off first (with m O).

Simplifying Formulas

The a s (`calc-simplify`) [`simplify`] command applies various algebraic rules to simplify a formula. This includes rules which are not part of the default simplifications because they may be too slow to apply all the time, or may not be desirable all of the time. For example, non-adjacent terms of sums are combined, as in `a + b + 2 a' to `b + 3 a', and some formulas like `sin(arcsin(x))' are simplified to `x'.

The sections below describe all the various kinds of algebraic simplifications Calc provides in full detail. None of Calc's simplification commands are designed to pull rabbits out of hats; they simply apply certain specific rules to put formulas into less redundant or more pleasing forms. Serious algebra in Calc must be done manually, usually with a combination of selections and rewrite rules. See section Rearranging Formulas using Selections. See section Rewrite Rules.

See section Simplification Modes, for commands to control what level of simplification occurs automatically. Normally only the "default simplifications" occur.

Default Simplifications

This section describes the "default simplifications," those which are normally applied to all results. For example, if you enter the variable x on the stack twice and push +, Calc's default simplifications automatically change x + x to 2 x.

The m O command turns off the default simplifications, so that x + x will remain in this form unless you give an explicit "simplify" command like = or a v. See section Algebraic Manipulation. The m D command turns the default simplifications back on.

The most basic default simplification is the evaluation of functions. For example, 2 + 3 is evaluated to 5, and `sqrt`(9) is evaluated to 3. Evaluation does not occur if the arguments to a function are somehow of the wrong type (`tan`([2,3,4]), range (`tan`(90)), or number (`tan`(3,5)), or if the function name is not recognized (`f`(5)), or if "symbolic" mode (see section Symbolic Mode) prevents evaluation (`sqrt`(2)).

Calc simplifies (evaluates) the arguments to a function before it simplifies the function itself. Thus `sqrt`(5+4) is simplified to `sqrt`(9) before the `sqrt` function itself is applied. There are very few exceptions to this rule: `quote`, `lambda`, and `condition` (the `::` operator) do not evaluate their arguments, `if` (the `? :` operator) does not evaluate all of its arguments, and `evalto` does not evaluate its lefthand argument.

Most commands apply the default simplifications to all arguments they take from the stack, perform a particular operation, then simplify the result before pushing it back on the stack. In the common special case of regular arithmetic commands like + and Q `[sqrt]`, the arguments are simply popped from the stack and collected into a suitable function call, which is then simplified (the arguments being simplified first as part of the process, as described above).

The default simplifications are too numerous to describe completely here, but this section will describe the ones that apply to the major arithmetic operators. This list will be rather technical in nature, and will probably be interesting to you only if you are a serious user of Calc's algebra facilities.

As well as the simplifications described here, if you have stored any rewrite rules in the variable `EvalRules` then these rules will also be applied before any built-in default simplifications. See section Automatic Rewrites, for details.

And now, on with the default simplifications:

Arithmetic operators like + and * always take two arguments in Calc's internal form. Sums and products of three or more terms are arranged by the associative law of algebra into a left-associative form for sums, ((a + b) + c) + d, and a right-associative form for products, a * (b * (c * d)). Formulas like (a + b) + (c + d) are rearranged to left-associative form, though this rarely matters since Calc's algebra commands are designed to hide the inner structure of sums and products as much as possible. Sums and products in their proper associative form will be written without parentheses in the examples below.

Sums and products are *not* rearranged according to the commutative law (a + b to b + a) except in a few special cases described below. Some algebra programs always rearrange terms into a canonical order, which enables them to see that a b + b a can be simplified to 2 a b. Calc assumes you have put the terms into the order you want and generally leaves that order alone, with the consequence that formulas like the above will only be simplified if you explicitly give the a s command. See section Algebraic Simplifications.

Differences a - b are treated like sums a + (-b) for purposes of simplification; one of the default simplifications is to rewrite a + (-b) or (-b) + a, where -b represents a "negative-looking" term, into a - b form. "Negative-looking" means negative numbers, negated formulas like -x, and products or quotients in which either term is negative-looking.

Other simplifications involving negation are -(-x) to x; -(a b) or -(a/b) where either a or b is negative-looking, simplified by negating that term, or else where a or b is any number, by negating that number; -(a + b) to -a - b, and -(b - a) to a - b. (This, and rewriting (-b) + a to a - b, are the only cases where the order of terms in a sum is changed by the default simplifications.)

The distributive law is used to simplify sums in some cases: a x + b x to (a + b) x, where a represents a number or an implicit 1 or *-1* (as in x or -x) and similarly for b. Use the a c, a f, or j M commands to merge sums with non-numeric coefficients using the distributive law.

The distributive law is only used for sums of two terms, or for adjacent terms in a larger sum. Thus a + b + b + c is simplified to a + 2 b + c, but a + b + c + b is not simplified. The reason is that comparing all terms of a sum with one another would require time proportional to the square of the number of terms; Calc relegates potentially slow operations like this to commands that have to be invoked explicitly, like a s.

Finally, a + 0 and 0 + a are simplified to a. A consequence of the above rules is that 0 - a is simplified to -a.

The products 1 a and a 1 are simplified to a; (-1) a and a (-1) are simplified to -a; 0 a and a 0 are simplified to 0, except that in matrix mode where a is not provably scalar the result is the generic zero matrix `idn(0)', and that if a is infinite the result is `nan'.

Also, (-a) b and a (-b) are simplified to -(a b), where this occurs for negated formulas but not for regular negative numbers.

Products are commuted only to move numbers to the front: a b 2 is commuted to 2 a b.

The product a (b + c) is distributed over the sum only if a and at least one of b and c are numbers: 2 (x + 3) goes to 2 x + 6. The formula (-a) (b - c), where -a is a negative number, is rewritten to a (c - b).

The distributive law of products and powers is used for adjacent terms of the product: x^a x^b goes to @c{x^{a+b}} x^(a+b) where a is a number, or an implicit 1 (as in x), or the implicit one-half of `sqrt`(x), and similarly for b. The result is written using `sqrt' or `1/sqrt' if the sum of the powers is 1/2 or -1/2, respectively. If the sum of the powers is zero, the product is simplified to 1 or to `idn(1)' if matrix mode is enabled.

The product of a negative power times anything but another negative power is changed to use division: @c{$x^{-2} y$} x^(-2) y goes to y / x^2 unless matrix mode is in effect and neither x nor y are scalar (in which case it is considered unsafe to rearrange the order of the terms).

Finally, a (b/c) is rewritten to (a b)/c, and also (a/b) c is changed to (a c)/b unless in matrix mode.

Simplifications for quotients are analogous to those for products. The quotient 0 / x is simplified to 0, with the same exceptions that were noted for 0 x. Likewise, x / 1 and x / (-1) are simplified to x and -x, respectively.

The quotient x / 0 is left unsimplified or changed to an infinite quantity, as directed by the current infinite mode. See section Infinite Mode.

The expression @c{a / b^{-c}} a / b^(-c) is changed to a b^c, where -c is any negative-looking pow
Also, 1 / b^c is changed to @c{b^{-c}} b^(-c) for any power c.

Also, (-a) / b and a / (-b) go to -(a/b); (a/b) / c goes to a / (b c); and a / (b/c) goes to (a c) / b unless matrix mode prevents this rearrangement. Similarly, a / (b:c) is simplified to (c:b) a for any fraction b:c.

The distributive law is applied to (a + b) / c only if c and at least one of a and b are numbers. Quotients of powers and square roots are distributed just as described for multiplication.

Quotients of products cancel only in the leading terms of the numerator and denominator. In other words, a x b / a y b is cancelled to x b / y b but not to x / y. Once again this is because full cancellation can be slow; use a s to cancel all terms of the quotient.

Quotients of negative-looking values are simplified according to (-a) / (-b) to a / b, (-a) / (b - c) to a / (c - b), and (a - b) / (-c) to (b - a) / c.

The formula x^0 is simplified to 1, or to `idn(1)' in matrix mode. The formula 0^x is simplified to 0 unless x is a negative number or complex number, in which case the result is an infinity or an unsimplified formula according to the current infinite mode. Note that 0^0 is an indeterminate form, as evidenced by the fact that the simplifications for x^0 and 0^x conflict when x=0.

Powers of products or quotients (a b)^c, (a/b)^c are distributed to a^c b^c, a^c / b^c only if c is an integer, or if either a or b are nonnegative real numbers. Powers of powers (a^b)^c are simplified to a^(b c) only when c is an integer and b c also evaluates to an integer. Without these restrictions these simplifications would not be safe because of problems with principal values. (In other words, @c{$((-3)^{1/2})^2$} ((-3)^1:2)^2 is safe to simplify, but ((-3)^2)^1:2 is not.) See section Declarations, for ways to inform Calc that your variables satisfy these requirements.

As a special case of this rule, `sqrt`(x)^n is simplified to x^(n/2) only for even integers n.

If a is known to be real, b is an even integer, and c is a half- or quarter-integer, then (a^b)^c is simplified to @c{$`abs`(a^{b c})$} `abs`(a^(b c)).

Also, (-a)^b is simplified to a^b if b is an even integer, or to -(a^b) if b is an odd integer, for any negative-looking expression -a.

Square roots `sqrt`(x) generally act like one-half powers x^1:2 for the purposes of the above-listed simplifications.

Also, note that @c{$1 / x^{1:2}$} 1 / x^1:2 is changed to @c{$x^{-1:2}$} x^(-1:2), but 1 / `sqrt`(x) is left alone.

Generic identity matrices (see section Matrix and Scalar Modes) are simplified by the following rules: `idn`(a) + b to a + b if b is provably scalar, or expanded out if b is a matrix; `idn`(a) + `idn`(b) to `idn`(a + b); -`idn`(a) to `idn`(-a); a `idn`(b) to `idn`(a b) if a is provably scalar, or to a b if a is provably non-scalar; `idn`(a) `idn`(b) to `idn`(a b); analogous simplifications for quotients involving `idn`; and `idn`(a)^n to `idn`(a^n) where n is an integer.

The `floor` function and other integer truncation functions vanish if the argument is provably integer-valued, so that `floor`(`round`(x)) simplifies to `round`(x). Also, combinations of `float`, `floor` and its friends, and `ffloor` and its friends, are simplified in appropriate ways. See section Integer

Truncation.

The expression `abs`(-x) changes to `abs`(x). The expression `abs`(`abs`(x)) changes to `abs`(x); in fact, `abs`(x) changes to x or -x if x is provably nonnegative or nonpositive (see section Declarations).

While most functions do not recognize the variable `i` as an imaginary number, the `arg` function does handle the two cases `arg`(`i`) and `arg`(-`i`) just for convenience.

The expression `conj`(`conj`(x)) simplifies to x. Various other expressions involving `conj`, `re`, and `im` are simplified, especially if some of the arguments are provably real or involve the constant `i`. For example, `conj`(a + b i) is changed to `conj`(a) - `conj`(b) i, or to a - b i if a and b are known to be real.

Functions like `sin` and `arctan` generally don't have any default simplifications beyond simply evaluating the functions for suitable numeric arguments and infinity. The a s command described in the next section does provide some simplifications for these functions, though.

One important simplification that does occur is that `ln`(`e`) is simplified to 1, and `ln`(`e`^x) is simplified to x for any x. This occurs even if you have stored a different value in the Calc variable `e'; but this would be a bad idea in any case if you were also using natural logarithms!

Among the logical functions, `!`*(a <= b)* changes to a > b and so on. Equations and inequalities where both sides are either negative-looking or zero are simplified by negating both sides and reversing the inequality. While it might seem reasonable to simplify !!x to x, this would not be valid in general because !!2 is 1, not 2.

Most other Calc functions have few if any default simplifications defined, aside of course from evaluation when the arguments are suitable numbers.

Algebraic Simplifications

The a s command makes simplifications that may be too slow to do all the time, or that may not be desirable all of the time. If you find these simplifications are worthwhile, you can type m A to have Calc apply them automatically.

This section describes all simplifications that are performed by the a s command. Note that these occur in addition to the default simplifications; even if the default simplifications have been turned off by an m O command, a s will turn them back on temporarily while it simplifies the formula.

There is a variable, `AlgSimpRules`, in which you can put rewrites to be applied by a s. Its use is analogous to `EvalRules`, but without the special restrictions. Basically, the simplifier does `a r AlgSimpRules' with an infinite repeat count on the whole expression being simplified, then it traverses the expression applying the built-in rules described below. If the result is different from the original expression, the process repeats with the default simplifications (including `EvalRules`), then `AlgSimpRules`, then the built-in simplifications, and so on.

Sums are simplified in two ways. Constant terms are commuted to the end of the sum, so that a + 2 + b changes to a + b + 2. The only exception is that a constant will not be commuted away from the first position of a difference, i.e., 2 - x is not commuted to -x + 2.

Also, terms of sums are combined by the distributive law, as in x + y + 2 x to y + 3 x. This always occurs

for adjacent terms, but a s compares all pairs of terms including non-adjacent ones.

Products are sorted into a canonical order using the commutative law. For example, b c a is commuted to a b c. This allows easier comparison of products; for example, the default simplifications will not change x y + y x to 2 x y, but a s will; it first rewrites the sum to x y + x y, and then the default simplifications are able to recognize a sum of identical terms.

The canonical ordering used to sort terms of products has the property that real-valued numbers, interval forms and infinities come first, and are sorted into increasing order. The V S command uses the same ordering when sorting a vector.

Sorting of terms of products is inhibited when matrix mode is turned on; in this case, Calc will never exchange the order of two terms unless it knows at least one of the terms is a scalar.

Products of powers are distributed by comparing all pairs of terms, using the same method that the default simplifications use for adjacent terms of products.

Even though sums are not sorted, the commutative law is still taken into account when terms of a product are being compared. Thus (x + y) (y + x) will be simplified to (x + y)^2. A subtle point is that (x - y) (y - x) will *not* be simplified to -(x - y)^2; Calc does not notice that one term can be written as a constant times the other, even if that constant is *-1*.

A fraction times any expression, (a:b) x, is changed to a quotient involving integers: a x / b. This is not done for floating-point numbers like 0.5, however. This is one reason why you may find it convenient to turn Fraction mode on while doing algebra; see section Fraction Mode.

Quotients are simplified by comparing all terms in the numerator with all terms in the denominator for possible cancellation using the distributive law. For example, a x^2 b / c x^3 d will cancel x^2 from both sides to get a b / c x d. (The terms in the denominator will then be rearranged to c d x as described above.) If there is any common integer or fractional factor in the numerator and denominator, it is cancelled out; for example, (4 x + 6) / 8 x simplifies to (2 x + 3) / 4 x.

Non-constant common factors are not found even by a s. To cancel the factor a in (a x + a) / a^2 you could first use j M on the product a x to Merge the numerator to a (1+x), which can then be simplified successfully.

Integer powers of the variable `i` are simplified according to the identity i^2 = -1. If you store a new value other than the complex number (0,1) in `i`, this simplification will no longer occur. This is done by a s instead of by default in case someone (unwisely) uses the name `i` for a variable unrelated to complex numbers; it would be unfortunate if Calc quietly and automatically changed this formula for reasons the user might not have been thinking of.

Square roots of integer or rational arguments are simplified in several ways. (Note that these will be left unevaluated only in Symbolic mode.) First, square integer or rational factors are pulled out so that `sqrt`(8) is rewritten as 2 sqrt(2). Conceptually speaking this implies factoring the argument into primes and moving pairs of primes out of the square root, but for reasons of efficiency Calc only looks for primes up to 29.

Square roots in the denominator of a quotient are moved to the numerator: 1 / `sqrt`(3) changes to `sqrt`(3) / 3. The same effect occurs for the square root of a fraction: `sqrt`(2:3) changes to `sqrt`(6) / 3.

The % (modulo) operator is simplified in several ways when the modulus M is a positive real number. First,

if the argument is of the form x + n for some real number n, then n is itself reduced modulo M. For example, `(x - 23) % 10' is simplified to `(x + 7) % 10'.

If the argument is multiplied by a constant, and this constant has a common integer divisor with the modulus, then this factor is cancelled out. For example, `12 x % 15' is changed to `3 (4 x % 5)' by factoring out 3. Also, `(12 x + 1) % 15' is changed to `3 ((4 x + 1:3) % 5)'. While these forms may not seem "simpler," they allow Calc to discover useful information about modulo forms in the presence of declarations.

If the modulus is 1, then Calc can use `int` declarations to evaluate the expression. For example, the idiom `x % 2' is often used to check whether a number is odd or even. As described above, `2 n % 2' and `(2 n + 1) % 2' are simplified to `2 (n % 1)' and `2 ((n + 1:2) % 1)', respectively; Calc can simplify these to 0 and 1 (respectively) if `n` has been declared to be an integer.

Trigonometric functions are simplified in several ways. First, `sin`(`arcsin`(x)) is simplified to x, and similarly for `cos` and `tan`. If the argument to `sin` is negative-looking, it is simplified to `-sin`(x), and similarly for `cos` and `tan`. Finally, certain special values of the argument are recognized; see section Trigonometric/Hyperbolic Functions.

Trigonometric functions of inverses of different trigonometric functions can also be simplified, as in `sin`(`arccos`(x)) to `sqrt`(1 - x^2).

Hyperbolic functions of their inverses and of negative-looking arguments are also handled, as are exponentials of inverse hyperbolic functions.

No simplifications for inverse trigonometric and hyperbolic functions are known, except for negative arguments of `arcsin`, `arctan`, `arcsinh`, and `arctanh`. Note that `arcsin`(`sin`(x)) can *not* safely change to x, since this only correct within an integer multiple of @c{2π} 2 pi radians or 360 degrees. However, `arcsinh`(`sinh`(x)) is simplified to x if x is known to be real.

Several simplifications that apply to logarithms and exponentials are that `exp`(`ln`(x)), @c{$e^{\ln(x)}$} e^`ln`(x), and 10^`log10`(x) all reduce to x. Also, `ln`(`exp`(x)), etc., can reduce to x if x is provably real. The form `exp`(x)^y is simplified to `exp`(x y). If x is a suitable multiple of @c{πi} pi i (as described above for the trigonometric functions), then `exp`(x) or e^x will be expanded. Finally, `ln`(x) is simplified to a form involving `pi` and `i` where x is provably negative, positive imaginary, or negative imaginary.

The error functions `erf` and `erfc` are simplified when their arguments are negative-looking or are calls to the `conj` function.

Equations and inequalities are simplified by cancelling factors of products, quotients, or sums on both sides. Inequalities change sign if a negative multiplicative factor is cancelled. Non-constant multiplicative factors as in a b = a c are cancelled from equations only if they are provably nonzero (generally because they were declared so; see section Declarations). Factors are cancelled from inequalities only if they are nonzero and their sign is known.

Simplification also replaces an equation or inequality with 1 or 0 ("true" or "false") if it can through the use of declarations. If x is declared to be an integer greater than 5, then x < 3, x = 3, and x = 7.5 are all simplified to 0, but x > 3 is simplified to 1. By a similar analysis, abs(x) >= 0 is simplified to 1, as is x^2 >= 0 if x is known to be real.

"Unsafe" Simplifications

The a e (`calc-simplify-extended`) [`esimplify`] command is like a s except that it applies some additional simplifications which are not "safe" in all cases. Use this only if you know the values in your formula lie in the restricted ranges for which these simplifications are valid. The symbolic integrator uses a e; one effect of this is that the integrator's results must be used with caution. Where an integral table will often attach conditions like "for positive a only," Calc (like most other symbolic integration programs) will simply produce an unqualified result.

Because a e's simplifications are unsafe, it is sometimes better to type C-u -3 a v, which does extended simplification only on the top level of the formula without affecting the sub-formulas. In fact, C-u -3 j v allows you to target extended simplification to any specific part of a formula.

The variable `ExtSimpRules` contains rewrites to be applied by the a e command. These are applied in addition to `EvalRules` and `AlgSimpRules`. (The a r AlgSimpRules step described above is simply followed by an a r ExtSimpRules step.)

Following is a complete list of "unsafe" simplifications performed by a e.

Inverse trigonometric or hyperbolic functions, called with their corresponding non-inverse functions as arguments, are simplified by a e. For example, `arcsin`(`sin`(x)) changes to x. Also, `arcsin`(`cos`(x)) and `arccos`(`sin`(x)) both change to `pi`/2 - x. These simplifications are unsafe because they are valid only for values of x in a certain range; outside that range, values are folded down to the 360-degree range that the inverse trigonometric functions always produce.

Powers of powers (x^a)^b are simplified to @c{$x^{a b}$} x^(a b) for all a and b. These results will be valid only in a restricted range of x; for example, in @c{$(x^2)^{1:2}$} (x^2)^1:2 the powers cancel to get x, which is valid for positive values of x but not for negative or complex values.

Similarly, `sqrt`(x^a) and `sqrt`(x)^a are both simplified (possibly unsafely) to @c{$x^{a/2}$} x^(a/2).

Forms like `sqrt`(1 - `sin`(x)^2) are simplified to, e.g., `cos`(x). Calc has identities of this sort for `sin`, `cos`, `tan`, `sinh`, and `cosh`.

Arguments of square roots are partially factored to look for squared terms that can be extracted. For example, `sqrt`(a^2 b^3 + a^3 b^2) simplifies to a b `sqrt`(a+b).

The simplifications of `ln`(`exp`(x)), `ln`(`e`^x), and `log10`(10^x) to x are also unsafe because of problems with principal values (although these simplifications are safe if x is known to be real).

Common factors are cancelled from products on both sides of an equation, even if those factors may be zero: a x / b x to a / b. Such factors are never cancelled from inequalities: Even a e is not bold enough to reduce a x < b x to a < b (or a > b, depending on whether you believe x is positive or negative). The a M / command can be used to divide a factor out of both sides of an inequality.

Simplification of Units

The simplifications described in this section are applied by the u s (`calc-simplify-units`) command. These are in addition to the regular a s (but not a e) simplifications described earlier. See section Basic Operations on Units.

The variable `UnitSimpRules` contains rewrites to be applied by the u s command. These are applied in addition to `EvalRules` and `AlgSimpRules`.

Scalar mode is automatically put into effect when simplifying units. See section Matrix and Scalar Modes.

Sums a + b involving units are simplified by extracting the units of a as if by the u x command (call the result u_a), then simplifying the expression b / u_a using u b and u s. If the result has units then the sum is inconsistent and is left alone. Otherwise, it is rewritten in terms of the units u_a.

If units auto-ranging mode is enabled, products or quotients in which the first argument is a number which is out of range for the leading unit are modified accordingly.

When cancelling and combining units in products and quotients, Calc accounts for unit names that differ only in the prefix letter. For example, `2 km m' is simplified to `2000 m^2'. However, compatible but different units like `ft` and `in` are not combined in this way.

Quotients a / b are simplified in three additional ways. First, if b is a number or a product beginning with a number, Calc computes the reciprocal of this number and moves it to the numerator.

Second, for each pair of unit names from the numerator and denominator of a quotient, if the units are compatible (e.g., they are both units of area) then they are replaced by the ratio between those units. For example, in `3 s in N / kg cm' the units `in / cm' will be replaced by 2.54.

Third, if the units in the quotient exactly cancel out, so that a u b command on the quotient would produce a dimensionless number for an answer, then the quotient simplifies to that number.

For powers and square roots, the "unsafe" simplifications (a b)^c to a^c b^c, (a/b)^c to a^c / b^c, and (a^b)^c to @c{$a^{b c}$} a^(b c) are done if the powers are real numbers. (These are safe in the context of units because all numbers involved can reasonably be assumed to be real.)

Also, if a unit name is raised to a fractional power, and the base units in that unit name all occur to powers which are a multiple of the denominator of the power, then the unit name is expanded out into its base units, which can then be simplified according to the previous paragraph. For example, `acre^1.5' is simplified by noting that 1.5 = 3:2, that `acre' is defined in terms of `m^2', and that the 2 in the power of `m` is a multiple of 2 in 3:2. Thus, `acre^1.5` is replaced by approximately @c{$(4046 m^2)^{1.5}$} (4046 m^2)^1.5, which is then changed to @c{$4046^{1.5} \, (m^2)^{1.5}$} 4046^1.5 (m^2)^1.5, then to 257440 m^3.

The functions `float`, `frac`, `clean`, `abs`, as well as `floor` and the other integer truncation functions, applied to unit names or products or quotients involving units, are simplified. For example, `round(1.6 in)' is changed to `round(1.6) round(in)'; the lefthand term evaluates to 2, and the righthand term simplifies to `in`.

The functions `sin`, `cos`, and `tan` with arguments that have angular units like `rad` or `arcmin` are simplified by converting to base units (radians), then evaluating with the angular mode temporarily set to radians.

Polynomials

A polynomial is a sum of terms which are coefficients times various powers of a "base" variable. For example, 2 x^2 + 3 x - 4 is a polynomial in x. Some formulas can be considered polynomials in several different variables: 1 + 2 x + 3 y + 4 x y^2 is a polynomial in both x and y. Polynomial coefficients are often numbers, but they may in general be any formulas not involving the base variable.

The a f (`calc-factor`) [`factor`] command factors a polynomial into a product of terms. For example, the polynomial x^3 + 2 x^2 + x is factored into `x*(x+1)^2'. As another example, a c + b d + b c + a d is factored into the product (a + b) (c + d).

Calc currently has three algorithms for factoring. Formulas which are linear in several variables, such as the second example above, are merged according to the distributive law. Formulas which are polynomials in a single variable, with constant integer or fractional coefficients, are factored into irreducible linear and/or quadratic terms. The first example above factors into three linear terms (x, x+1, and x+1 again). Finally, formulas which do not fit the above criteria are handled by the algebraic rewrite mechanism.

Calc's polynomial factorization algorithm works by using the general root-finding command (a P) to solve for the roots of the polynomial. It then looks for roots which are rational numbers or complex-conjugate pairs, and converts these into linear and quadratic terms, respectively. Because it uses floating-point arithmetic, it may be unable to find terms that involve large integers (whose number of digits approaches the current precision). Also, irreducible factors of degree higher than quadratic are not found, and polynomials in more than one variable are not treated. (A more robust factorization algorithm may be included in a future version of Calc.)

The rewrite-based factorization method uses rules stored in the variable `FactorRules`. See section Rewrite Rules, for a discussion of the operation of rewrite rules. The default `FactorRules` are able to factor quadratic forms symbolically into two linear terms, (a x + b) (c x + d). You can edit these rules to include other cases if you wish. To use the rules, Calc builds the formula `thecoefs(x, [a, b, c, ...])' where `x` is the polynomial base variable and `a`, `b`, etc., are polynomial coefficients (which may be numbers or formulas). The constant term is written first, i.e., in the `a` position. When the rules complete, they should have changed the formula into the form `thefactors(x, [f1, f2, f3, ...])' where each `fi` should be a factored term, e.g., `x - ai'. Calc then multiplies these terms together to get the complete factored form of the polynomial. If the rules do not change the `thecoefs` call to a `thefactors` call, a f leaves the polynomial alone on the assumption that it is unfactorable. (Note that the function names `thecoefs` and `thefactors` are used only as placeholders; there are no actual Calc functions by those names.)

The H a f [`factors`] command also factors a polynomial, but it returns a list of factors instead of an expression which is the product of the factors. Each factor is represented by a sub-vector of the factor, and the power with which it appears. For example, x^5 + x^4 - 33 x^3 + 63 x^2 factors to (x + 7) x^2 (x - 3)^2 in a f, or to [[x, 2], [x+7, 1], [x-3, 2]] in H a f. If there is an overall numeric factor, it always comes first in the list. The functions `factor` and `factors` allow a second argument when written in algebraic form; `factor(x,v)' factors x with respect to the specific variable v. The default is to factor with respect to all the variables that appear in x.

The a c (`calc-collect`) [`collect`] command rearranges a formula as a polynomial in a given variable, ordered in decreasing powers of that variable. For example, given 1 + 2 x + 3 y + 4 x y^2 on the stack, a c x would produce (2 + 4 y^2) x + (1 + 3 y), and a c y would produce (4 x) y^2 + 3 y + (1 + 2 x).

The polynomial will be expanded out using the distributive law as necessary: Collecting x in (x - 1)^3 produces x^3 - 3 x^2 + 3 x - 1. Terms not involving x will not be expanded.

The "variable" you specify at the prompt can actually be any expression: a c ln(x+1) will collect together all terms multiplied by `ln(x+1)' or integer powers thereof. If `x' also appears in the formula in a context other than `ln(x+1)', a c will treat those occurrences as unrelated to `ln(x+1)', i.e., as constants.

The a x (`calc-expand') [`expand'] command expands an expression by applying the distributive law everywhere. It applies to products, quotients, and powers involving sums. By default, it fully distributes all parts of the expression. With a numeric prefix argument, the distributive law is applied only the specified number of times, then the partially expanded expression is left on the stack.

The a x and j D commands are somewhat redundant. Use a x if you want to expand all products of sums in your formula. Use j D if you want to expand a particular specified term of the formula. There is an exactly analogous correspondence between a f and j M. (The j D and j M commands also know many other kinds of expansions, such as `exp(a + b) = exp(a) exp(b)', which a x and a f do not do.)

Calc's automatic simplifications will sometimes reverse a partial expansion. For example, the first step in expanding (x+1)^3 is to write (x+1) (x+1)^2. If a x stops there and tries to put this formula onto the stack, though, Calc will automatically simplify it back to (x+1)^3 form. The solution is to turn simplification off first (see section Simplification Modes), or to run a x without a numeric prefix argument so that it expands all the way in one step.

The a a (`calc-apart') [`apart'] command expands a rational function by partial fractions. A rational function is the quotient of two polynomials; `apart' pulls this apart into a sum of rational functions with simple denominators. In algebraic notation, the `apart' function allows a second argument that specifies which variable to use as the "base"; by default, Calc chooses the base variable automatically.

The a n (`calc-normalize-rat') [`nrat'] command attempts to arrange a formula into a quotient of two polynomials. For example, given 1 + (a + b/c) / d, the result would be (b + a c + c d) / c d. The quotient is reduced, so that a n will simplify (x^2 + 2x + 1) / (x^2 - 1) by dividing out the common factor x + 1, yielding (x + 1) / (x - 1).

The a \ (`calc-poly-div') [`pdiv'] command divides two polynomials u and v, yielding a new polynomial q. If several variables occur in the inputs, the inputs are considered multivariate polynomials. (Calc divides by the variable with the largest power in u first, or, in the case of equal powers, chooses the variables in alphabetical order.) For example, dividing x^2 + 3 x + 2 by x + 2 yields x + 1. The remainder from the division, if any, is reported at the bottom of the screen and is also placed in the Trail along with the quotient.

Using `pdiv' in algebraic notation, you can specify the particular variable to be used as the base: `pdiv(*a*,*b*,*x*)'. If `pdiv' is given only two arguments (as is always the case with the a \ command), then it does a multivariate division as outlined above.

The a % (`calc-poly-rem') [`prem'] command divides two polynomials and keeps the remainder r. The quotient q is discarded. For any formulas a and b, the results of a \ and a % satisfy a = q b + r. (This is analogous to plain \ and %, which compute the integer quotient and remainder from dividing two numbers.)

The a / (`calc-poly-div-rem') [`pdivrem'] command divides two polynomials and reports both the quotient and the remainder as a vector [q, r]. The H a / [`pdivide'] command divides two polynomials and

constructs the formula q + r/b on the stack. (Naturally if the remainder is zero, this will immediately simplify to q.)

The a g (`calc-poly-gcd`) [`pgcd`] command computes the greatest common divisor of two polynomials. (The GCD actually is unique only to within a constant multiplier; Calc attempts to choose a GCD which will be unsurprising.) For example, the a n command uses a g to take the GCD of the numerator and denominator of a quotient, then divides each by the result using a \. (The definition of GCD ensures that this division can take place without leaving a remainder.)

While the polynomials used in operations like a / and a g often have integer coefficients, this is not required. Calc can also deal with polynomials over the rationals or floating-point reals. Polynomials with modulo-form coefficients are also useful in many applications; if you enter `(x^2 + 3 x - 1) mod 5', Calc automatically transforms this into a polynomial over the field of integers mod 5: `(1 mod 5) x^2 + (3 mod 5) x + (4 mod 5)'.

Congratulations and thanks go to Ove Ewerlid (`ewerlid@mizar.DoCS.UU.SE`), who contributed many of the polynomial routines used in the above commands.

See section Decomposing Polynomials, for several useful functions for extracting the individual coefficients of a polynomial.

Calculus

The following calculus commands do not automatically simplify their inputs or outputs using `calc-simplify`. You may find it helps to do this by hand by typing a s or a e. It may also help to use a x and/or a c to arrange a result in the most readable way.

Differentiation

The a d (`calc-derivative`) [`deriv`] command computes the derivative of the expression on the top of the stack with respect to some variable, which it will prompt you to enter. Normally, variables in the formula other than the specified differentiation variable are considered constant, i.e., `deriv(y,x)' is reduced to zero. With the Hyperbolic flag, the `tderiv` (total derivative) operation is used instead, in which derivatives of variables are not reduced to zero unless those variables are known to be "constant," i.e., independent of any other variables. (The built-in special variables like `pi` are considered constant, as are variables that have been declared `const`; see section Declarations.)

With a numeric prefix argument n, this command computes the nth derivative.

When working with trigonometric functions, it is best to switch to radians mode first (with m r). The derivative of `sin(x)' in degrees is `(pi/180) cos(x)', probably not the expected answer!

If you use the `deriv` function directly in an algebraic formula, you can write `deriv(f,x,x0)' which represents the derivative of f with respect to x, evaluated at the point @c{$x=x_0$} x=x0.

If the formula being differentiated contains functions which Calc does not know, the derivatives of those functions are produced by adding primes (apostrophe characters). For example, `deriv(f(2x), x)' produces `2 f'(2 x)', where the function `f'` represents the derivative of `f`.

For functions you have defined with the Z F command, Calc expands the functions according to their defining formulas unless you have also defined `f'` suitably. For example, suppose we define `sinc(x) = sin(x)/x' using Z F. If we then differentiate the formula `sinc(2 x)', the formula will be expanded to `sin(2 x) / (2 x)' and differentiated. However, if we also define `sinc'(x) = dsinc(x)', say, then Calc will write the result as `2 dsinc(2 x)'. See section Programming with Formulas.

For multi-argument functions `f(x,y,z)', the derivative with respect to the first argument is written `f'(x,y,z)'; derivatives with respect to the other arguments are `f'2(x,y,z)' and `f'3(x,y,z)'. Various higher-order derivatives can be formed in the obvious way, e.g., `f'''(x) (the second derivative of `f`) or `f'''2'3(x,y,z) (`f` differentiated with respect to each argument once).

Integration

The a i (`calc-integral`) [`integ`] command computes the indefinite integral of the expression on the top of the stack with respect to a variable. The integrator is not guaranteed to work for all integrable functions, but it is able to integrate several large classes of formulas. In particular, any polynomial or rational function (a polynomial divided by a polynomial) is acceptable. (Rational functions don't have to be in explicit quotient form, however; @c{$x/(1+x^{-2})$} x/(1+x^-2) is not strictly a quotient of polynomials, but it is equivalent to x^3/(x^2+1), which is.) Also, square roots of terms involving x and x^2 may appear in rational functions being integrated. Finally, rational functions involving trigonometric or hyperbolic functions can be integrated.

Please note that the current implementation of Calc's integrator sometimes produces results that are significantly more complex than they need to be. For example, the integral Calc finds for @c{$1/(x+\sqrt{x^2+1})$} 1/(x+sqrt(x^2+1)) is several times more complicated than the answer Mathematica returns for the same input, although the two forms are numerically equivalent. Also, any indefinite integral should be considered to have an arbitrary constant of integration added to it, although Calc does not write an explicit constant of integration in its result. For example, Calc's solution for @c{$1/(1+\tan x)$} 1/(1+tan(x)) differs from the solution given in the *CRC Math Tables* by a constant factor of @c{$\pi i / 2$} pi i / 2, due to a different choice of constant of integration.

The Calculator remembers all the integrals it has done. If conditions change in a way that would invalidate the old integrals, say, a switch from degrees to radians mode, then they will be thrown out. If you suspect this is not happening when it should, use the `calc-flush-caches` command; see section Caches.

Calc normally will pursue integration by substitution or integration by parts up to 3 nested times before abandoning an approach as fruitless. If the integrator is taking too long, you can lower this limit by storing a number (like 2) in the variable `IntegLimit`. (The s I command is a convenient way to edit `IntegLimit`.) If this variable has no stored value or does not contain a nonnegative integer, a limit of 3 is used. The lower this limit is, the greater the chance that Calc will be unable to integrate a function it could otherwise handle. Raising this limit allows the Calculator to solve more integrals, though the time it takes may grow exponentially. You can monitor the integrator's actions by creating an Emacs buffer called `*Trace*`. If such a buffer exists, the a i command will write a log of its actions there.

If you want to manipulate integrals in a purely symbolic way, you can set the integration nesting limit to 0 to prevent all but fast table-lookup solutions of integrals. You might then wish to define rewrite rules for integration by parts, various kinds of substitutions, and so on. See section Rewrite Rules.

Customizing the Integrator

Calc has two built-in rewrite rules called `IntegRules` and `IntegAfterRules` which you can edit to define new integration methods. See section Rewrite Rules. At each step of the integration process, Calc wraps the current integrand in a call to the fictitious function `integtry(expr,var)', where expr is the integrand and var is the integration variable. If your rules rewrite this to be a plain formula (not a call to `integtry`), then Calc will use this formula as the integral of expr. For example, the rule `integtry(mysin(x),x) := -mycos(x)' would define a rule to integrate a function `mysin` that acts like the sine function. Then, putting `4 mysin(2y+1)' on the stack and typing a i y will produce the integral `-2 mycos(2y+1)'. Note that Calc has automatically made various transformations on the integral to allow it to use your rule; integral tables generally give rules for `mysin(a x + b)', but you don't need to use this much generality in your `IntegRules`.

As a more serious example, the expression `exp(x)/x' cannot be integrated in terms of the standard functions, so the "exponential integral" function @c{${\rm Ei}(x)$} Ei(x) was invented to describe it. We can get Calc to do this integral in terms of a made-up `Ei` function by adding the rule `[integtry(exp(x)/x, x) := Ei(x)]' to `IntegRules`. Now entering `exp(2x)/x' on the stack and typing a i x yields `Ei(2 x)'. This new rule will work with Calc's various built-in integration methods (such as integration by substitution) to solve a variety of other problems involving `Ei`: For example, now Calc will also be able to integrate `exp(exp(x))' and `ln(ln(x))' (to get `Ei(exp(x))' and `x ln(ln(x)) - Ei(ln(x))', respectively).

Your rule may do further integration by calling `integ`. For example, `integtry(twice(u),x) := twice(integ(u))' allows Calc to integrate `twice(sin(x))' to get `twice(-cos(x))'. Note that `integ` was called with only one argument. This notation is allowed only within `IntegRules`; it means "integrate this with respect to the same integration variable." If Calc is unable to integrate `u`, the integration that invoked `IntegRules` also fails. Thus integrating `twice(f(x))' fails, returning the unevaluated integral `integ(twice(f(x)), x)'. It is still legal to call `integ` with two or more arguments, however; in this case, if `u` is not integrable, `twice` itself will still be integrated: If the above rule is changed to `... := twice(integ(u,x))', then integrating `twice(f(x))' will yield `twice(integ(f(x),x))'.

If a rule instead produces the formula `integsubst(sexpr, svar)', either replacing the top-level `integtry` call or nested anywhere inside the expression, then Calc will apply the substitution `u = sexpr(svar)' to try to integrate the original expr. For example, the rule `sqrt(a) := integsubst(sqrt(x),x)' says that if Calc ever finds a square root in the integrand, it should attempt the substitution `u = sqrt(x)'. (This particular rule is unnecessary because Calc always tries "obvious" substitutions where sexpr actually appears in the integrand.) The variable svar may be the same as the var that appeared in the call to `integtry`, but it need not be.

When integrating according to an `integsubst`, Calc uses the equation solver to find the inverse of sexpr (if the integrand refers to var anywhere except in subexpressions that exactly match sexpr). It uses the differentiator to find the derivative of sexpr and/or its inverse (it has two methods that use one derivative or the other). You can also specify these items by adding extra arguments to the `integsubst` your rules construct; the general form is `integsubst(sexpr, svar, sinv, sprime)', where sinv is the inverse of sexpr (still written as a function of svar), and sprime is the derivative of sexpr with respect to svar. If you don't specify these things, and Calc is not able to work them out on its own with the information it knows, then your substitution rule will work only in very specific, simple cases.

Calc applies `IntegRules` as if by C-u 1 a r IntegRules; in other words, Calc stops rewriting as soon as

any rule in your rule set succeeds. (If it weren't for this, the `integsubst(sqrt(x),x)' example above would keep on adding layers of `integsubst` calls forever!)

Another set of rules, stored in `IntegSimpRules`, are applied every time the integrator uses a s to simplify an intermediate result. For example, putting the rule `twice(x) := 2 x' into `IntegSimpRules` would tell Calc to convert the `twice` function into a form it knows whenever integration is attempted.

One more way to influence the integrator is to define a function with the Z F command (see section Programming with Formulas). Calc's integrator automatically expands such functions according to their defining formulas, even if you originally asked for the function to be left unevaluated for symbolic arguments. (Certain other Calc systems, such as the differentiator and the equation solver, also do this.)

Sometimes Calc is able to find a solution to your integral, but it expresses the result in a way that is unnecessarily complicated. If this happens, you can either use `integsubst` as described above to try to hint at a more direct path to the desired result, or you can use `IntegAfterRules`. This is an extra rule set that runs after the main integrator returns its result; basically, Calc does an a r IntegAfterRules on the result before showing it to you. (It also does an a s, without `IntegSimpRules`, after that to further simplify the result.) For example, Calc's integrator sometimes produces expressions of the form `ln(1+x) - ln(1-x)'; the default `IntegAfterRules` rewrite this into the more readable form `2 arctanh(x)'. Note that, unlike `IntegRules`, `IntegSimpRules` and `IntegAfterRules` are applied any number of times until no further changes are possible. Rewriting by `IntegAfterRules` occurs only after the main integrator has finished, not at every step as for `IntegRules` and `IntegSimpRules`.

Numerical Integration

If you want a purely numerical answer to an integration problem, you can use the a I (`calc-num-integral`) [`ninteg`] command. This command prompts for an integration variable, a lower limit, and an upper limit. Except for the integration variable, all other variables that appear in the integrand formula must have stored values. (A stored value, if any, for the integration variable itself is ignored.)

Numerical integration works by evaluating your formula at many points in the specified interval. Calc uses an "open Romberg" method; this means that it does not evaluate the formula actually at the endpoints (so that it is safe to integrate `sin(x)/x' from zero, for example). Also, the Romberg method works especially well when the function being integrated is fairly smooth. If the function is not smooth, Calc will have to evaluate it at quite a few points before it can accurately determine the value of the integral.

Integration is much faster when the current precision is small. It is best to set the precision to the smallest acceptable number of digits before you use a I. If Calc appears to be taking too long, press C-g to halt it and try a lower precision. If Calc still appears to need hundreds of evaluations, check to make sure your function is well-behaved in the specified interval.

It is possible for the lower integration limit to be `-inf' (minus infinity). Likewise, the upper limit may be plus infinity. Calc internally transforms the integral into an equivalent one with finite limits. However, integration to or across singularities is not supported: The integral of `1/sqrt(x)' from 0 to 1 exists (it can be found by Calc's symbolic integrator, for example), but a I will fail because the integrand goes to infinity at one of the endpoints.

Taylor Series

The a t (`calc-taylor`) [`taylor`] command computes a power series expansion or Taylor series of a function. You specify the variable and the desired number of terms. You may give an expression of the form `var = a' or `var - a' instead of just a variable to produce a Taylor expansion about the point a. You may specify the number of terms with a numeric prefix argument; otherwise the command will prompt you for the number of terms. Note that many series expansions have coefficients of zero for some terms, so you may appear to get fewer terms than you asked for.

If the a i command is unable to find a symbolic integral for a function, you can get an approximation by integrating the function's Taylor series.

Solving Equations

The a S (`calc-solve-for`) [`solve`] command rearranges an equation to solve for a specific variable. An equation is an expression of the form L = R. For example, the command a S x will rearrange y = 3x + 6 to the form, x = y/3 - 2. If the input is not an equation, it is treated like an equation of the form X = 0.

This command also works for inequalities, as in y < 3x + 6. Some inequalities cannot be solved where the analogous equation could be; for example, solving @c{$a < b \, c$} a < b c for b is impossible without knowing the sign of c. In this case, a S will produce the result @c{$b \mathbin{\hbox{\code{!=}}} a/c$} b != a/c (using the not-equal-to operator) to signify that the direction of the inequality is now unknown. The inequality @c{$a \le b \, c$} a <= b c is not even partially solved. See section Declarations, for a way to tell Calc that the signs of the variables in a formula are in fact known.

Two useful commands for working with the result of a S are a . (see section Logical Operations), which converts x = y/3 - 2 to y/3 - 2, and s l (see section The Let Command) which evaluates another formula with x set equal to y/3 - 2.

Multiple Solutions

Some equations have more than one solution. The Hyperbolic flag (`H a S`) [`fsolve`] tells the solver to report the fully general family of solutions. It will invent variables `n1`, `n2`, ..., which represent independent arbitrary integers, and `s1`, `s2`, ..., which represent independent arbitrary signs (either *+1* or *-1*). If you don't use the Hyperbolic flag, Calc will use zero in place of all arbitrary integers, and plus one in place of all arbitrary signs. Note that variables like `n1` and `s1` are not given any special interpretation in Calc except by the equation solver itself. As usual, you can use the s l (`calc-let`) command to obtain solutions for various actual values of these variables.

For example, ' x^2 = y RET H a S x RET solves to get `x = s1 sqrt(y)', indicating that the two solutions to the equation are `sqrt(y)' and `-sqrt(y)'. Another way to think about it is that the square-root operation is really a two-valued function; since every Calc function must return a single result, `sqrt` chooses to return the positive result. Then H a S doctors this result using `s1` to indicate the full set of possible values of the mathematical square-root.

There is a similar phenomenon going the other direction: Suppose we solve `sqrt(y) = x' for `y`. Calc squares both sides to get `y = x^2'. This is correct, except that it introduces some dubious solutions. Consider

solving `sqrt(y) = -3': Calc will report y = 9 as a valid solution, which is true in the mathematical sense square-root, but false (there is no solution) for the actual Calc positive-valued `sqrt`. This happens for a S and H a S.

If you store a positive integer in the Calc variable `GenCount`, then Calc will generate formulas of the form `as(n)' for arbitrary signs, and `an(n)' for arbitrary integers, where n represents successive values taken by incrementing `GenCount` by one. While the normal arbitrary sign and integer symbols start over at `s1` and `n1` with each new Calc command, the `GenCount` approach will give each arbitrary value a name that is unique throughout the entire Calc session. Also, the arbitrary values are function calls instead of variables, which is advantageous in some cases. For example, you can make a rewrite rule that recognizes all arbitrary signs using a pattern like `as(n)'. The s l command only works on variables, but you can use the a b (`calc-substitute`) command to substitute actual values for function calls like `as(3)'.

The s G (`calc-edit-GenCount`) command is a convenient way to create or edit this variable. Press M-# M-# to finish.

If you have not stored a value in `GenCount`, or if the value in that variable is not a positive integer, the regular `s1`/`n1` notation is used.

With the Inverse flag, I a S [`finv`] treats the expression on top of the stack as a function of the specified variable and solves to find the inverse function, written in terms of the same variable. For example, I a S x inverts 2x + 6 to x/2 - 3. You can use both Inverse and Hyperbolic [`ffinv`] to obtain a fully general inverse, as described above.

Some equations, specifically polynomials, have a known, finite number of solutions. The a P (`calc-poly-roots`) [`roots`] command uses H a S to solve an equation in general form, then, for all arbitrary-sign variables like `s1`, and all arbitrary-integer variables like `n1` for which `n1` only usefully varies over a finite range, it expands these variables out to all their possible values. The results are collected into a vector, which is returned. For example, `roots(x^4 = 1, x)' returns the four solutions `[1, -1, (0, 1), (0, -1)]'. Generally an nth degree polynomial will always have n roots on the complex plane. (If you have given a `real` declaration for the solution variable, then only the real-valued solutions, if any, will be reported; see section Declarations.)

Note that because a P uses H a S, it is able to deliver symbolic solutions if the polynomial has symbolic coefficients. Also note that Calc's solver is not able to get exact symbolic solutions to all polynomials. Polynomials containing powers up to x^4 can always be solved exactly; polynomials of higher degree sometimes can be: x^6 + x^3 + 1 is converted to (x^3)^2 + (x^3) + 1, which can be solved for x^3 using the quadratic equation, and then for x by taking cube roots. But in many cases, like x^6 + x + 1, Calc does not know how to rewrite the polynomial into a form it can solve. The a P command can still deliver a list of numerical roots, however, provided that symbolic mode (m s) is not turned on. (If you work with symbolic mode on, recall that the N (`calc-eval-num`) key is a handy way to reevaluate the formula on the stack with symbolic mode temporarily off.) Naturally, a P can only provide numerical roots if the polynomial coefficents are all numbers (real or complex).

Solving Systems of Equations

You can also use the commands described above to solve systems of simultaneous equations. Just create a vector of equations, then specify a vector of variables for which to solve. (You can omit the surrounding

brackets when entering the vector of variables at the prompt.)

For example, putting `[x + y = a, x - y = b]' on the stack and typing a S x,y RET produces the vector of solutions `[x = a - (a-b)/2, y = (a-b)/2]'. The result vector will have the same length as the variables vector, and the variables will be listed in the same order there. Note that the solutions are not always simplified as far as possible; the solution for x here could be improved by an application of the a n command.

Calc's algorithm works by trying to eliminate one variable at a time by solving one of the equations for that variable and then substituting into the other equations. Calc will try all the possibilities, but you can speed things up by noting that Calc first tries to eliminate the first variable with the first equation, then the second variable with the second equation, and so on. It also helps to put the simpler (e.g., more linear) equations toward the front of the list. Calc's algorithm will solve any system of linear equations, and also many kinds of nonlinear systems.

Normally there will be as many variables as equations. If you give fewer variables than equations (an "over-determined" system of equations), Calc will find a partial solution. For example, typing a S y RET with the above system of equations would produce `[y = a - x]'. There are now several ways to express this solution in terms of the original variables; Calc uses the first one that it finds. You can control the choice by adding variable specifiers of the form `elim(v)' to the variables list. This says that v should be eliminated from the equations; the variable will not appear at all in the solution. For example, typing a S y,elim(x) would yield `[y = a - (b+a)/2]'.

If the variables list contains only `elim` specifiers, Calc simply eliminates those variables from the equations and then returns the resulting set of equations. For example, a S elim(x) produces `[a - 2 y = b]'. Every variable eliminated will reduce the number of equations in the system by one.

Again, a S gives you one solution to the system of equations. If there are several solutions, you can use H a S to get a general family of solutions, or, if there is a finite number of solutions, you can use a P to get a list. (In the latter case, the result will take the form of a matrix where the rows are different solutions and the columns correspond to the variables you requested.)

Another way to deal with certain kinds of overdetermined systems of equations is the a F command, which does least-squares fitting to satisfy the equations. See section Curve Fitting.

Decomposing Polynomials

The `poly` function takes a polynomial and a variable as arguments, and returns a vector of polynomial coefficients (constant coefficient first). For example, `poly(x^3 + 2 x, x)' returns [0, 2, 0, 1]. If the input is not a polynomial in x, the call to `poly` is left in symbolic form. If the input does not involve the variable x, the input is returned in a list of length one, representing a polynomial with only a constant coefficient. The call `poly(x, x)' returns the vector [0, 1]. The last element of the returned vector is guaranteed to be nonzero; note that `poly(0, x)' returns the empty vector []. Note also that x may actually be any formula; for example, `poly(sin(x)^2 - sin(x) + 3, sin(x))' returns [3, -1, 1].

To get the x^k coefficient of polynomial p, use `poly(p, x)_(k+1)'. To get the degree of polynomial p, use `vlen(poly(p, x)) - 1'. For example, `poly((x+1)^4, x)' returns `[1, 4, 6, 4, 1]', so `poly((x+1)^4, x)_(2+1)' gives the x^2 coefficient of this polynomial, 6.

One important feature of the solver is its ability to recognize formulas which are "essentially" polynomials.

This ability is made available to the user through the `gpoly` function, which is used just like `poly`: `gpoly(expr, var)'. If expr is a polynomial in some term which includes var, then this function will return a vector `[x, c, a]' where x is the term that depends on var, c is a vector of polynomial coefficients (like the one returned by `poly`), and a is a multiplier which is usually 1. Basically, `expr = a*(c_1 + c_2 x + c_3 x^2 + ...)'. The last element of c is guaranteed to be non-zero, and c will not equal `[1]' (i.e., the trivial decomposition expr = x is not considered a polynomial). One side effect is that `gpoly(x, x)' and `gpoly(6, x)', both of which might be expected to recognize their arguments as polynomials, will not because the decomposition is considered trivial.

For example, `gpoly((x-2)^2, x)' returns `[x, [4, -4, 1], 1]', since the expanded form of this polynomial is 4 - 4 x + x^2.

The term x may itself be a polynomial in var. This is done to reduce the size of the c vector. For example, `gpoly(x^4 + x^2 - 1, x)' returns `[x^2, [-1, 1, 1], 1]', since a quadratic polynomial in x^2 is easier to solve than a quartic polynomial in x.

A few more examples of the kinds of polynomials `gpoly` can discover:

```
sin(x) - 1                [sin(x), [-1, 1], 1]
x + 1/x - 1               [x, [1, -1, 1], 1/x]
x + 1/x                   [x^2, [1, 1], 1/x]
x^3 + 2 x                 [x^2, [2, 1], x]
x + x^2:3 + sqrt(x)       [x^1:6, [1, 1, 0, 1], x^1:2]
x^(2a) + 2 x^a + 5        [x^a, [5, 2, 1], 1]
(exp(-x) + exp(x)) / 2    [e^(2 x), [0.5, 0.5], e^-x]
```

The `poly` and `gpoly` functions accept a third integer argument which specifies the largest degree of polynomial that is acceptable. If this is n, then only c vectors of length n+1 or less will be returned. Otherwise, the `poly` or `gpoly` call will remain in symbolic form. For example, the equation solver can handle quartics and smaller polynomials, so it calls `gpoly(expr, var, 4)' to discover whether expr can be treated by its linear, quadratic, cubic, or quartic formulas.

The `pdeg` function computes the degree of a polynomial; `pdeg(p,x)' is the highest power of `x` that appears in `p`. This is the same as `vlen(poly(p,x))-1', but is much more efficient. If `p` is constant with respect to `x`, then `pdeg(p,x) = 0'. If `p` is not a polynomial in `x` (e.g., `pdeg(2 cos(x), x)', the function remains unevaluated. It is possible to omit the second argument `x`, in which case `pdeg(p)' returns the highest total degree of any term of the polynomial, counting all variables that appear in `p`. Note that `pdeg(c) = pdeg(c,x) = 0` for any nonzero constant `c`; the degree of the constant zero is considered to be `-inf` (minus infinity).

The `plead` function finds the leading term of a polynomial. Thus `plead(p,x)' is equivalent to `poly(p,x)_vlen(poly(p,x))', though again more efficient. In particular, `plead((2x+1)^10, x)' returns 1024 without expanding out the list of coefficients. The value of `plead(p,x)` will be zero only if p = 0.

The `pcont` function finds the content of a polynomial. This is the greatest common divisor of all the coefficients of the polynomial. With two arguments, `pcont(p,x)` effectively uses `poly(p,x)' to get a list of coefficients, then uses `pgcd` (the polynomial GCD function) to combine these into an answer. For example, `pcont(4 x y^2 + 6 x^2 y, x)' is `2 y'. The content is basically the "biggest" polynomial that can be divided into `p` exactly. The sign of the content is the same as the sign of the leading coefficient.

With only one argument, `pcont(p)' computes the numerical content of the polynomial, i.e., the `gcd` of all numerical coefficients of all the terms in the formula. Note that `gcd` is defined on rational numbers as well as integers; it computes the `gcd` of the numerators and the `lcm` of the denominators. Thus `pcont(4:3 x y^2 + 6 x^2 y)' returns 2:3. Dividing the polynomial by this number will clear all the denominators, as well as dividing by any common content in the numerators. The numerical content of a polynomial is negative only if all the coefficients in the polynomial are negative.

The `pprim` function finds the primitive part of a polynomial, which is simply the polynomial divided (using `pdiv` if necessary) by its content. If the input polynomial has rational coefficients, the result will have integer coefficients in simplest terms.

Numerical Solutions

Not all equations can be solved symbolically. The commands in this section use numerical algorithms that can find a solution to a specific instance of an equation to any desired accuracy. Note that the numerical commands are slower than their algebraic cousins; it is a good idea to try a S before resorting to these commands.

(See section Curve Fitting, for some other, more specialized, operations on numerical data.)

Root Finding

The a R (`calc-find-root`) [`root`] command finds a numerical solution (or root) of an equation. (This command treats inequalities the same as equations. If the input is any other kind of formula, it is interpreted as an equation of the form X = 0.)

The a R command requires an initial guess on the top of the stack, and a formula in the second-to-top position. It prompts for a solution variable, which must appear in the formula. All other variables that appear in the formula must have assigned values, i.e., when a value is assigned to the solution variable and the formula is evaluated with =, it should evaluate to a number. Any assigned value for the solution variable itself is ignored and unaffected by this command.

When the command completes, the initial guess is replaced on the stack by a vector of two numbers: The value of the solution variable that solves the equation, and the difference between the lefthand and righthand sides of the equation at that value. Ordinarily, the second number will be zero or very nearly zero. (Note that Calc uses a slightly higher precision while finding the root, and thus the second number may be slightly different from the value you would compute from the equation yourself.)

The v h (`calc-head`) command is a handy way to extract the first element of the result vector, discarding the error term.

The initial guess can be a real number, in which case Calc searches for a real solution near that number, or a complex number, in which case Calc searches the whole complex plane near that number for a solution, or it can be an interval form which restricts the search to real numbers inside that interval.

Calc tries to use a d to take the derivative of the equation. If this succeeds, it uses Newton's method. If the equation is not differentiable Calc uses a bisection method. (If Newton's method appears to be going astray, Calc switches over to bisection if it can, or otherwise gives up. In this case it may help to try again with a

slightly different initial guess.) If the initial guess is a complex number, the function must be differenti

If the formula (or the difference between the sides of an equation) is negative at one end of the interval you specify and positive at the other end, the root finder is guaranteed to find a root. Otherwise, Calc subdivides the interval into small parts looking for positive and negative values to bracket the root. When your guess is an interval, Calc will not look outside that interval for a root.

The H a R [`wroot`] command is similar to a R, except that if the initial guess is an interval for which the function has the same sign at both ends, then rather than subdividing the interval Calc attempts to widen it to enclose a root. Use this mode if you are not sure if the function has a root in your interval.

If the function is not differentiable, and you give a simple number instead of an interval as your initial guess, Calc uses this widening process even if you did not type the Hyperbolic flag. (If the function *is* differentiable, Calc uses Newton's method which does not require a bounding interval in order to work.)

If Calc leaves the `root` or `wroot` function in symbolic form on the stack, it will normally display an explanation for why no root was found. If you miss this explanation, press w (`calc-why`) to get it back.

Minimization

The a N (`calc-find-minimum`) [`minimize`] command finds a minimum value for a formula. It is very similar in operation to a R (`calc-find-root`): You give the formula and an initial guess on the stack, and are prompted for the name of a variable. The guess may be either a number near the desired minimum, or an interval enclosing the desired minimum. The function returns a vector containing the value of the the variable which minimizes the formula's value, along with the minimum value itself.

Note that this command looks for a *local* minimum. Many functions have more than one minimum; some, like @c{$x \sin x$} x sin(x), have infinitely many. In fact, there is no easy way to define the "global" minimum of @c{$x \sin x$} x sin(x) but Calc can still locate any particular local minimum for you. Calc basically goes downhill from the initial guess until it finds a point at which the function's value is greater both to the left and to the right. Calc does not use derivatives when minimizing a function.

If your initial guess is an interval and it looks like the minimum occurs at one or the other endpoint of the interval, Calc will return that endpoint only if that endpoint is closed; thus, minimizing 17 x over [2..3] will return [2, 38], but minimizing over (2..3] would report no minimum found. In general, you should use closed intervals to find literally the minimum value in that range of x, or open intervals to find the local minimum, if any, that happens to lie in that range.

Most functions are smooth and flat near their minimum values. Because of this flatness, if the current precision is, say, 12 digits, the variable can only be determined meaningfully to about six digits. Thus you should set the precision to twice as many digits as you need in your answer.

The H a N [`wminimize`] command, analogously to H a R, expands the guess interval to enclose a minimum rather than requiring that the minimum lie inside the interval you supply.

The a X (`calc-find-maximum`) [`maximize`] and H a X [`wmaximize`] commands effectively minimize the negative of the formula you supply.

The formula must evaluate to a real number at all points inside the interval (or near the initial guess if the guess is a number). If the initial guess is a complex number the variable will be minimized over the

complex numbers; if it is real or an interval it will be minimized over the reals.

Systems of Equations

The a R command can also solve systems of equations. In this case, the equation should instead be a vector of equations, the guess should instead be a vector of numbers (intervals are not supported), and the variable should be a vector of variables. You can omit the brackets while entering the list of variables. Each equation must be differentiable by each variable for this mode to work. The result will be a vector of two vectors: The variable values that solved the system of equations, and the differences between the sides of the equations with those variable values. There must be the same number of equations as variables. Since only plain numbers are allowed as guesses, the Hyperbolic flag has no effect when solving a system of equations.

It is also possible to minimize over many variables with a N (or maximize with a X). Once again the variable name should be replaced by a vector of variables, and the initial guess should be an equal-sized vector of initial guesses. But, unlike the case of multidimensional a R, the formula being minimized should still be a single formula, *not* a vector. Beware that multidimensional minimization is currently *very* slow.

Curve Fitting

The a F command fits a set of data to a model formula, such as y = m x + b where m and b are parameters to be determined. For a typical set of measured data there will be no single m and b that exactly fit the data; in this case, Calc chooses values of the parameters that provide the closest possible fit.

Linear Fits

The a F (`calc-curve-fit`) [`fit`] command attempts to fit a set of data (x and y vectors of numbers) to a straight line, polynomial, or other function of x. For the moment we will consider only the case of fitting to a line, and we will ignore the issue of whether or not the model was in fact a good fit for the data.

In a standard linear least-squares fit, we have a set of (x,y) data points that we wish to fit to the model y = m x + b by adjusting the parameters m and b to make the y values calculated from the formula be as close as possible to the actual y values in the data set. (In a polynomial fit, the model is instead, say, y = a x^3 + b x^2 + c x + d. In a multilinear fit, we have data points of the form (x_1,x_2,x_3,y) and our model is y = a x_1 + b x_2 + c x_3 + d. These will be discussed later.)

In the model formula, variables like x and x_2 are called the independent variables, and y is the dependent variable. Variables like m, a, and b are called the parameters of the model.

The a F command takes the data set to be fitted from the stack. By default, it expects the data in the form of a matrix. For example, for a linear or polynomial fit, this would be a @c{$2\times N$} 2xN matrix where the first row is a list of x values and the second row has the corresponding y values. For the multilinear fit shown above, the matrix would have four rows (x_1, x_2, x_3, and y, respectively).

If you happen to have an @c{$N\times2$} Nx2 matrix instead of a @c{$2\times N$} 2xN matrix, just press v t first to transpose the matrix.

After you type a F, Calc prompts you to select a model. For a linear fit, press the digit 1.

Calc then prompts for you to name the variables. By default it chooses high letters like x and y for independent variables and low letters like a and b for parameters. (The dependent variable doesn't need a name.) The two kinds of variables are separated by a semicolon. Since you generally care more about the names of the independent variables than of the parameters, Calc also allows you to name only those and let the parameters use default names.

For example, suppose the data matrix

is on the stack and we wish to do a simple linear fit. Type a F, then 1 for the model, then RET to use the default names. The result will be the formula 3 + 2 x on the stack. Calc has created the model expression a + b x, then found the optimal values of a and b to fit the data. (In this case, it was able to find an exact fit.) Calc then substituted those values for a and b in the model formula.

The a F command puts two entries in the trail. One is, as always, a copy of the result that went to the stack; the other is a vector of the actual parameter values, written as equations: [a = 3, b = 2], in case you'd rather read them in a list than pick them out of the formula. (You can type t y to move this vector to the stack; see section Trail Commands.)

Specifying a different independent variable name will affect the resulting formula: a F 1 k RET produces 3 + 2 k. Changing the parameter names (say, a F 1 k;b,m RET) will affect the equations that go into the trail.

To see what happens when the fit is not exact, we could change the number 13 in the data matrix to 14 and try the fit again. The result is:

```
2.6 + 2.2 x
```

Evaluating this formula, say with v x 5 RET TAB V M $ RET, shows a reasonably close match to the y-values in the data.

```
[4.8, 7., 9.2, 11.4, 13.6]
```

Since there is no line which passes through all the *N* data points, Calc has chosen a line that best approximates the data points using the method of least squares. The idea is to define the chi-square error measure

which is clearly zero if a + b x exactly fits all data points, and increases as various a + b x_i values fail to match the corresponding y_i values. There are several reasons why the summand is squared, one of them being to ensure that @c{$\chi^2 \ge 0$} chi^2 >= 0. Least-squares fitting simply chooses the values of a and b for which the error @c{χ^2} chi^2 is as small as possible.

Other kinds of models do the same thing but with a different model formula in place of a + b x_i.

A numeric prefix argument causes the a F command to take the data in some other form than one big matrix. A positive argument *N* will take *N* items from the stack, corresponding to the *N* rows of a data matrix. In the linear case, *N* must be 2 since there is always one independent variable and one dependent variable.

A prefix of zero or plain C-u is a compromise; Calc takes two items from the stack, an *N*-row matrix of x values, and a vector of y values. If there is only one independent variable, the x values can be either a

one-row matrix or a plain vector, in which case the C-u prefix is the same as a C-u 2 prefix.

Polynomial and Multilinear Fits

To fit the data to higher-order polynomials, just type one of the digits 2 through 9 when prompted for a model. For example, we could fit the original data matrix from the previous section (with 13, not 14) to a parabola instead of a line by typing a F 2 RET.

```
2.00000000001 x - 1.5e-12 x^2 + 2.99999999999
```

Note that since the constant and linear terms are enough to fit the data exactly, it's no surprise that Calc chose a tiny contribution for x^2. (The fact that it's not exactly zero is due only to roundoff error. Since our data are exact integers, we could get an exact answer by typing m f first to get fraction mode. Then the x^2 term would vanish altogether. Usually, though, the data being fitted will be approximate floats so fraction mode won't help.)

Doing the a F 2 fit on the data set with 14 instead of 13 gives a much larger x^2 contribution, as Calc bends the line slightly to improve the fit.

```
0.142857142855 x^2 + 1.34285714287 x + 3.59999999998
```

An important result from the theory of polynomial fitting is that it is always possible to fit *N* data points exactly using a polynomial of degree *N-1*, sometimes called an interpolating polynomial. Using the modified (14) data matrix, a model number of 4 gives a polynomial that exactly matches all five data points:

```
0.04167 x^4 - 0.4167 x^3 + 1.458 x^2 - 0.08333 x + 4.
```

The actual coefficients we get with a precision of 12, like 0.0416666663588, clearly suffer from loss of precision. It is a good idea to increase the working precision to several digits beyond what you need when you do a fitting operation. Or, if your data are exact, use fraction mode to get exact results.

You can type i instead of a digit at the model prompt to fit the data exactly to a polynomial. This just counts the number of columns of the data matrix to choose the degree of the polynomial automatically.

Fitting data "exactly" to high-degree polynomials is not always a good idea, though. High-degree polynomials have a tendency to wiggle uncontrollably in between the fitting data points. Also, if the exact-fit polynomial is going to be used to interpolate or extrapolate the data, it is numerically better to use the a p command described below. See section Polynomial Interpolation.

Another generalization of the linear model is to assume the y values are a sum of linear contributions from several x values. This is a multilinear fit, and it is also selected by the 1 digit key. (Calc decides whether the fit is linear or multilinear by counting the rows in the data matrix.)

Given the data matrix,

```
[ [  1,   2,   3,    4,   5  ]
  [  7,   2,   3,    5,   2  ]
```

```
  [ 14.5, 15, 18.5, 22.5, 24 ] ]
```

the command a F 1 RET will call the first row x and the second row y, and will fit the values in the third row to the model a + b x + c y.

```
8. + 3. x + 0.5 y
```

Calc can do multilinear fits with any number of independent variables (i.e., with any number of data rows).

Yet another variation is homogeneous linear models, in which the constant term is known to be zero. In the linear case, this means the model formula is simply a x; in the multilinear case, the model might be a x + b y + c z; and in the polynomial case, the model could be a x + b x^2 + c x^3. You can get a homogeneous linear or multilinear model by pressing the letter h followed by a regular model key, like 1 or 2.

It is certainly possible to have other constrained linear models, like 2.3 + a x or a - 4 x. While there is no single key to select models like these, a later section shows how to enter any desired model by hand. In the first case, for example, you would enter a F ' 2.3 + a x.

Another class of models that will work but must be entered by hand are multinomial fits, e.g., a + b x + c y + d x^2 + e y^2 + f x y.

Error Estimates for Fits

With the Hyperbolic flag, H a F `efit` performs the same fitting operation as a F, but reports the coefficients as error forms instead of plain numbers. Fitting our two data matrices (first with 13, then with 14) to a line with H a F gives the results,

```
3. + 2. x
2.6 +/- 0.382970843103 + 2.2 +/- 0.115470053838 x
```

In the first case the estimated errors are zero because the linear fit is perfect. In the second case, the errors are nonzero but moderately small, because the data are still very close to linear.

It is also possible for the *input* to a fitting operation to contain error forms. The data values must either all include errors or all be plain numbers. Error forms can go anywhere but generally go on the numbers in the last row of the data matrix. If the last row contains error forms `*y_i* +/- @c{σ_i} *sigma_i*', then the @c{χ^2} chi^2 statistic is now,

so that data points with larger error estimates contribute less to the fitting operation.

If there are error forms on other rows of the data matrix, all the errors for a given data point are combined; the square root of the sum of the squares of the errors forms the @c{σ_i} sigma_i used for the data point.

Both a F and H a F can accept error forms in the input matrix, although if you are concerned about error analysis you will probably use H a F so that the output also contains error estimates.

If the input contains error forms but all the @c{σ_i} sigma_i values are the same, it is easy to see that the resulting fitted model will be the same as if the input did not have error forms at all (@c{χ^2} chi^2 is simply scaled uniformly by @c{$1 / \sigma^2$} 1 / sigma^2, which doesn't affect where it has a

minimum). But there *will* be a difference in the estimated errors of the coefficients reported by H a F.

Consult any text on statistical modelling of data for a discussion of where these error estimates come from and how they should be interpreted.

With the Inverse flag, I a F [`xfit`] produces even more information. The result is a vector of six items:

1. The model formula with error forms for its coefficients or parameters. This is the result that H a F would have produced.
2. A vector of "raw" parameter values for the model. These are the polynomial coefficients or other parameters as plain numbers, in the same order as the parameters appeared in the final prompt of the I a F command. For polynomials of degree d, this vector will have length M = d+1 with the constant term first.
3. The covariance matrix C computed from the fit. This is an *M*x*M* symmetric matrix; the diagonal elements C_j_j are the variances @c{σ_j^2} sigma_j^2 of the parameters. The other elements are covariances @c{σ_{ij}^2} sigma_i_j^2 that describe the correlation between pairs of parameters. (A related set of numbers, the linear correlation coefficients @c{r_{ij}} r_i_j, are defined as @c{$\sigma_{ij}^2 / \sigma_i \, \sigma_j$} sigma_i_j^2 / sigma_i sigma_j.)
4. A vector of M "parameter filter" functions whose meanings are described below. If no filters are necessary this will instead be an empty vector; this is always the case for the polynomial and multilinear fits described so far.
5. The value of @c{χ^2} chi^2 for the fit, calculated by the formulas shown above. This gives a measure of the quality of the fit; statisticians consider @c{$\chi^2 \approx N - M$} chi^2 = N - M to indicate a moderately good fit (where again N is the number of data points and M is the number of parameters).
6. A measure of goodness of fit expressed as a probability Q. This is computed from the `utpc` probability distribution function using @c{χ^2} chi^2 with N - M degrees of freedom. A value of 0.5 implies a good fit; some texts recommend that often Q = 0.1 or even 0.001 can signify an acceptable fit. In particular, @c{χ^2} chi^2 statistics assume the errors in your inputs follow a normal (Gaussian) distribution; if they don't, you may have to accept smaller values of Q.

   The Q value is computed only if the input included error estimates. Otherwise, Calc will report the symbol `nan` for Q. The reason is that in this case the @c{χ^2} chi^2 value has effectively been used to estimate the original errors in the input, and thus there is no redundant information left over to use for a confidence test.

Standard Nonlinear Models

The a F command also accepts other kinds of models besides lines and polynomials. Some common models have quick single-key abbreviations; others must be entered by hand as algebraic formulas.

Here is a complete list of the standard models recognized by a F:

1

Linear or multilinear. *a + b x + c y + d z*.

2-9

Polynomials. *a + b x + c x^2 + d x^3*.

e

Exponential. *a* `exp`*(b x)* `exp`*(c y)*.

E

Base-10 exponential. *a* `10^`*(b x)* `10^`*(c y)*.

x

Exponential (alternate notation). `exp`*(a + b x + c y)*.

X

Base-10 exponential (alternate). `10^`*(a + b x + c y)*.

l

Logarithmic. *a + b* `ln`*(x) + c* `ln`*(y)*.

L

Base-10 logarithmic. *a + b* `log10`*(x) + c* `log10`*(y)*.

^

General exponential. *a b^x c^y*.

p

Power law. *a x^b y^c*.

q

Quadratic. *a + b (x-c)^2 + d (x-e)^2*.

g

Gaussian. @c{${a \over b \sqrt{2 \pi}} \exp\left(-{1 \over 2} \left(x - c \over b \right)^2 \right)$} *(a / b sqrt(2 pi)) exp(-0.5*((x-c)/b)^2)*.

All of these models are used in the usual way; just press the appropriate letter at the model prompt, and choose variable names if you wish. The result will be a formula as shown in the above table, with the best-fit values of the parameters substituted. (You may find it easier to read the parameter values from the vector that is placed in the trail.)

All models except Gaussian and polynomials can generalize as shown to any number of independent variables. Also, all the built-in models have an additive or multiplicative parameter shown as a in the above table which can be replaced by zero or one, as appropriate, by typing h before the model key.

Note that many of these models are essentially equivalent, but express the parameters slightly differently. For example, a b^x and the other two exponential models are all algebraic rearrangements of each other. Also, the "quadratic" model is just a degree-2 polynomial with the parameters expressed differently. Use whichever form best matches the problem.

The HP-28/48 calculators support four different models for curve fitting, called `LIN`, `LOG`, `EXP`, and `PWR`. These correspond to Calc models `a + b x', `a + b ln(x)', `a exp(b x)', and `a x^b', respectively. In each case, a is what the HP-48 identifies as the "intercept," and b is what it calls the "slope."

If the model you want doesn't appear on this list, press ' (the apostrophe key) at the model prompt to enter any algebraic formula, such as m x - b, as the model. (Not all models will work, though--see the next section for details.)

The model can also be an equation like y = m x + b. In this case, Calc thinks of all the rows of the data matrix on equal terms; this model effectively has two parameters (m and b) and two independent variables (x and y), with no "dependent" variables. Model equations do not need to take this y = form. For example, the implicit line equation a x + b y = 1 works fine as a model.

When you enter a model, Calc makes an alphabetical list of all the variables that appear in the model. These are used for the default parameters, independent variables, and dependent variable (in that order). If you enter a plain formula (not an equation), Calc assumes the dependent variable does not appear in the formula and thus does not need a name.

For example, if the model formula has the variables a,mu,sigma,t,x, and the data matrix has three rows (meaning two independent variables), Calc will use a,mu,sigma as the default parameters, and the data rows will be named t and x, respectively. If you enter an equation instead of a plain formula, Calc will use a,mu as the parameters, and sigma,t,x as the three independent variables.

You can, of course, override these choices by entering something different at the prompt. If you leave some variables out of the list, those variables must have stored values and those stored values will be used as constants in the model. (Stored values for the parameters and independent variables are ignored by the a F command.) If you list only independent variables, all the remaining variables in the model formula will become parameters.

If there are $ signs in the model you type, they will stand for parameters and all other variables (in alphabetical order) will be independent. Use $ for one parameter, $$ for another, and so on. Thus $ x + $$ is another way to describe a linear model.

If you type a $ instead of ' at the model prompt itself, Calc will take the model formula from the stack. (The data must then appear at the second stack level.) The same conventions are used to choose which variables in the formula are independent by default and which are parameters.

Models taken from the stack can also be expressed as vectors of two or three elements, [model, vars] or [model, vars, params]. Each of vars and params may be either a variable or a vector of variables. (If params is omitted, all variables in model except those listed as vars are parameters.)

When you enter a model manually with ', Calc puts a 3-vector describing the model in the trail so you can get it back if you wish.

Finally, you can store a model in one of the Calc variables `Model1` or `Model2`, then use this model by typing a F u or a F U (respectively). The value stored in the variable can be any of the formats that a F $ would accept for a model on the stack.

Calc uses the principal values of inverse functions like `ln` and `arcsin` when doing fits. For example, when you enter the model `y = sin(a t + b)' Calc actually uses the easier form `arcsin(y) = a t + b'. The `arcsin` function always returns results in the range from -*90* to 90 degrees (or the equivalent range in radians). Suppose you had data that you believed to represent roughly three oscillations of a sine wave, so that the argument of the sine might go from zero to @c{3×360} *3*360* degrees. The above model would appear to be a good way to determine the true frequency and phase of the sine wave, but in practice it would fail utterly. The righthand side of the actual model `arcsin(y) = a t + b' will grow smoothly with t, but the lefthand side will bounce back and forth between -*90* and 90. No values of a and b can make the two sides match, even approximately.

There is no good solution to this problem at present. You could restrict your data to small enough rang that the above problem doesn't occur (i.e., not straddling any peaks in the sine wave). Or, in this case, y could use a totally different method such as Fourier analysis, which is beyond the scope of the a F command. (Unfortunately, Calc does not currently have any facilities for taking Fourier and related transforms.)

Curve Fitting Details

Calc's internal least-squares fitter can only handle multilinear models. More precisely, it can handle any model of the form a f(x,y,z) + b g(x,y,z) + c h(x,y,z), where a,b,c are the parameters and x,y,z are the independent variables (of course there can be any number of each, not just three).

In a simple multilinear or polynomial fit, it is easy to see how to convert the model into this form. For example, if the model is a + b x + c x^2, then f(x) = 1, g(x) = x, and h(x) = x^2 are suitable functions.

For other models, Calc uses a variety of algebraic manipulations to try to put the problem into the form

```
Y(x,y,z) = A(a,b,c) F(x,y,z) + B(a,b,c) G(x,y,z) + C(a,b,c) H(x,y,z)
```

where Y,A,B,C,F,G,H are arbitrary functions. It computes Y, F, G, and H for all the data points, does a standard linear fit to find the values of A, B, and C, then uses the equation solver to solve for a,b,c in terms of A,B,C.

A remarkable number of models can be cast into this general form. We'll look at two examples here to see how it works. The power-law model y = a x^b with two independent variables and two parameters can be rewritten as follows:

```
y = a x^b
y = a exp(b ln(x))
y = exp(ln(a) + b ln(x))
ln(y) = ln(a) + b ln(x)
```

which matches the desired form with @c{$Y = \ln(y)$} Y = ln(y), @c{$A = \ln(a)$} A = ln(a), F = 1, B = b, and @c{$G = \ln(x)$} G = ln(x). Calc thus computes the logarithms of your y and x values, does a linear fit for A and B, then solves to get @c{$a = \exp(A)$} a = exp(A) and b = B.

Another interesting example is the "quadratic" model, which can be handled by expanding according to the distributive law.

```
y = a + b*(x - c)^2
y = a + b c^2 - 2 b c x + b x^2
```

which matches with Y = y, A = a + b c^2, F = 1, B = -2 b c, G = x (the -*2* factor could just as easily have been put into G instead of B), C = b, and H = x^2.

The Gaussian model looks quite complicated, but a closer examination shows that it's actually similar to the quadratic model but with an exponential that can be brought to the top and moved into Y.

An example of a model that cannot be put into general linear form is a Gaussian with a constant

background added on, i.e., d + the regular Gaussian formula. If you have a model like this, your best bet is to replace enough of your parameters with constants to make the model linearizable, then adjust the constants manually by doing a series of fits. You can compare the fits by graphing them, by examining the goodness-of-fit measures returned by I a F, or by some other method suitable to your application. Note that some models can be linearized in several ways. The Gaussian-plus-*d* model can be linearized by setting d (the background) to a constant, or by setting b (the standard deviation) and c (the mean) to constants.

To fit a model with constants substituted for some parameters, just store suitable values in those parameter variables, then omit them from the list of parameters when you answer the variables prompt.

A last desperate step would be to use the general-purpose `minimize` function rather than `fit`. After all, both functions solve the problem of minimizing an expression (the @c{χ^2} chi^2 sum) by adjusting certain parameters in the expression. The a F command is able to use a vastly more efficient algorithm due to its special knowledge about linear chi-square sums, but the a N command can do the same thing by brute force.

A compromise would be to pick out a few parameters without which the fit is linearizable, and use `minimize` on a call to `fit` which efficiently takes care of the rest of the parameters. The thing to be minimized would be the value of @c{χ^2} chi^2 returned as the fifth result of the `xfit` function:

```
minimize(xfit(gaus(a,b,c,d,x), x, [a,b,c], data)_5, d, guess)
```

where `gaus` represents the Gaussian model with background, `data` represents the data matrix, and `guess` represents the initial guess for d that `minimize` requires. This operation will only be, shall we say, extraordinarily slow rather than astronomically slow (as would be the case if `minimize` were used by itself to solve the problem).

The I a F [`xfit`] command is somewhat trickier when nonlinear models are used. The second item in the result is the vector of "raw" parameters A, B, C. The covariance matrix is written in terms of those raw parameters. The fifth item is a vector of filter expressions. This is the empty vector `[]' if the raw parameters were the same as the requested parameters, i.e., if A = a, B = b, and so on (which is always true if the model is already linear in the parameters as written, e.g., for polynomial fits). If the parameters had to be rearranged, the fifth item is instead a vector of one formula per parameter in the original model. The raw parameters are expressed in these "filter" formulas as `fitdummy(1)' for A, `fitdummy(2)' for B, and so on.

When Calc needs to modify the model to return the result, it replaces `fitdummy(1)' in all the filters with the first item in the raw parameters list, and so on for the other raw parameters, then evaluates the resulting filter formulas to get the actual parameter values to be substituted into the original model. In the case of H a F and I a F where the parameters must be error forms, Calc uses the square roots of the diagonal entries of the covariance matrix as error values for the raw parameters, then lets Calc's standard error-form arithmetic take it from there.

If you use I a F with a nonlinear model, be sure to remember that the covariance matrix is in terms of the raw parameters, *not* the actual requested parameters. It's up to you to figure out how to interpret the covariances in the presence of nontrivial filter functions.

Things are also complicated when the input contains error forms. Suppose there are three independent and dependent variables, x, y, and z, one or more of which are error forms in the data. Calc combines all the error values by taking the square root of the sum of the squares of the errors. It then changes x and y to be

plain numbers, and makes z into an error form with this combined error. The Y(x,y,z) part of the linear model is evaluated, and the result should be an error form. The error part of that result is used for @c{σ_i} sigma_i for the data point. If for some reason Y(x,y,z) does not return an error form, the combined error from z is used directly for @c{σ_i} sigma_i. Finally, z is also stripped of its error for use in computing F(x,y,z), G(x,y,z) and so on; the righthand side of the linearized model is computed in regular arithmetic with no error forms.

(While these rules may seem complicated, they are designed to do the most reasonable thing in the typical case that Y(x,y,z) depends only on the dependent variable z, and in fact is often simply equal to z. For common cases like polynomials and multilinear models, the combined error is simply used as the sigma for the data point with no further ado.)

It may be the case that the model you wish to use is linearizable, but Calc's built-in rules are unable to figure it out. Calc uses its algebraic rewrite mechanism to linearize a model. The rewrite rules are kept in the variable `FitRules`. You can edit this variable using the s e FitRules command; in fact, there is a special s F command just for editing `FitRules`. See section Other Operations on Variables.

See section Rewrite Rules, for a discussion of rewrite rules.

Calc uses `FitRules` as follows. First, it converts the model to an equation if necessary and encloses the model equation in a call to the function `fitmodel` (which is not actually a defined function in Calc; it is only used as a placeholder by the rewrite rules). Parameter variables are renamed to function calls `fitparam(1)', `fitparam(2)', and so on, and independent variables are renamed to `fitvar(1)', `fitvar(2)', etc. The dependent variable is the highest-numbered `fitvar`. For example, the power law model a x^b is converted to y = a x^b, then to

```
fitmodel(fitvar(2) = fitparam(1) fitvar(1)^fitparam(2))
```

Calc then applies the rewrites as if by `C-u 0 a r FitRules'. (The zero prefix means that rewriting should continue until no further changes are possible.)

When rewriting is complete, the `fitmodel` call should have been replaced by a `fitsystem` call that looks like this:

```
fitsystem(Y, FGH, abc)
```

where Y is a formula that describes the function Y(x,y,z), FGH is the vector of formulas [F(x,y,z), G(x,y,z), H(x,y,z)], and abc is the vector of parameter filters which refer to the raw parameters as `fitdummy(1)' for A, `fitdummy(2)' for B, etc. While the number of raw parameters (the length of the FGH vector) is usually the same as the number of original parameters (the length of the abc vector), this is not required.

The power law model eventually boils down to

```
fitsystem(ln(fitvar(2)),
          [1, ln(fitvar(1))],
          [exp(fitdummy(1)), fitdummy(2)])
```

The actual implementation of `FitRules` is complicated; it proceeds in four phases. First, common rearrangements are done to try to bring linear terms together and to isolate functions like `exp` and `ln` either

all the way "out" (so that they can be put into Y) or all the way "in" (so that they can be put into abc or FGH). In particular, all non-constant powers are converted to logs-and-exponentials form, and the distributive law is used to expand products of sums. Quotients are rewritten to use the `fitinv' function, where `fitinv(x)' represents 1/x while the `FitRules` are operating. (The use of `fitinv` makes recognition of linear-looking forms easier.) If you modify `FitRules`, you will probably only need to modify the rules for this phase.

Phase two, whose rules can actually also apply during phases one and three, first rewrites `fitmodel` to a two-argument form `fitmodel(Y, model)', where Y is initially zero and model has been changed from a=b to a-b form. It then tries to peel off invertible functions from the outside of model and put them into Y instead, calling the equation solver to invert the functions. Finally, when this is no longer possible, the `fitmodel` is changed to a four-argument `fitsystem`, where the fourth argument is model and the FGH and abc vectors are initially empty. (The last vector is really ABC, corresponding to raw parameters, for now.)

Phase three converts a sum of items in the model to a sum of `fitpart(a, b, c)' terms which represent terms `a*b*c' of the sum, where a is all factors that do not involve any variables, b is all factors that involve only parameters, and c is the factors that involve only independent variables. (If this decomposition is not possible, the rule set will not complete and Calc will complain that the model is too complex.) Then `fitparts` with equal b or c components are merged back together using the distributive law in order to minimize the number of raw parameters needed.

Phase four moves the `fitpart` terms into the FGH and ABC vectors. Also, some of the algebraic expansions that were done in phase 1 are undone now to make the formulas more computationally efficient. Finally, it calls the solver one more time to convert the ABC vector to an abc vector, and removes the fourth model argument (which by now will be zero) to obtain the three-argument `fitsystem` that the linear least-squares solver wants to see.

Two functions which are useful in connection with `FitRules` are `hasfitparams(x)' and `hasfitvars(x)', which check whether x refers to any parameters or independent variables, respectively. Specifically, these functions return "true" if the argument contains any `fitparam` (or `fitvar`) function calls, and "false" otherwise. (Recall that "true" means a nonzero number, and "false" means zero. The actual nonzero number returned is the largest n from all the `fitparam(n)'s or `fitvar(n)'s, respectively, that appear in the formula.)

The `fit` function in algebraic notation normally takes four arguments, `fit(model, vars, params, data)', where model is the model formula as it would be typed after a F ', vars is the independent variable or a vector of independent variables, params likewise gives the parameter(s), and data is the data matrix. Note that the length of vars must be equal to the number of rows in data if model is an equation, or one less than the number of rows if model is a plain formula. (Actually, a name for the dependent variable is allowed but will be ignored in the plain-formula case.)

If params is omitted, the parameters are all variables in model except those that appear in vars. If vars is also omitted, Calc sorts all the variables that appear in model alphabetically and uses the higher ones for vars and the lower ones for params.

Alternatively, `fit(modelvec, data)' is allowed where modelvec is a 2- or 3-vector describing the model and variables, as discussed previously.

If Calc is unable to do the fit, the `fit` function is left in symbolic form, ordinarily with an explanatory

message. The message will be "Model expression is too complex" if the linearizer was unable to put th model into the required form.

The `efit` (corresponding to H a F) and `xfit` (for I a F) functions are completely analogous.

Polynomial Interpolation

The a p (`calc-poly-interp`) [`polint`] command does a polynomial interpolation at a particular x value. It takes two arguments from the stack: A data matrix of the sort used by a F, and a single number which represents the desired x value. Calc effectively does an exact polynomial fit as if by a F i, then substitutes the x value into the result in order to get an approximate y value based on the fit. (Calc does not actually use a F i, however; it uses a direct method which is both more efficient and more numerically stable.)

The result of a p is actually a vector of two values: The y value approximation, and an error measure dy that reflects Calc's estimation of the probable error of the approximation at that value of x. If the input x is equal to any of the x values in the data matrix, the output y will be the corresponding y value from the matrix, and the output dy will be exactly zero.

A prefix argument of 2 causes a p to take separate x- and y-vectors from the stack instead of one data matrix.

If x is a vector of numbers, a p will return a matrix of interpolated results for each of those x values. (The matrix will have two columns, the y values and the dy values.) If x is a formula instead of a number, the `polint` function remains in symbolic form; use the a " command to expand it out to a formula that describes the fit in symbolic terms.

In all cases, the a p command leaves the data vectors or matrix on the stack. Only the x value is replaced by the result.

The H a p [`ratint`] command does a rational function interpolation. It is used exactly like a p, except that it uses as its model the quotient of two polynomials. If there are N data points, the numerator and denominator polynomials will each have degree N/2 (if N is odd, the denominator will have degree one higher than the numerator).

Rational approximations have the advantage that they can accurately describe functions that have poles (points at which the function's value goes to infinity, so that the denominator polynomial of the approximation goes to zero). If x corresponds to a pole of the fitted rational function, then the result will be a division by zero. If Infinite mode is enabled, the result will be `[uinf, uinf]'.

There is no way to get the actual coefficients of the rational function used by H a p. (The algorithm never generates these coefficients explicitly, and quotients of polynomials are beyond a F's capabilities to fit.)

Summations

The a + (`calc-summation`) [`sum`] command computes the sum of a formula over a certain range of index values. The formula is taken from the top of the stack; the command prompts for the name of the summation index variable, the lower limit of the sum (any formula), and the upper limit of the sum. If you enter a blank line at any of these prompts, that prompt and any later ones are answered by reading

additional elements from the stack. Thus, ' k^2 RET ' k RET 1 RET 5 RET a + RET produces the resul

The choice of index variable is arbitrary, but it's best not to use a variable with a stored value. In particular, while `i` is often a favorite index variable, it should be avoided in Calc because `i` has the imaginary constant (0, 1) as a value. If you pressed = on a sum over `i`, it would be changed to a nonsensical sum over the "variable" (0, 1)! If you really want to use `i` as an index variable, use s u i RET first to "unstore" this variable. (See section Storing Variables.)

A numeric prefix argument steps the index by that amount rather than by one. Thus ' a_k RET C-u -2 a + k RET 10 RET 0 RET yields `a_10 + a_8 + a_6 + a_4 + a_2 + a_0'. A prefix argument of plain C-u causes a + to prompt for the step value, in which case you can enter any formula or enter a blank line to take the step value from the stack. With the C-u prefix, a + can take up to five arguments from the stack: The formula, the variable, the lower limit, the upper limit, and (at the top of the stack), the step value.

Calc knows how to do certain sums in closed form. For example, `sum(6 k^2, k, 1, n) = 2 n^3 + 3 n^2 + n'. In particular, this is possible if the formula being summed is polynomial or exponential in the index variable. Sums of logarithms are transformed into logarithms of products. Sums of trigonometric and hyperbolic functions are transformed to sums of exponentials and then done in closed form. Also, of course, sums in which the lower and upper limits are both numbers can always be evaluated just by grinding them out, although Calc will use closed forms whenever it can for the sake of efficiency.

The notation for sums in algebraic formulas is `sum(expr, var, low, high, step)'. If step is omitted, it defaults to one. If high is omitted, low is actually the upper limit and the lower limit is one. If low is also omitted, the limits are `-inf' and `inf', respectively.

Infinite sums can sometimes be evaluated: `sum(.5^k, k, 1, inf)' returns 1. This is done by evaluating the sum in closed form (to `1. - 0.5^n' in this case), then evaluating this formula with `n` set to `inf`. Calc's usual rules for "infinite" arithmetic can find the answer from there. If infinite arithmetic yields a `nan', or if the sum cannot be solved in closed form, Calc leaves the `sum` function in symbolic form. See section Infinities.

As a special feature, if the limits are infinite (or omitted, as described above) but the formula includes vectors subscripted by expressions that involve the iteration variable, Calc narrows the limits to include only the range of integers which result in legal subscripts for the vector. For example, the sum `sum(k [a,b,c,d,e,f,g]_(2k),k)' evaluates to `b + 2 d + 3 f'.

The limits of a sum do not need to be integers. For example, `sum(a_k, k, 0, 2 n, n)' produces `a_0 + a_n + a_(2 n)'. Calc computes the number of iterations using the formula `1 + (high - low) / step', which must, after simplification as if by a s, evaluate to an integer.

If the number of iterations according to the above formula does not come out to an integer, the sum is illegal and will be left in symbolic form. However, closed forms are still supplied, and you are on your honor not to misuse the resulting formulas by substituting mismatched bounds into them. For example, `sum(k, k, 1, 10, 2)' is invalid, but Calc will go ahead and evaluate the closed form solution for the limits 1 and 10 to get the rather dubious answer, 29.25.

If the lower limit is greater than the upper limit (assuming a positive step size), the result is generally zero. However, Calc only guarantees a zero result when the upper limit is exactly one step less than the lower limit, i.e., if the number of iterations is *-1*. Thus `sum(f(k), k, n, n-1)' is zero but the sum from `n' to `n-2' may report a nonzero value if Calc used a closed form solution.

Calc's logical predicates like a < b return 1 for "true" and 0 for "false." See section Logical Operations. can be used to advantage for building conditional sums. For example, `sum(prime(k)*k^2, k, 1, 20)' is the sum of the squares of all prime numbers from 1 to 20; the `prime` predicate returns 1 if its argument is prime and 0 otherwise. You can read this expression as "the sum of k^2, where k is prime." Indeed, `sum(prime(k)*k^2, k)' would represent the sum of *all* primes squared, since the limits default to plus and minus infinity, but there are no such sums that Calc's built-in rules can do in closed form.

As another example, `sum((k != k_0) * f(k), k, 1, n)' is the sum of f(k) for all k from 1 to n, excluding one value k_0. Slightly more tricky is the summand `(k != k_0) / (k - k_0)', which is an attempt to describe the sum of all 1/(k-k_0) except at k = k_0, where this would be a division by zero. But at k = k_0, this formula works out to the indeterminate form 0 / 0, which Calc will not assume is zero. Better would be to use `(k != k_0) ? 1/(k-k_0) : 0'; the `? :' operator does an "if-then-else" test: This expression says, "if @c{$k \ne k_0$} k != k_0, then 1/(k-k_0), else zero." Now the formula 1/(k-k_0) will not even be evaluated by Calc when k = k_0.

The a - (`calc-alt-summation`) [`asum`] command computes an alternating sum. Successive terms of the sequence are given alternating signs, with the first term (corresponding to the lower index value) being positive. Alternating sums are converted to normal sums with an extra term of the form `(-1)^(k-low)'. This formula is adjusted appropriately if the step value is other than one. For example, the Taylor series for the sine function is `asum(x^k / k!, k, 1, inf, 2)'. (Calc cannot evaluate this infinite series, but it can approximate it if you replace `inf` with any particular odd number.) Calc converts this series to a regular sum with a step of one, namely `sum((-1)^k x^(2k+1) / (2k+1)!, k, 0, inf)'.

The a * (`calc-product`) [`prod`] command is the analogous way to take a product of many terms. Calc also knows some closed forms for products, such as `prod(k, k, 1, n) = n!'. Conditional products can be written `prod(k^prime(k), k, 1, n)' or `prod(prime(k) ? k : 1, k, 1, n)'.

The a T (`calc-tabulate`) [`table`] command evaluates a formula at a series of iterated index values, just like `sum` and `prod`, but its result is simply a vector of the results. For example, `table(a_i, i, 1, 7, 2)' produces `[a_1, a_3, a_5, a_7]'.

Logical Operations

The following commands and algebraic functions return true/false values, where 1 represents "true" and 0 represents "false." In cases where a truth value is required (such as for the condition part of a rewrite rule, or as the condition for a Z [Z] control structure), any nonzero value is accepted to mean "true." (Specifically, anything for which `dnonzero` returns 1 is "true," and anything for which `dnonzero` returns 0 or cannot decide is assumed "false." Note that this means that Z [Z] will execute the "then" portion if its condition is provably true, but it will execute the "else" portion for any condition like a = b that is not provably true, even if it might be true. Algebraic functions that have conditions as arguments, like `? :` and &&, remain unevaluated if the condition is neither provably true nor provably false. See section Declarations.)

The a = (`calc-equal-to`) command, or `eq(a,b)' function (which can also be written `a = b' or `a == b' in an algebraic formula) is true if a and b are equal, either because they are identical expressions, or because they are numbers which are numerically equal. (Thus the integer 1 is considered equal to the float 1.0.) If the equality of a and b cannot be determined, the comparison is left in symbolic form. Note that as a

command, this operation pops two values from the stack and pushes back either a 1 or a 0, or a formula b' if the values' equality cannot be determined.

Many Calc commands use `=' formulas to represent equations. For example, the a S (`calc-solve-for`) command rearranges an equation to solve for a given variable. The a M (`calc-map-equation`) command can be used to apply any function to both sides of an equation; for example, 2 a M * multiplies both sides of the equation by two. Note that just 2 * would not do the same thing; it would produce the formula `2 (a = b)' which represents 2 if the equality is true or zero if not.

The `eq` function with more than two arguments (e.g., C-u 3 a = or `a = b = c') tests if all of its arguments are equal. In algebraic notation, the `=' operator is unusual in that it is neither left- nor right-associative: `a = b = c' is not the same as `(a = b) = c' or `a = (b = c)' (which each compare one variable with the 1 or 0 that results from comparing two other variables).

The a # (`calc-not-equal-to`) command, or `neq(a,b)' or `a != b' function, is true if a and b are not equal. This also works with more than two arguments; `a != b != c != d' tests that all four of a, b, c, and d are distinct numbers.

The a < (`calc-less-than`) [`lt(a,b)' or `a < b'] operation is true if a is less than b. Similar functions are a > (`calc-greater-than`) [`gt(a,b)' or `a > b'], a [(`calc-less-equal`) [`leq(a,b)' or `a <= b'], and a] (`calc-greater-equal`) [`geq(a,b)' or `a >= b'].

While the inequality functions like `lt` do not accept more than two arguments, the syntax `a <= b < c' is translated to an equivalent expression involving intervals: `b in [a .. c)'. (See the description of `in` below.) All four combinations of `<' and `<=' are allowed, or any of the four combinations of `>' and `>='. Four-argument constructions like `a < b < c < d', and mixtures like `a < b = c' that involve both equalities and inequalities, are not allowed.

The a . (`calc-remove-equal`) [`rmeq`] command extracts the righthand side of the equation or inequality on the top of the stack. It also works elementwise on vectors. For example, if `[x = 2.34, y = z / 2]' is on the stack, then a . produces `[2.34, z / 2]'. As a special case, if the righthand side is a variable and the lefthand side is a number (as in `2.34 = x'), then Calc keeps the lefthand side instead. Finally, this command works with assignments `x := 2.34' as well as equations, always taking the the righthand side, and for `=>' (evaluates-to) operators, always taking the lefthand side.

The a & (`calc-logical-and`) [`land(a,b)' or `a && b'] function is true if both of its arguments are true, i.e., are non-zero numbers. In this case, the result will be either a or b, chosen arbitrarily. If either argument is zero, the result is zero. Otherwise, the formula is left in symbolic form.

The a | (`calc-logical-or`) [`lor(a,b)' or `a || b'] function is true if either or both of its arguments are true (nonzero). The result is whichever argument was nonzero, choosing arbitrarily if both are nonzero. If both a and b are zero, the result is zero.

The a ! (`calc-logical-not`) [`lnot(a)' or `! a'] function is true if a is false (zero), or false if a is true (nonzero). It is left in symbolic form if a is not a number.

The a : (`calc-logical-if`) [`if(a,b,c)' or `a ? b : c'] function is equal to either b or c if a is a nonzero number or zero, respectively. If a is not a number, the test is left in symbolic form and neither b nor c is evaluated in any way. In algebraic formulas, this is one of the few Calc functions whose arguments are not automatically evaluated when the function itself is evaluated. The others are `lambda`, `quote`, and

`condition`.

One minor surprise to watch out for is that the formula `a?3:4' will not work because the `3:4' is parsed as a fraction instead of as three separate symbols. Type something like `a ? 3 : 4' or `a?(3):4' instead.

As a special case, if a evaluates to a vector, then both b and c are evaluated; the result is a vector of the same length as a whose elements are chosen from corresponding elements of b and c according to whether each element of a is zero or nonzero. Each of b and c must be either a vector of the same length as a, or a non-vector which is matched with all elements of a.

The a { (`calc-in-set`) [`in(a,b)'] function is true if the number a is in the set of numbers represented by b. If b is an interval form, a must be one of the values encompassed by the interval. If b is a vector, a must be equal to one of the elements of the vector. (If any vector elements are intervals, a must be in any of the intervals.) If b is a plain number, a must be numerically equal to b. See section Set Operations using Vectors, for a group of commands that manipulate sets of this sort.

The `typeof(a)' function produces an integer or variable which characterizes a. If a is a number, vector, or variable, the result will be one of the following numbers:

```
 1   Integer
 2   Fraction
 3   Floating-point number
 4   HMS form
 5   Rectangular complex number
 6   Polar complex number
 7   Error form
 8   Interval form
 9   Modulo form
10   Date-only form
11   Date/time form
12   Infinity (inf, uinf, or nan)
100  Variable
101  Vector (but not a matrix)
102  Matrix
```

Otherwise, a is a formula, and the result is a variable which represents the name of the top-level function call.

The `integer(a)' function returns true if a is an integer. The `real(a)' function is true if a is a real number, either integer, fraction, or float. The `constant(a)' function returns true if a is any of the objects for which `typeof` would produce an integer code result except for variables, and provided that the components of an object like a vector or error form are themselves constant. Note that infinities do not satisfy any of these tests, nor do special constants like `pi` and `e`.

See section Declarations, for a set of similar functions that recognize formulas as well as actual numbers. For example, `dint(floor(x))' is true because `floor(x)' is provably integer-valued, but `integer(floor(x))' does not because `floor(x)' is not literally an integer constant.

The `refers(a,b)' function is true if the variable (or sub-expression) b appears in a, or false otherwise. Unlike

the other tests described here, this function returns a definite "no" answer even if its arguments are still in symbolic form. The only case where `refers` will be left unevaluated is if a is a plain variable (different from b).

The `negative(a)' function returns true if a "looks" negative, because it is a negative number, because it is of the form -x, or because it is a product or quotient with a term that looks negative. This is most useful in rewrite rules. Beware that `negative(a)' evaluates to 1 or 0 for *any* argument a, so it can only be stored in a formula if the default simplifications are turned off first with m O (or if it appears in an unevaluated context such as a rewrite rule condition).

The `variable(a)' function is true if a is a variable, or false if not. If a is a function call, this test is left in symbolic form. Built-in variables like `pi` and `inf` are considered variables like any others by this test.

The `nonvar(a)' function is true if a is a non-variable. If its argument is a variable it is left unsimplified; it never actually returns zero. However, since Calc's condition-testing commands consider "false" anything not provably true, this is often good enough.

The functions `lin`, `linnt`, `islin`, and `islinnt` check if an expression is "linear," i.e., can be written in the form a + b x for some constants a and b, and some variable or subformula x. The function `islin(f,x)' checks if formula f is linear in x, returning 1 if so. For example, `islin(x,x)', `islin(-x,x)', `islin(3,x)', and `islin(x y / 3 - 2, x)' all return 1. The `lin(f,x)' function is similar, except that instead of returning 1 it returns the vector [a, b, x]. For the above examples, this vector would be [0, 1, x], [0, -1, x], [3, 0, x], and [-2, y/3, x], respectively. Both `lin` and `islin` generally remain unevaluated for expressions which are not linear, e.g., `lin(2 x^2, x)' and `lin(sin(x), x)'. The second argument can also be a formula; `islin(2 + 3 sin(x), sin(x))' returns true.

The `linnt` and `islinnt` functions perform a similar check, but require a "non-trivial" linear form, which means that the b coefficient must be non-zero. For example, `lin(2,x)' returns [2, 0, x] and `lin(y,x)' returns [y, 0, x], but `linnt(2,x)' and `linnt(y,x)' are left unevaluated (in other words, these formulas are considered to be only "trivially" linear in x).

All four linearity-testing functions allow you to omit the second argument, in which case the input may be linear in any non-constant formula. Here, the a=0, b=1 case is also considered trivial, and only constant values for a and b are recognized. Thus, `lin(2 x y)' returns [0, 2, x y], `lin(2 - x y)' returns [2, -1, x y], and `lin(x y)' returns [0, 1, x y]. The `linnt` function would allow the first two cases but not the third. Also, neither `lin` nor `linnt` accept plain constants as linear in the one-argument case: `islin(2,x)' is true, but `islin(2)' is false.

The `istrue(a)' function returns 1 if a is a nonzero number or provably nonzero formula, or 0 if a is anything else. Calls to `istrue` can only be manipulated if m O mode is used to make sure they are not evaluated prematurely. (Note that declarations are used when deciding whether a formula is true; `istrue` returns 1 when `dnonzero` would return 1, and it returns 0 when `dnonzero` would return 0 or leave itself in symbolic form.)

Rewrite Rules

The a r (`calc-rewrite`) [`rewrite`] command makes substitutions in a formula according to a specified pattern or patterns known as rewrite rules. Whereas a b (`calc-substitute`) matches literally,

so that substituting `sin(x)' with `cos(x)' matches only the `sin` function applied to the variable `x`, rewri rules match general kinds of formulas; rewriting using the rule `sin(x) := cos(x)' matches `sin` of any argument and replaces it with `cos` of that same argument. The only significance of the name `x` is that the same name is used on both sides of the rule.

Rewrite rules rearrange formulas already in Calc's memory. See section Syntax Tables, to read about syntax rules, which are similar to algebraic rewrite rules but operate when new algebraic entries are being parsed, converting strings of characters into Calc formulas.

Entering Rewrite Rules

Rewrite rules normally use the "assignment" operator `old := new'. This operator is equivalent to the function call `assign(old, new)'. The `assign` function is undefined by itself in Calc, so an assignment formula such as a rewrite rule will be left alone by ordinary Calc commands. But certain commands, like the rewrite system, interpret assignments in special ways.

For example, the rule `sin(x)^2 := 1-cos(x)^2' says to replace every occurrence of the sine of something, squared, with one minus the square of the cosine of that same thing. All by itself as a formula on the stack it does nothing, but when given to the a r command it turns that command into a sine-squared-to-cosine-squared converter.

To specify a set of rules to be applied all at once, make a vector of rules.

When a r prompts you to enter the rewrite rules, you can answer in several ways:

1. With a rule: f(x) := g(x) RET.
2. With a vector of rules: [f1(x) := g1(x), f2(x) := g2(x)] RET. (You can omit the enclosing square brackets if you wish.)
3. With the name of a variable that contains the rule or rules vector: myrules RET.
4. With any formula except a rule, a vector, or a variable name; this will be interpreted as the old half of a rewrite rule, and you will be prompted a second time for the new half: f(x) RET g(x) RET.
5. With a blank line, in which case the rule, rules vector, or variable will be taken from the top of the stack (and the formula to be rewritten will come from the second-to-top position).

If you enter the rules directly (as opposed to using rules stored in a variable), those rules will be put into the Trail so that you can retrieve them later. See section Trail Commands.

It is most convenient to store rules you use often in a variable and invoke them by giving the variable name. The s e (`calc-edit-variable`) command is an easy way to create or edit a rule set stored in a variable. You may also wish to use s p (`calc-permanent-variable`) to save your rules permanently; see section Other Operations on Variables.

Rewrite rules are compiled into a special internal form for faster matching. If you enter a rule set directly it must be recompiled every time. If you store the rules in a variable and refer to them through that variable, they will be compiled once and saved away along with the variable for later reference. This is another good reason to store your rules in a variable.

Calc also accepts an obsolete notation for rules, as vectors `[old, new]'. But because it is easily confused with a vector of two rules, the use of this notation is no longer recommended.

Basic Rewrite Rules

To match a particular formula x with a particular rewrite rule `old := new', Calc compares the structure of x with the structure of old. Variables that appear in old are treated as meta-variables; the corresponding positions in x may contain any sub-formulas. For example, the pattern `f(x,y)' would match the expression `f(12, a+1)' with the meta-variable `x' corresponding to 12 and with `y' corresponding to `a+1'. However, this pattern would not match `f(12)' or `g(12, a+1)', since there is no assignment of the meta-variables that will make the pattern match these expressions. Notice that if the pattern is a single meta-variable, it will match any expression.

If a given meta-variable appears more than once in old, the corresponding sub-formulas of x must be identical. Thus the pattern `f(x,x)' would match `f(12, 12)' and `f(a+1, a+1)' but not `f(12, a+1)' or `f(a+b, b+a)'. (See section Conditional Rewrite Rules, for a way to match the latter.)

Things other than variables must match exactly between the pattern and the target formula. To match a particular variable exactly, use the pseudo-function `quote(v)' in the pattern. For example, the pattern `x+quote(y)' matches `x+y', `2+y', or `sin(a)+y'.

The special variable names `e', `pi', `i', `phi', `gamma', `inf', `uinf', and `nan' always match literally. Thus the pattern `sin(d + e + f)' acts exactly like `sin(d + quote(e) + f)'.

If the old pattern is found to match a given formula, that formula is replaced by new, where any occurrences in new of meta-variables from the pattern are replaced with the sub-formulas that they matched. Thus, applying the rule `f(x,y) := g(y+x,x)' to `f(12, a+1)' would produce `g(a+13, 12)'.

The normal a r command applies rewrite rules over and over throughout the target formula until no further changes are possible (up to a limit of 100 times). Use C-u 1 a r to make only one change at a time.

Conditional Rewrite Rules

A rewrite rule can also be conditional, written in the form `old := new :: cond'. (There is also the obsolete form `[old, new, cond]'.) If a cond part is present in the rule, this is an additional condition that must be satisfied before the rule is accepted. Once old has been successfully matched to the target expression, cond is evaluated (with all the meta-variables substituted for the values they matched) and simplified with a s (`calc-simplify`). If the result is a nonzero number or any other object known to be nonzero (see section Declarations), the rule is accepted. If the result is zero or if it is a symbolic formula that is not known to be nonzero, the rule is rejected. See section Logical Operations, for a number of functions that return 1 or 0 according to the results of various tests.

For example, the formula `n > 0' simplifies to 1 or 0 if n is replaced by a positive or nonpositive number, respectively (or if n has been declared to be positive or nonpositive). Thus, the rule `f(x,y) := g(y+x,x) :: x+y > 0' would apply to `f(0, 4)' but not to `f(-3, 2)' or `f(12, a+1)' (assuming no outstanding declarations for a). In the case of `f(-3, 2)', the condition can be shown not to be satisfied; in the case of `f(12, a+1)', the condition merely cannot be shown to be satisfied, but that is enough to reject the rule.

While Calc will use declarations to reason about variables in the formula being rewritten, declarations do not apply to meta-variables. For example, the rule `f(a) := g(a+1)' will match for any values of `a', such as complex numbers, vectors, or formulas, even if `a' has been declared to be real or scalar. If you want the

meta-variable `a' to match only literal real numbers, use `f(a) := g(a+1) :: real(a)'. If you want `a' to match only reals and formulas which are provably real, use `dreal(a)' as the condition.

The `::' operator is a shorthand for the `condition` function; `old := new :: cond' is equivalent to the formula `condition(assign(old, new), cond)'.

If you have several conditions, you can use `... :: c1 :: c2 :: c3' or `... :: c1 && c2 && c3'. The two are entirely equivalent.

It is also possible to embed conditions inside the pattern: `f(x :: x>0, y) := g(y+x, x)'. This is purely a notational convenience, though; where a condition appears in a rule has no effect on when it is tested. The rewrite-rule compiler automatically decides when it is best to test each condition while a rule is being matched.

Certain conditions are handled as special cases by the rewrite rule system and are tested very efficiently: Where x is any meta-variable, these conditions are `integer(x)', `real(x)', `constant(x)', `negative(x)', `x >= y' where y is either a constant or another meta-variable and `>=' may be replaced by any of the six relational operators, and `x % a = b' where a and b are constants. Other conditions, like `x >= y+1' or `dreal(x)', will be less efficient to check since Calc must bring the whole evaluator and simplifier into play.

An interesting property of `::' is that neither of its arguments will be touched by Calc's default simplifications. This is important because conditions often are expressions that cannot safely be evaluated early. For example, the `typeof` function never remains in symbolic form; entering `typeof(a)' will put the number 100 (the type code for variables like `a') on the stack. But putting the condition `... :: typeof(a) = 6' on the stack is safe since `::' prevents the `typeof` from being evaluated until the condition is actually used by the rewrite system.

Since `::' protects its lefthand side, too, you can use a dummy condition to protect a rule that must itself not evaluate early. For example, it's not safe to put `a(f,x) := apply(f, [x])' on the stack because it will immediately evaluate to `a(f,x) := f(x)', where the meta-variable-ness of `f` on the righthand side has been lost. But `a(f,x) := apply(f, [x]) :: 1' is safe, and of course the condition `1' is always true (nonzero) so it has no effect on the functioning of the rule. (The rewrite compiler will ensure that it doesn't even impact the speed of matching the rule.)

Algebraic Properties of Rewrite Rules

The rewrite mechanism understands the algebraic properties of functions like `+' and `*'. In particular, pattern matching takes the associativity and commutativity of the following functions into account:

```
+ - *  = != && ||  and or xor  vint vunion vxor  gcd lcm  max min  beta
```

For example, the rewrite rule:

```
a x + b x  :=  (a + b) x
```

will match formulas of the form,

```
a x + b x,  x a + x b,  a x + x b,  x a + b x
```

Rewrites also understand the relationship between the `+' and `-' operators. The above rewrite rule will match the formulas,

```
a x - b x,  x a - x b,  a x - x b,  x a - b x
```

by matching `b' in the pattern to `-b' from the formula.

Applied to a sum of many terms like `r + a x + s + b x + t', this pattern will check all pairs of terms for possible matches. The rewrite will take whichever suitable pair it discovers first.

In general, a pattern using an associative operator like `a + b' will try *2 n* different ways to match a sum of *n* terms like `x + y + z - w'. First, `a' is matched against each of `x', `y', `z', and `-w' in turn, with `b' being matched to the remainders `y + z - w', `x + z - w', etc. If none of these succeed, then `b' is matched against each of the four terms with `a' matching the remainder. Half-and-half matches, like `(x + y) + (z - w)', are not tried.

Note that `*' is not commutative when applied to matrices, but rewrite rules pretend that it is. If you type m v to enable matrix mode (see section Matrix and Scalar Modes), rewrite rules will match `*' literally, ignoring its usual commutativity property. (In the current implementation, the associativity also vanishes--it is as if the pattern had been enclosed in a `plain` marker; see below.) If you are applying rewrites to formulas with matrices, it's best to enable matrix mode first to prevent algebraically incorrect rewrites from occurring.

The pattern `-x' will actually match any expression. For example, the rule

```
f(-x)  :=  -f(x)
```

will rewrite `f(a)' to `-f(-a)'. To avoid this, either use a `plain` marker as described below, or add a `negative(x)' condition. The `negative` function is true if its argument "looks" negative, for example, because it is a negative number or because it is a formula like `-x'. The new rule using this condition is:

```
f(x)  :=  -f(-x)  :: negative(x)    or, equivalently,
f(-x)  :=  -f(x)  :: negative(-x)
```

In the same way, the pattern `x - y' will match the sum `a + b' by matching `y' to `-b'.

The pattern `a b' will also match the formula `x/y' if `y' is a number. Thus the rule `a x + b x := (a+b) x' will also convert `a x + x / 2' to `(a + 0.5) x' (or `(a + 1:2) x', depending on the current fraction mode).

Calc will *not* take other liberties with `*', `/', and `^'. For example, the pattern `f(a b)' will not match `f(x^2)', and `f(a + b)' will not match `f(2 x)', even though conceivably these patterns could match with `a = b = x'. Nor will `f(a b)' match `f(x / y)' if `y' is not a constant, even though it could be considered to match with `a = x' and `b = 1/y'. The reasons are partly for efficiency, and partly because while few mathematical operations are substantively different for addition and subtraction, often it is preferable to treat the cases of multiplication, division, and integer powers separately.

Even more subtle is the rule set

```
[ f(a) + f(b) := f(a + b),  -f(a) := f(-a) ]
```

attempting to match `f(x) - f(y)'. You might think that Calc will view this subtraction as `f(x) + (-f(y))' and then apply the above two rules in turn, but actually this will not work because Calc only does this when considering rules for `+' (like the first rule in this set). So it will see first that `f(x) + (-f(y))' does not match `f(a) + f(b)' for any assignments of the meta-variables, and then it will see that `f(x) - f(y)' does not match `-f(a)' for any assignment of `a'. Because Calc tries only one rule at a time, it will not be able to rewrite `f(x) - f(y)' with this rule set. An explicit `f(a) - f(b)' rule will have to be added.

Another thing patterns will *not* do is break up complex numbers. The pattern `myconj(a + b i) := a - b i' will work for formulas involving the special constant `i' (such as `3 - 4 i'), but it will not match actual complex numbers like `(3, -4)'. A version of the above rule for complex numbers would be

```
myconj(a)  :=  re(a) - im(a) (0,1)  :: im(a) != 0
```

(Because the `re` and `im` functions understand the properties of the special constant `i', this rule will also work for `3 - 4 i'. In fact, this particular rule would probably be better without the `im(a) != 0' condition, since if `im(a) = 0' the righthand side of the rule will still give the correct answer for the conjugate of a real number.)

It is also possible to specify optional arguments in patterns. The rule

```
opt(a) x + opt(b) (x^opt(c) + opt(d))  :=  f(a, b, c, d)
```

will match the formula

```
5 (x^2 - 4) + 3 x
```

in a fairly straightforward manner, but it will also match reduced formulas like

```
x + x^2,    2(x + 1) - x,    x + x
```

producing, respectively,

```
f(1, 1, 2, 0),   f(-1, 2, 1, 1),   f(1, 1, 1, 0)
```

(The latter two formulas can be entered only if default simplifications have been turned off with m O.)

The default value for a term of a sum is zero. The default value for a part of a product, for a power, or for the denominator of a quotient, is one. Also, `-x' matches the pattern `opt(a) b' with `a = -1'.

In particular, the distributive-law rule can be refined to

```
opt(a) x + opt(b) x  :=  (a + b) x
```

so that it will convert, e.g., `a x - x', to `(a - 1) x'.

The pattern `opt(a) + opt(b) x' matches almost any formulas which are linear in `x'. You can also use the `lin` and `islin` functions with rewrite conditions to test for this; see section Logical Operations. These functions are not as convenient to use in rewrite rules, but they recognize more kinds of formulas as linear: `x/z' is considered linear with b = 1/z by `lin`, but it will not match the above pattern because that pattern

calls for a multiplication, not a division.

As another example, the obvious rule to replace `sin(x)^2 + cos(x)^2' by 1,

```
sin(x)^2 + cos(x)^2  :=  1
```

misses many cases because the sine and cosine may both be multiplied by an equal factor. Here's a more successful rule:

```
opt(a) sin(x)^2 + opt(a) cos(x)^2  :=  a
```

Note that this rule will *not* match `sin(x)^2 + 6 cos(x)^2' because one a would have "matched" 1 while the other matched 6.

Calc automatically converts a rule like

```
f(x-1, x)  :=  g(x)
```

into the form

```
f(temp, x)  :=  g(x)  :: temp = x-1
```

(where `temp` stands for a new, invented meta-variable that doesn't actually have a name). This modified rule will successfully match `f(6, 7)', binding `temp' and `x' to 6 and 7, respectively, then verifying that they differ by one even though `6' does not superficially look like `x-1'.

However, Calc does not solve equations to interpret a rule. The following rule,

```
f(x-1, x+1)  :=  g(x)
```

will not work. That is, it will match `f(a - 1 + b, a + 1 + b)' but not `f(6, 8)'. Calc always interprets at least one occurrence of a variable by literal matching. If the variable appears "isolated" then Calc is smart enough to use it for literal matching. But in this last example, Calc is forced to rewrite the rule to `f(x-1, temp) := g(x) :: temp = x+1' where the `x-1' term must correspond to an actual "something-minus-one" in the target formula.

A successful way to write this would be `f(x, x+2) := g(x+1)'. You could make this resemble the original form more closely by using `let` notation, which is described in the next section:

```
f(xm1, x+1)  :=  g(x)  :: let(x := xm1+1)
```

Calc does this rewriting or "conditionalizing" for any sub-pattern which involves only the functions in the following list, operating only on constants and meta-variables which have already been matched elsewhere in the pattern. When matching a function call, Calc is careful to match arguments which are plain variables before arguments which are calls to any of the functions below, so that a pattern like `f(x-1, x)' can be conditionalized even though the isolated `x' comes after the `x-1'.

```
+ - * / \ % ^  abs sign  round rounde roundu trunc floor ceil
```

```
max min  re im conj arg
```

You can suppress all of the special treatments described in this section by surrounding a function call with a `plain` marker. This marker causes the function call which is its argument to be matched literally, without regard to commutativity, associativity, negation, or conditionalization. When you use `plain`, the "deep structure" of the formula being matched can show through. For example,

```
plain(a - a b)  :=  f(a, b)
```

will match only literal subtractions. However, the `plain` marker does not affect its arguments' arguments. In this case, commutativity and associativity is still considered while matching the `a b' sub-pattern, so the whole pattern will match `x - y x' as well as `x - x y'. We could go still further and use

```
plain(a - plain(a b))  :=  f(a, b)
```

which would do a completely strict match for the pattern.

By contrast, the `quote` marker means that not only the function name but also the arguments must be literally the same. The above pattern will match `x - x y' but

```
quote(a - a b)  :=  f(a, b)
```

will match only the single formula `a - a b'. Also,

```
quote(a - quote(a b))  :=  f(a, b)
```

will match only `a - quote(a b)'---probably not the desired effect!

A certain amount of algebra is also done when substituting the meta-variables on the righthand side of a rule. For example, in the rule

```
a + f(b)  :=  f(a + b)
```

matching `f(x) - y' would produce `f((-y) + x)' if taken literally, but the rewrite mechanism will simplify the righthand side to `f(x - y)' automatically. (Of course, the default simplifications would do this anyway, so this special simplification is only noticeable if you have turned the default simplifications off.) This rewriting is done only when a meta-variable expands to a "negative-looking" expression. If this simplification is not desirable, you can use a `plain` marker on the righthand side:

```
a + f(b)  :=  f(plain(a + b))
```

In this example, we are still allowing the pattern-matcher to use all the algebra it can muster, but the righthand side will always simplify to a literal addition like `f((-y) + x)'.

Other Features of Rewrite Rules

Certain "function names" serve as markers in rewrite rules. Here is a complete list of these markers. First are listed the markers that work inside a pattern; then come the markers that work in the righthand side of a rule.

One kind of marker, `import(x)', takes the place of a whole rule. Here x is the name of a variable containing another rule set; those rules are "spliced into" the rule set that imports them. For example, if `[f(a+b) := f(a) + f(b), f(a b) := a f(b) :: real(a)]' is stored in variable `linearF', then the rule set `[f(0) := 0, import(linearF)]' will apply all three rules. It is possible to modify the imported rules slightly: `import(x, v1, x1, v2, x2, ...)' imports the rule set x with all occurrences of @c{$v_1$} v1, as either a variable name or a function name, replaced with @c{$x_1$} x1 and so on. (If @c{$v_1$} v1 is used as a function name, then @c{$x_1$} x1 must be either a function name itself or a `< >' nameless function; see section Specifying Operators.) For example, `[g(0) := 0, import(linearF, f, g)]' applies the linearity rules to the function `g' instead of `f'. Imports can be nested, but the import-with-renaming feature may fail to rename sub-imports properly.

The special functions allowed in patterns are:

`quote(x)'

> This pattern matches exactly x; variable names in x are not interpreted as meta-variables. The only flexibility is that numbers are compared for numeric equality, so that the pattern `f(quote(12))' will match both `f(12)' and `f(12.0)'. (Numbers are always treated this way by the rewrite mechanism: The rule `f(x,x) := g(x)' will match `f(12, 12.0)'. The rewrite may produce either `g(12)' or `g(12.0)' as a result in this case.)

`plain(x)'

> Here x must be a function call `f(x1,x2,...)'. This pattern matches a call to function f with the specified argument patterns. No special knowledge of the properties of the function f is used in this case; `+' is not commutative or associative. Unlike `quote`, the arguments `x1,x2,...' are treated as patterns. If you wish them to be treated "plainly" as well, you must enclose them with more `plain` markers: `plain(plain(-a) + plain(b c))'.

`opt(x,def)'

> Here x must be a variable name. This must appear as an argument to a function or an element of a vector; it specifies that the argument or element is optional. As an argument to `+', `-', `*', `&&', or `||', or as the second argument to `/' or `^', the value def may be omitted. The pattern `x + opt(y)' matches a sum by binding one summand to x and the other to y, and it matches anything else by binding the whole expression to x and zero to y. The other operators above work similarly.
>
> For general miscellanous functions, the default value `def` must be specified. Optional arguments are dropped starting with the rightmost one during matching. For example, the pattern `f(opt(a,0), b, opt(c,b))' will match `f(b)', `f(a,b)', or `f(a,b,c)'. Default values of zero and b are supplied in this example for the omitted arguments. Note that the literal variable b will be the default in the latter case, *not* the value that matched the meta-variable b. In other words, the default def is effectively quoted.

`condition(x,c)'

> This matches the pattern x, with the attached condition c. It is the same as `x :: c'.

`pand(x,y)'

This matches anything that matches both pattern x and pattern y. It is the same as `x &&& y'. see section Composing Patterns in Rewrite Rules.

`por(x,y)'

This matches anything that matches either pattern x or pattern y. It is the same as `x ||| y'.

`pnot(x)'

This matches anything that does not match pattern x. It is the same as `!!! x'.

`cons(h,t)'

This matches any vector of one or more elements. The first element is matched to h; a vector of the remaining elements is matched to t. Note that vectors of fixed length can also be matched as actual vectors: The rule `cons(a,cons(b,[])) := cons(a+b,[])' is equivalent to the rule `[a,b] := [a+b]'.

`rcons(t,h)'

This is like `cons`, except that the *last* element is matched to h, with the remaining elements matched to t.

`apply(f,args)'

This matches any function call. The name of the function, in the form of a variable, is matched to f. The arguments of the function, as a vector of zero or more objects, are matched to `args'. Constants, variables, and vectors do *not* match an `apply` pattern. For example, `apply(f,x)' matches any function call, `apply(quote(f),x)' matches any call to the function `f', `apply(f,[a,b])' matches any function call with exactly two arguments, and `apply(quote(f), cons(a,cons(b,x)))' matches any call to the function `f' with two or more arguments. Another way to implement the latter, if the rest of the rule does not need to refer to the first two arguments of `f' by name, would be `apply(quote(f), x :: vlen(x) >= 2)'. Here's a more interesting sample use of `apply`:

```
apply(f,[x+n])  :=  n + apply(f,[x])
   :: in(f, [floor,ceil,round,trunc]) :: integer(n)
```

Note, however, that this will be slower to match than a rule set with four separate rules. The reason is that Calc sorts the rules of a rule set according to top-level function name; if the top-level function is `apply`, Calc must try the rule for every single formula and sub-formula. If the top-level function in the pattern is, say, `floor`, then Calc invokes the rule only for sub-formulas which are calls to `floor`.

Formulas normally written with operators like + are still considered function calls: `apply(f,x)` matches `a+b' with `f = add', `x = [a,b]'.

You must use `apply` for meta-variables with function names on both sides of a rewrite rule: `apply(f, [x]) := f(x+1)' is *not* correct, because it rewrites `spam(6)' into `f(7)'. The righthand side should be `apply(f, [x+1])'. Also note that you will have to use no-simplify (m O) mode when entering this rule so that the `apply` isn't evaluated immediately to get the new rule `f(x) := f(x+1)'. Or, use s e to enter the rule without going through the stack, or enter the rule as `apply(f, [x]) := apply(f, [x+1]) :: 1'. See section Conditional Rewrite Rules.

`select(x)'

This is used for applying rules to formulas with selections; see section Selections with Rewrite Rules.

Special functions for the righthand sides of rules are:

`quote(x)'

The notation `quote(x)' is changed to `x' when the righthand side is used. As far as the rewrite rule is concerned, `quote` is invisible. However, `quote` has the special property in Calc that its argument is not evaluated. Thus, while it will not work to put the rule `t(a) := typeof(a)' on the stack because `typeof(a)' is evaluated immediately to produce `t(a) := 100', you can use `quote` to protect the righthand side: `t(a) := quote(typeof(a))'. (See section Conditional Rewrite Rules, for another trick for protecting rules from evaluation.)

`plain(x)'

Special properties of and simplifications for the function call x are not used. One interesting case where `plain` is useful is the rule, `q(x) := quote(x)', trying to expand a shorthand notation for the `quote` function. This rule will not work as shown; instead of replacing `q(foo)' with `quote(foo)', it will replace it with `foo'! The correct rule would be `q(x) := plain(quote(x))'.

`cons(h,t)'

Where t is a vector, this is converted into an expanded vector during rewrite processing. Note that `cons` is a regular Calc function which normally does this anyway; the only way `cons` is treated specially by rewrites is that `cons` on the righthand side of a rule will be evaluated even if default simplifications have been turned off.

`rcons(t,h)'

Analogous to `cons` except putting h at the *end* of the vector t.

`apply(f,args)'

Where f is a variable and args is a vector, this is converted to a function call. Once again, note that `apply` is also a regular Calc function.

`eval(x)'

The formula x is handled in the usual way, then the default simplifications are applied to it even if they have been turned off normally. This allows you to treat any function similarly to the way `cons` and `apply` are always treated. However, there is a slight difference: `cons(2+3, [])' with default simplifications off will be converted to `[2+3]', whereas `eval(cons(2+3, []))' will be converted to `[5]'.

`evalsimp(x)'

The formula x has meta-variables substituted in the usual way, then algebraically simplified as if by the a s command.

`evalextsimp(x)'

The formula x has meta-variables substituted in the normal way, then "extendedly" simplified as if by the a e command.

`select(x)'

See section Selections with Rewrite Rules.

There are also some special functions you can use in conditions.

`let(v := x)'

The expression x is evaluated with meta-variables substituted. The a s command's simplifications are

not applied by default, but x can include calls to `evalsimp` or `evalextsimp` as described above to invoke higher levels of simplification. The result of x is then bound to the meta-variable v. As usual, if this meta-variable has already been matched to something else the two values must be equal; if the meta-variable is new then it is bound to the result of the expression. This variable can then appear in later conditions, and on the righthand side of the rule. In fact, v may be any pattern in which case the result of evaluating x is matched to that pattern, binding any meta-variables that appear in that pattern. Note that `let` can only appear by itself as a condition, or as one term of an `&&' which is a whole condition: It cannot be inside an `||' term or otherwise buried.

The alternate, equivalent form `let(v, x)' is also recognized. Note that the use of `:=' by `let`, while still being assignment-like in character, is unrelated to the use of `:=' in the main part of a rewrite rule.

As an example, `f(a) := g(ia) :: let(ia := 1/a) :: constant(ia)' replaces `f(a)' with `g' of the inverse of `a', if that inverse exists and is constant. For example, if `a' is a singular matrix the operation `1/a' is left unsimplified and `constant(ia)' fails, but if `a' is an invertible matrix then the rule succeeds. Without `let` there would be no way to express this rule that didn't have to invert the matrix twice. Note that, because the meta-variable `ia' is otherwise unbound in this rule, the `let` condition itself always "succeeds" because no matter what `1/a' evaluates to, it can successfully be bound to `ia`.

Here's another example, for integrating cosines of linear terms: `myint(cos(y),x) := sin(y)/b :: let([a,b,x] := lin(y,x))'. The `lin` function returns a 3-vector if its argument is linear, or leaves itself unevaluated if not. But an unevaluated `lin` call will not match the 3-vector on the lefthand side of the `let`, so this `let` both verifies that `y` is linear, and binds the coefficients `a` and `b` for use elsewhere in the rule. (It would have been possible to use `sin(a x + b)/b' for the righthand side instead, but using `sin(y)/b' avoids gratuitous rearrangement of the argument of the sine.)

Similarly, here is a rule that implements an inverse-`erf` function. It uses `root` to search for a solution. If `root` succeeds, it will return a vector of two numbers where the first number is the desired solution. If no solution is found, `root` remains in symbolic form. So we use `let` to check that the result was indeed a vector.

```
ierf(x)  :=  y  :: let([y,z] := root(erf(a) = x, a, .5))
```

`matches(v,p)'

The meta-variable v, which must already have been matched to something elsewhere in the rule, is compared against pattern p. Since `matches` is a standard Calc function, it can appear anywhere in a condition. But if it appears alone or as a term of a top-level `&&', then you get the special extra feature that meta-variables which are bound to things inside p can be used elsewhere in the surrounding rewrite rule.

The only real difference between `let(p := v)' and `matches(v, p)' is that the former evaluates `v' using the default simplifications, while the latter does not.

`remember'

This is actually a variable, not a function. If `remember` appears as a condition in a rule, then when that rule succeeds the original expression and rewritten expression are added to the front of the rule set that contained the rule. If the rule set was not stored in a variable, `remember` is ignored. The lefthand side is enclosed in `quote` in the added rule if it contains any variables.

For example, the rule `f(n) := n f(n-1) :: remember' applied to `f(7)' will add the rule `f(7) := 7 f(6)' to the front of the rule set. The rule set `EvalRules` works slightly differently: There, the evaluation of `f(6)' will complete before the result is added to the rule set, in this case as `f(7) := 5040'. Thus `remember` is most useful inside `EvalRules`.

It is up to you to ensure that the optimization performed by `remember` is safe. For example, the rule `foo(n) := n :: evalv(eatfoo) > 0 :: remember' is a bad idea (`evalv` is the function equivalent of the = command); if the variable `eatfoo` ever contains 1, rules like `foo(7) := 7' will be added to the rule set and will continue to operate even if `eatfoo` is later changed to 0.

`remember(c)'

Remember the match as described above, but only if condition c is true. For example, `remember(n % 4 = 0)' in the above factorial rule remembers only every fourth result. Note that `remember(1)' is equivalent to `remember', and `remember(0)' has no effect.

Composing Patterns in Rewrite Rules

There are three operators, `&&&', `|||', and `!!!', that combine rewrite patterns to make larger patterns. The combinations are "and," "or," and "not," respectively, and these operators are the pattern equivalents of `&&', `||' and `!' (which operate on zero-or-nonzero logical values).

Note that `&&&', `|||', and `!!!' are left in symbolic form by all regular Calc features; they have special meaning only in the context of rewrite rule patterns.

The pattern `p1 &&& p2' matches anything that matches both p1 and p2. One especially useful case is when one of p1 or p2 is a meta-variable. For example, here is a rule that operates on error forms:

```
f(x &&& a +/- b, x)  :=  g(x)
```

This does the same thing, but is arguably simpler than, the rule

```
f(a +/- b, a +/- b)  :=  g(a +/- b)
```

Here's another interesting example:

```
ends(cons(a, x) &&& rcons(y, b))  :=  [a, b]
```

which effectively clips out the middle of a vector leaving just the first and last elements. This rule will change a one-element vector `[a]' to `[a, a]'. The similar rule

```
ends(cons(a, rcons(y, b)))  :=  [a, b]
```

would do the same thing except that it would fail to match a one-element vector.

The pattern `p1 ||| p2' matches anything that matches either p1 or p2. Calc first tries matching against p1; if that fails, it goes on to try p2.

A simple example of `|||' is

```
curve(inf ||| -inf)  :=  0
```

which converts both `curve(inf)' and `curve(-inf)' to zero.

Here is a larger example:

```
log(a, b) ||| (ln(a) :: let(b := e))  :=  mylog(a, b)
```

This matches both generalized and natural logarithms in a single rule. Note that the `::' term must be enclosed in parentheses because that operator has lower precedence than `|||' or `:='.

(In practice this rule would probably include a third alternative, omitted here for brevity, to take care of `log10'.)

While Calc generally treats interior conditions exactly the same as conditions on the outside of a rule, it does guarantee that if all the variables in the condition are special names like `e', or already bound in the pattern to which the condition is attached (say, if `a' had appeared in this condition), then Calc will process this condition right after matching the pattern to the left of the `::'. Thus, we know that `b' will be bound to `e' only if the `ln' branch of the `|||' was taken.

Note that this rule was careful to bind the same set of meta-variables on both sides of the `|||'. Calc does not check this, but if you bind a certain meta-variable only in one branch and then use that meta-variable elsewhere in the rule, results are unpredictable:

```
f(a,b) ||| g(b)  :=  h(a,b)
```

Here if the pattern matches `g(17)', Calc makes no promises about the value that will be substituted for `a' on the righthand side.

The pattern `!!! pat' matches anything that does not match pat. Any meta-variables that are bound while matching pat remain unbound outside of pat.

For example,

```
f(x &&& !!! a +/- b, !!![])  :=  g(x)
```

converts `f' whose first argument is anything *except* an error form, and whose second argument is not the empty vector, into a similar call to `g' (but without the second argument).

If we know that the second argument will be a vector (empty or not), then an equivalent rule would be:

```
f(x, y)  :=  g(x)  :: typeof(x) != 7 :: vlen(y) > 0
```

where of course 7 is the `typeof' code for error forms. Another final condition, that works for any kind of `y', would be `!istrue(y == [])'. (The `istrue' function returns an explicit 0 if its argument was left in symbolic form; plain `!(y == [])' or `y != []' would not work to replace `!!![]' since these would be left unsimplified, and thus cause the rule to fail, if `y' was something like a variable name.)

It is possible for a `!!!' to refer to meta-variables bound elsewhere in the pattern. For example,

```
f(a, !!!a)  :=  g(a)
```

matches any call to `f` with different arguments, changing this to `g` with only the first argument.

If a function call is to be matched and one of the argument patterns contains a `!!!' somewhere inside it, that argument will be matched last. Thus

```
f(!!!a, a)  :=  g(a)
```

will be careful to bind `a' to the second argument of `f` before testing the first argument. If Calc had tried to match the first argument of `f` first, the results would have been disasterous: Since `a` was unbound so far, the pattern `a' would have matched anything at all, and the pattern `!!!a' therefore would *not* have matched anything at all!

Nested Formulas with Rewrite Rules

When a r (`calc-rewrite`) is used, it takes an expression from the top of the stack and attempts to match any of the specified rules to any part of the expression, starting with the whole expression and then, if that fails, trying deeper and deeper sub-expressions. For each part of the expression, the rules are tried in the order they appear in the rules vector. The first rule to match the first sub-expression wins; it replaces the matched sub-expression according to the new part of the rule.

Often, the rule set will match and change the formula several times. The top-level formula is first matched and substituted repeatedly until it no longer matches the pattern; then, sub-formulas are tried, and so on. Once every part of the formula has gotten its chance, the rewrite mechanism starts over again with the top-level formula (in case a substitution of one of its arguments has caused it again to match). This continues until no further matches can be made anywhere in the formula.

It is possible for a rule set to get into an infinite loop. The most obvious case, replacing a formula with itself, is not a problem because a rule is not considered to "succeed" unless the righthand side actually comes out to something different than the original formula or sub-formula that was matched. But if you accidentally had both `ln(a b) := ln(a) + ln(b)' and the reverse `ln(a) + ln(b) := ln(a b)' in your rule set, Calc would run forever switching a formula back and forth between the two forms.

To avoid disaster, Calc normally stops after 100 changes have been made to the formula. This will be enough for most multiple rewrites, but it will keep an endless loop of rewrites from locking up the computer forever. (On most systems, you can also type C-g to halt any Emacs command prematurely.)

To change this limit, give a positive numeric prefix argument. In particular, M-1 a r applies only one rewrite at a time, useful when you are first testing your rule (or just if repeated rewriting is not what is called for by your application).

You can also put a "function call" `iterations(n)' in place of a rule anywhere in your rules vector (but usually at the top). Then, n will be used instead of 100 as the default number of iterations for this rule set. You can use `iterations(inf)' if you want no iteration limit by default. A prefix argument will override the `iterations` limit in the rule set.

```
[ iterations(1),
  f(x) := f(x+1) ]
```

More precisely, the limit controls the number of "iterations," where each iteration is a successful match of a rule pattern whose righthand side, after substituting meta-variables and applying the default simplifications, is different from the original sub-formula that was matched.

A prefix argument of zero sets the limit to infinity. Use with caution!

Given a negative numeric prefix argument, a r will match and substitute the top-level expression up to that many times, but will not attempt to match the rules to any sub-expressions.

In a formula, `rewrite(expr, rules, n)` does a rewriting operation. Here expr is the expression being rewritten, rules is the rule, vector of rules, or variable containing the rules, and n is the optional iteration limit, which may be a positive integer, a negative integer, or `inf' or `-inf'. If n is omitted the `iterations` value from the rule set is used; if both are omitted, 100 is used.

Multi-Phase Rewrite Rules

It is possible to separate a rewrite rule set into several phases. During each phase, certain rules will be enabled while certain others will be disabled. A phase schedule controls the order in which phases occur during the rewriting process.

If a call to the marker function `phase` appears in the rules vector in place of a rule, all rules following that point will be members of the phase(s) identified in the arguments to `phase`. Phases are given integer numbers. The markers `phase()' and `phase(all)' both mean the following rules belong to all phases; this is the default at the start of the rule set.

If you do not explicitly schedule the phases, Calc sorts all phase numbers that appear in the rule set and executes the phases in ascending order. For example, the rule set

```
[ f0(x) := g0(x),
  phase(1),
  f1(x) := g1(x),
  phase(2),
  f2(x) := g2(x),
  phase(3),
  f3(x) := g3(x),
  phase(1,2),
  f4(x) := g4(x) ]
```

has three phases, 1 through 3. Phase 1 consists of the `f0`, `f1`, and `f4` rules (in that order). Phase 2 consists of `f0`, `f2`, and `f4`. Phase 3 consists of `f0` and `f3`.

When Calc rewrites a formula using this rule set, it first rewrites the formula using only the phase 1 rules until no further changes are possible. Then it switches to the phase 2 rule set and continues until no further changes occur, then finally rewrites with phase 3. When no more phase 3 rules apply, rewriting finishes. (This is assuming a r with a large enough prefix argument to allow the rewriting to run to completion; the sequence just described stops early if the number of iterations specified in the prefix argument, 100 by default, is reached.)

During each phase, Calc descends through the nested levels of the formula as described previously. (See

section Nested Formulas with Rewrite Rules.) Rewriting starts at the top of the formula, then works its down to the parts, then goes back to the top and works down again. The phase 2 rules do not begin until its phase 1 rules apply anywhere in the formula.

A `schedule` marker appearing in the rule set (anywhere, but conventionally at the top) changes the default schedule of phases. In the simplest case, `schedule` has a sequence of phase numbers for arguments; each phase number is invoked in turn until the arguments to `schedule` are exhausted. Thus adding `schedule(3,2,1)' at the top of the above rule set would reverse the order of the phases; `schedule(1,2,3)' would have no effect since this is the default schedule; and `schedule(1,2,1,3)' would give phase 1 a second chance after phase 2 has completed, before moving on to phase 3.

Any argument to `schedule` can instead be a vector of phase numbers (or even of sub-vectors). Then the sub-sequence of phases described by the vector are tried repeatedly until no change occurs in any phase in the sequence. For example, `schedule([1, 2], 3)' tries phase 1, then phase 2, then, if either phase made any changes to the formula, repeats these two phases until they can make no further progress. Finally, it goes on to phase 3 for finishing touches.

Also, items in `schedule` can be variable names as well as numbers. A variable name is interpreted as the name of a function to call on the whole formula. For example, `schedule(1, simplify)' says to apply the phase-1 rules (presumably, all of them), then to call `simplify` which is the function name equivalent of a s. Likewise, `schedule([1, simplify])' says to alternate between phase 1 and a s until no further changes occur.

Phases can be used purely to improve efficiency; if it is known that a certain group of rules will apply only at the beginning of rewriting, and a certain other group will apply only at the end, then rewriting will be faster if these groups are identified as separate phases. Once the phase 1 rules are done, Calc can put them aside and no longer spend any time on them while it works on phase 2.

There are also some problems that can only be solved with several rewrite phases. For a real-world example of a multi-phase rule set, examine the set `FitRules`, which is used by the curve-fitting command to convert a model expression to linear form. See section Curve Fitting Details. This set is divided into four phases. The first phase rewrites certain kinds of expressions to be more easily linearizable, but less computationally efficient. After the linear components have been picked out, the final phase includes the opposite rewrites to put each component back into an efficient form. If both sets of rules were included in one big phase, Calc could get into an infinite loop going back and forth between the two forms.

Elsewhere in `FitRules`, the components are first isolated, then recombined where possible to reduce the complexity of the linear fit, then finally packaged one component at a time into vectors. If the packaging rules were allowed to begin before the recombining rules were finished, some components might be put away into vectors before they had a chance to recombine. By putting these rules in two separate phases, this problem is neatly avoided.

Selections with Rewrite Rules

If a sub-formula of the current formula is selected (as by j s; see section Selecting Sub-Formulas), the a r (`calc-rewrite`) command applies only to that sub-formula. Together with a negative prefix argument, you can use this fact to apply a rewrite to one specific part of a formula without affecting any other parts.

The j r (`calc-rewrite-selection`) command allows more sophisticated operations on selections.

This command prompts for the rules in the same way as a r, but it then applies those rules to the whole formula in question even though a sub-formula of it has been selected. However, the selected sub-formula will first have been surrounded by a `select( )' function call. (Calc's evaluator does not understand the function name `select'; this is only a tag used by the j r command.)

For example, suppose the formula on the stack is `2 (a + b)^2' and the sub-formula `a + b' is selected. This formula will be rewritten to `2 select(a + b)^2' and then the rewrite rules will be applied in the usual way. The rewrite rules can include references to `select' to tell where in the pattern the selected sub-formula should appear.

If there is still exactly one `select( )' function call in the formula after rewriting is done, it indicates which part of the formula should be selected afterwards. Otherwise, the formula will be unselected.

You can make j r act much like a r by enclosing both parts of the rewrite rule with `select()'. However, j r allows you to use the current selection in more flexible ways. Suppose you wished to make a rule which removed the exponent from the selected term; the rule `select(a)^x := select(a)' would work. In the above example, it would rewrite `2 select(a + b)^2' to `2 select(a + b)'. This would then be returned to the stack as `2 (a + b)' with the `a + b' selected.

The j r command uses one iteration by default, unlike a r which defaults to 100 iterations. A numeric prefix argument affects j r in the same way as a r. See section Nested Formulas with Rewrite Rules.

As with other selection commands, j r operates on the stack entry that contains the cursor. (If the cursor is on the top-of-stack `.' marker, it works as if the cursor were on the formula at stack level 1.)

If you don't specify a set of rules, the rules are taken from the top of the stack, just as with a r. In this case, the cursor must indicate stack entry 2 or above as the formula to be rewritten (otherwise the same formula would be used as both the target and the rewrite rules).

If the indicated formula has no selection, the cursor position within the formula temporarily selects a sub-formula for the purposes of this command. If the cursor is not on any sub-formula (e.g., it is in the line-number area to the left of the formula), the `select( )' markers are ignored by the rewrite mechanism and the rules are allowed to apply anywhere in the formula.

As a special feature, the normal a r command also ignores `select( )' calls in rewrite rules. For example, if you used the above rule `select(a)^x := select(a)' with a r, it would apply the rule as if it were `a^x := a'. Thus, you can write general purpose rules with `select( )' hints inside them so that they will "do the right thing" in both a r and j r, both with and without selections.

Matching Commands

The a m (`calc-match') [`match'] function takes a vector of formulas and a rewrite-rule-style pattern, and produces a vector of all formulas which match the pattern. The command prompts you to enter the pattern; as for a r, you can enter a single pattern (i.e., a formula with meta-variables), or a vector of patterns, or a variable which contains patterns, or you can give a blank response in which case the patterns are taken from the top of the stack. The pattern set will be compiled once and saved if it is stored in a variable. If there are several patterns in the set, vector elements are kept if they match any of the patterns.

For example, `match(a+b, [x, x+y, x-y, 7, x+y+z])' will return `[x+y, x-y, x+y+z]'.

The `import` mechanism is not available for pattern sets.

The a m command can also be used to extract all vector elements which satisfy any condition: The pattern `x :: x>0' will select all the positive vector elements.

With the Inverse flag [`matchnot`], this command extracts all vector elements which do *not* match the given pattern.

There is also a function `matches(x, p)' which evaluates to 1 if expression x matches pattern p, or to 0 otherwise. This is sometimes useful for including into the conditional clauses of other rewrite rules.

The function `vmatches` is just like `matches`, except that if the match succeeds it returns a vector of assignments to the meta-variables instead of the number 1. For example, `vmatches(f(1,2), f(a,b))' returns `[a := 1, b := 2]'. If the match fails, the function returns the number 0.

Automatic Rewrites

It is possible to get Calc to apply a set of rewrite rules on all results, effectively adding to the built-in set of default simplifications. To do this, simply store your rule set in the variable `EvalRules`. There is a convenient s E command for editing `EvalRules`; see section Other Operations on Variables.

For example, suppose you want `sin(a + b)' to be expanded out to `sin(b) cos(a) + cos(b) sin(a)' wherever it appears, and similarly for `cos(a + b)'. The corresponding rewrite rule set would be,

```
[ sin(a + b)  :=  cos(a) sin(b) + sin(a) cos(b),
  cos(a + b)  :=  cos(a) cos(b) - sin(a) sin(b) ]
```

To apply these manually, you could put them in a variable called `trigexp` and then use a r trigexp every time you wanted to expand trig functions. But if instead you store them in the variable `EvalRules`, they will automatically be applied to all sines and cosines of sums. Then, with `2 x' and `45' on the stack, typing + S will (assuming degrees mode) result in `0.7071 sin(2 x) + 0.7071 cos(2 x)' automatically.

As each level of a formula is evaluated, the rules from `EvalRules` are applied before the default simplifications. Rewriting continues until no further `EvalRules` apply. Note that this is different from the usual order of application of rewrite rules: `EvalRules` works from the bottom up, simplifying the arguments to a function before the function itself, while a r applies rules from the top down.

Because the `EvalRules` are tried first, you can use them to override the normal behavior of any built-in Calc function.

It is important not to write a rule that will get into an infinite loop. For example, the rule set `[f(0) := 1, f(n) := n f(n-1)]' appears to be a good definition of a factorial function, but it is unsafe. Imagine what happens if `f(2.5)' is simplified. Calc will continue to subtract 1 from this argument forever without reaching zero. A safer second rule would be `f(n) := n f(n-1) :: n>0'. Another dangerous rule is `g(x, y) := g(y, x)'. Rewriting `g(2, 4)', this would bounce back and forth between that and `g(4, 2)' forever. If an infinite loop in `EvalRules` occurs, Emacs will eventually stop with a "Computation got stuck or ran too long" message.

Another subtle difference between `EvalRules` and regular rewrites concerns rules that rewrite a formula into an identical formula. For example, `f(n) := f(floor(n))' "fails to match" when n is already an integer. But in `EvalRules` this case is detected only if the righthand side literally becomes the original formula

before any further simplification. This means that `f(n) := f(floor(n))' will get into an infinite loop if it occurs in `EvalRules'. Calc will replace `f(6)' with `f(floor(6))', which is different from `f(6)', so it will consider the rule to have matched and will continue simplifying that formula; first the argument is simplified to get `f(6)', then the rule matches again to get `f(floor(6))' again, ad infinitum. A much safer rule would check its argument first, say, with `f(n) := f(floor(n)) :: !dint(n)'.

(What really happens is that the rewrite mechanism substitutes the meta-variables in the righthand side of a rule, compares to see if the result is the same as the original formula and fails if so, then uses the default simplifications to simplify the result and compares again (and again fails if the formula has simplified back to its original form). The only special wrinkle for the `EvalRules' is that the same rules will come back into play when the default simplifications are used. What Calc wants to do is build `f(floor(6))', see that this is different from the original formula, simplify to `f(6)', see that this is the same as the original formula, and thus halt the rewriting. But while simplifying, `f(6)' will again trigger the same `EvalRules' rule and Calc will get into a loop inside the rewrite mechanism itself.)

The `phase', `schedule', and `iterations' markers do not work in `EvalRules'. If the rule set is divided into phases, only the phase 1 rules are applied, and the schedule is ignored. The rules are always repeated as many times as possible.

The `EvalRules' are applied to all function calls in a formula, but not to numbers (and other number-like objects like error forms), nor to vectors or individual variable names. (Though they will apply to *components* of vectors and error forms when appropriate.) You might try to make a variable `phihat' which automatically expands to its definition without the need to press = by writing the rule `quote(phihat) := (1-sqrt(5))/2', but unfortunately this rule will not work as part of `EvalRules'.

Finally, another limitation is that Calc sometimes calls its built-in functions directly rather than going through the default simplifications. When it does this, `EvalRules' will not be able to override those functions. For example, when you take the absolute value of the complex number (2, 3), Calc computes `sqrt(2*2 + 3*3)' by calling the multiplication, addition, and square root functions directly rather than applying the default simplifications to this formula. So an `EvalRules' rule that (perversely) rewrites `sqrt(13) := 6' would not apply. (However, if you put Calc into symbolic mode so that `sqrt(13)' will be left in symbolic form by the built-in square root function, your rule will be able to apply. But if the complex number were (3,4), so that `sqrt(25)' must be calculated, then symbolic mode will not help because `sqrt(25)' can be evaluated exactly to 5.)

One subtle restriction that normally only manifests itself with `EvalRules' is that while a given rewrite rule is in the process of being checked, that same rule cannot be recursively applied. Calc effectively removes the rule from its rule set while checking the rule, then puts it back once the match succeeds or fails. (The technical reason for this is that compiled pattern programs are not reentrant.) For example, consider the rule `foo(x) := x :: foo(x/2) > 0' attempting to match `foo(8)'. This rule will be inactive while the condition `foo(4) > 0' is checked, even though it might be an integral part of evaluating that condition. Note that this is not a problem for the more usual recursive type of rule, such as `foo(x) := foo(x/2)', because there the rule has succeeded and been reactivated by the time the righthand side is evaluated.

If `EvalRules' has no stored value (its default state), or if anything but a vector is stored in it, then it is ignored.

Even though Calc's rewrite mechanism is designed to compare rewrite rules to formulas as quickly as possible, storing rules in `EvalRules' may make Calc run substantially slower. This is particularly true of

rules where the top-level call is a commonly used function, or is not fixed. The rule `f(n) := n f(n-1) :: r will only activate the rewrite mechanism for calls to the function `f`, but `lg(n) + lg(m) := lg(n m)' will check every `+' operator. And `apply(f, [a*b]) := apply(f, [a]) + apply(f, [b]) :: in(f, [ln, log10])' may seem more "efficient" than two separate rules for `ln` and `log10`, but actually it is vastly less efficient because rules with `apply` as the top-level pattern must be tested against *every* function call that is simplified.

Suppose you want `sin(a + b)' to be expanded out not all the time, but only when a s is used to simplify the formula. The variable `AlgSimpRules` holds rules for this purpose. The a s command will apply `EvalRules` and `AlgSimpRules` to the formula, as well as all of its built-in simplifications.

Most of the special limitations for `EvalRules` don't apply to `AlgSimpRules`. Calc simply does an a r AlgSimpRules command with an infinite repeat count as the first step of a s. It then applies its own built-in simplifications throughout the formula, and then repeats these two steps (along with applying the default simplifications) until no further changes are possible.

There are also `ExtSimpRules` and `UnitSimpRules` variables that are used by a e and u s, respectively; these commands also apply `EvalRules` and `AlgSimpRules`. The variable `IntegSimpRules` contains simplification rules that are used only during integration by a i.

Debugging Rewrites

If a buffer named `*Trace*' exists, the rewrite mechanism will record some useful information there as it operates. The original formula is written there, as is the result of each successful rewrite, and the final result of the rewriting. All phase changes are also noted.

Calc always appends to `*Trace*'. You must empty this buffer yourself periodically if it is in danger of growing unwieldy.

Note that the rewriting mechanism is substantially slower when the `*Trace*' buffer exists, even if the buffer is not visible on the screen. Once you are done, you will probably want to kill this buffer (with C-x k *Trace* RET). If you leave it in existence and forget about it, all your future rewrite commands will be needlessly slow.

Examples of Rewrite Rules

Returning to the example of substituting the pattern `sin(x)^2 + cos(x)^2' with 1, we saw that the rule `opt(a) sin(x)^2 + opt(a) cos(x)^2 := a' does a good job of finding suitable cases. Another solution would be to use the rule `cos(x)^2 := 1 - sin(x)^2', followed by algebraic simplification if necessary. This rule will be the most effective way to do the job, but at the expense of making some changes that you might not desire.

Another algebraic rewrite rule is `exp(x+y) := exp(x) exp(y)'. To make this work with the j r command so that it can be easily targeted to a particular exponential in a large formula, you might wish to write the rule as `select(exp(x+y)) := select(exp(x) exp(y))'. The `select' markers will be ignored by the regular a r command (see section Selections with Rewrite Rules).

A surprisingly useful rewrite rule is `a/(b-c) := a*(b+c)/(b^2-c^2)'. This will simplify the formula whenever b and/or c can be made simpler by squaring. For example, applying this rule to `2 / (sqrt(2) + 3)' yields `6:7 - 2:7 sqrt(2)' (assuming Symbolic Mode has been enabled to keep the square root from being evaulated to a floating-point approximation). This rule is also useful when working with symbolic complex numbers, e.g.,

`(a + b i) / (c + d i)'.

As another example, we could define our own "triangular numbers" function with the rules `[tri(0) := 0, tri(n) := n + tri(n-1) :: n>0]'. Enter this vector and store it in a variable: s t trirules. Now, given a suitable formula like `tri(5)' on the stack, type `a r trirules' to apply these rules repeatedly. After six applications, a r will stop with 15 on the stack. Once these rules are debugged, it would probably be most useful to add them to `EvalRules` so that Calc will evaluate the new `tri` function automatically. We could then use Z K on the keyboard macro ' tri($) RET to make a command that applies `tri` to the value on the top of the stack. See section Programming.

The following rule set, contributed by @c{Fran\c cois} Francois Pinard, implements quaternions, a generalization of the concept of complex numbers. Quaternions have four components, and are here represented by function calls `quat(w, [x, y, z])' with "real part" w and the three "imaginary" parts collected into a vector. Various arithmetical operations on quaternions are supported. To use these rules, either add them to `EvalRules`, or create a command based on a r for simplifying quaternion formulas. A convenient way to enter quaternions would be a command defined by a keyboard macro containing: ' quat($$$$, [$$$, $$, $]) RET.

```
[ quat(w, x, y, z) := quat(w, [x, y, z]),
  quat(w, [0, 0, 0]) := w,
  abs(quat(w, v)) := hypot(w, v),
  -quat(w, v) := quat(-w, -v),
  r + quat(w, v) := quat(r + w, v) :: real(r),
  r - quat(w, v) := quat(r - w, -v) :: real(r),
  quat(w1, v1) + quat(w2, v2) := quat(w1 + w2, v1 + v2),
  r * quat(w, v) := quat(r * w, r * v) :: real(r),
  plain(quat(w1, v1) * quat(w2, v2))
     := quat(w1 * w2 - v1 * v2, w1 * v2 + w2 * v1 + cross(v1, v2)),
  quat(w1, v1) / r := quat(w1 / r, v1 / r) :: real(r),
  z / quat(w, v) := z * quatinv(quat(w, v)),
  quatinv(quat(w, v)) := quat(w, -v) / (w^2 + v^2),
  quatsqr(quat(w, v)) := quat(w^2 - v^2, 2 * w * v),
  quat(w, v)^k := quatsqr(quat(w, v)^(k / 2))
                  :: integer(k) :: k > 0 :: k % 2 = 0,
  quat(w, v)^k := quatsqr(quat(w, v)^((k - 1) / 2)) * quat(w, v)
                  :: integer(k) :: k > 2,
  quat(w, v)^-k := quatinv(quat(w, v)^k) :: integer(k) :: k > 0 ]
```

Quaternions, like matrices, have non-commutative multiplication. In other words, q1 * q2 = q2 * q1 is not necessarily true if q1 and q2 are `quat` forms. The `quat*quat' rule above uses `plain` to prevent Calc from rearranging the product. It may also be wise to add the line `[quat(), matrix]' to the `Decls` matrix, to ensure that Calc's other algebraic operations will not rearrange a quaternion product. See section Declarations.

These rules also accept a four-argument `quat` form, converting it to the preferred form in the first rule. If you would rather see results in the four-argument form, just append the two items `phase(2), quat(w, [x, y, z]) := quat(w, x, y, z)' to the end of the rule set. (But remember that multi-phase rule sets don't work in

TOC

`EvalRules`.)

Go to the previous, next section.

Operating on Units

One special interpretation of algebraic formulas is as numbers with units. For example, the formula `5 m / s^2' can be read "five meters per second squared." The commands in this chapter help you manipulate units expressions in this form. Units-related commands begin with the u prefix key.

Basic Operations on Units

A units expression is a formula which is basically a number multiplied and/or divided by one or more unit names, which may optionally be raised to integer powers. Actually, the value part need not be a number; any product or quotient involving unit names is a units expression. Many of the units commands will also accept any formula, where the command applies to all units expressions which appear in the formula.

A unit name is a variable whose name appears in the unit table, or a variable whose name is a prefix character like `k' (for "kilo") or `u' (for "micro") followed by a name in the unit table. A substantial table of built-in units is provided with Calc; see section Predefined Units. You can also define your own unit names; see section User-Defined Units.

Note that if the value part of a units expression is exactly `1', it will be removed by the Calculator's automatic algebra routines: The formula `1 mm' is "simplified" to `mm'. This is only a display anomaly, however; `mm' will work just fine as a representation of one millimeter.

You may find that Algebraic Mode (see section Algebraic Entry) makes working with units expressions easier. Otherwise, you will have to remember to hit the apostrophe key every time you wish to enter units.

The u s (`calc-simplify-units`) [`usimplify`] command simplifies a units expression. It uses a s (`calc-simplify`) to simplify the expression first as a regular algebraic formula; it then looks for features that can be further simplified by converting one object's units to be compatible with another's. For example, `5 m + 23 mm' will simplify to `5.023 m'. When different but compatible units are added, the righthand term's units are converted to match those of the lefthand term. See section Simplification Modes, for a way to have this done automatically at all times.

Units simplification also handles quotients of two units with the same dimensionality, as in `2 in s/L cm' to `5.08 s/L'; fractional powers of unit expressions, as in `sqrt(9 mm^2)' to `3 mm' and `sqrt(9 acre)' to a quantity in meters; and `floor`, `ceil`, `round`, `rounde`, `roundu`, `trunc`, `float`, `frac`, `abs`, and `clean` applied to units expressions, in which case the operation in question is applied only to the numeric part of the expression. Finally, trigonometric functions of quantities with units of angle are evaluated, regardless of the current angular mode.

The u c (`calc-convert-units`) command converts a units expression to new, compatible units. For example, given the units expression `55 mph', typing u c m/s RET produces `24.5872 m/s'. If the units

you request are inconsistent with the original units, the number will be converted into your units times whatever "remainder" units are left over. For example, converting `55 mph' into acres produces `6.08 acre / m s'. (Recall that multiplication binds more strongly than division in Calc formulas, so the units here are acres per meter-second.) Remainder units are expressed in terms of "fundamental" units like `m' and `s', regardless of the input units.

One special exception is that if you specify a single unit name, and a compatible unit appears somewhere in the units expression, then that compatible unit will be converted to the new unit and the remaining units in the expression will be left alone. For example, given the input `980 cm/s^2', the command u c ms will change the `s' to `ms' to get `9.8e-4 cm/ms^2'. The "remainder unit" `cm' is left alone rather than being changed to the base unit `m'.

You can use explicit unit conversion instead of the u s command to gain more control over the units of the result of an expression. For example, given `5 m + 23 mm', you can type u c m or u c mm to express the result in either meters or millimeters. (For that matter, you could type u c fath to express the result in fathoms, if you preferred!)

In place of a specific set of units, you can also enter one of the units system names `si`, `mks` (equivalent), or `cgs`. For example, u c si RET converts the expression into International System of Units (SI) base units. Also, u c base converts to Calc's base units, which are the same as `si` units except that `base` uses `g' as the fundamental unit of mass whereas `si` uses `kg'.

The u c command also accepts composite units, which are expressed as the sum of several compatible unit names. For example, converting `30.5 in' to units `mi+ft+in' (miles, feet, and inches) produces `2 ft + 6.5 in'. Calc first sorts the unit names into order of decreasing relative size. It then accounts for as much of the input quantity as it can using an integer number times the largest unit, then moves on to the next smaller unit, and so on. Only the smallest unit may have a non-integer amount attached in the result. A few standard unit names exist for common combinations, such as `mfi` for `mi+ft+in', and `tpo` for `ton+lb+oz'. Composite units are expanded as if by a x, so that `(ft+in)/hr' is first converted to `ft/hr+in/hr'.

If the value on the stack does not contain any units, u c will prompt first for the old units which this value should be considered to have, then for the new units. Assuming the old and new units you give are consistent with each other, the result also will not contain any units. For example, u c cm RET in RET converts the number 2 on the stack to 5.08.

The u b (`calc-base-units`) command is shorthand for u c base; it converts the units expression on the top of the stack into `base` units. If u s does not simplify a units expression as far as you would like, try u b.

The u c and u b commands treat temperature units (like `degC' and `K') as relative temperatures. For example, u c converts `10 degC' to `18 degF': A change of 10 degrees Celsius corresponds to a change of 18 degrees Fahrenheit.

The u t (`calc-convert-temperature`) command converts absolute temperatures. The value on the stack must be a simple units expression with units of temperature only. This command would convert `10 degC' to `50 degF', the equivalent temperature on the Fahrenheit scale.

The u r (`calc-remove-units`) command removes units from the formula at the top of the stack. The

u x (`calc-extract-units`) command extracts only the units portion of a formula. These comm essentially replace every term of the formula that does or doesn't (respectively) look like a unit name the constant 1, then resimplify the formula.

The u a (`calc-autorange-units`) command turns on and off a mode in which unit prefixes like `k` ("kilo") are automatically applied to keep the numeric part of a units expression in a reasonable range. This mode affects u s and all units conversion commands except u b. For example, with autoranging on, `12345 Hz' will be simplified to `12.345 kHz'. Autoranging is useful for some kinds of units (like `Hz` and `m`), but is probably undesirable for non-metric units like `ft` and `tbsp`. (Composite units are more appropriate for those; see above.)

Autoranging always applies the prefix to the leftmost unit name. Calc chooses the largest prefix that causes the number to be greater than or equal to 1.0. Thus an increasing sequence of adjusted times would be `1 ms, 10 ms, 100 ms, 1 s, 10 s, 100 s, 1 ks'. Generally the rule of thumb is that the number will be adjusted to be in the interval `[1 .. 1000)', although there are several exceptions to this rule. First, if the unit has a power then this is not possible; `0.1 s^2' simplifies to `100000 ms^2'. Second, the "centi-" prefix is allowed to form `cm` (centimeters), but will not apply to other units. The "deci-," "deka-," and "hecto-" prefixes are never used. Thus the allowable interval is `[1 .. 10)' for millimeters and `[1 .. 100)' for centimeters. Finally, a prefix will not be added to a unit if the resulting name is also the actual name of another unit; `1e-15 t' would normally be considered a "femto-ton," but it is written as `1000 at' (1000 atto-tons) instead because `ft` would be confused with feet.

The Units Table

The u v (`calc-enter-units-table`) command displays the units table in another buffer called `*Units Table*`. Each entry in this table gives the unit name as it would appear in an expression, the definition of the unit in terms of simpler units, and a full name or description of the unit. Fundamental units are defined as themselves; these are the units produced by the u b command. The fundamental units are meters, seconds, grams, kelvins, amperes, candelas, moles, radians, and steradians.

The Units Table buffer also displays the Unit Prefix Table. Note that two prefixes, "kilo" and "hecto," accept either upper- or lower-case prefix letters. `Meg' is also accepted as a synonym for the `M' prefix. Whenever a unit name can be interpreted as either a built-in name or a prefix followed by another built-in name, the former interpretation wins. For example, `2 pt' means two pints, not two pico-tons.

The Units Table buffer, once created, is not rebuilt unless you define new units. To force the buffer to be rebuilt, give any numeric prefix argument to u v.

The u V (`calc-view-units-table`) command is like u v except that the cursor is not moved into the Units Table buffer. You can type u V again to remove the Units Table from the display. To return from the Units Table buffer after a u v, type M-# c again or use the regular Emacs C-x o (`other-window`) command. You can also kill the buffer with C-x k if you wish; the actual units table is safely stored inside the Calculator.

The u g (`calc-get-unit-definition`) command retrieves a unit's defining expression and pushes it onto the Calculator stack. For example, u g in will produce the expression `2.54 cm'. This is the same definition for the unit that would appear in the Units Table buffer. Note that this command works only

for actual unit names; u g km will report that no such unit exists, for example, because `km` is really th unit `m` with a `k` ("kilo") prefix. To see a definition of a unit in terms of base units, it is easier to push unit name on the stack and then reduce it to base units with u b.

The u e (`calc-explain-units`) command displays an English description of the units of the expression on the stack. For example, for the expression `62 km^2 g / s^2 mol K', the description is "Square-Kilometer Gram per (Second-squared Mole Degree-Kelvin)." This command uses the English descriptions that appear in the righthand column of the Units Table.

Predefined Units

Since the exact definitions of many kinds of units have evolved over the years, and since certain countries sometimes have local differences in their definitions, it is a good idea to examine Calc's definition of a unit before depending on its exact value. For example, there are three different units for gallons, corresponding to the US (`gal`), Canadian (`galC`), and British (`galUK`) definitions. Also, note that `oz` is a standard ounce of mass, `ozt` is a Troy ounce, and `ozfl` is a fluid ounce.

The temperature units corresponding to degrees Kelvin and Centigrade (Celsius) are the same in this table, since most units commands treat temperatures as being relative. The `calc-convert-temperature` command has special rules for handling the different absolute magnitudes of the various temperature scales.

The unit of volume "liters" can be referred to by either the lower-case `l` or the upper-case `L`.

The unit `A` stands for Amperes; the name `Ang` is used

The unit `pt` stands for pints; the name `point` stands for a typographical point, defined by `72 point = 1 in'. There is also `tpt`, which stands for a printer's point as defined by the TeX typesetting system: `72.27 tpt = 1 in'.

The unit `e` stands for the elementary (electron) unit of charge; because algebra command could mistake this for the special constant e, Calc provides the alternate unit name `ech` which is preferable to `e`.

The name `g` stands for one gram of mass; there is also `gf`, one gram of force. (Likewise for lb, pounds, and lbf.) Meanwhile, one "g" of acceleration is denoted `ga`.

The unit `ton` is a U.S. ton of `2000 lb', and `t` is a metric ton of `1000 kg'.

The names `s` (or `sec`) and `min` refer to units of time; `arcsec` and `arcmin` are units of angle.

Some "units" are really physical constants; for example, `c` represents the speed of light, and `h` represents Planck's constant. You can use these just like other units: converting `.5 c' to `m/s' expresses one-half the speed of light in meters per second. You can also use this merely as a handy reference; the u g command gets the definition of one of these constants in its normal terms, and u b expresses the definition in base units.

Two units, `pi` and `fsc` (the fine structure constant, approximately *1/137*) are dimensionless. The units simplification commands simply treat these names as equivalent to their corresponding values. However you can, for example, use u c to convert a pure number into multiples of the fine structure constant, or u

b to convert this back into a pure number. (When u c prompts for the "old units," just enter a blank li signify that the value really is unitless.)

User-Defined Units

Calc provides ways to get quick access to your selected "favorite" units, as well as ways to define your own new units.

To select your favorite units, store a vector of unit names or expressions in the Calc variable `Units`. The u 1 through u 9 commands (`calc-quick-units`) provide access to these units. If the value on the top of the stack is a plain number (with no units attached), then u 1 gives it the specified units. (Basically, it multiplies the number by the first item in the `Units` vector.) If the number on the stack *does* have units, then u 1 converts that number to the new units. For example, suppose the vector `[in, ft]' is stored in `Units`. Then 30 u 1 will create the expression `30 in', and u 2 will convert that expression to `2.5 ft'.

The u 0 command accesses the tenth element of `Units`. Only ten quick units may be defined at a time. If the `Units` variable has no stored value (the default), or if its value is not a vector, then the quick-units commands will not function. The s U command is a convenient way to edit the `Units` variable; see section Other Operations on Variables.

The u d (`calc-define-unit`) command records the units expression on the top of the stack as the definition for a new, user-defined unit. For example, putting `16.5 ft' on the stack and typing u d rod defines the new unit `rod' to be equivalent to 16.5 feet. The unit conversion and simplification commands will now treat `rod` just like any other unit of length. You will also be prompted for an optional English description of the unit, which will appear in the Units Table.

The u u (`calc-undefine-unit`) command removes a user-defined unit. It is not possible to remove one of the predefined units, however.

If you define a unit with an existing unit name, your new definition will replace the original definition of that unit. If the unit was a predefined unit, the old definition will not be replaced, only "shadowed." The built-in definition will reappear if you later use u u to remove the shadowing definition.

To create a new fundamental unit, use either 1 or the unit name itself as the defining expression. Otherwise the expression can involve any other units that you like (except for composite units like `mfi'). You can create a new composite unit with a sum of other units as the defining expression. The next unit operation like u c or u v will rebuild the internal unit table incorporating your modifications. Note that erroneous definitions (such as two units defined in terms of each other) will not be detected until the unit table is next rebuilt; u v is a convenient way to force this to happen.

Temperature units are treated specially inside the Calculator; it is not possible to create user-defined temperature units.

The u p (`calc-permanent-units`) command stores the user-defined units in your `.emacs' file, so that the units will still be available in subsequent Emacs sessions. If there was already a set of user-defined units in your `.emacs' file, it is replaced by the new set. (See section General Mode Commands, for a way to tell Calc to use a different file instead of `.emacs'.)

Go to the previous, next section.

Go to the previous, next section.

Storing and Recalling

Calculator variables are really just Lisp variables that contain numbers or formulas in a form that Calc can understand. The commands in this section allow you to manipulate variables conveniently. Commands related to variables use the s prefix key.

Storing Variables

The s s (`calc-store`) command stores the value at the top of the stack into a specified variable. It prompts you to enter the name of the variable. If you press a single digit, the value is stored immediately in one of the "quick" variables `var-q0` through `var-q9`. Or you can enter any variable name. The prefix `var-' is supplied for you; when a name appears in a formula (as in `a+q2') the prefix `var-' is also supplied there, so normally you can simply forget about `var-' everywhere. Its only purpose is to enable you to use Calc variables without fear of accidentally clobbering some variable in another Emacs package. If you really want to store in an arbitrary Lisp variable, just backspace over the `var-'.

The s s command leaves the stored value on the stack. There is also an s t (`calc-store-into`) command, which removes a value from the stack and stores it in a variable.

If the top of stack value is an equation `a = 7' or assignment `a := 7' with a variable on the lefthand side, then Calc will assign that variable with that value by default, i.e., if you type s s RET or s t RET. In this example, the value 7 would be stored in the variable `a'. (If you do type a variable name at the prompt, the top-of-stack value is stored in its entirety, even if it is an equation: `s s b RET' with `a := 7' on the stack stores `a := 7' in `b`.)

In fact, the top of stack value can be a vector of equations or assignments with different variables on their lefthand sides; the default will be to store all the variables with their corresponding righthand sides simultaneously.

It is also possible to type an equation or assignment directly at the prompt for the s s or s t command: s s foo = 7. In this case the expression to the right of the = or := symbol is evaluated as if by the = command, and that value is stored in the variable. No value is taken from the stack; s s and s t are equivalent when used in this way.

The prefix keys s and t may be followed immediately by a digit; s 9 is equivalent to s s 9, and t 9 is equivalent to s t 9. (The t prefix is otherwise used for trail and time/date commands.)

There are also several "arithmetic store" commands. For example, s + removes a value from the stack and adds it to the specified variable. The other arithmetic stores are s -, s *, s /, s ^, and s | (vector concatenation), plus s n and s & which negate or invert the value in a variable, and s [and s] which decrease or increase a variable by one.

All the arithmetic stores accept the Inverse prefix to reverse the order of the operands. If v represents the contents of the variable, and a is the value drawn from the stack, then regular s - assigns @c{$v \coloneq

v - a$} v := v - a, but I s - assigns v := a - v. While I s * might seem pointless, it is useful if matrix multiplication is involved. Actually, all the arithmetic stores use formulas designed to behave usefully both forwards and backwards:

```
s +         v := v + a          v := a + v
s -         v := v - a          v := a - v
s *         v := v * a          v := a * v
s /         v := v / a          v := a / v
s ^         v := v ^ a          v := a ^ v
s |         v := v | a          v := a | v
s n         v := v / (-1)       v := (-1) / v
s &         v := v ^ (-1)       v := (-1) ^ v
s [         v := v - 1          v := 1 - v
s ]         v := v - (-1)       v := (-1) - v
```

In the last four cases, a numeric prefix argument will be used in place of the number one. (For example, M-2 s] increases a variable by 2, and M-2 I s] replaces a variable by minus-two minus the variable.

The first six arithmetic stores can also be typed s t +, s t -, etc. The commands s s +, s s -, and so on are analogous arithmetic stores that don't remove the value a from the stack.

All arithmetic stores report the new value of the variable in the Trail for your information. They signal an error if the variable previously had no stored value. If default simplifications have been turned off, the arithmetic stores temporarily turn them on for numeric arguments only (i.e., they temporarily do an m N command). See section Simplification Modes. Large vectors put in the trail by these commands always use abbreviated (t .) mode.

The s m command is a general way to adjust a variable's value using any Calc function. It is a "mapping" command analogous to V M, V R, etc. See section Reducing and Mapping Vectors, to see how to specify a function for a mapping command. Basically, all you do is type the Calc command key that would invoke that function normally. For example, s m n applies the n key to negate the contents of the variable, so s m n is equivalent to s n. Also, s m Q takes the square root of the value stored in a variable, s m v v uses v v to reverse the vector stored in the variable, and s m H I S takes the hyperbolic arcsine of the variable contents.

If the mapping function takes two or more arguments, the additional arguments are taken from the stack; the old value of the variable is provided as the first argument. Thus s m - with a on the stack computes v - a, just like s -. With the Inverse prefix, the variable's original value becomes the *last* argument instead of the first. Thus I s m - is also equivalent to I s -.

The s x (`calc-store-exchange`) command exchanges the value of a variable with the value on the top of the stack. Naturally, the variable must already have a stored value for this to work.

You can type an equation or assignment at the s x prompt. The command s x a=6 takes no values from the stack; instead, it pushes the old value of `a' on the stack and stores `a = 6'.

Until you store something in them, variables are "void," that is, they contain no value at all. If they appear in an algebraic formula they will be left alone even if you press = (`calc-evaluate`). The s u

(`calc-unstore`) command returns a variable to the void state.

The only variables with predefined values are the "special constants" `pi`, `e`, `i`, `phi`, and `gamma`. You are free to unstore these variables or to store new values into them if you like, although some of the algebraic-manipulation functions may assume these variables represent their standard values. Calc displays a warning if you change the value of one of these variables, or of one of the other special variables `inf`, `uinf`, and `nan` (which are normally void).

Note that `var-pi` doesn't actually have 3.14159265359 stored in it, but rather a special magic value that evaluates to @c{π} pi at the current precision. Likewise `var-e`, `var-i`, and `var-phi` evaluate according to the current precision or polar mode. If you recall a value from `pi` and store it back, this magic property will be lost.

The s c (`calc-copy-variable`) command copies the stored value of one variable to another. It differs from a simple s r followed by an s t in two important ways. First, the value never goes on the stack and thus is never rounded, evaluated, or simplified in any way; it is not even rounded down to the current precision. Second, the "magic" contents of a variable like `var-e` can be copied into another variable with this command, perhaps because you need to unstore `var-e` right now but you wish to put it back when you're done. The s c command is the only way to manipulate these magic values intact.

Recalling Variables

The most straightforward way to extract the stored value from a variable is to use the s r (`calc-recall`) command. This command prompts for a variable name (similarly to `calc-store`), looks up the value of the specified variable, and pushes that value onto the stack. It is an error to try to recall a void variable.

It is also possible to recall the value from a variable by evaluating a formula containing that variable. For example, ' a RET = is the same as s r a RET except that if the variable is void, the former will simply leave the formula `a' on the stack whereas the latter will produce an error message.

The r prefix may be followed by a digit, so that r 9 is equivalent to s r 9. (The r prefix is otherwise unused in the current version of Calc.)

Other Operations on Variables

The s e (`calc-edit-variable`) command edits the stored value of a variable without ever putting that value on the stack or simplifying or evaluating the value. It prompts for the name of the variable to edit. If the variable has no stored value, the editing buffer will start out empty. If the editing buffer is empty when you press M-# M-# to finish, the variable will be made void. See section Editing Stack Entries, for a general description of editing.

The s e command is especially useful for creating and editing rewrite rules which are stored in variables. Sometimes these rules contain formulas which must not be evaluated until the rules are actually used. (For example, they may refer to `deriv(x,y)', where `x` will someday become some expression involving `y`; if you let Calc evaluate the rule while you are defining it, Calc will replace `deriv(x,y)' with 0 because

the formula `x` does not itself refer to `y`.) By contrast, recalling the variable, editing with `, and storing will evaluate the variable's value as a side effect of putting the value on the stack.

There are several special-purpose variable-editing commands that use the s prefix followed by a shifted letter:

s A
: Edit `AlgSimpRules`. See section Algebraic Simplifications.

s D
: Edit `Decls`. See section Declarations.

s E
: Edit `EvalRules`. See section Default Simplifications.

s F
: Edit `FitRules`. See section Curve Fitting.

s G
: Edit `GenCount`. See section Solving Equations.

s H
: Edit `Holidays`. See section Business Days.

s I
: Edit `IntegLimit`. See section Calculus.

s L
: Edit `LineStyles`. See section Graphics.

s P
: Edit `PointStyles`. See section Graphics.

s R
: Edit `PlotRejects`. See section Graphics.

s T
: Edit `TimeZone`. See section Time Zones.

s U
: Edit `Units`. See section User-Defined Units.

s X
: Edit `ExtSimpRules`. See section "Unsafe" Simplifications.

These commands are just versions of s e that use fixed variable names rather than prompting for the variable name.

The s p (`calc-permanent-variable`) command saves a variable's value permanently in your `.emacs' file, so that its value will still be available in future Emacs sessions. You can re-execute s p later on to update the saved value, but the only way to remove a saved variable is to edit your

`.emacs' file by hand. (See section General Mode Commands, for a way to tell Calc to use a diffe file instead of `.emacs'.)

If you do not specify the name of a variable to save (i.e., s p RET), all `var-' variables with defined values are saved except for the special constants `pi', `e', `i', `phi', and `gamma'; the variables `TimeZone' and `PlotRejects'; `FitRules', `DistribRules', and other built-in rewrite rules; and `PlotDatan' variables generated by the graphics commands. (You can still save these variables by explicitly naming them in an s p command.)

The s i (`calc-insert-variables') command writes the values of all `var-' variables into a specified buffer. The variables are written in the form of Lisp `setq' commands which store the values in string form. You can place these commands in your `.emacs' buffer if you wish, though in this case it would be easier to use s p RET. (Note that s i omits the same set of variables as s p RET; the difference is that s i will store the variables in any buffer, and it also stores in a more human-readable format.)

The Let Command

If you have an expression like `a+b^2' on the stack and you wish to compute its value where b=3, you can simply store 3 in b and then press = to reevaluate the formula. This has the side-effect of leaving the stored value of 3 in b for future operations.

The s l (`calc-let') command evaluates a formula under a *temporary* assignment of a variable. It stores the value on the top of the stack into the specified variable, then evaluates the second-to-top stack entry, then restores the original value (or lack of one) in the variable. Thus after ' a+b^2 RET 3 s l b RET, the stack will contain the formula `a + 9'. The subsequent command 5 s l a RET will replace this formula with the number 14. The variables `a' and `b' are not permanently affected in any way by these commands.

The value on the top of the stack may be an equation or assignment, or a vector of equations or assignments, in which case the default will be analogous to the case of s t RET. See section Storing Variables.

Also, you can answer the variable-name prompt with an equation or assignment: s l b=3 RET is the same as storing 3 on the stack and typing s l b RET.

The a b (`calc-substitute') command is another way to substitute a variable with a value in a formula. It does an actual substitution rather than temporarily assigning the variable and evaluating. For example, letting n=2 in `f(n pi)' with a b will produce `f(2 pi)', whereas s l would give `f(6.28)' since the evaluation step will also evaluate `pi'.

The Evaluates-To Operator

The special algebraic symbol `=>' is known as the evaluates-to operator. (It will show up as an `evalto' function call in other language modes like Pascal and TeX.) This is a binary operator, that is, it has a lefthand and a righthand argument, although it can be entered with the righthand argument omitted.

A formula like `a => b' is evaluated by Calc as follows: First, a is not simplified or modified in any w
The previous value of argument b is thrown away; the formula a is then copied and evaluated as if by
= command according to all current modes and stored variable values, and the result is installed as the
new value of b.

For example, suppose you enter the algebraic formula `2 + 3 => 17'. The number 17 is ignored, and the lefthand argument is left in its unevaluated form; the result is the formula `2 + 3 => 5'.

You can enter an `=>' formula either directly using algebraic entry (in which case the righthand side may be omitted since it is going to be replaced right away anyhow), or by using the s = (`calc-evalto`) command, which takes a from the stack and replaces it with `a => b'.

Calc keeps track of all `=>' operators on the stack, and recomputes them whenever anything changes that might affect their values, i.e., a mode setting or variable value. This occurs only if the `=>' operator is at the top level of the formula, or if it is part of a top-level vector. In other words, pushing `2 + (a => 17)' will change the 17 to the actual value of `a' when you enter the formula, but the result will not be dynamically updated when `a' is changed later because the `=>' operator is buried inside a sum. However, a vector of `=>' operators will be recomputed, since it is convenient to push a vector like `[a =>, b =>, c =>]' on the stack to make a concise display of all the variables in your problem. (Another way to do this would be to use `[a, b, c] =>', which provides a slightly different format of display. You can use whichever you find easiest to read.)

The m C (`calc-auto-recompute`) command allows you to turn this automatic recomputation on or off. If you turn recomputation off, you must explicitly recompute an `=>' operator on the stack in one of the usual ways, such as by pressing =. Turning recomputation off temporarily can save a lot of time if you will be changing several modes or variables before you look at the `=>' entries again.

Most commands are not especially useful with `=>' operators as arguments. For example, given `x + 2 => 17', it won't work to type 1 + to get `x + 3 => 18'. If you want to operate on the lefthand side of the `=>' operator on the top of the stack, type j 1 (that's the digit "one") to select the lefthand side, execute your commands, then type j u to unselect.

All current modes apply when an `=>' operator is computed, including the current simplification mode. Recall that the formula `x + y + x' is not handled by Calc's default simplifications, but the a s command will reduce it to the simpler form `y + 2 x'. You can also type m A to enable an algebraic-simplification mode in which the equivalent of a s is used on all of Calc's results. If you enter `x + y + x =>' normally, the result will be `x + y + x => x + y + x'. If you change to algebraic-simplification mode, the result will be `x + y + x => y + 2 x'. However, just pressing a s once will have no effect on `x + y + x => x + y + x', because the righthand side depends only on the lefthand side and the current mode settings, and the lefthand side is not affected by commands like a s.

The "let" command (s l) has an interesting interaction with the `=>' operator. The s l command evaluates the second-to-top stack entry with the top stack entry supplying a temporary value for a given variable. As you might expect, if that stack entry is an `=>' operator its righthand side will temporarily show this value for the variable. In fact, all `=>'s on the stack will be updated if they refer to that variable. But this change is temporary in the sense that the next command that causes Calc to look at those stack entries will make them revert to the old variable value.

```
2:  a => a              2:  a => 17          2:  a => a
1:  a + 1 => a + 1      1:  a + 1 => 18      1:  a + 1 => a + 1
    .                       .                    .

                            17 s l a RET         p 8 RET
```

Here the p 8 command changes the current precision, thus causing the `=>' forms to be recomputed after the influence of the "let" is gone. The d SPC command (`calc-refresh`) is a handy way to force the `=>' operators on the stack to be recomputed without any other side effects.

Embedded Mode also uses `=>' operators. In embedded mode, the lefthand side of an `=>' operator can refer to variables assigned elsewhere in the file by `:=' operators. The assignment operator `a := 17' does not actually do anything by itself. But Embedded Mode recognizes it and marks it as a sort of file-local definition of the variable. You can enter `:=' operators in algebraic mode, or by using the s : (`calc-assign`) [`assign`] command which takes a variable and value from the stack and replaces them with an assignment.

See section TeX Language Mode, for the way `=>' appears in TeX language output. The eqn mode gives similar treatment to `=>'.

Go to the previous, next section.

Go to the previous, next section.

Graphics

The commands for graphing data begin with the g prefix key. Calc uses GNUPLOT 2.0 or 3.0 to do graphics. These commands will only work if GNUPLOT is available on your system. (While GNUPLOT sounds like a relative of GNU Emacs, it is actually completely unrelated. However, it is free software and can be obtained from the Free Software Foundation's machine `prep.ai.mit.edu'.)

If you have GNUPLOT installed on your system but Calc is unable to find it, you may need to set the `calc-gnuplot-name` variable in your `.emacs' file. You may also need to set some Lisp variables to show Calc how to run GNUPLOT on your system; these are described under g D and g O below. If you are using the X window system, Calc will configure GNUPLOT for you automatically. If you have GNUPLOT 3.0 and you are not using X, Calc will configure GNUPLOT to display graphs using simple character graphics that will work on any terminal.

Basic Graphics

The easiest graphics command is g f (`calc-graph-fast`). This command takes two vectors of equal length from the stack. The vector at the top of the stack represents the "y" values of the various data points. The vector in the second-to-top position represents the corresponding "x" values. This command runs GNUPLOT (if it has not already been started by previous graphing commands) and displays the set of data points. The points will be connected by lines, and there will also be some kind of symbol to indicate the points themselves.

The "x" entry may instead be an interval form, in which case suitable "x" values are interpolated between the minimum and maximum values of the interval (whether the interval is open or closed is ignored).

The "x" entry may also be a number, in which case Calc uses the sequence of "x" values x, x+1, x+2, etc. (Generally the number 0 or 1 would be used for x in this case.)

The "y" entry may be any formula instead of a vector. Calc effectively uses N (`calc-eval-num`) to evaluate variables in the formula; the result of this must be a formula in a single (unassigned) variable. The formula is plotted with this variable taking on the various "x" values. Graphs of formulas by default use lines without symbols at the computed data points. Note that if neither "x" nor "y" is a vector, Calc guesses at a reasonable number of data points to use. See the g N command below. (The "x" values must be either a vector or an interval if "y" is a formula.)

If "y" is (or evaluates to) a formula of the form `xy(x, y)' then the result is a parametric plot. The two arguments of the fictitious `xy` function are used as the "x" and "y" coordinates of the curve, respectively. In this case the "x" vector or interval you specified is not directly visible in the graph. For example, if "x" is the interval `[0..360]' and "y" is the formula `xy(sin(t), cos(t))', the resulting graph will be a circle.

Also, "x" and "y" may each be variable names, in which case Calc looks for suitable vectors, intervals, or formulas stored in those variables.

The "x" and "y" values for the data points (as pulled from the vectors, calculated from the formulas, or interpolated from the intervals) should be real numbers (integers, fractions, or floats). If either the "x" value or the "y" value of a given data point is not a real number, that data point will be omitted from the graph. The points on either side of the invalid point will *not* be connected by a line.

See the documentation for g a below for a description of the way numeric prefix arguments affect g f.

If you store an empty vector in the variable `PlotRejects` (i.e., [ ] s t PlotRejects), Calc will append information to this vector for every data point which was rejected because its "x" or "y" values were not real numbers. The result will be a matrix where each row holds the curve number, data point number, "x" value, and "y" value for a rejected data point. See section The Evaluates-To Operator, for a handy way to keep tabs on the current value of `PlotRejects`. See section Other Operations on Variables, for the s R command which is another easy way to examine `PlotRejects`.

To clear the graphics display, type g c (`calc-graph-clear`). If the GNUPLOT output device is an X window, the window will go away. Effects on other kinds of output devices will vary. You don't need to use g c if you don't want to--if you give another g f or g p command later on, it will reuse the existing graphics window if there is one.

Three-Dimensional Graphics

The g F (`calc-graph-fast-3d`) command makes a three-dimensional graph. It works only if you have GNUPLOT 3.0 or later; with GNUPLOT 2.0, you will see a GNUPLOT error message if you try this command.

The g F command takes three values from the stack, called "x", "y", and "z", respectively. As was the case for 2D graphs, there are several options for these values.

In the first case, "x" and "y" are each vectors (not necessarily of the same length); either or both may instead be interval forms. The "z" value must be a matrix with the same number of rows as elements in "x", and the same number of columns as elements in "y". The result is a surface plot where @c{z_{ij}} z_ij is the height of the point at coordinate (x_i, y_j) on the surface. The 3D graph will be displayed from a certain default viewpoint; you can change this viewpoint by adding a `set view' to the `*Gnuplot Commands*' buffer as described later. See the GNUPLOT 3.0 documentation for a description of the `set view' command.

Each point in the matrix will be displayed as a dot in the graph, and these points will be connected by a grid of lines (isolines).

In the second case, "x", "y", and "z" are all vectors of equal length. The resulting graph displays a 3D line instead of a surface, where the coordinates of points along the line are successive triplets of values from the input vectors.

In the third case, "x" and "y" are vectors or interval forms, and "z" is any formula involving two variables (not counting variables with assigned values). These variables are sorted into alphabetical order; the first takes on values from "x" and the second takes on values from "y" to form a matrix of results that are graphed as a 3D surface.

If the "z" formula evaluates to a call to the fictitious function `xyz(x, y, z)', then the result is a "parametric surface." In this case, the axes of the graph are taken from the x and y values in these calls, and the "x" and "y" values from the input vectors or intervals are used only to specify the range of inputs to the formula. For example, plotting `[0..360], [0..180], xyz(sin(x)*sin(y), cos(x)*sin(y), cos(y))' will draw a sphere. (Since the default resolution for 3D plots is 5 steps in each of "x" and "y", this will draw a very crude sphere. You could use the g N command, described below, to increase this resolution, or specify the "x" and "y" values as vectors with more than 5 elements.

It is also possible to have a function in a regular g f plot evaluate to an `xyz` call. Since g f plots a line, not a surface, the result will be a 3D parametric line. For example, `[[0..720], xyz(sin(x), cos(x), x)]' will plot two turns of a helix (a three-dimensional spiral).

As for g f, each of "x", "y", and "z" may instead be variables containing the relevant data.

Managing Curves

The g f command is really shorthand for the following commands: C-u g d g a g p. Likewise, g F is shorthand for C-u g d g A g p. You can gain more control over your graph by using these commands directly.

The g a (`calc-graph-add`) command adds the "curve" represented by the two values on the top of the stack to the current graph. You can have any number of curves in the same graph. When you give the g p command, all the curves will be drawn superimposed on the same axes.

The g a command (and many others that affect the current graph) will cause a special buffer, `*Gnuplot Commands*', to be displayed in another window. This buffer is a template of the commands that will be sent to GNUPLOT when it is time to draw the graph. The first g a command adds a `plot` command to this buffer. Succeeding g a commands add extra curves onto that `plot` command. Other graph-related commands put other GNUPLOT commands into this buffer. In normal usage you never need to work with this buffer directly, but you can if you wish. The only constraint is that there must be only one `plot` command, and it must be the last command in the buffer. If you want to save and later restore a complete graph configuration, you can use regular Emacs commands to save and restore the contents of the `*Gnuplot Commands*' buffer.

If the values on the stack are not variable names, g a will invent variable names for them (of the form `PlotDatan') and store the values in those variables. The "x" and "y" variables are what go into the `plot` command in the template. If you add a curve that uses a certain variable and then later change that variable, you can replot the graph without having to delete and re-add the curve. That's because the variable name, not the vector, interval or formula itself, is what was added by g a.

A numeric prefix argument on g a or g f changes the way stack entries are interpreted as curves. With a positive prefix argument n, the top n stack entries are "y" values for n different curves which share a common "x" value in the n+1st stack entry. (Thus g a with no prefix argument is equivalent to C-u 1 g a.)

A prefix of zero or plain C-u means to take two stack entries, "x" and "y" as usual, but to interpret "y" as a vector of "y" values for several curves that share a common "x".

A negative prefix argument tells Calc to read n vectors from the stack; each vector [x, y] describes an

independent curve. This is the only form of g a that creates several curves at once that don't have common "x" values. (Of course, the range of "x" values covered by all the curves ought to be roughly same if they are to look nice on the same graph.)

For example, to plot @c{$\sin n x$} sin(n x) for integers n from 1 to 5, you could use v x to create a vector of integers (n), then V M ' or V M $ to map `sin(n x)' across this vector. The resulting vector of formulas is suitable for use as the "y" argument to a C-u g a or C-u g f command.

The g A (`calc-graph-add-3d`) command adds a 3D curve to the graph. It is not legal to intermix 2D and 3D curves in a single graph. This command takes three arguments, "x", "y", and "z", from the stack. With a positive prefix n, it takes n+2 arguments (common "x" and "y", plus n separate "z"s). With a zero prefix, it takes three stack entries but the "z" entry is a vector of curve values. With a negative prefix -n, it takes n vectors of the form [x, y, z]. The g A command works by adding a `splot` (surface-plot) command to the `*Gnuplot Commands*' buffer.

(Although g a adds a 2D `plot` command to the `*Gnuplot Commands*' buffer, Calc changes this to `splot` before sending it to GNUPLOT if it notices that the data points are evaluating to `xyz` calls. It will not work to mix 2D and 3D g a curves in a single graph, although Calc does not currently check for this.)

The g d (`calc-graph-delete`) command deletes the most recently added curve from the graph. It has no effect if there are no curves in the graph. With a numeric prefix argument of any kind, it deletes all of the curves from the graph.

The g H (`calc-graph-hide`) command "hides" or "unhides" the most recently added curve. A hidden curve will not appear in the actual plot, but information about it such as its name and line and point styles will be retained.

The g j (`calc-graph-juggle`) command moves the curve at the end of the list (the "most recently added curve") to the front of the list. The next-most-recent curve is thus exposed for g d or similar commands to use. With g j you can work with any curve in the graph even though curve-related commands only affect the last curve in the list.

The g p (`calc-graph-plot`) command uses GNUPLOT to draw the graph described in the `*Gnuplot Commands*' buffer. Any GNUPLOT parameters which are not defined by commands in this buffer are reset to their default values. The variables named in the `plot` command are written to a temporary data file and the variable names are then replaced by the file name in the template. The resulting plotting commands are fed to the GNUPLOT program. See the documentation for the GNUPLOT program for more specific information. All temporary files are removed when Emacs or GNUPLOT exits.

If you give a formula for "y", Calc will remember all the values that it calculates for the formula so that later plots can reuse these values. Calc throws out these saved values when you change any circumstances that may affect the data, such as switching from Degrees to Radians mode, or changing the value of a parameter in the formula. You can force Calc to recompute the data from scratch by giving a negative numeric prefix argument to g p.

Calc uses a fairly rough step size when graphing formulas over intervals. This is to ensure quick response. You can "refine" a plot by giving a positive numeric prefix argument to g p. Calc goes through the data points it has computed and saved from previous plots of the function, and computes and inserts a

new data point midway between each of the existing points. You can refine a plot any number of tim but beware that the amount of calculation involved doubles each time.

Calc does not remember computed values for 3D graphs. This means the numerix prefix argument, if any, to g p is effectively ignored if the current graph is three-dimensional.

The g P (`calc-graph-print`) command is like g p, except that it sends the output to a printer instead of to the screen. More precisely, g p looks for `set terminal' or `set output' commands in the `*Gnuplot Commands*' buffer; lacking these it uses the default settings. However, g P ignores `set terminal' and `set output' commands and uses a different set of default values. All of these values are controlled by the g D and g O commands discussed below. Provided everything is set up properly, g p will plot to the screen unless you have specified otherwise and g P will always plot to the printer.

Graphics Options

The g g (`calc-graph-grid`) command turns the "grid" on and off. It is off by default; tick marks appear only at the edges of the graph. With the grid turned on, dotted lines appear across the graph at each tick mark. Note that this command only changes the setting in `*Gnuplot Commands*'; to see the effects of the change you must give another g p command.

The g b (`calc-graph-border`) command turns the border (the box that surrounds the graph) on and off. It is on by default. This command will only work with GNUPLOT 3.0 and later versions.

The g k (`calc-graph-key`) command turns the "key" on and off. The key is a chart in the corner of the graph that shows the correspondence between curves and line styles. It is off by default, and is only really useful if you have several curves on the same graph.

The g N (`calc-graph-num-points`) command allows you to select the number of data points in the graph. This only affects curves where neither "x" nor "y" is specified as a vector. Enter a blank line to revert to the default value (initially 15). With no prefix argument, this command affects only the current graph. With a positive prefix argument this command changes or, if you enter a blank line, displays the default number of points used for all graphs created by g a that don't specify the resolution explicitly. With a negative prefix argument, this command changes or displays the default value (initially 5) used for 3D graphs created by g A. Note that a 3D setting of 5 means that a total of 5^2 = 25 points will be computed for the surface.

Data values in the graph of a function are normally computed to a precision of five digits, regardless of the current precision at the time. This is usually more than adequate, but there are cases where it will not be. For example, plotting 1 + x with x in the interval `[0 .. 1e-6]' will round all the data points down to 1.0! Putting the command `set precision n' in the `*Gnuplot Commands*' buffer will cause the data to be computed at precision n instead of 5. Since this is such a rare case, there is no keystroke-based command to set the precision.

The g h (`calc-graph-header`) command sets the title for the graph. This will show up centered above the graph. The default title is blank (no title).

The g n (`calc-graph-name`) command sets the title of an individual curve. Like the other curve-manipulating commands, it affects the most recently added curve, i.e., the last curve on the list in

the `*Gnuplot Commands*' buffer. To set the title of the other curves you must first juggle them to t
end of the list with g j, or edit the `*Gnuplot Commands*' buffer by hand. Curve titles appear in the l
if the key is turned off they are not used.

The g t (`calc-graph-title-x`) and g T (`calc-graph-title-y`) commands set the titles on the "x" and "y" axes, respectively. These titles appear next to the tick marks on the left and bottom edges of the graph, respectively. Calc does not have commands to control the tick marks themselves, but you can edit them into the `*Gnuplot Commands*' buffer if you wish. See the GNUPLOT documentation for details.

The g r (`calc-graph-range-x`) and g R (`calc-graph-range-y`) commands set the range of values on the "x" and "y" axes, respectively. You are prompted to enter a suitable range. This should be either a pair of numbers of the form, `min:max', or a blank line to revert to the default behavior of setting the range based on the range of values in the data, or `$' to take the range from the top of the stack. Ranges on the stack can be represented as either interval forms or vectors: `[min .. max]' or `[min, max]'.

The g l (`calc-graph-log-x`) and g L (`calc-graph-log-y`) commands allow you to set either or both of the axes of the graph to be logarithmic instead of linear.

For 3D plots, g C-t, g C-r, and g C-l (those are letters with the Control key held down) are the corresponding commands for the "z" axis.

The g z (`calc-graph-zero-x`) and g Z (`calc-graph-zero-y`) commands control whether a dotted line is drawn to indicate the "x" and/or "y" zero axes. (These are the same dotted lines that would be drawn there anyway if you used g g to turn the "grid" feature on.) Zero-axis lines are on by default, and may be turned off only in GNUPLOT 3.0 and later versions. They are not available for 3D plots.

The g s (`calc-graph-line-style`) command turns the connecting lines on or off for the most recently added curve, and optionally selects the style of lines to be used for that curve. Plain g s simply toggles the lines on and off. With a numeric prefix argument, g s turns lines on and sets a particular line style. Line style numbers start at one and their meanings vary depending on the output device. GNUPLOT guarantees that there will be at least six different line styles available for any device.

The g S (`calc-graph-point-style`) command similarly turns the symbols at the data points on or off, or sets the point style. If you turn both lines and points off, the data points will show as tiny dots.

Another way to specify curve styles is with the `LineStyles` and `PointStyles` variables. These variables initially have no stored values, but if you store a vector of integers in one of these variables, the g a and g f commands will use those style numbers instead of the defaults for new curves that are added to the graph. An entry should be a positive integer for a specific style, or 0 to let the style be chosen automatically, or *-1* to turn off lines or points altogether. If there are more curves than elements in the vector, the last few curves will continue to have the default styles. Of course, you can later use g s and g S to change any of these styles.

For example, '[2 -1 3] RET s t LineStyles causes the first curve to have lines in style number 2, the second curve to have no connecting lines, and the third curve to have lines in style 3. Point styles will still be assigned automatically, but you could store another vector in `PointStyles` to define them, too.

Graphical Devices

The g D (`calc-graph-device`) command sets the device name (or "terminal name" in GNUPLOT lingo) to be used by g p commands on this graph. It does not affect the permanent default device name. If you enter a blank name, the device name reverts to the default. Enter `?' to see a list of supported devices.

With a positive numeric prefix argument, g D instead sets the default device name, used by all plots in the future which do not override it with a plain g D command. If you enter a blank line this command shows you the current default. The special name `default` signifies that Calc should choose `x11` if the X window system is in use (as indicated by the presence of a `DISPLAY` environment variable), or otherwise `dumb` under GNUPLOT 3.0 and later, or `postscript` under GNUPLOT 2.0. This is the initial default value.

The `dumb` device is an interface to "dumb terminals," i.e., terminals with no special graphics facilities. It writes a crude picture of the graph composed of characters like `-` and `|` to a buffer called `*Gnuplot Trail*', which Calc then displays. The graph is made the same size as the Emacs screen, which on most dumb terminals will be @c{80×24} 80x24 characters. The graph is displayed in an Emacs "recursive edit"; type q or M-# M-# to exit the recursive edit and return to Calc. Note that the `dumb` device is present only in GNUPLOT 3.0 and later versions.

The word `dumb` may be followed by two numbers separated by spaces. These are the desired width and height of the graph in characters. Also, the device name `big` is like `dumb` but creates a graph four times the width and height of the Emacs screen. You will then have to scroll around to view the entire graph. In the `*Gnuplot Trail*' buffer, SPC, DEL, <, and > are defined to scroll by one screenful in each of the four directions.

With a negative numeric prefix argument, g D sets or displays the device name used by g P (`calc-graph-print`). This is initially `postscript`. If you don't have a PostScript printer, you may decide once again to use `dumb` to create a plot on any text-only printer.

The g O (`calc-graph-output`) command sets the name of the output file used by GNUPLOT. For some devices, notably `x11`, there is no output file and this information is not used. Many other "devices" are really file formats like `postscript`; in these cases the output in the desired format goes into the file you name with g O. Type g O stdout RET to set GNUPLOT to write to its standard output stream, i.e., to `*Gnuplot Trail*'. This is the default setting.

Another special output name is `tty`, which means that GNUPLOT is going to write graphics commands directly to its standard output, which you wish Emacs to pass through to your terminal. Tektronix graphics terminals, among other devices, operate this way. Calc does this by telling GNUPLOT to write to a temporary file, then running a sub-shell executing the command `cat tempfile >/dev/tty'. On typical Unix systems, this will copy the temporary file directly to the terminal, bypassing Emacs entirely. You will have to type C-l to Emacs afterwards to refresh the screen.

Once again, g O with a positive or negative prefix argument sets the default or printer output file names, respectively. In each case you can specify `auto`, which causes Calc to invent a temporary file name for each g p (or g P) command. This temporary file will be deleted once it has been displayed or printed. If the output file name is not `auto`, the file is not automatically deleted.

The default and printer devices and output files can be saved permanently by the m m (`calc-save-modes`) command. The default number of data points (see g N) and the X geometry (see g X) are also saved. Other graph information is *not* saved; you can save a graph's configuration simply by saving the contents of the `*Gnuplot Commands*' buffer.

If you are installing Calc you may wish to configure the default and printer devices and output files for the whole system. The relevant Lisp variables are `calc-gnuplot-default-device` and `-output`, and `calc-gnuplot-print-device` and `-output`. The output file names must be either strings as described above, or Lisp expressions which are evaluated on the fly to get the output file names.

Other important Lisp variables are `calc-gnuplot-plot-command` and `calc-gnuplot-print-command`, which give the system commands to display or print the output of GNUPLOT, respectively. These may be `nil` if no command is necessary, or strings which can include `%s' to signify the name of the file to be displayed or printed. Or, these variables may contain Lisp expressions which are evaluated to display or print the output.

The g x (`calc-graph-display`) command lets you specify on which X window system display your graphs should be drawn. Enter a blank line to see the current display name. This command has no effect unless the current device is `x11`.

The g X (`calc-graph-geometry`) command is a similar command for specifying the position and size of the X window. The normal value is `default`, which generally means your window manager will let you place the window interactively. Entering `800x500+0+0' would create an 800-by-500 pixel window in the upper-left corner of the screen.

The buffer called `*Gnuplot Trail*' holds a transcript of the session with GNUPLOT. This shows the commands Calc has "typed" to GNUPLOT and the responses it has received. Calc tries to notice when an error message has appeared here and display the buffer for you when this happens. You can check this buffer yourself if you suspect something has gone wrong.

The g C (`calc-graph-command`) command prompts you to enter any line of text, then simply sends that line to the current GNUPLOT process. The `*Gnuplot Trail*' buffer looks deceptively like a Shell buffer but you can't type commands in it yourself. Instead, you must use g C for this purpose.

The g v (`calc-graph-view-commands`) and g V (`calc-graph-view-trail`) commands display the `*Gnuplot Commands*' and `*Gnuplot Trail*' buffers, respectively, in another window. This happens automatically when Calc thinks there is something you will want to see in either of these buffers. If you type g v or g V when the relevant buffer is already displayed, the buffer is hidden again.

One reason to use g v is to add your own commands to the `*Gnuplot Commands*' buffer. Press g v, then use C-x o to switch into that window. For example, GNUPLOT has `set label' and `set arrow' commands that allow you to annotate your plots. Since Calc doesn't understand these commands, you have to add them to the `*Gnuplot Commands*' buffer yourself, then use g p to replot using these new commands. Note that your commands must appear *before* the `plot` command. To get help on any GNUPLOT feature, type, e.g., g C help set label. You may have to type g C RET a few times to clear the "press return for more" or "subtopic of ..." requests. Note that Calc always sends commands (like `set nolabel') to reset all plotting parameters to the defaults before each plot, so to delete a label all you need

to do is delete the `set label' line you added (or comment it out with `#') and then replot with g p.

You can use g q (`calc-graph-quit`) to kill the GNUPLOT process that is running. The next graphing command you give will start a fresh GNUPLOT process. The word `Graph' appears in the Calc window's mode line whenever a GNUPLOT process is currently running. The GNUPLOT process is automatically killed when you exit Emacs if you haven't killed it manually by then.

The g K (`calc-graph-kill`) command is like g q except that it also views the `*Gnuplot Trail*' buffer so that you can see the process being killed. This is better if you are killing GNUPLOT because you think it has gotten stuck.

Go to the previous, next section.

Go to the previous, next section.

Kill and Yank Functions

The commands in this chapter move information between the Calculator and other Emacs editing buffers.

In many cases Embedded Mode is an easier and more natural way to work with Calc from a regular editing buffer. See section Embedded Mode.

Killing from the Stack

Kill commands are Emacs commands that insert text into the "kill ring," from which it can later be "yanked" by a C-y command. Three common kill commands in normal Emacs are C-k, which kills one line, C-w, which kills the region between mark and point, and M-w, which puts the region into the kill ring without actually deleting it. All of these commands work in the Calculator, too. Also, M-k has been provided to complete the set; it puts the current line into the kill ring without deleting anything.

The kill commands are unusual in that they pay attention to the location of the cursor in the Calculator buffer. If the cursor is on or below the bottom line, the kill commands operate on the top of the stack. Otherwise, they operate on whatever stack element the cursor is on. Calc's kill commands always operate on whole stack entries. (They act the same as their standard Emacs cousins except they "round up" the specified region to encompass full lines.) The text is copied into the kill ring exactly as it appears on the screen, including line numbers if they are enabled.

A numeric prefix argument to C-k or M-k affects the number of lines killed. A positive argument kills the current line and n-1 lines below it. A negative argument kills the -n lines above the current line. Again this mirrors the behavior of the standard Emacs C-k command. Although a whole line is always deleted, C-k with no argument copies only the number itself into the kill ring, whereas C-k with a prefix argument of 1 copies the number with its trailing newline.

Yanking into the Stack

The C-y command yanks the most recently killed text back into the Calculator. It pushes this value onto the top of the stack regardless of the cursor position. In general it re-parses the killed text as a number or formula (or a list of these separated by commas or newlines). However if the thing being yanked is something that was just killed from the Calculator itself, its full internal structure is yanked. For example, if you have set the floating-point display mode to show only four significant digits, then killing and re-yanking 3.14159 (which displays as 3.142) will yank the full 3.14159, even though yanking it into any other buffer would yank the number in its displayed form, 3.142. (Since the default display modes show all objects to their full precision, this feature normally makes no difference.)

Grabbing from Other Buffers

The M-# g (`calc-grab-region`) command takes the text between point and mark in the current buffer and attempts to parse it as a vector of values. Basically, it wraps the text in vector brackets `[ ]' unless the text already is enclosed in vector brackets, then reads the text as if it were an algebraic entry. The contents of the vector may be numbers, formulas, or any other Calc objects. If the M-# g command works successfully, it does an automatic M-# c to enter the Calculator buffer.

A numeric prefix argument grabs the specified number of lines around point, ignoring the mark. A positive prefix grabs from point to the nth following newline (so that M-1 M-# g grabs from point to the end of the current line); a negative prefix grabs from point back to the n+1st preceding newline. In these cases the text that is grabbed is exactly the same as the text that C-k would delete given that prefix argument.

A prefix of zero grabs the current line; point may be anywhere on the line.

A plain C-u prefix interprets the region between point and mark as a single number or formula rather than a vector. For example, M-# g on the text `2 a b' produces the vector of three values `[2, a, b]', but C-u M-# g on the same region reads a formula which is a product of three things: `2 a b'. (The text `a + b', on the other hand, will be grabbed as a vector of one element by plain M-# g because the interpretation `[a, +, b]' would be a syntax error.)

If a different language has been specified (see section Language Modes), the grabbed text will be interpreted according to that language.

The M-# r (`calc-grab-rectangle`) command takes the text between point and mark and attempts to parse it as a matrix. If point and mark are both in the leftmost column, the lines in between are parsed in their entirety. Otherwise, point and mark define the corners of a rectangle whose contents are parsed.

Each line of the grabbed area becomes a row of the matrix. The result will actually be a vector of vectors, which Calc will treat as a matrix only if every row contains the same number of values.

If a line contains a portion surrounded by square brackets (or curly braces), that portion is interpreted as a vector which becomes a row of the matrix. Any text surrounding the bracketed portion on the line is ignored.

Otherwise, the entire line is interpreted as a row vector as if it were surrounded by square brackets. Leading line numbers (in the format used in the Calc stack buffer) are ignored. If you wish to force this interpretation (even if the line contains bracketed portions), give a negative numeric prefix argument to the M-# r command.

If you give a numeric prefix argument of zero or plain C-u, each line is instead interpreted as a single formula which is converted into a one-element vector. Thus the result of C-u M-# r will be a one-column matrix. For example, suppose one line of the data is the expression `2 a'. A plain M-# r will interpret this as `[2 a]', which in turn is read as a two-element vector that forms one row of the matrix. But a C-u M-# r will interpret this row as `[2*a]'.

If you give a positive numeric prefix argument n, then each line will be split up into columns of width n;

each column is parsed separately as a matrix element. If a line contained `2 +/- 3 4 +/- 5', then grabbi with a prefix argument of 8 would correctly split the line into two error forms.

See section Vector/Matrix Functions, to see how to pull the matrix apart into its constituent rows and columns. (If it is a @c{1×1} 1x1 matrix, just hit v u (`calc-unpack`) twice.)

The M-# : (`calc-grab-sum-down`) command is a handy way to grab a rectangle of data and sum its columns. It is equivalent to typing M-# r, followed by V R : + (the vector reduction command that sums the columns of a matrix; see section Reducing). The result of the command will be a vector of numbers, one for each column in the input data. The M-# _ (`calc-grab-sum-across`) command similarly grabs a rectangle and sums its rows by executing V R _ +.

As well as being more convenient, M-# : and M-# _ are also much faster because they don't actually place the grabbed vector on the stack. In a M-# r V R : + sequence, formatting the vector for display on the stack takes a large fraction of the total time (unless you have planned ahead and used v . and t . modes).

For example, suppose we have a column of numbers in a file which we wish to sum. Go to one corner of the column and press C-@ to set the mark; go to the other corner and type M-# :. Since there is only one column, the result will be a vector of one number, the sum. (You can type v u to unpack this vector into a plain number if you want to do further arithmetic with it.)

To compute the product of the column of numbers, we would have to do it "by hand" since there's no special grab-and-multiply command. Use M-# r to grab the column of numbers into the calculator in the form of a column matrix. The statistics command u * is a handy way to find the product of a vector or matrix of numbers. See section Statistical Operations on Vectors. Another approach would be to use an explicit column reduction command, V R : *.

Yanking into Other Buffers

The plain y (`calc-copy-to-buffer`) command inserts the number at the top of the stack into the most recently used normal editing buffer. (More specifically, this is the most recently used buffer which is displayed in a window and whose name does not begin with `*'. If there is no such buffer, this is the most recently used buffer except for Calculator and Calc Trail buffers.) The number is inserted exactly as it appears and without a newline. (If line-numbering is enabled, the line number is normally not included.) The number is *not* removed from the stack.

With a prefix argument, y inserts several numbers, one per line. A positive argument inserts the specified number of values from the top of the stack. A negative argument inserts the nth value from the top of the stack. An argument of zero inserts the entire stack. Note that y with an argument of 1 is slightly different from y with no argument; the former always copies full lines, whereas the latter strips off the trailing newline.

With a lone C-u as a prefix argument, y *replaces* the region in the other buffer with the yanked text, then quits the Calculator, leaving you in that buffer. A typical use would be to use M-# g to read a region of data into the Calculator, operate on the data to produce a new matrix, then type C-u y to replace the original data with the new data. One might wish to alter the matrix display style (see section Vector and

Matrix Display Formats) or change the current display language (see section Language Modes) befo doing this. Also, note that this command replaces a linear region of text (as grabbed by M-# g), not a rectangle (as grabbed by M-# r).

If the editing buffer is in overwrite (as opposed to insert) mode, and the C-u prefix was not used, then the yanked number will overwrite the characters following point rather than being inserted before those characters. The usual conventions of overwrite mode are observed; for example, characters will be inserted at the end of a line rather than overflowing onto the next line. Yanking a multi-line object such as a matrix in overwrite mode overwrites the next n lines in the buffer, lengthening or shortening each line as necessary. Finally, if the thing being yanked is a simple integer or floating-point number (like `-1.2345e-3') and the characters following point also make up such a number, then Calc will replace that number with the new number, lengthening or shortening as necessary. The concept of "overwrite mode" has thus been generalized from overwriting characters to overwriting one complete number with another.

The M-# y key sequence is equivalent to y except that it can be typed anywhere, not just in Calc. This provides an easy way to guarantee that Calc knows which editing buffer you want to use!

X Cut and Paste

If you are using Emacs with the X window system, there is an easier way to move small amounts of data into and out of the calculator: Use the mouse-oriented cut and paste facilities of X.

The default bindings for a three-button mouse cause the left button to move the Emacs cursor to the given place, the right button to select the text between the cursor and the clicked location, and the middle button to yank the selection into the buffer at the clicked location. So, if you have a Calc window and an editing window on your Emacs screen, you can use left-click/right-click to select a number, vector, or formula from one window, then middle-click to paste that value into the other window. When you paste text into the Calc window, Calc interprets it as an algebraic entry. It doesn't matter where you click in the Calc window; the new value is always pushed onto the top of the stack.

The `xterm` program that is typically used for general-purpose shell windows in X interprets the mouse buttons in the same way. So you can use the mouse to move data between Calc and any other Unix program. One nice feature of `xterm` is that a double left-click selects one word, and a triple left-click selects a whole line. So you can usually transfer a single number into Calc just by double-clicking on it in the shell, then middle-clicking in the Calc window.

Go to the previous, next section.

Go to the previous, next section.

"Keypad" Mode

The M-# k (`calc-keypad`) command starts the Calculator and displays a picture of a calculator-style keypad. If you are using the X window system, you can click on any of the "keys" in the keypad using the left mouse button to operate the calculator. The original window remains the selected window; in keypad mode you can type in your file while simultaneously performing calculations with the mouse.

If you have used M-# b first, M-# k instead invokes the `full-calc-keypad` command, which takes over the whole Emacs screen and displays the keypad, the Calc stack, and the Calc trail all at once. This mode would normally be used when running Calc standalone (see section Standalone Operation).

If you aren't using the X window system, you must switch into the `*Calc Keypad*' window, place the cursor on the desired "key," and type SPC or RET. If you think this is easier than using Calc normally, go right ahead.

Calc commands are more or less the same in keypad mode. Certain keypad keys differ slightly from the corresponding normal Calc keystrokes; all such deviations are described below.

Keypad Mode includes many more commands than will fit on the keypad at once. Click the right mouse button [`calc-keypad-menu`] to switch to the next menu. The bottom five rows of the keypad stay the same; the top three rows change to a new set of commands. To return to earlier menus, click the middle mouse button [`calc-keypad-menu-back`] or simply advance through the menus until you wrap around. Typing TAB inside the keypad window is equivalent to clicking the right mouse button there.

You can always click the EXEC button and type any normal Calc key sequence. This is equivalent to switching into the Calc buffer, typing the keys, then switching back to your original buffer.

```
|EXEC |  1  |  2  |  3  |  -  |
|-----+-----+-----+-----+-----|
| OFF |  0  |  .  | PI  |  +  |
|-----+-----+-----+-----+-----+
```

This is the menu that appears the first time you start Keypad Mode. It will show up in a vertical window on the right side of your screen. Above this menu is the traditional Calc stack display. On a 24-line screen you will be able to see the top three stack entries.

The ten digit keys, decimal point, and EEX key are used for entering numbers in the obvious way. EEX begins entry of an exponent in scientific notation. Just as with regular Calc, the number is pushed onto the stack as soon as you press ENTER or any other function key.

The +/- key corresponds to normal Calc's n key. During numeric entry it changes the sign of the number or of the exponent. At other times it changes the sign of the number on the top of the stack.

The INV and HYP keys modify other keys. As well as having the effects described elsewhere in this manual, Keypad Mode defines several other "inverse" operations. These are described below and in the following sections.

The ENTER key finishes the current numeric entry, or otherwise duplicates the top entry on the stack.

The UNDO key undoes the most recent Calc operation. INV UNDO is the "redo" command, and HYP UNDO is "last arguments" (M-RET).

The <- key acts as a "backspace" during numeric entry. At other times it removes the top stack entry. INV <- clears the entire stack. HYP <- takes an integer from the stack, then removes that many additional stack elements.

The EXEC key prompts you to enter any keystroke sequence that would normally work in Calc mode. This can include a numeric prefix if you wish. It is also possible simply to switch into the Calc window and type commands in it; there is nothing "magic" about this window when Keypad Mode is active.

The other keys in this display perform their obvious calculator functions. CLN2 rounds the top-of-stack by temporarily reducing the precision by 2 digits. FLT converts an integer or fraction on the top of the stack to floating-point.

The INV and HYP keys combined with several of these keys give you access to some common functions even if the appropriate menu is not displayed. Obviously you don't need to learn these keys unless you find yourself wasting time switching among the menus.

INV +/-

is the same as 1/x.

INV +

is the same as SQRT.

INV -

is the same as CONJ.

INV *

is the same as y^x.

INV /

is the same as INV y^x (the xth root of y).

HYP/INV 1

are the same as SIN / INV SIN.

HYP/INV 2

are the same as COS / INV COS.

HYP/INV 3

are the same as TAN / INV TAN.

INV/HYP 4

are the same as LN / HYP LN.

INV/HYP 5

are the same as EXP / HYP EXP.

INV 6

is the same as ABS.

INV 7

is the same as RND (`calc-round`).

INV 8

is the same as CLN2.

INV 9

is the same as FLT (`calc-float`).

INV 0

is the same as IMAG.

INV .

is the same as PREC.

INV ENTER

is the same as SWAP.

HYP ENTER

is the same as RLL3.

INV HYP ENTER

is the same as OVER.

HYP +/-

packs the top two stack entries as an error form.

HYP EEX

packs the top two stack entries as a modulo form.

INV EEX

creates an interval form; this removes an integer which is one of 0 `[]', 1 `[)', 2 `(]' or 3 `()', followed by the two limits of the interval.

The OFF key turns Calc off; typing M-# k or M-# M-# again has the same effect. This is analogous to typing q or hitting M-# c again in the normal calculator. If Calc is running standalone (the `full-calc-keypad` command appeared in the command line that started Emacs), then OFF is replaced with EXIT; clicking on this actually exits Emacs itself.

Functions Menu

```
|----+----+----+----+----+----2
|IGAM|BETA|IBET|ERF |BESJ|BESY|
|----+----+----+----+----+----|
|IMAG|CONJ| RE |ATN2|RAND|RAGN|
|----+----+----+----+----+----|
|GCD |FACT|DFCT|BNOM|PERM|NXTP|
|----+----+----+----+----+----|
```

This menu provides various operations from the f and k prefix keys.

IMAG multiplies the number on the stack by the imaginary number i = (0, 1).

RE extracts the real part a complex number. INV RE extracts the imaginary part.

RAND takes a number from the top of the stack and computes a random number greater than or equal to zero but less than that number. (See section Random Numbers.) RAGN is the "random again" command; it computes another random number using the same limit as last time.

INV GCD computes the LCM (least common multiple) function.

INV FACT is the gamma function. @c{$\Gamma(x) = (x-1)!$} gamma(x) = (x-1)!.

PERM is the number-of-permutations function, which is on the H k c key in normal Calc.

NXTP finds the next prime after a number. INV NXTP finds the previous prime.

Binary Menu

```
|----+----+----+----+----+----3
|AND | OR |XOR |NOT |LSH |RSH |
|----+----+----+----+----+----|
|DEC |HEX |OCT |BIN |WSIZ|ARSH|
|----+----+----+----+----+----|
| A  | B  | C  | D  | E  | F  |
|----+----+----+----+----+----|
```

The keys in this menu perform operations on binary integers. Note that both logical and arithmetic right-shifts are provided. INV LSH rotates one bit to the left.

The "difference" function (normally on b d) is on INV AND. The "clip" function (normally on b c) is on INV NOT.

The DEC, HEX, OCT, and BIN keys select the current radix for display and entry of numbers: Decimal, hexadecimal, octal, or binary. The six letter keys A through F are used for entering hexadecimal numbers.

The WSIZ key displays the current word size for binary operations and allows you to enter a new word size. You can respond to the prompt using either the keyboard or the digits and ENTER from the keypad. The initial word size is 32 bits.

Vectors Menu

```
|----+----+----+----+----+----4
|SUM |PROD|MAX |MAP*|MAP^|MAP$|
|----+----+----+----+----+----|
|MINV|MDET|MTRN|IDNT|CRSS|"x" |
|----+----+----+----+----+----|
|PACK|UNPK|INDX|BLD |LEN |... |
|----+----+----+----+----+----|
```

The keys in this menu operate on vectors and matrices.

PACK removes an integer n from the top of the stack; the next n stack elements are removed and packed into a vector, which is replaced onto the stack. Thus the sequence 1 ENTER 3 ENTER 5 ENTER 3 PACK enters the vector `[1, 3, 5]' onto the stack. To enter a matrix, build each row on the stack as a vector, then use a final PACK to collect the rows into a matrix.

UNPK unpacks the vector on the stack, pushing each of its components separately.

INDX removes an integer n, then builds a vector of integers from 1 to n. INV INDX takes three numbers from the stack: The vector size n, the starting number, and the increment. BLD takes an integer n and any value x and builds a vector of n copies of x.

IDNT removes an integer n, then builds an n-by-n identity matrix.

LEN replaces a vector by its length, an integer.

... turns on or off "abbreviated" display mode for large vectors.

MINV, MDET, MTRN, and CROSS are the matrix inverse, determinant, and transpose, and vector cross product.

SUM replaces a vector by the sum of its elements. It is equivalent to u + in normal Calc (see section Statistical Operations on Vectors). PROD computes the product of the elements of a vector, and MAX

computes the maximum of all the elements of a vector.

INV SUM computes the alternating sum of the first element minus the second, plus the third, minus the fourth, and so on. INV MAX computes the minimum of the vector elements.

HYP SUM computes the mean of the vector elements. HYP PROD computes the sample standard deviation. HYP MAX computes the median.

MAP* multiplies two vectors elementwise. It is equivalent to the V M * command. MAP^ computes powers elementwise. The arguments must be vectors of equal length, or one must be a vector and the other must be a plain number. For example, 2 MAP^ squares all the elements of a vector.

MAP$ maps the formula on the top of the stack across the vector in the second-to-top position. If the formula contains several variables, Calc takes that many vectors starting at the second-to-top position and matches them to the variables in alphabetical order. The result is a vector of the same size as the input vectors, whose elements are the formula evaluated with the variables set to the various sets of numbers in those vectors. For example, you could simulate MAP^ using MAP$ with the formula `x^y'.

The "x" key pushes the variable name x onto the stack. To build the formula x^2 + 6, you would use the key sequence "x" 2 y^x 6 +. This formula would then be suitable for use with the MAP$ key described above. With INV, HYP, or INV and HYP, the "x" key pushes the variable names y, z, and t, respectively.

Modes Menu

```
|----+----+----+----+----+----5
|FLT |FIX |SCI |ENG |GRP |    |
|----+----+----+----+----+----|
|RAD |DEG |FRAC|POLR|SYMB|PREC|
|----+----+----+----+----+----|
|SWAP|RLL3|RLL4|OVER|STO |RCL |
|----+----+----+----+----+----|
```

The keys in this menu manipulate modes, variables, and the stack.

The FLT, FIX, SCI, and ENG keys select floating-point, fixed-point, scientific, or engineering notation. FIX displays two digits after the decimal by default; the others display full precision. With the INV prefix, these keys pop a number-of-digits argument from the stack.

The GRP key turns grouping of digits with commas on or off. INV GRP enables grouping to the right of the decimal point as well as to the left.

The RAD and DEG keys switch between radians and degrees for trigonometric functions.

The FRAC key turns Fraction mode on or off. This affects whether commands like / with integer arguments produce fractional or floating-point results.

The POLR key turns Polar mode on or off, determining whether polar or rectangular complex numbers are used by default.

The SYMB key turns Symbolic mode on or off, in which operations that would produce inexact floating-point results are left unevaluated as algebraic formulas.

The PREC key selects the current precision. Answer with the keyboard or with the keypad digit and ENTER keys.

The SWAP key exchanges the top two stack elements. The RLL3 key rotates the top three stack elements upwards. The RLL4 key rotates the top four stack elements upwards. The OVER key duplicates the second-to-top stack element.

The STO and RCL keys are analogous to s t and s r in regular Calc. See section Storing and Recalling. Click the STO or RCL key, then one of the ten digits. (Named variables are not available in Keypad Mode.) You can also use, for example, STO + 3 to add to register 3.

Go to the previous, next section.

Go to the previous, next section.

Embedded Mode

Embedded Mode in Calc provides an alternative to copying numbers and formulas back and forth between editing buffers and the Calc stack. In Embedded Mode, your editing buffer becomes temporarily linked to the stack and this copying is taken care of automatically.

Basic Embedded Mode

To enter Embedded mode, position the Emacs point (cursor) on a formula in any buffer and press M-# e (`calc-embedded`). Note that M-# e is not to be used in the Calc stack buffer like most Calc commands, but rather in regular editing buffers that are visiting your own files.

Calc normally scans backward and forward in the buffer for the nearest opening and closing formula delimiters. The simplest delimiters are blank lines. Other delimiters that Embedded Mode understands are:

1. The TeX and LaTeX math delimiters `$ $', `$$ $$', `\[ \]', and `\(\)';
2. Lines beginning with `\begin' and `\end';
3. Lines beginning with `@' (Texinfo delimiters).
4. Lines beginning with `.EQ' and `.EN' (eqn delimiters);
5. Lines containing a single `%' or `.\"' symbol and nothing else.

See section Customizing Embedded Mode, to see how to make Calc recognize your own favorite delimiters. Delimiters like `$ $' can appear on their own separate lines or in-line with the formula.

If you give a positive or negative numeric prefix argument, Calc instead uses the current point as one end of the formula, and moves forward or backward (respectively) by that many lines to find the other end. Explicit delimiters are not necessary in this case.

With a prefix argument of zero, Calc uses the current region (delimited by point and mark) instead of formula delimiters.

With a prefix argument of C-u only, Calc scans for the first non-numeric character (i.e., the first character that is not a digit, sign, decimal point, or upper- or lower-case `e') forward and backward to delimit the formula. M-# w (`calc-embedded-word`) is equivalent to C-u M-# e.

When you enable Embedded mode for a formula, Calc reads the text between the delimiters and tries to interpret it as a Calc formula. It's best if the current Calc language mode is correct for the formula, but Calc can generally identify TeX formulas and Big-style formulas even if the language mode is wrong. If Calc can't make sense of the formula, it beeps and refuses to enter Embedded mode. But if the current language is wrong, Calc can sometimes parse the formula successfully (but incorrectly); for example, the C expression `atan(a[1])' can be parsed in Normal language mode, but the `atan` won't correspond to the built-in `arctan` function, and the `a[1]' will be interpreted as `a' times the vector `[1]'!

If you press M-# e or M-# w to activate an embedded formula which is blank, say with the cursor on space between the two delimiters `$ $', Calc will immediately prompt for an algebraic entry.

Only one formula in one buffer can be enabled at a time. If you move to another area of the current buffer and give Calc commands, Calc turns Embedded mode off for the old formula and then tries to restart Embedded mode at the new position. Other buffers are not affected by Embedded mode.

When Embedded mode begins, Calc pushes the current formula onto the stack. No Calc stack window is created; however, Calc copies the top-of-stack position into the original buffer at all times. You can create a Calc window by hand with M-# o if you find you need to see the entire stack.

For example, typing M-# e while somewhere in the formula `n>2' in the following line enables Embedded mode on that inequality:

```
We define $F_n = F_(n-1)+F_(n-2)$ for all $n>2$.
```

The formula n>2 will be pushed onto the Calc stack, and the top of stack will be copied back into the editing buffer. This means that spaces will appear around the `>' symbol to match Calc's usual display style:

```
We define $F_n = F_(n-1)+F_(n-2)$ for all $n > 2$.
```

No spaces have appeared around the `+' sign because it's in a different formula, one which we have not yet touched with Embedded mode.

Now that Embedded mode is enabled, keys you type in this buffer are interpreted as Calc commands. At this point we might use the "commute" command j C to reverse the inequality. This is a selection-based command for which we first need to move the cursor onto the operator (`>' in this case) that needs to be commuted.

```
We define $F_n = F_(n-1)+F_(n-2)$ for all $2 < n$.
```

The M-# o command is a useful way to open a Calc window without actually selecting that window. Giving this command verifies that `2 < n' is also on the Calc stack. Typing 17 RET would produce:

```
We define $F_n = F_(n-1)+F_(n-2)$ for all $17$.
```

with `2 < n' and `17' on the stack; typing TAB at this point will exchange the two stack values and restore `2 < n' to the embedded formula. Even though you can't normally see the stack in Embedded mode, it is still there and it still operates in the same way. But, as with old-fashioned RPN calculators, you can only see the value at the top of the stack at any given time (unless you use M-# o).

Typing M-# e again turns Embedded mode off. The Calc window reveals that the formula `2 < n' is automatically removed from the stack, but the `17' is not. Entering Embedded mode always pushes one thing onto the stack, and leaving Embedded mode always removes one thing. Anything else that happens on the stack is entirely your business as far as Embedded mode is concerned.

If you press M-# e in the wrong place by accident, it is possible that Calc will be able to parse the nearby

text as a formula and will mangle that text in an attempt to redisplay it "properly" in the current langu mode. If this happens, press M-# e again to exit Embedded mode, then give the regular Emacs "undo command (C-_ or C-x u) to put the text back the way it was before Calc edited it. Note that Calc's own Undo command (typed before you turn Embedded mode back off) will not do you any good, because as far as Calc is concerned you haven't done anything with this formula yet.

More About Embedded Mode

When Embedded mode "activates" a formula, i.e., when it examines the formula for the first time since the buffer was created or loaded, Calc tries to sense the language in which the formula was written. If the formula contains any TeX-like `\' sequences, it is parsed (i.e., read) in TeX mode. If the formula appears to be written in multi-line Big mode, it is parsed in Big mode. Otherwise, it is parsed according to the current language mode.

Note that Calc does not change the current language mode according to what it finds. Even though it can read a TeX formula when not in TeX mode, it will immediately rewrite this formula using whatever language mode is in effect. You must then type d T to switch Calc permanently into TeX mode if that is what you desire.

Calc's parser is unable to read certain kinds of formulas. For example, with v] (`calc-matrix-brackets`) you can specify matrix display styles which the parser is unable to recognize as matrices. The d p (`calc-show-plain`) command turns on a mode in which a "plain" version of a formula is placed in front of the fully-formatted version. When Calc reads a formula that has such a plain version in front, it reads the plain version and ignores the formatted version.

Plain formulas are preceded and followed by `%%%' signs by default. This notation has the advantage that the `%' character begins a comment in TeX, so if your formula is embedded in a TeX document its plain version will be invisible in the final printed copy. See section Customizing Embedded Mode, to see how to change the "plain" formula delimiters, say to something that eqn or some other formatter will treat as a comment.

There are several notations which Calc's parser for "big" formatted formulas can't yet recognize. In particular, it can't read the large symbols for `sum`, `prod`, and `integ`, and it can't handle `=>' with the righthand argument omitted. Also, Calc won't recognize special formats you have defined with the Z C command (see section User-Defined Compositions). In these cases it is important to use "plain" mode to make sure Calc will be able to read your formula later.

Another example where "plain" mode is important is if you have specified a float mode with few digits of precision. Normally any digits that are computed but not displayed will simply be lost when you save and re-load your embedded buffer, but "plain" mode allows you to make sure that the complete number is present in the file as well as the rounded-down number.

Embedded buffers remember active formulas for as long as they exist in Emacs memory. Suppose you have an embedded formula which is @c{π} pi to the normal 12 decimal places, and then type C-u 5 d n to display only five decimal places. If you then type d n, all 12 places reappear because the full number is still there on the Calc stack. More surprisingly, even if you exit Embedded mode and later re-enter it for that formula, typing d n will restore all 12 places because each buffer remembers all its active

formulas. However, if you save the buffer in a file and reload it in a new Emacs session, all non-displayed digits will have been lost unless you used "plain" mode.

In some applications of Embedded mode, you will want to have a sequence of copies of a formula that show its evolution as you work on it. For example, you might want to have a sequence like this in your file (elaborating here on the example from the "Getting Started" chapter):

```
The derivative of

                                ln(ln(x))

is

                    (the derivative of ln(ln(x)))

whose value at x = 2 is

                               (the value)

and at x = 3 is

                               (the value)
```

The M-# d (`calc-embedded-duplicate`) command is a handy way to make sequences like this. If you type M-# d, the formula under the cursor (which may or may not have Embedded mode enabled for it at the time) is copied immediately below and Embedded mode is then enabled for that copy.

For this example, you would start with just

```
The derivative of

                                ln(ln(x))
```

and press M-# d with the cursor on this formula. The result is

```
The derivative of

                                ln(ln(x))

                                ln(ln(x))
```

with the second copy of the formula enabled in Embedded mode. You can now press a d x RET to take the derivative, and M-# d M-# d to make two more copies of the derivative. To complete the computations, type 3 s l x RET to evaluate the last formula, then move up to the second-to-last formula and type 2 s l x RET.

Finally, you would want to press M-# e to exit Embedded mode, then go up and insert the necessary in between the various formulas and numbers.

The M-# f (`calc-embedded-new-formula`) command creates a new embedded formula at the current point. It inserts some default delimiters, which are usually just blank lines, and then does an algebraic entry to get the formula (which is then enabled for Embedded mode). This is just shorthand for typing the delimiters yourself, positioning the cursor between the new delimiters, and pressing M-# e. The key sequence M-# ' is equivalent to M-# f.

The M-# n (`calc-embedded-next`) and M-# p (`calc-embedded-previous`) commands move the cursor to the next or previous active embedded formula in the buffer. They can take positive or negative prefix arguments to move by several formulas. Note that these commands do not actually examine the text of the buffer looking for formulas; they only see formulas which have previously been activated in Embedded mode. In fact, M-# n and M-# p are a useful way to tell which embedded formulas are currently active. Also, note that these commands do not enable Embedded mode on the next or previous formula, they just move the cursor. (By the way, M-# n is not as awkward to type as it may seem, because M-# ignores Shift and Meta on the second keystroke: M-# M-N can be typed by holding down Shift and Meta and alternately typing two keys.)

The M-# ` (`calc-embedded-edit`) command edits the embedded formula at the current point as if by ` (`calc-edit`). Embedded mode does not have to be enabled for this to work. Press M-# M-# to finish the edit, or M-# x to cancel.

Assignments in Embedded Mode

The `:=' (assignment) and `=>' ("evaluates-to") operators are especially useful in Embedded mode. They allow you to make a definition in one formula, then refer to that definition in other formulas embedded in the same buffer.

An embedded formula which is an assignment to a variable, as in

```
foo := 5
```

records 5 as the stored value of `foo` for the purposes of Embedded mode operations in the current buffer. It does *not* actually store 5 as the "global" value of `foo`, however. Regular Calc operations, and Embedded formulas in other buffers, will not see this assignment.

One way to use this assigned value is simply to create an Embedded formula elsewhere that refers to `foo`, and to press = in that formula. However, this permanently replaces the `foo` in the formula with its current value. More interesting is to use `=>' elsewhere:

```
foo + 7 => 12
```

See section The Evaluates-To Operator, for a general discussion of `=>'.

If you move back and change the assignment to `foo`, any `=>' formulas which refer to it are automatically updated.

```
foo := 17

foo + 7 => 24
```

The obvious question then is, *how* can one easily change the assignment to `foo`? If you simply select the formula in Embedded mode and type 17, the assignment itself will be replaced by the 17. The effect on the other formula will be that the variable `foo` becomes unassigned:

```
17

foo + 7 => foo + 7
```

The right thing to do is first to use a selection command (j 2 will do the trick) to select the righthand side of the assignment. Then, 17 TAB DEL will swap the 17 into place (see section Selecting Sub-Formulas, to see how this works).

The M-# j (`calc-embedded-select`) command provides an easy way to operate on assigments. It is just like M-# e, except that if the enabled formula is an assignment, it uses j 2 to select the righthand side. If the enabled formula is an evaluates-to, it uses j 1 to select the lefthand side. A formula can also be a combination of both:

```
bar := foo + 3 => 20
```

in which case M-# j will select the middle part (`foo + 3').

The formula is automatically deselected when you leave Embedded mode.

Another way to change the assignment to `foo` would simply be to edit the number using regular Emacs editing rather than Embedded mode. Then, we have to find a way to get Embedded mode to notice the change. The M-# u or M-# = (`calc-embedded-update-formula`) command is a convenient way to do this.

```
foo := 6

foo + 7 => 13
```

Pressing M-# u is much like pressing M-# e = M-# e, that is, temporarily enabling Embedded mode for the formula under the cursor and then evaluating it with =. But M-# u does not actually use M-# e, and in fact another formula somewhere else can be enabled in Embedded mode while you use M-# u and that formula will not be disturbed.

With a numeric prefix argument, M-# u updates all active `=>' formulas in the buffer. Formulas which have not yet been activated in Embedded mode, and formulas which do not have `=>' as their top-level operator, are not affected by this. (This is useful only if you have used m C; see below.)

With a plain C-u prefix, C-u M-# u updates only in the region between mark and point rather than in the whole buffer.

M-# u is also a handy way to activate a formula, such as an `=>' formula that has freshly been typed in or loaded from a file.

The M-# a (`calc-embedded-activate`) command scans through the current buffer and activates all embedded formulas that contain `:=' or `=>' symbols. This does not mean that Embedded mode is actually turned on, but only that the formulas' positions are registered with Embedded mode so that the `=>' values can be properly updated as assignments are changed.

It is a good idea to type M-# a right after loading a file that uses embedded `=>' operators. Emacs includes a nifty "buffer-local variables" feature that you can use to do this automatically. The idea is to place near the end of your file a few lines that look like this:

```
--- Local Variables: ---
--- eval:(calc-embedded-activate) ---
--- End: ---
```

where the leading and trailing `---' can be replaced by any suitable strings (which must be the same on all three lines) or omitted altogether; in a TeX file, `%' would be a good leading string and no trailing string would be necessary. In a C program, `/*' and `*/' would be good leading and trailing strings.

When Emacs loads a file into memory, it checks for a Local Variables section like this one at the end of the file. If it finds this section, it does the specified things (in this case, running M-# a automatically) before editing of the file begins. The Local Variables section must be within 3000 characters of the end of the file for Emacs to find it, and it must be in the last page of the file if the file has any page separators. See section 'Local Variables in Files' in the Emacs manual.

Note that M-# a does not update the formulas it finds. To do this, type, say, M-1 M-# u after M-# a. Generally this should not be a problem, though, because the formulas will have been up-to-date already when the file was saved.

Normally, M-# a activates all the formulas it finds, but any previous active formulas remain active as well. With a positive numeric prefix argument, M-# a first deactivates all current active formulas, then actives the ones it finds in its scan of the buffer. With a negative prefix argument, M-# a simply deactivates all formulas.

Embedded mode has two symbols, `Active' and `~Active', which it puts next to the major mode name in a buffer's mode line. It puts `Active' if it has reason to believe that all formulas in the buffer are active, because you have typed M-# a and Calc has not since had to deactivate any formulas (which can happen if Calc goes to update an `=>' formula somewhere because a variable changed, and finds that the formula is no longer there due to some kind of editing outside of Embedded mode). Calc puts `~Active' in the mode line if some, but probably not all, formulas in the buffer are active. This happens if you activate a few formulas one at a time but never use M-# a, or if you used M-# a but then Calc had to deactivate a formula because it lost track of it. If neither of these symbols appears in the mode line, no embedded formulas are active in the buffer (e.g., before Embedded mode has been used, or after a M-- M-# a).

Embedded formulas can refer to assignments both before and after them in the buffer. If there are several assignments to a variable, the nearest preceding assignment is used if there is one, otherwise the following assignment is used.

```
x => 1

x := 1

x => 1

x := 2

x => 2
```

As well as simple variables, you can also assign to subscript expressions of the form `var_number' (as in `x_0`), or `var_var' (as in `x_max`). Assignments to other kinds of objects can be represented by Calc, but the automatic linkage between assignments and references works only for plain variables and these two kinds of subscript expressions.

If there are no assignments to a given variable, the global stored value for the variable is used (see section Storing Variables), or, if no value is stored, the variable is left in symbolic form. Note that global stored values will be lost when the file is saved and loaded in a later Emacs session, unless you have used the s p (`calc-permanent-variable`) command to save them; see section Other Operations on Variables.

The m C (`calc-auto-recompute`) command turns automatic recomputation of `=>' forms on and off. If you turn automatic recomputation off, you will have to use M-# u to update these formulas manually after an assignment has been changed. If you plan to change several assignments at once, it may be more efficient to type m C, change all the assignments, then use M-1 M-# u to update the entire buffer afterwards. The m C command also controls `=>' formulas on the stack; see section The Evaluates-To Operator. When you turn automatic recomputation back on, the stack will be updated but the Embedded buffer will not; you must use M-# u to update the buffer by hand.

Mode Settings in Embedded Mode

Embedded Mode has a rather complicated mechanism for handling mode settings in Embedded formulas. It is possible to put annotations in the file that specify mode settings either global to the entire file or local to a particular formula or formulas. In the latter case, different modes can be specified for use when a formula is the enabled Embedded Mode formula.

When you give any mode-setting command, like m f (for fraction mode) or d s (for scientific notation), Embedded Mode adds a line like the following one to the file just before the opening delimiter of the formula.

```
% [calc-mode: fractions: t]
% [calc-mode: float-format: (sci 0)]
```

When Calc interprets an embedded formula, it scans the text before the formula for mode-setting annotations like these and sets the Calc buffer to match these modes. Modes not explicitly described in

the file are not changed. Calc scans all the way to the top of the file, or up to a line of the form

```
% [calc-defaults]
```

which you can insert at strategic places in the file if this backward scan is getting too slow, or just to provide a barrier between one "zone" of mode settings and another.

If the file contains several annotations for the same mode, the closest one before the formula is used. Annotations after the formula are never used (except for global annotations, described below).

The scan does not look for the leading `% ', only for the square brackets and the text they enclose. You can edit the mode annotations to a style that works better in context if you wish. See section Customizing Embedded Mode, to see how to change the style that Calc uses when it generates the annotations. You can write mode annotations into the file yourself if you know the syntax; the easiest way to find the syntax for a given mode is to let Calc write the annotation for it once and see what it does.

If you give a mode-changing command for a mode that already has a suitable annotation just above the current formula, Calc will modify that annotation rather than generating a new, conflicting one.

Mode annotations have three parts, separated by colons. (Spaces after the colons are optional.) The first identifies the kind of mode setting, the second is a name for the mode itself, and the third is the value in the form of a Lisp symbol, number, or list. Annotations with unrecognizable text in the first or second parts are ignored. The third part is not checked to make sure the value is of a legal type or range; if you write an annotation by hand, be sure to give a proper value or results will be unpredictable. Mode-setting annotations are case-sensitive.

While Embedded Mode is enabled, the word `Local` appears in the mode line. This is to show that mode setting commands generate annotations that are "local" to the current formula or set of formulas. The m R (`calc-mode-record-mode`) command causes Calc to generate different kinds of annotations. Pressing m R repeatedly cycles through the possible modes.

`LocEdit` and `LocPerm` modes generate annotations that look like this, respectively:

```
% [calc-edit-mode: float-format: (sci 0)]
% [calc-perm-mode: float-format: (sci 5)]
```

The first kind of annotation will be used only while a formula is enabled in Embedded Mode. The second kind will be used only when the formula is *not* enabled. (Whether the formula is "active" or not, i.e., whether Calc has seen this formula yet, is not relevant here.)

`Global` mode generates an annotation like this at the end of the file:

```
% [calc-global-mode: fractions t]
```

Global mode annotations affect all formulas throughout the file, and may appear anywhere in the file. This allows you to tuck your mode annotations somewhere out of the way, say, on a new page of the file, as long as those mode settings are suitable for all formulas in the file.

Enabling a formula with M-# e causes a fresh scan for local mode annotations; you will have to use this

after adding annotations above a formula by hand to get the formula to notice them. Updating a form with M-# u will also re-scan the local modes, but global modes are only re-scanned by M-# a.

Another way that modes can get out of date is if you add a local mode annotation to a formula that has another formula after it. In this example, we have used the d s command while the first of the two embedded formulas is active. But the second formula has not changed its style to match, even though by the rules of reading annotations the `(sci 0)' applies to it, too.

```
% [calc-mode: float-format: (sci 0)]
1.23e2

456.
```

We would have to go down to the other formula and press M-# u on it in order to get it to notice the new annotation.

Two more mode-recording modes selectable by m R are `Save` (which works even outside of Embedded Mode), in which mode settings are recorded permanently in your Emacs startup file `` `~/.emacs' `` rather than by annotating the current document, and no-recording mode (where there is no symbol like `Save` or `Local` in the mode line), in which mode-changing commands do not leave any annotations at all.

When Embedded Mode is not enabled, mode-recording modes except for `Save` have no effect.

Customizing Embedded Mode

You can modify Embedded Mode's behavior by setting various Lisp variables described here. Use M-x set-variable or M-x edit-options to adjust a variable on the fly, or put a suitable `setq` statement in your `` `~/.emacs' `` file to set a variable permanently. (Another possibility would be to use a file-local variable annotation at the end of the file; see section 'Local Variables in Files' in the Emacs manual.)

While none of these variables will be buffer-local by default, you can make any of them local to any embedded-mode buffer. (Their values in the `*Calculator*' buffer are never used.)

The `calc-embedded-open-formula` variable holds a regular expression for the opening delimiter of a formula. See section 'Regular Expression Search' in the Emacs manual, to see how regular expressions work. Basically, a regular expression is a pattern that Calc can search for. A regular expression that considers blank lines, `$', and `$$' to be opening delimiters is `"\\`\\|^\n\\|\\$\\$?"`. Just in case the meaning of this regular expression is not completely plain, let's go through it in detail.

The surrounding `" "' marks quote the text between them as a Lisp string. If you left them off, `set-variable` or `edit-options` would try to read the regular expression as a Lisp program.

The most obvious property of this regular expression is that it contains indecently many backslashes. There are actually two levels of backslash usage going on here. First, when Lisp reads a quoted string, all pairs of characters beginning with a backslash are interpreted as special characters. Here, `\n` changes to a

new-line character, and \\ changes to a single backslash. So the actual regular expression seen by C is `\`\|^ (newline) \|\$\$?'.

Regular expressions also consider pairs beginning with backslash to have special meanings. Sometimes the backslash is used to quote a character that otherwise would have a special meaning in a regular expression, like `$', which normally means "end-of-line," or `?', which means that the preceding item is optional. So `\$\$?' matches either one or two dollar signs.

The other codes in this regular expression are `^', which matches "beginning-of-line," `\|', which means "or," and `\`', which matches "beginning-of-buffer." So the whole pattern means that a formula begins at the beginning of the buffer, or on a newline that occurs at the beginning of a line (i.e., a blank line), or at one or two dollar signs.

The default value of `calc-embedded-open-formula` looks just like this example, with several more alternatives added on to recognize various other common kinds of delimiters.

By the way, the reason to use `^\n' rather than `^$' or `\n\n', which also would appear to match blank lines, is that the former expression actually "consumes" only one newline character as *part of* the delimiter, whereas the latter expressions consume zero or two newlines, respectively. The former choice gives the most natural behavior when Calc must operate on a whole formula including its delimiters.

See the Emacs manual for complete details on regular expressions. But just for your convenience, here is a list of all characters which must be quoted with backslash (like `\$') to avoid some special interpretation: `. * + ? [ ] ^ $ \'. (Note the backslash in this list; for example, to match `\[' you must use `"\\\\\\["`. An exercise for the reader is to account for each of these six backslashes!)

The `calc-embedded-close-formula` variable holds a regular expression for the closing delimiter of a formula. A closing regular expression to match the above example would be `"\\'\\|\n$\\|\\$\\$?"`. This is almost the same as the other one, except it now uses `\'' ("end-of-buffer") and `\n$' (newline occurring at end of line, yet another way of describing a blank line that is more appropriate for this case).

The `calc-embedded-open-word` and `calc-embedded-close-word` variables are similar expressions used when you type M-# w instead of M-# e to enable Embedded mode.

The `calc-embedded-open-plain` variable is a string which begins a "plain" formula written in front of the formatted formula when d p mode is turned on. Note that this is an actual string, not a regular expression, because Calc must be able to write this string into a buffer as well as to recognize it. The default string is `"%%% "` (note the trailing space).

The `calc-embedded-close-plain` variable is a string which ends a "plain" formula. The default is `" %%%\n"`. Without the trailing newline here, the first line of a "big" mode formula that followed might be shifted over with respect to the other lines.

The `calc-embedded-open-new-formula` variable is a string which is inserted at the front of a new formula when you type M-# f. Its default value is `"\n\n"`. If this string begins with a newline character and the M-# f is typed at the beginning of a line, M-# f will skip this first newline to avoid introducing unnecessary blank lines in the file.

The `calc-embedded-close-new-formula` variable is the corresponding string which is inserted

at the end of a new formula. Its default value is also `"\n\n"`. The final newline is omitted by M-# f typed at the end of a line. (It follows that if M-# f is typed on a blank line, both a leading opening newline and a trailing closing newline are omitted.)

The `calc-embedded-announce-formula` variable is a regular expression which is sure to be followed by an embedded formula. The M-# a command searches for this pattern as well as for `=>' and `:=' operators. Note that M-# a will not activate just anything surrounded by formula delimiters; after all, blank lines are considered formula delimiters by default! But if your language includes a delimiter which can only occur actually in front of a formula, you can take advantage of it here. The default pattern is `"%Embed\n\\(% .*\n\\)*"`, which checks for `%Embed' followed by any number of lines beginning with `%' and a space. This last is important to make Calc consider mode annotations part of the pattern, so that the formula's opening delimiter really is sure to follow the pattern.

The `calc-embedded-open-mode` variable is a string (not a regular expression) which should precede a mode annotation. Calc never scans for this string; Calc always looks for the annotation itself. But this is the string that is inserted before the opening bracket when Calc adds an annotation on its own. The default is `"% "`.

The `calc-embedded-close-mode` variable is a string which follows a mode annotation written by Calc. Its default value is simply a newline, `"\n"`. If you change this, it is a good idea still to end with a newline so that mode annotations will appear on lines by themselves.

Programming

There are several ways to "program" the Emacs Calculator, depending on the nature of the problem you need to solve.

1. Keyboard macros allow you to record a sequence of keystrokes and play them back at a later time. This is just the standard Emacs keyboard macro mechanism, dressed up with a few more features such as loops and conditionals.
2. Algebraic definitions allow you to use any formula to define a new function. This function can then be used in algebraic formulas or as an interactive command.
3. Rewrite rules are discussed in the section on algebra commands. See section Rewrite Rules. If you put your rewrite rules in the variable `EvalRules`, they will be applied automatically to all Calc results in just the same way as an internal "rule" is applied to evaluate `sqrt(9)' to 3 and so on. See section Automatic Rewrites.
4. Lisp is the programming language that Calc (and most of Emacs) is written in. If the above techniques aren't powerful enough, you can write Lisp functions to do anything that built-in Calc commands can do. Lisp code is also somewhat faster than keyboard macros or rewrite rules.

Programming features are available through the z and Z prefix keys. New commands that you define are two-key sequences beginning with z. Commands for managing these definitions use the shift-Z prefix. (The Z T (`calc-timing`) command is described elsewhere; see section Troubleshooting Commands. The Z C (`calc-user-define-composition`) command is also described elsewhere; see section User-Defined Compositions.)

Creating User Keys

Any Calculator command may be bound to a key using the Z D (`calc-user-define`) command. Actually, it is bound to a two-key sequence beginning with the lower-case z prefix.

The Z D command first prompts for the key to define. For example, press Z D a to define the new key sequence z a. You are then prompted for the name of the Calculator command that this key should run. For example, the `calc-sincos` command is not normally available on a key. Typing Z D s sincos RET programs the z s key sequence to run `calc-sincos`. This definition will remain in effect for the rest of this Emacs session, or until you redefine z s to be something else.

You can actually bind any Emacs command to a z key sequence by backspacing over the `calc-' when you are prompted for the command name.

As with any other prefix key, you can type z ? to see a list of all the two-key sequences you have defined that start with z. Initially, no z sequences (except z ? itself) are defined.

User keys are typically letters, but may in fact be any key. (META-keys are not permitted, nor are a terminal's special function keys which generate multi-character sequences when pressed.) You can define different commands on the shifted and unshifted versions of a letter if you wish.

The Z U (`calc-user-undefine`) command unbinds a user key. For example, the key sequence Z U s will

undefine the `sincos` key we defined above.

The Z P (`calc-user-define-permanent`) command makes a key binding permanent so that it will remain in effect even in future Emacs sessions. (It does this by adding a suitable bit of Lisp code into your `` `.emacs' `` file.) For example, Z P s would register our `sincos` command permanently. If you later wish to unregister this command you must edit your `` `.emacs' `` file by hand. (See section General Mode Commands, for a way to tell Calc to use a different file instead of `` `.emacs' ``.)

The Z P command also saves the user definition, if any, for the command bound to the key. After Z F and Z C, a given user key could invoke a command, which in turn calls an algebraic function, which might have one or more special display formats. A single Z P command will save all of these definitions.

To save a command or function without its key binding (or if there is no key binding for the command or function), type ' (the apostrophe) when prompted for a key. Then, type the function name, or backspace to change the `calcFunc-' prefix to `calc-' and enter a command name. (If the command you give implies a function, the function will be saved, and if the function has any display formats, those will be saved, but not the other way around: Saving a function will not save any commands or key bindings associated with the function.)

The Z E (`calc-user-define-edit`) command edits the definition of a user key. This works for keys that have been defined by either keyboard macros or formulas; further details are contained in the relevant following sections.

Programming with Keyboard Macros

The easiest way to "program" the Emacs Calculator is to use standard keyboard macros. Press C-x (to begin recording a macro. From this point on, keystrokes you type will be saved away as well as performing their usual functions. Press C-x) to end recording. Press shift-X (or the standard Emacs key sequence C-x e) to execute your keyboard macro by replaying the recorded keystrokes. See section 'Keyboard Macros' in the Emacs Manual, for further information.

When you use X to invoke a keyboard macro, the entire macro is treated as a single command by the undo and trail features. The stack display buffer is not updated during macro execution, but is instead fixed up once the macro completes. Thus, commands defined with keyboard macros are convenient and efficient. The C-x e command, on the other hand, invokes the keyboard macro with no special treatment: Each command in the macro will record its own undo information and trail entry, and update the stack buffer accordingly. If your macro uses features outside of Calc's control to operate on the contents of the Calc stack buffer, or if it includes Undo, Redo, or last-arguments commands, you must use C-x e to make sure the buffer and undo list are up-to-date at all times. You could also consider using K (`calc-keep-args`) instead of M-RET (`calc-last-args`).

Calc extends the standard Emacs keyboard macros in several ways. Keyboard macros can be used to create user-defined commands. Keyboard macros can include conditional and iteration structures, somewhat analogous to those provided by a traditional programmable calculator.

Naming Keyboard Macros

Once you have defined a keyboard macro, you can bind it to a z key sequence with the Z K (`calc-user-define-kbd-macro`) command. This command prompts first for a key, then for a command name. For example, if you type C-x (n TAB n TAB C-x) you will define a keyboard macro which negates the top two numbers on the stack (TAB swaps the top two stack elements). Now you can type Z K n RET to define

this keyboard macro onto the z n key sequence. The default command name (if you answer the second pror with just the RET key as in this example) will be something like `calc-User-n'. The keyboard macro will nc available as both z n and M-x calc-User-n. You can backspace and enter a more descriptive command name if you wish.

Macros defined by Z K act like single commands; they are executed in the same way as by the X key. If you wish to define the macro as a standard no-frills Emacs macro (to be executed as if by C-x e), give a negative prefix argument to Z K.

Once you have bound your keyboard macro to a key, you can use Z P to register it permanently with Emacs. See section Creating User Keys.

The Z E (`calc-user-define-edit`) command on a key that has been defined by a keyboard macro tries to use the `edit-kbd-macro` command to edit the macro. This command may be found in the `` `macedit' `` package, a copy of which comes with Calc. It decomposes the macro definition into full Emacs command names, like `calc-pop` and `calc-add`. Type M-# M-# to finish editing and update the definition stored on the key, or, to cancel the edit, type M-# x.

If you give a negative numeric prefix argument to Z E, the keyboard macro is edited in spelled-out keystroke form. For example, the editing buffer might contain the nine characters `1 RET 2 +'. When you press M-# M-#, the `read-kbd-macro` feature of the `` `macedit' `` package is used to reinterpret these key names. The notations `RET`, `LFD`, `TAB`, `SPC`, `DEL`, and `NUL` must be written in all uppercase, as must the prefixes `C-` and `M-`. Spaces and line breaks are ignored. Other characters are copied verbatim into the keyboard macro. Basically, the notation is the same as is used in all of this manual's examples, except that the manual takes some liberties with spaces: When we say ' [1 2 3] RET, we take it for granted that it is clear we really mean ' [1 SPC 2 SPC 3] RET, which is what `read-kbd-macro` wants to see.

If `` `macedit' `` is not available, Z E edits the keyboard macro in "raw" form; the editing buffer simply contains characters like `1^M2+' (here `^M' represents the carriage-return character). Editing in this mode, you will have to use C-q to enter new control characters into the buffer.

The M-# m (`read-kbd-macro`) command reads an Emacs "region" of spelled-out keystrokes and defines it as the current keyboard macro. It is a convenient way to define a keyboard macro that has been stored in a file, or to define a macro without executing it at the same time. The M-# m command works only if `` `macedit' `` is present.

Conditionals in Keyboard Macros

The Z [(`calc-kbd-if`) and Z] (`calc-kbd-end-if`) commands allow you to put simple tests in a keyboard macro. When Calc sees the Z [, it pops an object from the stack and, if the object is a non-zero value, continues executing keystrokes. But if the object is zero, or if it is not provably nonzero, Calc skips ahead to the matching Z] keystroke. See section Logical Operations, for a set of commands for performing tests which conveniently produce 1 for true and 0 for false.

For example, RET 0 a < Z [n Z] implements an absolute-value function in the form of a keyboard macro. This macro duplicates the number on the top of the stack, pushes zero and compares using a < (`calc-less-than`), then, if the number was less than zero, executes n (`calc-change-sign`). Otherwise, the change-sign command is skipped.

To program this macro, type C-x (, type the above sequence of keystrokes, then type C-x). Note that the keystrokes will be executed while you are making the definition as well as when you later re-execute the macro

by typing X. Thus you should make sure a suitable number is on the stack before defining the macro so that you don't get a stack-underflow error during the definition process.

Conditionals can be nested arbitrarily. However, there should be exactly one Z] for each Z [in a keyboard macro.

The Z : (`calc-kbd-else`) command allows you to choose between two keystroke sequences. The general format is cond Z [then-part Z : else-part Z]. If cond is true (i.e., if the top of stack contains a non-zero number after cond has been executed), the then-part will be executed and the else-part will be skipped. Otherwise, the then-part will be skipped and the else-part will be executed.

The Z | (`calc-kbd-else-if`) command allows you to choose between any number of alternatives. For example, cond1 Z [part1 Z : cond2 Z | part2 Z : part3 Z] will execute part1 if cond1 is true, otherwise it will execute part2 if cond2 is true, otherwise it will execute part3.

More precisely, Z [pops a number and conditionally skips to the next matching Z : or Z] key. Z] has no effect when actually executed. Z : skips to the next matching Z]. Z | pops a number and conditionally skips to the next matching Z : or Z]; thus, Z [and Z | are functionally equivalent except that Z [participates in nesting but Z | does not.

Calc's conditional and looping constructs work by scanning the keyboard macro for occurrences of character sequences like `Z:' and `Z]'. One side-effect of this is that if you use these constructs you must be careful that these character pairs do not occur by accident in other parts of the macros. Since Calc rarely uses shift-Z for any purpose except as a prefix character, this is not likely to be a problem. Another side-effect is that it will not work to define your own custom key bindings for these commands. Only the standard shift-Z bindings will work correctly.

If Calc gets stuck while skipping characters during the definition of a macro, type Z C-g to cancel the definition. (Typing plain C-g actually adds a C-g keystroke to the macro.)

Loops in Keyboard Macros

The Z < (`calc-kbd-repeat`) and Z > (`calc-kbd-end-repeat`) commands pop a number from the stack, which must be an integer, then repeat the keystrokes between the brackets the specified number of times. If the integer is zero or negative, the body is skipped altogether. For example, 1 TAB Z < 2 * Z > computes two to a nonnegative integer power. First, we push 1 on the stack and then swap the integer argument back to the top. The Z < pops that argument leaving the 1 back on top of the stack. Then, we repeat a multiply-by-two step however many times.

Once again, the keyboard macro is executed as it is being entered. In this case it is especially important to set up reasonable initial conditions before making the definition: Suppose the integer 1000 just happened to be sitting on the stack before we typed the above definition! Another approach is to enter a harmless dummy definition for the macro, then go back and edit in the real one with a Z E command. Yet another approach is to type the macro as written-out keystroke names in a buffer, then use M-# m (`read-kbd-macro`) to read the macro.

The Z / (`calc-kbd-break`) command allows you to break out of a keyboard macro loop prematurely. It pops an object from the stack; if that object is true (a non-zero number), control jumps out of the innermost enclosing Z < ... Z > loop and continues after the Z >. If the object is false, the Z / has no effect. Thus cond Z / is similar to `if (cond) break;' in the C language.

The Z ((`calc-kbd-for`) and Z) (`calc-kbd-end-for`) commands are similar to Z < and Z >, except that they make the value of the counter available inside the loop. The general layout is init final Z (body step Z).

The Z (command pops initial and final values from the stack. It then creates a temporary internal counter a initializes it with the value init. The Z (command then repeatedly pushes the counter value onto the stack a executes body and step, adding step to the counter each time until the loop finishes.

By default, the loop finishes when the counter becomes greater than (or less than) final, assuming initial is less than (greater than) final. If initial is equal to final, the body executes exactly once. The body of the loop always executes at least once. For example, 0 1 10 Z (2 ^ + 1 Z) computes the sum of the squares of the integers from 1 to 10, in steps of 1.

If you give a numeric prefix argument of 1 to Z (, the loop is forced to use upward-counting conventions. In this case, if initial is greater than final the body will not be executed at all. Note that step may still be negative in this loop; the prefix argument merely constrains the loop-finished test. Likewise, a prefix argument of *-1* forces downward-counting conventions.

The Z { (`calc-kbd-loop`) and Z } (`calc-kbd-end-loop`) commands are similar to Z < and Z >, except that they do not pop a count from the stack--they effectively create an infinite loop. Every Z { ... Z } loop ought to include at least one Z / to make sure the loop doesn't run forever. (If any error message occurs which causes Emacs to beep, the keyboard macro will also be halted; this is a standard feature of Emacs. You can also generally press C-g to halt a running keyboard macro, although not all versions of Unix support this feature.)

The conditional and looping constructs are not actually tied to keyboard macros, but they are most often used in that context. For example, the keystrokes 10 Z < 23 RET Z > push ten copies of 23 onto the stack. This can be typed "live" just as easily as in a macro definition.

See section Conditionals in Keyboard Macros, for some additional notes about conditional and looping commands.

Local Values in Macros

Keyboard macros sometimes want to operate under known conditions without affecting surrounding conditions. For example, a keyboard macro may wish to turn on Fraction Mode, or set a particular precision, independent of the user's normal setting for those modes.

Macros also sometimes need to use local variables. Assignments to local variables inside the macro should not affect any variables outside the macro. The Z ` (`calc-kbd-push`) and Z ' (`calc-kbd-pop`) commands give you both of these capabilities.

When you type Z ` (with a backquote or accent grave character), the values of various mode settings are saved away. The ten "quick" variables `q0` through `q9` are also saved. When you type Z ' (with an apostrophe), these values are restored. Pairs of Z ` and Z ' commands may be nested.

If a keyboard macro halts due to an error in between a Z ` and a Z ', the saved values will be restored correctly even though the macro never reaches the Z ' command. Thus you can use Z ` and Z ' without having to worry about what happens in exceptional conditions.

If you type Z ` "live" (not in a keyboard macro), Calc puts you into a "recursive edit." You can tell you are in a recursive edit because there will be extra square brackets in the mode line, as in `[(Calculator)]'. These brackets will go away when you type the matching Z ' command. The modes and quick variables will be saved and restored in just the same way as if actual keyboard macros were involved.

The modes saved by Z ` and Z ' are the current precision and binary word size, the angular mode (Deg, Rad, or HMS), the simplification mode, Algebraic mode, Symbolic mode, Infinite mode, Matrix or Scalar mode,

Fraction mode, and the current complex mode (Polar or Rectangular). The ten "quick" variables' values (or thereof) are also saved.

Most mode-setting commands act as toggles, but with a numeric prefix they force the mode either on (positive prefix) or off (negative or zero prefix). Since you don't know what the environment might be when you invoke your macro, it's best to use prefix arguments for all mode-setting commands inside the macro.

In fact, C-u Z ` is like Z ` except that it sets the modes listed above to their default values. As usual, the matching Z ' will restore the modes to their settings from before the C-u Z `. Also, Z ` with a negative prefix argument resets algebraic mode to its default (off) but leaves the other modes the same as they were outside the construct.

The contents of the stack and trail, values of non-quick variables, and other settings such as the language mode and the various display modes, are *not* affected by Z ` and Z '.

Queries in Keyboard Macros

The Z = (`calc-kbd-report`) command displays an informative message including the value on the top of the stack. You are prompted to enter a string. That string, along with the top-of-stack value, is displayed unless m w (`calc-working`) has been used to turn such messages off.

The Z # (`calc-kbd-query`) command displays a prompt message (which you enter during macro definition), then does an algebraic entry which takes its input from the keyboard, even during macro execution. This command allows your keyboard macros to accept numbers or formulas as interactive input. All the normal conventions of algebraic input, including the use of $ characters, are supported.

See section 'Kbd Macro Query' in the Emacs Manual, for a description of C-x q (`kbd-macro-query`), the standard Emacs way to accept keyboard input during a keyboard macro. In particular, you can use C-x q to enter a recursive edit, which allows the user to perform any Calculator operations interactively before pressing C-M-c to return control to the keyboard macro.

Invocation Macros

Calc provides one special keyboard macro, called up by M-# z (`calc-user-invocation`), that is intended to allow you to define your own special way of starting Calc. To define this "invocation macro," create the macro in the usual way with C-x (and C-x), then type Z I (`calc-user-define-invocation`). There is only one invocation macro, so you don't need to type any additional letters after Z I. From now on, you can type M-# z at any time to execute your invocation macro.

For example, suppose you find yourself often grabbing rectangles of numbers into Calc and multiplying their columns. You can do this by typing M-# r to grab, and V R : * to multiply columns. To make this into an invocation macro, just type C-x (M-# r V R : * C-x), then Z I. Then, to multiply a rectangle of data, just mark the data in its buffer in the usual way and type M-# z.

Invocation macros are treated like regular Emacs keyboard macros; all the special features described above for Z K-style macros do not apply. M-# z is just like C-x e, except that it uses the macro that was last stored by Z I. (In fact, the macro does not even have to have anything to do with Calc!)

The m m command saves the last invocation macro defined by Z I along with all the other Calc mode settings. See section General Mode Commands.

Programming with Formulas

Another way to create a new Calculator command uses algebraic formulas. The Z F (`calc-user-define-formula`) command stores the formula at the top of the stack as the definition for a key. This command prompts for five things: The key, the command name, the function name, the argument list, and the behavior of the command when given non-numeric arguments.

For example, suppose we type ' a+2b RET to push the formula `a + 2*b' onto the stack. We now type Z F m to define this formula on the z m key sequence. The next prompt is for a command name, beginning with `calc-', which should be the long (M-x) form for the new command. If you simply press RET, a default name like `calc-User-m` will be constructed. In our example, suppose we enter spam RET to define the new command as `calc-spam`.

If you want to give the formula a long-style name only, you can press SPC or RET when asked which single key to use. For example Z F RET spam RET defines the new command as M-x calc-spam, with no keyboard equivalent.

The third prompt is for a function name. The default is to use the same name as the command name but with `calcFunc-' in place of `calc-'. This is the name you will use if you want to enter your new function in an algebraic formula. Suppose we enter yow RET. Then the new function can be invoked by pushing two numbers on the stack and typing z m or x spam, or by entering the algebraic formula `yow(x,y)'.

The fourth prompt is for the function's argument list. This is used to associate values on the stack with the variables that appear in the formula. The default is a list of all variables which appear in the formula, sorted into alphabetical order. In our case, the default would be `(a b)'. This means that, when the user types z m, the Calculator will remove two numbers from the stack, substitute these numbers for `a' and `b' (respectively) in the formula, then simplify the formula and push the result on the stack. In other words, 10 RET 100 z m would replace the 10 and 100 on the stack with the number 210, which is a + 2 b with a=10 and b=100. Likewise, the formula `yow(10, 100)' will be evaluated by substituting a=10 and b=100 in the definition.

You can rearrange the order of the names before pressing RET to control which stack positions go to which variables in the formula. If you remove a variable from the argument list, that variable will be left in symbolic form by the command. Thus using an argument list of `(b)' for our function would cause 10 z m to replace the 10 on the stack with the formula `a + 20'. If we had used an argument list of `(b a)', the result with inputs 10 and 100 would have been 120.

You can also put a nameless function on the stack instead of just a formula, as in `<a, b : a + 2 b>'. See section Specifying Operators. In this example, the command will be defined by the formula `a + 2 b' using the argument list `(a b)'.

The final prompt is a y-or-n question concerning what to do if symbolic arguments are given to your function. If you answer y, then executing z m (using the original argument list `(a b)') with arguments 10 and x will leave the function in symbolic form, i.e., `yow(10,x)'. On the other hand, if you answer n, then the formula will always be expanded, even for non-constant arguments: `10 + 2 x'. If you never plan to feed algebraic formulas to your new function, it doesn't matter how you answer this question.

If you answered y to this question you can still cause a function call to be expanded by typing a " (`calc-expand-formula`). Also, Calc will expand the function if necessary when you take a derivative or integral or solve an equation involving the function.

Once you have defined a formula on a key, you can retrieve this formula with the Z G

TOC

(`calc-user-define-get-defn`) command. Press a key, and this command pushes the formula that was used to define that key onto the stack. Actually, it pushes a nameless function that specifies both the argument list and the defining formula. You will get an error message if the key is undefined, or if the key was not defined by a Z F command.

The Z E (`calc-user-define-edit`) command on a key that has been defined by a formula uses a variant of the `calc-edit` command to edit the defining formula. Press M-# M-# to finish editing and store the new formula back in the definition, or M-# x to cancel the edit. (The argument list and other properties of the definition are unchanged; to adjust the argument list, you can use Z G to grab the function onto the stack, edit with `, and then re-execute the Z F command.)

As usual, the Z P command records your definition permanently. In this case it will permanently record all three of the relevant definitions: the key, the command, and the function.

You may find it useful to turn off the default simplifications with m O (`calc-no-simplify-mode`) when entering a formula to be used as a function definition. For example, the formula `deriv(a^2,v)' which might be used to define a new function `dsqr(a,v)' will be "simplified" to 0 immediately upon entry since `deriv` considers a to be constant with respect to v. Turning off default simplifications cures this problem: The definition will be stored in symbolic form without ever activating the `deriv` function. Press m D to turn the default simplifications back on afterwards.

Programming with Lisp

The Calculator can be programmed quite extensively in Lisp. All you do is write a normal Lisp function definition, but with `defmath` in place of `defun`. This has the same form as `defun`, but it automagically replaces calls to standard Lisp functions like `+` and `zerop` with calls to the corresponding functions in Calc's own library. Thus you can write natural-looking Lisp code which operates on all of the standard Calculator data types. You can then use Z D if you wish to bind your new command to a z-prefix key sequence. The Z E command will not edit a Lisp-based definition.

Emacs Lisp is described in the GNU Emacs Lisp Reference Manual. This section assumes a familiarity with Lisp programming concepts; if you do not know Lisp, you may find keyboard macros or rewrite rules to be an easier way to program the Calculator.

This section first discusses ways to write commands, functions, or small programs to be executed inside of Calc. Then it discusses how your own separate programs are able to call Calc from the outside. Finally, there is a list of internal Calc functions and data structures for the true Lisp enthusiast.

Defining New Functions

The `defmath` function (actually a Lisp macro) is like `defun` except that code in the body of the definition can make use of the full range of Calculator data types. The prefix `calcFunc-' is added to the specified name to get the actual Lisp function name. As a simple example,

```
(defmath myfact (n)
  (if (> n 0)
      (* n (myfact (1- n)))
    1))
```

This actually expands to the code,

```
(defun calcFunc-myfact (n)
  (if (math-posp n)
      (math-mul n (calcFunc-myfact (math-add n -1)))
    1))
```

This function can be used in algebraic expressions, e.g., `myfact(5)'.

The `myfact' function as it is defined above has the bug that an expression `myfact(a+b)' will be simplified to 1 because the formula `a+b' is not considered to be `posp'. A robust factorial function would be written along the following lines:

```
(defmath myfact (n)
  (if (> n 0)
      (* n (myfact (1- n)))
    (if (= n 0)
        1
      nil)))    ; this could be simplified as: (and (= n 0) 1)
```

If a function returns `nil', it is left unsimplified by the Calculator (except that its arguments will be simplified). Thus, `myfact(a+1+2)' will be simplified to `myfact(a+3)' but no further. Beware that every time the Calculator reexamines this formula it will attempt to resimplify it, so your function ought to detect the returning-`nil' case as efficiently as possible.

The following standard Lisp functions are treated by `defmath': `+', `-', `*', `/', `%', `^' or `expt', `=', `<', `>', `<=', `>=', `/=', `1+', `1-', `logand', `logior', `logxor', `logandc2', `lognot'. Also, `~=' is an abbreviation for `math-nearly-equal', which is useful in implementing Taylor series.

For other functions func, if a function by the name `calcFunc-func' exists it is used, otherwise if a function by the name `math-func' exists it is used, otherwise if func itself is defined as a function it is used, otherwise `calcFunc-func' is used on the assumption that this is a to-be-defined math function. Also, if the function name is quoted as in `('integerp a)' the function name is always used exactly as written (but not quoted).

Variable names have `var-' prepended to them unless they appear in the function's argument list or in an enclosing `let', `let*', `for', or `foreach' form, or their names already contain a `-' character. Thus a reference to `foo' is the same as a reference to `var-foo'.

A few other Lisp extensions are available in `defmath' definitions:

- The `elt' function accepts any number of index variables. Note that Calc vectors are stored as Lisp lists whose first element is the symbol `vec'; thus, `(elt v 2)' yields the second element of vector `v', and `(elt m i j)' yields one element of a Calc matrix.
- The `setq' function has been extended to act like the Common Lisp `setf' function. (The name `setf' is recognized as a synonym of `setq'.) Specifically, the first argument of `setq' can be an `nth', `elt', `car', or `cdr' form, in which case the effect is to store into the specified element of a list. Thus, `(setq (elt m i j) x)' stores x into one element of a matrix.
- A `for' looping construct is available. For example, `(for ((i 0 10)) body)' executes `body' once for each binding of i from zero to 10. This is like a `let' form in that i is temporarily bound to the loop count without disturbing its value outside the `for' construct. Nested loops, as in `(for ((i 0 10) (j 0 (1- i) 2)) body)', are also available. For each value of i from zero to 10, j counts from 0 to i-1 in steps of two. Note that `for' has the same general outline as `let*', except that each element of the header is a list of three or

four things, not just two.

- The `foreach` construct loops over elements of a list. For example, `(foreach ((x (cdr v))) body)' executes `body` with x bound to each element of Calc vector v in turn. The purpose of `cdr` here is to skip over the initial `vec` symbol in the vector.
- The `break` function breaks out of the innermost enclosing `while`, `for`, or `foreach` loop. If given a value, as in `(break x)', this value is returned by the loop. (Lisp loops otherwise always return `nil`.)
- The `return` function prematurely returns from the enclosing function. For example, `(return (+ x y))' returns x+y as the value of a function. You can use `return` anywhere inside the body of the function.

Non-integer numbers (and extremely large integers) cannot be included directly into a `defmath` definition. This is because the Lisp reader will fail to parse them long before `defmath` ever gets control. Instead, use the notation, `:"3.1415"'. In fact, any algebraic formula can go between the quotes. For example,

```
(defmath sqexp (x)     ; sqexp(x) == sqrt(exp(x)) == exp(x*0.5)
  (and (numberp x)
       (exp :"x * 0.5")))
```

expands to

```
(defun calcFunc-sqexp (x)
  (and (math-numberp x)
       (calcFunc-exp (math-mul x '(float 5 -1)))))
```

Note the use of `numberp` as a guard to ensure that the argument is a number first, returning `nil` if not. The exponential function could itself have been included in the expression, if we had preferred: `:"exp(x * 0.5)"'. As another example, the multiplication-and-recursion step of `myfact` could have been written

```
:"n * myfact(n-1)"
```

If a file named `.emacs' exists in your home directory, Emacs reads and executes the Lisp forms in this file as it starts up. While it may seem like a good idea to put your favorite `defmath` commands here, this has the unfortunate side-effect that parts of the Calculator must be loaded in to process the `defmath` commands whether or not you will actually use the Calculator! A better effect can be had by writing

```
(put 'calc-define 'thing '(progn
 (defmath ... )
 (defmath ... )
))
```

The `put` function adds a property to a symbol. Each Lisp symbol has a list of properties associated with it. Here we add a property with a name of `thing` and a `(progn ...)' form as its value. When Calc starts up, and at the start of every Calc command, the property list for the symbol `calc-define` is checked and the values of any properties found are evaluated as Lisp forms. The properties are removed as they are evaluated. The property names (like `thing`) are not used; you should choose something like the name of your project so as not to conflict with other properties.

The net effect is that you can put the above code in your `.emacs' file and it will not be executed until Calc is loaded. Or, you can put that same code in another file which you load by hand either before or after Calc itself is loaded.

The properties of `calc-define` are evaluated in the same order that they were added. They can assume that the Calc modules `` `calc.el' ``, `` `calc-ext.el' ``, and `` `calc-macs.el' `` have been fully loaded, and that the `*Calculator*' buffer will be the current buffer.

If your `calc-define` property only defines algebraic functions, you can be sure that it will have been evaluated before Calc tries to call your function, even if the file defining the property is loaded after Calc is loaded. But if the property defines commands or key sequences, it may not be evaluated soon enough. (Suppose it defines the new command `tweak-calc`; the user can load your file, then type M-x tweak-calc before Calc has had chance to do anything.) To protect against this situation, you can put

```
(run-hooks 'calc-check-defines)
```

at the end of your file. The `calc-check-defines` function is what looks for and evaluates properties on `calc-define`; `run-hooks` has the advantage that it is quietly ignored if `calc-check-defines` is not yet defined because Calc has not yet been loaded.

Examples of things that ought to be enclosed in a `calc-define` property are `defmath` calls, `define-key` calls that modify the Calc key map, and any calls that redefine things defined inside Calc. Ordinary `defun`s need not be enclosed with `calc-define`.

Defining New Simple Commands

If a `defmath` form contains an `interactive` clause, it defines a Calculator command. Actually such a `defmath` results in *two* function definitions: One, a `calcFunc-' function as was just described, with the `interactive` clause removed. Two, a `calc-' function with a suitable `interactive` clause and some sort of wrapper to make the command work in the Calc environment.

In the simple case, the `interactive` clause has the same form as for normal Emacs Lisp commands:

```
(defmath increase-precision (delta)
  "Increase precision by DELTA."     ; This is the "documentation string"
  (interactive "p")                  ; Register this as a M-x-able command
  (setq calc-internal-prec (+ calc-internal-prec delta)))
```

This expands to the pair of definitions,

```
(defun calc-increase-precision (delta)
  "Increase precision by DELTA."
  (interactive "p")
  (calc-wrapper
   (setq calc-internal-prec (math-add calc-internal-prec delta))))

(defun calcFunc-increase-precision (delta)
  "Increase precision by DELTA."
  (setq calc-internal-prec (math-add calc-internal-prec delta)))
```

where in this case the latter function would never really be used! Note that since the Calculator stores small integers as plain Lisp integers, the `math-add` function will work just as well as the native `+` even when the intent is to operate on native Lisp integers.

The `calc-wrapper' call invokes a macro which surrounds the body of the function with code that looks roughly like this:

```
(let ((calc-command-flags nil))
  (unwind-protect
      (save-excursion
        (calc-select-buffer)
        body of function
        renumber stack
        clear Working message)
    realign cursor and window
    clear Inverse, Hyperbolic, and Keep Args flags
    update Emacs mode line))
```

The `calc-select-buffer` function selects the `*Calculator*' buffer if necessary, say, because the command was invoked from inside the `*Calc Trail*' window.

You can call, for example, `(calc-set-command-flag 'no-align)` to set the above-mentioned command flags. The following command flags are recognized by Calc routines:

`renum-stack`

Stack line numbers `1:', `2:', and so on must be renumbered after this command completes. This is set by routines like `calc-push`.

`clear-message`

Calc should call `(message "")' if this command completes normally (to clear a "Working..." message out of the echo area).

`no-align`

Do not move the cursor back to the `.' top-of-stack marker.

`position-point`

Use the variables `calc-position-point-line` and `calc-position-point-column` to position the cursor after this command finishes.

`keep-flags`

Do not clear `calc-inverse-flag`, `calc-hyperbolic-flag`, and `calc-keep-args-flag` at the end of this command.

`do-edit`

Switch to buffer `*Calc Edit*' after this command.

`hold-trail`

Do not move trail pointer to end of trail when something is recorded there.

Calc reserves a special prefix key, shift-Y, for user-written extensions to Calc. There are no built-in commands that work with this prefix key; you must call `define-key` from Lisp (probably from inside a `calc-define` property) to add to it. Initially only Y ? is defined; it takes help messages from a list of strings (initially `nil`) in the variable `calc-Y-help-msgs`. All other undefined keys except for Y are reserved for use by future versions of Calc.

If you are writing a Calc enhancement which you expect to give to others, it is best to minimize the number of Y-key sequences you use. In fact, if you have more than one key sequence you should consider defining

three-key sequences with a Y, then a key that stands for your package, then a third key for the particular command within your package.

Users may wish to install several Calc enhancements, and it is possible that several enhancements will choose to use the same key. In the example below, a variable `inc-prec-base-key` has been defined to contain the key that identifies the `inc-prec` package. Its value is initially `"P"`, but a user can change this variable if necessary without having to modify the file.

Here is a complete file, `` `inc-prec.el' ``, which makes a Y P I command that increases the precision, and a Y P D command that decreases the precision.

```
;;; Increase and decrease Calc precision.  Dave Gillespie, 5/31/91.
;;; (Include copyright or copyleft stuff here.)

(defvar inc-prec-base-key "P"
  "Base key for inc-prec.el commands.")

(put 'calc-define 'inc-prec '(progn

(define-key calc-mode-map (format "Y%sI" inc-prec-base-key)
            'increase-precision)
(define-key calc-mode-map (format "Y%sD" inc-prec-base-key)
            'decrease-precision)

(setq calc-Y-help-msgs
      (cons (format "%s + Inc-prec, Dec-prec" inc-prec-base-key)
            calc-Y-help-msgs))

(defmath increase-precision (delta)
  "Increase precision by DELTA."
  (interactive "p")
  (setq calc-internal-prec (+ calc-internal-prec delta)))

(defmath decrease-precision (delta)
  "Decrease precision by DELTA."
  (interactive "p")
  (setq calc-internal-prec (- calc-internal-prec delta)))

))  ; end of calc-define property

(run-hooks 'calc-check-defines)
```

Defining New Stack-Based Commands

To define a new computational command which takes and/or leaves arguments on the stack, a special form of `interactive` clause is used.

```
(interactive num tag)
```

where num is an integer, and tag is a string. The effect is to pop num values off the stack, resimplify them by calling `calc-normalize`, and hand them to your function according to the function's argument list. Your function may include `&optional` and `&rest` parameters, so long as calling the function with num parameters is legal.

Your function must return either a number or a formula in a form acceptable to Calc, or a list of such numbers or formulas. These value(s) are pushed onto the stack when the function completes. They are also recorded in the Calc Trail buffer on a line beginning with tag, a string of (normally) four characters or less. If you omit tag or use `nil` as a tag, the result is not recorded in the trail.

As an example, the definition

```
(defmath myfact (n)
  "Compute the factorial of the integer at the top of the stack."
  (interactive 1 "fact")
  (if (> n 0)
      (* n (myfact (1- n)))
    (and (= n 0) 1)))
```

is a version of the factorial function shown previously which can be used as a command as well as an algebraic function. It expands to

```
(defun calc-myfact ()
  "Compute the factorial of the integer at the top of the stack."
  (interactive)
  (calc-slow-wrapper
   (calc-enter-result 1 "fact"
     (cons 'calcFunc-myfact (calc-top-list-n 1)))))

(defun calcFunc-myfact (n)
  "Compute the factorial of the integer at the top of the stack."
  (if (math-posp n)
      (math-mul n (calcFunc-myfact (math-add n -1)))
    (and (math-zerop n) 1)))
```

The `calc-slow-wrapper` function is a version of `calc-wrapper` that automatically puts up a `Working...' message before the computation begins. (This message can be turned off by the user with an m w (`calc-working`) command.)

The `calc-top-list-n` function returns a list of the specified number of values from the top of the stack. It resimplifies each value by calling `calc-normalize`. If its argument is zero it returns an empty list. It does not actually remove these values from the stack.

The `calc-enter-result` function takes an integer num and string tag as described above, plus a third argument which is either a Calculator data object or a list of such objects. These objects are resimplified and pushed onto the stack after popping the specified number of values from the stack. If tag is non-`nil`, the values being pushed are also recorded in the trail.

Note that if `calcFunc-myfact` returns `nil` this represents "leave the function in symbolic form." To return an actual empty list, in the sense that `calc-enter-result` will push zero elements back onto the stack, you should return the special value `'(nil)', a list containing the single symbol `nil`.

The `interactive` declaration can actually contain a limited Emacs-style code string as well which comes just before num and tag. Currently the only Emacs code supported is `'"p"', as in

```
(defmath foo (a b &optional c)
  (interactive "p" 2 "foo")
  body)
```

In this example, the command `calc-foo` will evaluate the expression `foo(a,b)' if executed with no argument, or `foo(a,b,n)' if executed with a numeric prefix argument of n.

The other code string allowed is `'"m"' (unrelated to the usual `'"m"' code as used with `defun`). It uses the numeric prefix argument as the number of objects to remove from the stack and pass to the function. In this case, the integer num serves as a default number of arguments to be used when no prefix is supplied.

Argument Qualifiers

Anywhere a parameter name can appear in the parameter list you can also use an argument qualifier. Thus the general form of a definition is:

```
(defmath name (param param...
               &optional param param...
               &rest param)
  body)
```

where each param is either a symbol or a list of the form

```
(qual param)
```

The following qualifiers are recognized:

`complete'

The argument must not be an incomplete vector, interval, or complex number. (This is rarely needed since the Calculator itself will never call your function with an incomplete argument. But there is nothing stopping your own Lisp code from calling your function with an incomplete argument.)

`integer'

The argument must be an integer. If it is an integer-valued float it will be accepted but converted to integer form. Non-integers and formulas are rejected.

`natnum'

Like `integer', but the argument must be non-negative.

`fixnum'

Like `integer', but the argument must fit into a native Lisp integer, which on most systems means less than 2^23 in absolute value. The argument is converted into Lisp-integer form if necessary.

`float'

The argument is converted to floating-point format if it is a number or vector. If it is a formula it is left alone. (The argument is never actually rejected by this qualifier.)

`pred'

The argument must satisfy predicate pred, which is one of the standard Calculator predicates. See se
Predicates.

`not-pred'

The argument must *not* satisfy predicate pred.

For example,

```
(defmath foo (a (constp (not-matrixp b)) &optional (float c)
              &rest (integer d))
  body)
```

expands to

```
(defun calcFunc-foo (a b &optional c &rest d)
  (and (math-matrixp b)
       (math-reject-arg b 'not-matrixp))
  (or (math-constp b)
      (math-reject-arg b 'constp))
  (and c (setq c (math-check-float c)))
  (setq d (mapcar 'math-check-integer d))
  body)
```

which performs the necessary checks and conversions before executing the body of the function.

Example Definitions

This section includes some Lisp programming examples on a larger scale. These programs make use of some of the Calculator's internal functions; see section Calculator Internals.

Bit-Counting

Calc does not include a built-in function for counting the number of "one" bits in a binary integer. It's easy to invent one using b u to convert the integer to a set, and V # to count the elements of that set; let's write a function that counts the bits without having to create an intermediate set.

```
(defmath bcount ((natnum n))
  (interactive 1 "bcnt")
  (let ((count 0))
    (while (> n 0)
      (if (oddp n)
          (setq count (1+ count)))
      (setq n (lsh n -1)))
    count))
```

When this is expanded by `defmath`, it will become the following Emacs Lisp function:

```
(defun calcFunc-bcount (n)
  (setq n (math-check-natnum n))
```

```
  (let ((count 0))
    (while (math-posp n)
      (if (math-oddp n)
          (setq count (math-add count 1)))
      (setq n (calcFunc-lsh n -1)))
    count))
```

If the input numbers are large, this function involves a fair amount of arithmetic. A binary right shift is essentially a division by two; recall that Calc stores integers in decimal form so bit shifts must involve actual division.

To gain a bit more efficiency, we could divide the integer into *n*-bit chunks, each of which can be handled quickly because they fit into Lisp integers. It turns out that Calc's arithmetic routines are especially fast when dividing by an integer less than 1000, so we can set *n = 9* bits and use repeated division by 512:

```
(defmath bcount ((natnum n))
  (interactive 1 "bcnt")
  (let ((count 0))
    (while (not (fixnump n))
      (let ((qr (idivmod n 512)))
        (setq count (+ count (bcount-fixnum (cdr qr)))
              n (car qr))))
    (+ count (bcount-fixnum n))))

(defun bcount-fixnum (n)
  (let ((count 0))
    (while (> n 0)
      (setq count (+ count (logand n 1))
            n (lsh n -1)))
    count))
```

Note that the second function uses `defun`, not `defmath`. Because this function deals only with native Lisp integers ("fixnums"), it can use the actual Emacs `+` and related functions rather than the slower but more general Calc equivalents which `defmath` uses.

The `idivmod` function does an integer division, returning both the quotient and the remainder at once. Again, note that while it might seem that `(logand n 511)' and `(lsh n -9)' are more efficient ways to split off the bottom nine bits of `n`, actually they are less efficient because each operation is really a division by 512 in disguise; `idivmod` allows us to do the same thing with a single division by 512.

The Sine Function

A somewhat limited sine function could be defined as follows, using the well-known Taylor series expansion for @c{$\sin x$} `sin(x)':

```
(defmath mysin ((float (anglep x)))
  (interactive 1 "mysn")
  (setq x (to-radians x))    ; Convert from current angular mode.
  (let ((sum x)              ; Initial term of Taylor expansion of sin.
        newsum
```

```
      (nfact 1)             ; "nfact" equals "n" factorial at all times
      (xnegsqr :"-(x^2)")) ; "xnegsqr" equals -x^2.
  (for ((n 3 100 2))        ; Upper limit of 100 is a good precaution.
    (working "mysin" sum)   ; Display "Working" message, if enabled.
    (setq nfact (* nfact (1- n) n)
          x (* x xnegsqr)
          newsum (+ sum (/ x nfact)))
    (if (~= newsum sum)     ; If newsum is "nearly equal to" sum,
        (break))            ;  then we are done.
    (setq sum newsum))
  sum))
```

The actual `sin` function in Calc works by first reducing the problem to a sine or cosine of a nonnegative number less than @c{$\pi \over 4$} pi/4. This ensures that the Taylor series will converge quickly. Also, the calculation is carried out with two extra digits of precision to guard against cumulative round-off in `sum'. Finally, complex arguments are allowed and handled by a separate algorithm.

```
(defmath mysin ((float (scalarp x)))
  (interactive 1 "mysn")
  (setq x (to-radians x))     ; Convert from current angular mode.
  (with-extra-prec 2          ; Evaluate with extra precision.
    (cond ((complexp x)
           (mysin-complex x))
          ((< x 0)
           (- (mysin-raw (- x)))    ; Always call mysin-raw with x >= 0.
          (t (mysin-raw x))))))

(defmath mysin-raw (x)
  (cond ((>= x 7)
         (mysin-raw (% x (two-pi))))     ; Now x < 7.
        ((> x (pi-over-2))
         (- (mysin-raw (- x (pi)))))     ; Now -pi/2 <= x <= pi/2.
        ((> x (pi-over-4))
         (mycos-raw (- x (pi-over-2))))  ; Now -pi/2 <= x <= pi/4.
        ((< x (- (pi-over-4)))
         (- (mycos-raw (+ x (pi-over-2)))))  ; Now -pi/4 <= x <= pi/4,
        (t (mysin-series x))))           ; so the series will be efficient.
```

where `mysin-complex` is an appropriate function to handle complex numbers, `mysin-series` is the routine to compute the sine Taylor series as before, and `mycos-raw` is a function analogous to `mysin-raw` for cosines.

The strategy is to ensure that x is nonnegative before calling `mysin-raw`. This function then recursively reduces its argument to a suitable range, namely, plus-or-minus @c{$\pi \over 4$} pi/4. Note that each test, and particularly the first comparison against 7, is designed so that small roundoff errors cannnot produce an infinite loop. (Suppose we compared with `(two-pi)' instead; if due to roundoff problems the modulo operator ever returned `(two-pi)' exactly, an infinite recursion could result!) We use modulo only for arguments that will clearly get reduced, knowing that the next rule will catch any reductions that this rule misses.

If a program is being written for general use, it is important to code it carefully as shown in this second

example. For quick-and-dirty programs, when you know that your own use of the sine function will never encounter a large argument, a simpler program like the first one shown is fine.

Calling Calc from Your Lisp Programs

A later section (see section Calculator Internals) gives a full description of Calc's internal Lisp functions. It's not hard to call Calc from inside your programs, but the number of these functions can be daunting. So Calc provides one special "programmer-friendly" function called `calc-eval` that can be made to do just about everything you need. It's not as fast as the low-level Calc functions, but it's much simpler to use!

It may seem that `calc-eval` itself has a daunting number of options, but they all stem from one simple operation.

In its simplest manifestation, `(calc-eval "1+2")' parses the string `"1+2"` as if it were a Calc algebraic entry and returns the result formatted as a string: `"3"`.

Since `calc-eval` is on the list of recommended `autoload` functions, you don't need to make any special preparations to load Calc before calling `calc-eval` the first time. Calc will be loaded and initialized for you.

All the Calc modes that are currently in effect will be used when evaluating the expression and formatting the result.

Additional Arguments to `calc-eval`

If the input string parses to a list of expressions, Calc returns the results separated by `", "`. You can specify a different separator by giving a second string argument to `calc-eval`: `(calc-eval "1+2,3+4" ";")' returns `"3;7"`.

The "separator" can also be any of several Lisp symbols which request other behaviors from `calc-eval`. These are discussed one by one below.

You can give additional arguments to be substituted for `$', `$$', and so on in the main expression. For example, `(calc-eval "$/$$" nil "7" "1+1")' evaluates the expression `"7/(1+1)"` to yield the result `"3.5"` (assuming Fraction mode is not in effect). Note the `nil` used as a placeholder for the item-separator argument.

Error Handling

If `calc-eval` encounters an error, it returns a list containing the character position of the error, plus a suitable message as a string. Note that `1 / 0' is *not* an error by Calc's standards; it simply returns the string `"1 / 0"` which is the division left in symbolic form. But `(calc-eval "1/")' will return the list `(2 "Expected a number")'.

If you bind the variable `calc-eval-error` to `t` using a `let` form surrounding the call to `calc-eval`, errors instead call the Emacs `error` function which aborts to the Emacs command loop with a beep and an error message.

If you bind this variable to the symbol `string`, error messages are returned as strings instead of lists. The character position is ignored.

As a courtesy to other Lisp code which may be using Calc, be sure to bind `calc-eval-error` using `let` rather than changing it permanently with `setq`.

Numbers Only

Sometimes it is preferable to treat `1 / 0' as an error rather than returning a symbolic result. If you pass the symbol `num` as the second argument to `calc-eval`, results that are not constants are treated as errors. The error message reported is the first `calc-why` message if there is one, or otherwise "Number expected."

A result is "constant" if it is a number, vector, or other object that does not include variables or function calls. If it is a vector, the components must themselves be constants.

Default Modes

If the first argument to `calc-eval` is a list whose first element is a formula string, then `calc-eval` sets all the various Calc modes to their default values while the formula is evaluated and formatted. For example, the precision is set to 12 digits, digit grouping is turned off, and the normal language mode is used.

This same principle applies to the other options discussed below. If the first argument would normally be x, then it can also be the list `(x)' to use the default mode settings.

If there are other elements in the list, they are taken as variable-name/value pairs which override the default mode settings. Look at the documentation at the front of the `` `calc.el' `` file to find the names of the Lisp variables for the various modes. The mode settings are restored to their original values when `calc-eval` is done.

For example, `(calc-eval '("$+$$" calc-internal-prec 8) 'num a b)' computes the sum of two numbers, requiring a numeric result, and using default mode settings except that the precision is 8 instead of the default of 12.

It's usually best to use this form of `calc-eval` unless your program actually considers the interaction with Calc's mode settings to be a feature. This will avoid all sorts of potential "gotchas"; consider what happens with `(calc-eval "sqrt(2)" 'num)' when the user has left Calc in symbolic mode or no-simplify mode.

As another example, `(equal (calc-eval '("$<$$") nil a b) "1")' checks if the number in string a is less than the one in string b. Without using a list, the integer 1 might come out in a variety of formats which would be hard to test for conveniently: `"1"`, `"8#1"`, `"00001"`. (But see "Predicates" mode, below.)

Raw Numbers

Normally all input and output for `calc-eval` is done with strings. You can do arithmetic with, say, `(calc-eval "$+$$" nil a b)' in place of `(+ a b)', but this is very inefficient since the numbers must be converted to and from string format as they are passed from one `calc-eval` to the next.

If the separator is the symbol `raw`, the result will be returned as a raw Calc data structure rather than a string. You can read about how these objects look in the following sections, but usually you can treat them as "black box" objects with no important internal structure.

There is also a `rawnum` symbol, which is a combination of `raw` (returning a raw Calc object) and `num` (signalling an error if that object is not a constant).

You can pass a raw Calc object to `calc-eval` in place of a string, either as the formula itself or as one of the `$' arguments. Thus `(calc-eval "$+$$" 'raw a b)' is an addition function that operates on raw Calc objects. Of course in this case it would be easier to call the low-level `math-add` function in Calc, if you can remember its name.

In particular, note that a plain Lisp integer is acceptable to Calc as a raw object. (All Lisp integers are accepted on input, but integers of more than six decimal digits are converted to "big-integer" form for output. See section

Data Type Formats.)

When it comes time to display the object, just use `(calc-eval a)' to format it as a string.

It is an error if the input expression evaluates to a list of values. The separator symbol `list` is like `raw` except that it returns a list of one or more raw Calc objects.

Note that a Lisp string is not a valid Calc object, nor is a list containing a string. Thus you can still safely distinguish all the various kinds of error returns discussed above.

Predicates

If the separator symbol is `pred`, the result of the formula is treated as a true/false value; `calc-eval` returns `t` or `nil`, respectively. A value is considered "true" if it is a non-zero number, or false if it is zero or if it is not a number.

For example, `(calc-eval "$<$$" 'pred a b)' tests whether one value is less than another.

As usual, it is also possible for `calc-eval` to return one of the error indicators described above. Lisp will interpret such an indicator as "true" if you don't check for it explicitly. If you wish to have an error register as "false", use something like `(eq (calc-eval ...) t)'.

Variable Values

Variables in the formula passed to `calc-eval` are not normally replaced by their values. If you wish this, you can use the `evalv` function (see section Algebraic Manipulation). For example, if 4 is stored in Calc variable `a` (i.e., in Lisp variable `var-a`), then `(calc-eval "a+pi")' will return the formula `"a + pi"`, but `(calc-eval "evalv(a+pi)")' will return `"7.14159265359"`.

To store in a Calc variable, just use `setq` to store in the corresponding Lisp variable. (This is obtained by prepending `var-' to the Calc variable name.) Calc routines will understand either string or raw form values stored in variables, although raw data objects are much more efficient. For example, to increment the Calc variable `a`:

```
(setq var-a (calc-eval "evalv(a+1)" 'raw))
```

Stack Access

If the separator symbol is `push`, the formula argument is evaluated (with possible `$' expansions, as usual). The result is pushed onto the Calc stack. The return value is `nil` (unless there is an error from evaluating the formula, in which case the return value depends on `calc-eval-error` in the usual way).

If the separator symbol is `pop`, the first argument to `calc-eval` must be an integer instead of a string. That many values are popped from the stack and thrown away. A negative argument deletes the entry at that stack level. The return value is the number of elements remaining in the stack after popping; `(calc-eval 0 'pop)' is a good way to measure the size of the stack.

If the separator symbol is `top`, the first argument to `calc-eval` must again be an integer. The value at that stack level is formatted as a string and returned. Thus `(calc-eval 1 'top)' returns the top-of-stack value. If the integer is out of range, `nil` is returned.

The separator symbol `rawtop` is just like `top` except that the stack entry is returned as a raw Calc object

instead of as a string.

In all of these cases the first argument can be made a list in order to force the default mode settings, as described above. Thus `(calc-eval '(2 calc-number-radix 16) 'top)' returns the second-to-top stack entry, formatted as a string using the default instead of current display modes, except that the radix is hexadecimal instead of decimal.

It is, of course, polite to put the Calc stack back the way you found it when you are done, unless the user of your program is actually expecting it to affect the stack.

Note that you do not actually have to switch into the `*Calculator*' buffer in order to use `calc-eval`; it temporarily switches into the stack buffer if necessary.

Keyboard Macros

If the separator symbol is `macro`, the first argument must be a string of characters which Calc can execute as a sequence of keystrokes. This switches into the Calc buffer for the duration of the macro. For example, `(calc-eval "vx5\rVR+" 'macro)' pushes the vector `[1,2,3,4,5]' on the stack and then replaces it with the sum of those numbers. Note that `\r' is the Lisp notation for the carriage-return, RET, character.

If your keyboard macro wishes to pop the stack, `\C-d' is safer than `\177' (the DEL character) because some installations may have switched the meanings of DEL and C-h. Calc always interprets C-d as a synonym for "pop-stack" regardless of key mapping.

If you provide a third argument to `calc-eval`, evaluation of the keyboard macro will leave a record in the Trail using that argument as a tag string. Normally the Trail is unaffected.

The return value in this case is always `nil`.

Lisp Evaluation

Finally, if the separator symbol is `eval`, then the Lisp `eval` function is called on the first argument, which must be a Lisp expression rather than a Calc formula. Remember to quote the expression so that it is not evaluated until inside `calc-eval`.

The difference from plain `eval` is that `calc-eval` switches to the Calc buffer before evaluating the expression. For example, `(calc-eval '(setq calc-internal-prec 17) 'eval)' will correctly affect the buffer-local Calc precision variable.

An alternative would be `(calc-eval '(calc-precision 17) 'eval)'. This is evaluating a call to the function that is normally invoked by the p key, giving it 17 as its "numeric prefix argument." Note that this function will leave a message in the echo area as a side effect. Also, all Calc functions switch to the Calc buffer automatically if not invoked from there, so the above call is also equivalent to `(calc-precision 17)' by itself. In all cases, Calc uses `save-excursion` to switch back to your original buffer when it is done.

As usual the first argument can be a list that begins with a Lisp expression to use default instead of current mode settings.

The result of `calc-eval` in this usage is just the result returned by the evaluated Lisp expression.

Example

Here is a sample Emacs command that uses `calc-eval`. Suppose you have a document with lots of refer to temperatures on the Fahrenheit scale, say "98.6 F", and you wish to convert these references to Centigra The following command does this conversion. Place the Emacs cursor right after the letter "F" and invoke th command to change "98.6 F" to "37 C". Or, if the temperature is already in Centigrade form, the command changes it back to Fahrenheit.

```
(defun convert-temp ()
  (interactive)
  (save-excursion
    (re-search-backward "[^-.0-9]\\([-.0-9]+\\) *\\([FC]\\)")
    (let* ((top1 (match-beginning 1))
           (bot1 (match-end 1))
           (number (buffer-substring top1 bot1))
           (top2 (match-beginning 2))
           (bot2 (match-end 2))
           (type (buffer-substring top2 bot2)))
      (if (equal type "F")
          (setq type "C"
                number (calc-eval "($ - 32)*5/9" nil number))
        (setq type "F"
              number (calc-eval "$*9/5 + 32" nil number)))
      (goto-char top2)
      (delete-region top2 bot2)
      (insert-before-markers type)
      (goto-char top1)
      (delete-region top1 bot1)
      (if (string-match "\\.$" number)   ; change "37." to "37"
          (setq number (substring number 0 -1)))
      (insert number))))
```

Note the use of `insert-before-markers` when changing between "F" and "C", so that the character winds up before the cursor instead of after it.

Calculator Internals

This section describes the Lisp functions defined by the Calculator that may be of use to user-written Calculator programs (as described in the rest of this chapter). These functions are shown by their names as they conventionally appear in `defmath`. Their full Lisp names are generally gotten by prepending `calcFunc-' or `math-' to their apparent names. (Names that begin with `calc-' are already in their full Lisp form.) You can use the actual full names instead if you prefer them, or if you are calling these functions from regular Lisp.

The functions described here are scattered throughout the various Calc component files. Note that `` `calc.el' `` includes `autoload`s for only a few component files; when Calc wants to call an advanced function it calls `(calc-extensions)' first; this function autoloads `` `calc-ext.el' ``, which in turn autoloads all the functions in the remaining component files.

Because `defmath` itself uses the extensions, user-written code generally always executes with the extensions already loaded, so normally you can use any Calc function and be confident that it will be autoloaded for you when necessary. If you are doing something special, check carefully to make sure each function you are using is

from `calc.el' or its components, and call `(calc-extensions)' before using any function based in `calc-ext.el' if you can't prove this file will already be loaded.

Data Type Formats

Integers are stored in either of two ways, depending on their magnitude. Integers less than one million in absolute value are stored as standard Lisp integers. This is the only storage format for Calc data objects which is not a Lisp list.

Large integers are stored as lists of the form `(bigpos d0 d1 d2 ...)' for positive integers 1000000 or more, or `(bigneg d0 d1 d2 ...)' for negative integers *-1000000* or less. Each d is a base-1000 "digit," a Lisp integer from 0 to 999. The least significant digit is d0; the last digit, dn, which is always nonzero, is the most significant digit. For example, the integer *-12345678* is stored as `(bigneg 678 345 12)'.

The distinction between small and large integers is entirely hidden from the user. In `defmath` definitions, the Lisp predicate `integerp` returns true for either kind of integer, and in general both big and small integers are accepted anywhere the word "integer" is used in this manual. If the distinction must be made, native Lisp integers are called fixnums and large integers are called bignums.

Fractions are stored as a list of the form, `(frac n d)' where n is an integer (big or small) numerator, d is an integer denominator greater than one, and n and d are relatively prime. Note that fractions where d is one are automatically converted to plain integers by all math routines; fractions where d is negative are normalized by negating the numerator and denominator.

Floating-point numbers are stored in the form, `(float mant exp)', where mant (the "mantissa") is an integer less than `10^p' in absolute value (p represents the current precision), and exp (the "exponent") is a fixnum. The value of the float is `mant * 10^exp'. For example, the number *-3.14* is stored as `(float -314 -2) = -314*10^-2'. Other constraints are that the number 0.0 is always stored as `(float 0 0)', and, except for the 0.0 case, the rightmost base-10 digit of mant is always nonzero. (If the rightmost digit is zero, the number is rearranged by dividing mant by ten and incrementing exp.)

Rectangular complex numbers are stored in the form `(cplx re im)', where re and im are each real numbers, either integers, fractions, or floats. The value is `re + imi'. The im part is nonzero; complex numbers with zero imaginary components are converted to real numbers automatically.

Polar complex numbers are stored in the form `(polar r theta)', where r is a positive real value and theta is a real value or HMS form representing an angle. This angle is usually normalized to lie in the interval `(-180 .. 180)' degrees, or `(-pi .. pi)' radians, according to the current angular mode. If the angle is 0 the value is converted to a real number automatically. (If the angle is 180 degrees, the value is usually also converted to a negative real number.)

Hours-minutes-seconds forms are stored as `(hms h m s)', where h is an integer or an integer-valued float (i.e., a float with `exp >= 0'), m is an integer or integer-valued float in the range `[0 .. 60)', and s is any real number in the range `[0 .. 60)'.

Date forms are stored as `(date n)', where n is a real number that counts days since midnight on the morning of January 1, 1 AD. If n is an integer, this is a pure date form. If n is a fraction or float, this is a date/time form.

Modulo forms are stored as `(mod n m)', where m is a positive real number or HMS form, and n is a real number or HMS form in the range `[0 .. m)'.

Error forms are stored as `(sdev x sigma)', where x is the mean value and sigma is the standard deviation. Each

component is either a number, an HMS form, or a symbolic object (a variable or function call). If sigma is a the value is converted to a plain real number. If sigma is negative or complex, it is automatically normalized to be a positive real.

Interval forms are stored as `(intv mask lo hi)', where mask is one of the integers 0, 1, 2, or 3, and lo and hi are real numbers, HMS forms, or symbolic objects. The mask is a binary integer where 1 represents the fact that the interval is closed on the high end, and 2 represents the fact that it is closed on the low end. (Thus 3 represents a fully closed interval.) The interval `(intv 3 x x)' is converted to the plain number x; intervals `(intv mask x x)' for any other mask represent empty intervals. If hi is less than lo, the interval is converted to a standard empty interval by replacing hi with lo.

Vectors are stored as `(vec v1 v2 ...)', where v1 is the first element of the vector, v2 is the second, and so on. An empty vector is stored as `(vec)'. A matrix is simply a vector where all v's are themselves vectors of equal lengths. Note that Calc vectors are unrelated to the Emacs Lisp "vector" type, which is generally unused by Calc data structures.

Variables are stored as `(var name sym)', where name is a Lisp symbol whose print name is used as the visible name of the variable, and sym is a Lisp symbol in which the variable's value is actually stored. Thus, `(var pi var-pi)' represents the special constant `pi'. Almost always, the form is `(var v var-v)'. If the variable name was entered with # signs (which are converted to hyphens internally), the form is `(var u v)', where u is a symbol whose name contains # characters, and v is a symbol that contains `-' characters instead. The value of a variable is the Calc object stored in its sym symbol's value cell. If the symbol's value cell is void or if it contains `nil', the variable has no value. Special constants have the form `(special-const value)' stored in their value cell, where value is a formula which is evaluated when the constant's value is requested. Variables which represent units are not stored in any special way; they are units only because their names appear in the units table. If the value cell contains a string, it is parsed to get the variable's value when the variable is used.

A Lisp list with any other symbol as the first element is a function call. The symbols `+', `-', `*', `/', `%', `^', and `|' represent special binary operators; these lists are always of the form `(op lhs rhs)' where lhs is the sub-formula on the lefthand side and rhs is the sub-formula on the right. The symbol `neg' represents unary negation; this list is always of the form `(neg arg)'. Any other symbol func represents a function that would be displayed in function-call notation; the symbol func is in general always of the form `calcFunc-name'. The function cell of the symbol func should contain a Lisp function for evaluating a call to func. This function is passed the remaining elements of the list (themselves already evaluated) as arguments; such functions should return `nil' or call `reject-arg' to signify that they should be left in symbolic form, or they should return a Calc object which represents their value, or a list of such objects if they wish to return multiple values. (The latter case is allowed only for functions which are the outer-level call in an expression whose value is about to be pushed on the stack; this feature is considered obsolete and is not used by any built-in Calc functions.)

Interactive Functions

The functions described here are used in implementing interactive Calc commands. Note that this list is not exhaustive! If there is an existing command that behaves similarly to the one you want to define, you may find helpful tricks by checking the source code for that command.

Function: **calc-set-command-flag** *flag*

Set the command flag flag. This is generally a Lisp symbol, but may in fact be anything. The effect is to add flag to the list stored in the variable `calc-command-flags', unless it is already there. See section Defining New Simple Commands.

Function: **calc-clear-command-flag** *flag*

If flag appears among the list of currently-set command flags, remove it from that list.

Function: **calc-record-undo** *rec*

Add the "undo record" rec to the list of steps to take if the current operation should need to be undone. Stack push and pop functions automatically call `calc-record-undo`, so the kinds of undo records you might need to create take the form `(set sym value)', which says that the Lisp variable sym was changed and had previously contained value; `(store var value)' which says that the Calc variable var (a string which is the name of the symbol that contains the variable's value) was stored and its previous value was value (either a Calc data object, or `nil` if the variable was previously void); or `(eval undo redo args ...)', which means that to undo requires calling the function `(undo args ...)' and, if the undo is later redone, calling `(redo args ...)'.

Function: **calc-record-why** *msg args*

Record the error or warning message msg, which is normally a string. This message will be replayed if the user types w (`calc-why`); if the message string begins with a `*', it is considered important enough to display even if the user doesn't type w. If one or more args are present, the displayed message will be of the form, `msg: arg1, arg2, ...', where the arguments are formatted on the assumption that they are either strings or Calc objects of some sort. If msg is a symbol, it is the name of a Calc predicate (such as `integerp` or `numvecp`) which the arguments did not satisfy; it is expanded to a suitable string such as "Expected an integer." The `reject-arg` function calls `calc-record-why` automatically; see section Predicates.

Function: **calc-is-inverse**

This predicate returns true if the current command is inverse, i.e., if the Inverse (I key) flag was set.

Function: **calc-is-hyperbolic**

This predicate is the analogous function for the H key.

Stack-Oriented Functions

The functions described here perform various operations on the Calc stack and trail. They are to be used in interactive Calc commands.

Function: **calc-push-list** *vals n*

Push the Calc objects in list vals onto the stack at stack level n. If n is omitted it defaults to 1, so that the elements are pushed at the top of the stack. If n is greater than 1, the elements will be inserted into the stack so that the last element will end up at level n, the next-to-last at level n+1, etc. The elements of vals are assumed to be valid Calc objects, and are not evaluated, rounded, or renormalized in any way. If vals is an empty list, nothing happens.

The stack elements are pushed without any sub-formula selections. You can give an optional third argument to this function, which must be a list the same size as vals of selections. Each selection must be `eq` to some sub-formula of the corresponding formula in vals, or `nil` if that formula should have no selection.

Function: **calc-top-list** *n m*

Return a list of the n objects starting at level m of the stack. If m is omitted it defaults to 1, so that the elements are taken from the top of the stack. If n is omitted, it also defaults to 1, so that the top stack element (in the form of a one-element list) is returned. If m is greater than 1, the mth stack element will be at the end of the list, the

m+1st element will be next-to-last, etc. If n or m are out of range, the command is aborted with a suitable error message. If n is zero, the function returns an empty list. The stack elements are not evaluated, rounded, or renormalized.

If any stack elements contain selections, and selections have not been disabled by the j e (`calc-enable-selections`) command, this function returns the selected portions rather than the entire stack elements. It can be given a third "selection-mode" argument which selects other behaviors. If it is the symbol `t`, then a selection in any of the requested stack elements produces an "illegal operation on selections" error. If it is the symbol `full`, the whole stack entry is always returned regardless of selections. If it is the symbol `sel`, the selected portion is always returned, or `nil` if there is no selection. (This mode ignores the j e command.) If the symbol is `entry`, the complete stack entry in list form is returned; the first element of this list will be the whole formula, and the third element will be the selection (or `nil`).

Function: **calc-pop-stack** *n m*

Remove the specified elements from the stack. The parameters n and m are defined the same as for `calc-top-list`. The return value of `calc-pop-stack` is uninteresting.

If there are any selected sub-formulas among the popped elements, and j e has not been used to disable selections, this produces an error without changing the stack. If you supply an optional third argument of `t`, the stack elements are popped even if they contain selections.

Function: **calc-record-list** *vals tag*

This function records one or more results in the trail. The vals are a list of strings or Calc objects. The tag is the four-character tag string to identify the values. If tag is omitted, a blank tag will be used.

Function: **calc-normalize** *n*

This function takes a Calc object and "normalizes" it. At the very least this involves re-rounding floating-point values according to the current precision and other similar jobs. Also, unless the user has selected no-simplify mode (see section Simplification Modes), this involves actually evaluating a formula object by executing the function calls it contains, and possibly also doing algebraic simplification, etc.

Function: **calc-top-list-n** *n m*

This function is identical to `calc-top-list`, except that it calls `calc-normalize` on the values that it takes from the stack. They are also passed through `check-complete`, so that incomplete objects will be rejected with an error message. All computational commands should use this in preference to `calc-top-list`; the only standard Calc commands that operate on the stack without normalizing are stack management commands like `calc-enter` and `calc-roll-up`. This function accepts the same optional selection-mode argument as `calc-top-list`.

Function: **calc-top-n** *m*

This function is a convenient form of `calc-top-list-n` in which only a single element of the stack is taken and returned, rather than a list of elements. This also accepts an optional selection-mode argument.

Function: **calc-enter-result** *n tag vals*

This function is a convenient interface to most of the above functions. The vals argument should be either a single Calc object, or a list of Calc objects; the object or objects are normalized, and the top n stack entries are replaced by the normalized objects. If tag is non-`nil`, the normalized objects are also recorded in the trail. A

typical stack-based computational command would take the form,

```
(calc-enter-result n tag (cons 'calcFunc-func
                               (calc-top-list-n n)))
```

If any of the n stack elements replaced contain sub-formula selections, and selections have not been disabled by j e, this function takes one of two courses of action. If n is equal to the number of elements in vals, then each element of vals is spliced into the corresponding selection; this is what happens when you use the TAB key, or when you use a unary arithmetic operation like `sqrt`. If vals has only one element but n is greater than one, there must be only one selection among the top n stack elements; the element from vals is spliced into that selection. This is what happens when you use a binary arithmetic operation like +. Any other combination of n and vals is an error when selections are present.

Function: **calc-unary-op** *tag func arg*

This function implements a unary operator that allows a numeric prefix argument to apply the operator over many stack entries. If the prefix argument arg is `nil`, this uses `calc-enter-result` as outlined above. Otherwise, it maps the function over several stack elements; see section Numeric Prefix Arguments. For example,

```
(defun calc-zeta (arg)
  (interactive "P")
  (calc-unary-op "zeta" 'calcFunc-zeta arg))
```

Function: **calc-binary-op** *tag func arg ident unary*

This function implements a binary operator, analogously to `calc-unary-op`. The optional ident and unary arguments specify the behavior when the prefix argument is zero or one, respectively. If the prefix is zero, the value ident is pushed onto the stack, if specified, otherwise an error message is displayed. If the prefix is one, the unary function unary is applied to the top stack element, or, if unary is not specified, nothing happens. When the argument is two or more, the binary function func is reduced across the top arg stack elements; when the argument is negative, the function is mapped between the next-to-top *-arg* stack elements and the top element.

Function: **calc-stack-size**

Return the number of elements on the stack as an integer. This count does not include elements that have been temporarily hidden by stack truncation; see section Truncating the Stack.

Function: **calc-cursor-stack-index** *n*

Move the point to the nth stack entry. If n is zero, this will be the `.' line. If n is from 1 to the current stack size, this will be the beginning of the first line of that stack entry's display. If line numbers are enabled, this will move to the first character of the line number, not the stack entry itself.

Function: **calc-substack-height** *n*

Return the number of lines between the beginning of the nth stack entry and the bottom of the buffer. If n is zero, this will be one (assuming no stack truncation). If all stack entries are one line long (i.e., no matrices are displayed), the return value will be equal n+1 as long as n is in range. (Note that in Big mode, the return value includes the blank lines that separate stack entries.)

Function: **calc-refresh**

Erase the `*Calculator*` buffer and reformat its contents from memory. This must be called after chang any parameter, such as the current display radix, which might change the appearance of existing stack entri (During a keyboard macro invoked by the X key, refreshing is suppressed, but a flag is set so that the entire stack will be refreshed rather than just the top few elements when the macro finishes.)

Predicates

The functions described here are predicates, that is, they return a true/false value where `nil` means false and anything else means true. These predicates are expanded by `defmath`, for example, from `zerop` to `math-zerop`. In many cases they correspond to native Lisp functions by the same name, but are extended to cover the full range of Calc data types.

Function: **zerop** *x*

Returns true if x is numerically zero, in any of the Calc data types. (Note that for some types, such as error forms and intervals, it never makes sense to return true.) In `defmath`, the expression `(= x 0)' will automatically be converted to `(math-zerop x)', and `(/= x 0)' will be converted to `(not (math-zerop x))'.

Function: **negp** *x*

Returns true if x is negative. This accepts negative real numbers of various types, negative HMS and date forms, and intervals in which all included values are negative. In `defmath`, the expression `(< x 0)' will automatically be converted to `(math-negp x)', and `(>= x 0)' will be converted to `(not (math-negp x))'.

Function: **posp** *x*

Returns true if x is positive (and non-zero). For complex numbers, none of these three predicates will return true.

Function: **looks-negp** *x*

Returns true if x is "negative-looking." This returns true if x is a negative number, or a formula with a leading minus sign such as `-a/b'. In other words, this is an object which can be made simpler by calling `(- x)`.

Function: **integerp** *x*

Returns true if x is an integer of any size.

Function: **fixnump** *x*

Returns true if x is a native Lisp integer.

Function: **natnump** *x*

Returns true if x is a nonnegative integer of any size.

Function: **fixnatnump** *x*

Returns true if x is a nonnegative Lisp integer.

Function: **num-integerp** *x*

Returns true if x is numerically an integer, i.e., either a true integer or a float with no significant digits to the right of the decimal point.

Function: **messy-integerp** *x*

Returns true if x is numerically, but not literally, an integer. A value is `num-integerp` if it is `integerp` | `messy-integerp` (but it is never both at once).

Function: **num-natnump** *x*

Returns true if x is numerically a nonnegative integer.

Function: **evenp** *x*

Returns true if x is an even integer.

Function: **looks-evenp** *x*

Returns true if x is an even integer, or a formula with a leading multiplicative coefficient which is an even integer.

Function: **oddp** *x*

Returns true if x is an odd integer.

Function: **ratp** *x*

Returns true if x is a rational number, i.e., an integer or a fraction.

Function: **realp** *x*

Returns true if x is a real number, i.e., an integer, fraction, or floating-point number.

Function: **anglep** *x*

Returns true if x is a real number or HMS form.

Function: **floatp** *x*

Returns true if x is a float, or a complex number, error form, interval, date form, or modulo form in which at least one component is a float.

Function: **complexp** *x*

Returns true if x is a rectangular or polar complex number (but not a real number).

Function: **rect-complexp** *x*

Returns true if x is a rectangular complex number.

Function: **polar-complexp** *x*

Returns true if x is a polar complex number.

Function: **numberp** *x*

Returns true if x is a real number or a complex number.

Function: **scalarp** *x*

Returns true if x is a real or complex number or an HMS form.

Function: **vectorp** *x*

Returns true if x is a vector (this simply checks if its argument is a list whose first element is the symbol `ve

Function: **numvecp** *x*

Returns true if x is a number or vector.

Function: **matrixp** *x*

Returns true if x is a matrix, i.e., a vector of one or more vectors, all of the same size.

Function: **square-matrixp** *x*

Returns true if x is a square matrix.

Function: **objectp** *x*

Returns true if x is any numeric Calc object, including real and complex numbers, HMS forms, date forms, error forms, intervals, and modulo forms. (Note that error forms and intervals may include formulas as their components; see `constp` below.)

Function: **objvecp** *x*

Returns true if x is an object or a vector. This also accepts incomplete objects, but it rejects variables and formulas (except as mentioned above for `objectp`).

Function: **primp** *x*

Returns true if x is a "primitive" or "atomic" Calc object, i.e., one whose components cannot be regarded as sub-formulas. This includes variables, and all `objectp` types except error forms and intervals.

Function: **constp** *x*

Returns true if x is constant, i.e., a real or complex number, HMS form, date form, or error form, interval, or vector all of whose components are `constp`.

Function: **lessp** *x y*

Returns true if x is numerically less than y. Returns false if x is greater than or equal to y, or if the order is undefined or cannot be determined. Generally speaking, this works by checking whether `x - y' is `negp`. In `defmath`, the expression `(< x y)' will automatically be converted to `(lessp x y)'; expressions involving `>`, `<=`, and `>=` are similarly converted in terms of `lessp`.

Function: **beforep** *x y*

Returns true if x comes before y in a canonical ordering of Calc objects. If x and y are both real numbers, this will be the same as `lessp`. But whereas `lessp` considers other types of objects to be unordered, `beforep` puts any two objects into a definite, consistent order. The `beforep` function is used by the V S vector-sorting command, and also by a s to put the terms of a product into canonical order: This allows `x y + y x' to be simplified easily to `2 x y'.

Function: **equal** *x y*

This is the standard Lisp `equal` predicate; it returns true if x and y are structurally identical. This is the usual way to compare numbers for equality, but note that `equal` will treat 0 and 0.0 as different.

Function: **math-equal** *x y*

Returns true if x and y are numerically equal, either because they are `equal`, or because their difference is `zerop`. In `defmath`, the expression `(= x y)' will automatically be converted to `(math-equal x y)'.

Function: **equal-int** *x n*

Returns true if x and n are numerically equal, where n is a fixnum which is not a multiple of 10. This will automatically be used by `defmath` in place of the more general `math-equal` whenever possible.

Function: **nearly-equal** *x y*

Returns true if x and y, as floating-point numbers, are equal except possibly in the last decimal place. For example, 314.159 and 314.166 are considered nearly equal if the current precision is 6 (since they differ by 7 units), but not if the current precision is 7 (since they differ by 70 units). Most functions which use series expansions use `with-extra-prec` to evaluate the series with 2 extra digits of precision, then use `nearly-equal` to decide when the series has converged; this guards against cumulative error in the series evaluation without doing extra work which would be lost when the result is rounded back down to the current precision. In `defmath`, this can be written `(~= x y)'. The x and y can be numbers of any kind, including complex.

Function: **nearly-zerop** *x y*

Returns true if x is nearly zero, compared to y. This checks whether x plus y would by be `nearly-equal` to y itself, to within the current precision, in other words, if adding x to y would have a negligible effect on y due to roundoff error. X may be a real or complex number, but y must be real.

Function: **is-true** *x*

Return true if the formula x represents a true value in Calc, not Lisp, terms. It tests if x is a non-zero number or a provably non-zero formula.

Function: **reject-arg** *val pred*

Abort the current function evaluation due to unacceptable argument values. This calls `(calc-record-why pred val)', then signals a Lisp error which `normalize` will trap. The net effect is that the function call which led here will be left in symbolic form.

Function: **inexact-value**

If Symbolic Mode is enabled, this will signal an error that causes `normalize` to leave the formula in symbolic form, with the message "Inexact result." (This function has no effect when not in Symbolic Mode.) Note that if your function calls `(sin 5)' in Symbolic Mode, the `sin` function will call `inexact-value`, which will cause your function to be left unsimplified. You may instead wish to call `(normalize (list 'calcFunc-sin 5))', which in Symbolic Mode will return the formula `sin(5)' to your function.

Function: **overflow**

This signals an error that will be reported as a floating-point overflow.

Function: **underflow**

This signals a floating-point underflow.

Computational Functions

The functions described here do the actual computational work of the Calculator. In addition to these, note any function described in the main body of this manual may be called from Lisp; for example, if the documentation refers to the `calc-sqrt` [`sqrt`] command, this means `calc-sqrt` is an interactive stack-based square-root command and `sqrt` (which `defmath` expands to `calcFunc-sqrt`) is the actual Lisp function for taking square roots.

The functions `math-add`, `math-sub`, `math-mul`, `math-div`, `math-mod`, and `math-neg` are not included in this list, since `defmath` allows you to write native Lisp `+`, `-`, `*`, `/`, `%`, and unary `-`, respectively, instead.

Function: **normalize** *val*

(Full form: `math-normalize`.) Reduce the value val to standard form. For example, if val is a fixnum, it will be converted to a bignum if it is too large, and if val is a bignum it will be normalized by clipping off trailing (i.e., most-significant) zero digits and converting to a fixnum if it is small. All the various data types are similarly converted to their standard forms. Variables are left alone, but function calls are actually evaluated in formulas. For example, normalizing `(+ 2 (calcFunc-abs -4))' will return 6.

If a function call fails, because the function is void or has the wrong number of parameters, or because it returns `nil` or calls `reject-arg` or `inexact-result`, `normalize` returns the formula still in symbolic form.

If the current Simplification Mode is "none" or "numeric arguments only," `normalize` will act appropriately. However, the more powerful simplification modes (like algebraic simplification) are not handled by `normalize`. They are handled by `calc-normalize`, which calls `normalize` and possibly some other routines, such as `simplify` or `simplify-units`. Programs generally will never call `calc-normalize` except when popping or pushing values on the stack.

Function: **evaluate-expr** *expr*

Replace all variables in expr that have values with their values, then use `normalize` to simplify the result. This is what happens when you press the = key interactively.

Macro: **with-extra-prec** *n body*

Evaluate the Lisp forms in body with precision increased by n digits. This is a macro which expands to

```
(math-normalize
  (let ((calc-internal-prec (+ calc-internal-prec n)))
    body))
```

The surrounding call to `math-normalize` causes a floating-point result to be rounded down to the original precision afterwards. This is important because some arithmetic operations assume a number's mantissa contains no more digits than the current precision allows.

Function: **make-frac** *n d*

Build a fraction `n:d'. This is equivalent to calling `(normalize (list 'frac n d))', but more efficient.

Function: **make-float** *mant exp*

Build a floating-point value out of mant and exp, both of which are arbitrary integers. This function will return a properly normalized float value, or signal an overflow or underflow if exp is out of range.

Function: **make-sdev** *x sigma*

Build an error form out of x and the absolute value of sigma. If sigma is zero, the result is the number x di
If sigma is negative or complex, its absolute value is used. If x or sigma is not a valid type of object for use in
error forms, this calls `reject-arg`.

Function: **make-intv** *mask lo hi*

Build an interval form out of mask (which is assumed to be an integer from 0 to 3), and the limits lo and hi. If lo is greater than hi, an empty interval form is returned. This calls `reject-arg` if lo or hi is unsuitable.

Function: **sort-intv** *mask lo hi*

Build an interval form, similar to `make-intv`, except that if lo is less than hi they are simply exchanged, and the bits of mask are swapped accordingly.

Function: **make-mod** *n m*

Build a modulo form out of n and the modulus m. Since modulo forms do not allow formulas as their components, if n or m is not a real number or HMS form the result will be a formula which is a call to `makemod`, the algebraic version of this function.

Function: **float** *x*

Convert x to floating-point form. Integers and fractions are converted to numerically equivalent floats; components of complex numbers, vectors, HMS forms, date forms, error forms, intervals, and modulo forms are recursively floated. If the argument is a variable or formula, this calls `reject-arg`.

Function: **compare** *x y*

Compare the numbers x and y, and return *-1* if `(lessp x y)', 1 if `(lessp y x)', 0 if `(math-equal x y)', or 2 if the order is undefined or cannot be determined.

Function: **numdigs** *n*

Return the number of digits of integer n, effectively `ceil(log10(n))', but much more efficient. Zero is considered to have zero digits.

Function: **scale-int** *x n*

Shift integer x left n decimal digits, or right *-n* digits with truncation toward zero.

Function: **scale-rounding** *x n*

Like `scale-int`, except that a right shift rounds to the nearest integer rather than truncating.

Function: **fixnum** *n*

Return the integer n as a fixnum, i.e., a native Lisp integer. If n is outside the permissible range for Lisp integers (usually 24 binary bits) the result is undefined.

Function: **sqr** *x*

Compute the square of x; short for `(* x x)'.

Function: **quotient** *x y*

Divide integer x by integer y; return an integer quotient and discard the remainder. If x or y is negative, the

direction of rounding is undefined.

Function: **idiv** *x y*

Perform an integer division; if x and y are both nonnegative integers, this uses the `quotient` function, otherwise it computes `floor(x/y)'. Thus the result is well-defined but slower than for `quotient`.

Function: **imod** *x y*

Divide integer x by integer y; return the integer remainder and discard the quotient. Like `quotient`, this works only for integer arguments and is not well-defined for negative arguments. For a more well-defined result, use `(% x y)'.

Function: **idivmod** *x y*

Divide integer x by integer y; return a cons cell whose `car` is `(quotient x y)' and whose `cdr` is `(imod x y)'.

Function: **pow** *x y*

Compute x to the power y. In `defmath` code, this can also be written `(^ x y)' or `(expt x y)'.

Function: **abs-approx** *x*

Compute a fast approximation to the absolute value of x. For example, for a rectangular complex number the result is the sum of the absolute values of the components.

Function: **pi**

The function `(pi)' computes `pi' to the current precision. Other related constant-generating functions are `two-pi`, `pi-over-2`, `pi-over-4`, `pi-over-180`, `sqrt-two-pi`, `e`, `sqrt-e`, `ln-2`, and `ln-10`. Each function returns a floating-point value in the current precision, and each uses caching so that all calls after the first are essentially free.

Macro: **math-defcache** *func initial form*

This macro, usually used as a top-level call like `defun` or `defvar`, defines a new cached constant analogous to `pi`, etc. It defines a function `func` which returns the requested value; if initial is non-`nil` it must be a `(float ...)' form which serves as an initial value for the cache. If func is called when the cache is empty or does not have enough digits to satisfy the current precision, the Lisp expression form is evaluated with the current precision increased by four, and the result minus its two least significant digits is stored in the cache. For example, calling `(pi)' with a precision of 30 computes `pi' to 34 digits, rounds it down to 32 digits for future use, then rounds it again to 30 digits for use in the present request.

Function: **full-circle** *symb*

If the current angular mode is Degrees or HMS, this function returns the integer 360. In Radians mode, this function returns either the corresponding value in radians to the current precision, or the formula `2*pi', depending on the Symbolic Mode. There are also similar function `half-circle` and `quarter-circle`.

Function: **power-of-2** *n*

Compute two to the integer power n, as a (potentially very large) integer. Powers of two are cached, so only the first call for a particular n is expensive.

Function: **integer-log2** *n*

Compute the base-2 logarithm of n, which must be an integer which is a power of two. If n is not a power of two, this function will return `nil`.

Function: **div-mod** *a b m*

Divide a by b, modulo m. This returns `nil` if there is no solution, or if any of the arguments are not integers.

Function: **pow-mod** *a b m*

Compute a to the power b, modulo m. If a, b, and m are integers, this uses an especially efficient algorithm. Otherwise, it simply computes `(% (^ a b) m)'.

Function: **isqrt** *n*

Compute the integer square root of n. This is the square root of n rounded down toward zero, i.e., `floor(sqrt(n))'. If n is itself an integer, the computation is especially efficient.

Function: **to-hms** *a ang*

Convert the argument a into an HMS form. If ang is specified, it is the angular mode in which to interpret a, either `deg` or `rad`. Otherwise, the current angular mode is used. If a is already an HMS form it is returned as-is.

Function: **from-hms** *a ang*

Convert the HMS form a into a real number. If ang is specified, it is the angular mode in which to express the result, otherwise the current angular mode is used. If a is already a real number, it is returned as-is.

Function: **to-radians** *a*

Convert the number or HMS form a to radians from the current angular mode.

Function: **from-radians** *a*

Convert the number a from radians to the current angular mode. If a is a formula, this returns the formula `deg(a)'.

Function: **to-radians-2** *a*

Like `to-radians`, except that in Symbolic Mode a degrees to radians conversion yields a formula like `a*pi/180'.

Function: **from-radians-2** *a*

Like `from-radians`, except that in Symbolic Mode a radians to degrees conversion yields a formula like `a*180/pi'.

Function: **random-digit**

Produce a random base-1000 digit in the range 0 to 999.

Function: **random-digits** *n*

Produce a random n-digit integer; this will be an integer in the interval `[0, 10^n)'.

Function: **random-float**

Produce a random float in the interval `[0, 1)'.

Function: **prime-test** *n iters*

Determine whether the integer n is prime. Return a list which has one of these forms: `(nil f)' means the number is non-prime because it was found to be divisible by f; `(nil)' means it was found to be non-prime by table look-up (so no factors are known); `(nil unknown)' means it is definitely non-prime but no factors are known because n was large enough that Fermat's probabilistic test had to be used; `(t)' means the number is definitely prime; and `(maybe i p)' means that Fermat's test, after i iterations, is p percent sure that the number is prime. The iters parameter is the number of Fermat iterations to use, in the case that this is necessary. If `prime-test` returns "maybe," you can call it again with the same n to get a greater certainty; `prime-test` remembers where it left off.

Function: **to-simple-fraction** *f*

If f is a floating-point number which can be represented exactly as a small rational number. return that number, else return f. For example, 0.75 would be converted to 3:4. This function is very fast.

Function: **to-fraction** *f tol*

Find a rational approximation to floating-point number f to within a specified tolerance tol; this corresponds to the algebraic function `frac`, and can be rather slow.

Function: **quarter-integer** *n*

If n is an integer or integer-valued float, this function returns zero. If n is a half-integer (i.e., an integer plus *1:2* or 0.5), it returns 2. If n is a quarter-integer, it returns 1 or 3. If n is anything else, this function returns `nil`.

Vector Functions

The functions described here perform various operations on vectors and matrices.

Function: **math-concat** *x y*

Do a vector concatenation; this operation is written `x | y' in a symbolic formula. See section Building Vectors.

Function: **vec-length** *v*

Return the length of vector v. If v is not a vector, the result is zero. If v is a matrix, this returns the number of rows in the matrix.

Function: **mat-dimens** *m*

Determine the dimensions of vector or matrix m. If m is not a vector, the result is an empty list. If m is a plain vector but not a matrix, the result is a one-element list containing the length of the vector. If m is a matrix with r rows and c columns, the result is the list `(r c)'. Higher-order tensors produce lists of more than two dimensions. Note that the object `[[1, 2, 3], [4, 5]]' is a vector of vectors not all the same size, and is treated by this and other Calc routines as a plain vector of two elements.

Function: **dimension-error**

Abort the current function with a message of "Dimension error." The Calculator will leave the function being evaluated in symbolic form; this is really just a special case of `reject-arg`.

Function: **build-vector** *args*

Return a Calc vector with the zero-or-more args as elements. For example, `(build-vector 1 2 3)' returns the Calc vector `[1, 2, 3]', stored internally as the list `(vec 1 2 3)'.

Function: **make-vec** *obj dims*

Return a Calc vector or matrix all of whose elements are equal to obj. For example, `(make-vec 27 3 4)' returns a 3x4 matrix filled with 27's.

Function: **row-matrix** *v*

If v is a plain vector, convert it into a row matrix, i.e., a matrix whose single row is v. If v is already a matrix, leave it alone.

Function: **col-matrix** *v*

If v is a plain vector, convert it into a column matrix, i.e., a matrix with each element of v as a separate row. If v is already a matrix, leave it alone.

Function: **map-vec** *f v*

Map the Lisp function f over the Calc vector v. For example, `(map-vec 'math-floor v)' returns a vector of the floored components of vector v.

Function: **map-vec-2** *f a b*

Map the Lisp function f over the two vectors a and b. If a and b are vectors of equal length, the result is a vector of the results of calling `(f ai bi)' for each pair of elements ai and bi. If either a or b is a scalar, it is matched with each value of the other vector. For example, `(map-vec-2 'math-add v 1)' returns the vector v with each element increased by one. Note that using `'+' would not work here, since `defmath` does not expand function names everywhere, just where they are in the function position of a Lisp expression.

Function: **reduce-vec** *f v*

Reduce the function f over the vector v. For example, if v is `[10, 20, 30, 40]', this calls `(f (f (f 10 20) 30) 40)'. If v is a matrix, this reduces over the rows of v.

Function: **reduce-cols** *f m*

Reduce the function f over the columns of matrix m. For example, if m is `[[1, 2], [3, 4], [5, 6]]', the result is a vector of the two elements `(f (f 1 3) 5)' and `(f (f 2 4) 6)'.

Function: **mat-row** *m n*

Return the nth row of matrix m. This is equivalent to `(elt m n)'. For a slower but safer version, use `mrow`. (See section Extracting Vector Elements.)

Function: **mat-col** *m n*

Return the nth column of matrix m, in the form of a vector. The arguments are not checked for correctness.

Function: **mat-less-row** *m n*

Return a copy of matrix m with its nth row deleted. The number n must be in range from 1 to the number of rows in m.

Function: **mat-less-col** *m n*

Return a copy of matrix m with its nth column deleted.

Function: **transpose** *m*

Return the transpose of matrix m.

Function: **flatten-vector** *v*

Flatten nested vector v into a vector of scalars. For example, if v is `[[1, 2, 3], [4, 5]]' the result is `[1, 2, 3, 4, 5]'.

Function: **copy-matrix** *m*

If m is a matrix, return a copy of m. This maps `copy-sequence` over the rows of m; in Lisp terms, each element of the result matrix will be `eq` to the corresponding element of m, but none of the `cons` cells that make up the structure of the matrix will be `eq`. If m is a plain vector, this is the same as `copy-sequence`.

Function: **swap-rows** *m r1 r2*

Exchange rows r1 and r2 of matrix m in-place. In other words, unlike most of the other functions described here, this function changes m itself rather than building up a new result matrix. The return value is m, i.e., `(eq (swap-rows m 1 2) m)' is true, with the side effect of exchanging the first two rows of m.

Symbolic Functions

The functions described here operate on symbolic formulas in the Calculator.

Function: **calc-prepare-selection** *num*

Prepare a stack entry for selection operations. If num is omitted, the stack entry containing the cursor is used; otherwise, it is the number of the stack entry to use. This function stores useful information about the current stack entry into a set of variables. `calc-selection-cache-num` contains the number of the stack entry involved (equal to num if you specified it); `calc-selection-cache-entry` contains the stack entry as a list (such as `calc-top-list` would return with `entry` as the selection mode); and `calc-selection-cache-comp` contains a special "tagged" composition (see section I/O and Formatting Functions) which allows Calc to relate cursor positions in the buffer with their corresponding sub-formulas.

A slight complication arises in the selection mechanism because formulas may contain small integers. For example, in the vector `[1, 2, 1]' the first and last elements are `eq` to each other; selections are recorded as the actual Lisp object that appears somewhere in the tree of the whole formula, but storing `1` would falsely select both `1`'s in the vector. So `calc-prepare-selection` also checks the stack entry and replaces any plain integers with "complex number" lists of the form `(cplx n 0)'. This list will be displayed the same as a plain n and the change will be completely invisible to the user, but it will guarantee that no two sub-formulas of the stack entry will be `eq` to each other. Next time the stack entry is involved in a computation, `calc-normalize` will replace these lists with plain numbers again, again invisibly to the user.

Function: **calc-encase-atoms** *x*

This modifies the formula x to ensure that each part of the formula is a unique atom, using the `(cplx n 0)' trick described above. This function may use `setcar` to modify the formula in-place.

Function: **calc-find-selected-part**

Find the smallest sub-formula of the current formula that contains the cursor. This assumes

`calc-prepare-selection` has been called already. If the cursor is not actually on any part of the fo this returns `nil`.

Function: **calc-change-current-selection** *selection*

Change the currently prepared stack element's selection to selection, which should be `eq` to some sub-formula of the stack element, or `nil` to unselect the formula. The stack element's appearance in the Calc buffer is adjusted to reflect the new selection.

Function: **calc-find-nth-part** *expr n*

Return the nth sub-formula of expr. This function is used by the selection commands, and (unless j b has been used) treats sums and products as flat many-element formulas. Thus if expr is `((a + b) - c) + d', calling `calc-find-nth-part` with n equal to four will return `d'.

Function: **calc-find-parent-formula** *expr part*

Return the sub-formula of expr which immediately contains part. If expr is `a*b + (c+1)*d' and part is `eq` to the `c+1' term of expr, then this function will return `(c+1)*d'. If part turns out not to be a sub-formula of expr, the function returns `nil`. If part is `eq` to expr, the function returns `t`. This function does not take associativity into account.

Function: **calc-find-assoc-parent-formula** *expr part*

This is the same as `calc-find-parent-formula`, except that (unless j b has been used) it continues widening the selection to contain a complete level of the formula. Given `a' from `((a + b) - c) + d', `calc-find-parent-formula` will return `a + b' but `calc-find-assoc-parent-formula` will return the whole expression.

Function: **calc-grow-assoc-formula** *expr part*

This expands sub-formula part of expr to encompass a complete level of the formula. If part and its immediate parent are not compatible associative operators, or if j b has been used, this simply returns part.

Function: **calc-find-sub-formula** *expr part*

This finds the immediate sub-formula of expr which contains part. It returns an index n such that `(calc-find-nth-part expr n)' would return part. If part is not a sub-formula of expr, it returns `nil`. If part is `eq` to expr, it returns `t`. This function does not take associativity into account.

Function: **calc-replace-sub-formula** *expr old new*

This function returns a copy of formula expr, with the sub-formula that is `eq` to old replaced by new.

Function: **simplify** *expr*

Simplify the expression expr by applying various algebraic rules. This is what the a s (`calc-simplify`) command uses. This always returns a copy of the expression; the structure expr points to remains unchanged in memory.

More precisely, here is what `simplify` does: The expression is first normalized and evaluated by calling `normalize`. If any `AlgSimpRules` have been defined, they are then applied. Then the expression is traversed in a depth-first, bottom-up fashion; at each level, any simplifications that can be made are made until no further changes are possible. Once the entire formula has been traversed in this way, it is compared with the original formula (from before the call to `normalize`) and, if it has changed, the entire procedure is repeated

(starting with `normalize`) until no further changes occur. Usually only two iterations are needed: one to simplify the formula, and another to verify that no further simplifications were possible.

Function: **simplify-extended** *expr*

Simplify the expression expr, with additional rules enabled that help do a more thorough job, while not being entirely "safe" in all circumstances. (For example, this mode will simplify `sqrt(x^2)' to `x', which is only valid when x is positive.) This is implemented by temporarily binding the variable `math-living-dangerously` to `t` (using a `let` form) and calling `simplify`. Dangerous simplification rules are written to check this variable before taking any action.

Function: **simplify-units** *expr*

Simplify the expression expr, treating variable names as units whenever possible. This works by binding the variable `math-simplifying-units` to `t` while calling `simplify`.

Macro: **math-defsimplify** *funcs body*

Register a new simplification rule; this is normally called as a top-level form, like `defun` or `defmath`. If funcs is a symbol (like `+` or `calcFunc-sqrt`), this simplification rule is applied to the formulas which are calls to the specified function. Or, funcs can be a list of such symbols; the rule applies to all functions on the list. The body is written like the body of a function with a single argument called `expr`. The body will be executed with `expr` bound to a formula which is a call to one of the functions funcs. If the function body returns `nil`, or if it returns a result `equal` to the original `expr`, it is ignored and Calc goes on to try the next simplification rule that applies. If the function body returns something different, that new formula is substituted for expr in the original formula.

At each point in the formula, rules are tried in the order of the original calls to `math-defsimplify`; the search stops after the first rule that makes a change. Thus later rules for that same function will not have a chance to trigger until the next iteration of the main `simplify` loop.

Note that, since `defmath` is not being used here, body must be written in true Lisp code without the conveniences that `defmath` provides. If you prefer, you can have body simply call another function (defined with `defmath`) which does the real work.

The arguments of a function call will already have been simplified before any rules for the call itself are invoked. Since a new argument list is consed up when this happens, this means that the rule's body is allowed to rearrange the function's arguments destructively if that is convenient. Here is a typical example of a simplification rule:

```
(math-defsimplify calcFunc-arcsinh
  (or (and (math-looks-negp (nth 1 expr))
           (math-neg (list 'calcFunc-arcsinh
                           (math-neg (nth 1 expr)))))
      (and (eq (car-safe (nth 1 expr)) 'calcFunc-sinh)
           (or math-living-dangerously
               (math-known-realp (nth 1 (nth 1 expr))))
           (nth 1 (nth 1 expr)))))
```

This is really a pair of rules written with one `math-defsimplify` for convenience; the first replaces `arcsinh(-x)' with `-arcsinh(x)', and the second, which is safe only for real `x', replaces `arcsinh(sinh(x))' with `x'.

Function: **common-constant-factor** *expr*

Check expr to see if it is a sum of terms all multiplied by the same rational value. If so, return this value. If not, return `nil`. For example, if called on `6x + 9y + 12z', it would return 3, since 3 is a common factor of all the terms.

Function: **cancel-common-factor** *expr factor*

Assuming expr is a sum with factor as a common factor, divide each term of the sum by factor. This is done by destructively modifying parts of expr, on the assumption that it is being used by a simplification rule (where such things are allowed; see above). For example, consider this built-in rule for square roots:

```
(math-defsimplify calcFunc-sqrt
  (let ((fac (math-common-constant-factor (nth 1 expr))))
    (and fac (not (eq fac 1))
         (math-mul (math-normalize (list 'calcFunc-sqrt fac))
                   (math-normalize
                    (list 'calcFunc-sqrt
                          (math-cancel-common-factor
                           (nth 1 expr) fac)))))))
```

Function: **frac-gcd** *a b*

Compute a "rational GCD" of a and b, which must both be rational numbers. This is the fraction composed of the GCD of the numerators of a and b, over the GCD of the denominators. It is used by `common-constant-factor`. Note that the standard `gcd` function uses the LCM to combine the denominators.

Function: **map-tree** *func expr many*

Try applying Lisp function func to various sub-expressions of expr. Initially, call func with expr itself as an argument. If this returns an expression which is not `equal` to expr, apply func again until eventually it does return expr with no changes. Then, if expr is a function call, recursively apply func to each of the arguments. This keeps going until no changes occur anywhere in the expression; this final expression is returned by `map-tree`. Note that, unlike simplification rules, func functions may *not* make destructive changes to expr. If a third argument many is provided, it is an integer which says how many times func may be applied; the default, as described above, is infinitely many times.

Function: **compile-rewrites** *rules*

Compile the rewrite rule set specified by rules, which should be a formula that is either a vector or a variable name. If the latter, the compiled rules are saved so that later `compile-rules` calls for that same variable can return immediately. If there are problems with the rules, this function calls `error` with a suitable message.

Function: **apply-rewrites** *expr crules heads*

Apply the compiled rewrite rule set crules to the expression expr. This will make only one rewrite and only checks at the top level of the expression. The result `nil` if no rules matched, or if the only rules that matched did not actually change the expression. The heads argument is optional; if is given, it should be a list of all function names that (may) appear in expr. The rewrite compiler tags each rule with the rarest-looking function name in the rule; if you specify heads, `apply-rewrites` can use this information to narrow its search down to just a few rules in the rule set.

Function: **rewrite-heads** *expr*

Compute a heads list for expr suitable for use with `apply-rewrites`, as discussed above.

Function: **rewrite** *expr rules many*

This is an all-in-one rewrite function. It compiles the rule set specified by rules, then uses `map-tree` to apply the rules throughout expr up to many (default infinity) times.

Function: **match-patterns** *pat vec not-flag*

Given a Calc vector vec and an uncompiled pattern set or pattern set variable pat, this function returns a new vector of all elements of vec which do (or don't, if not-flag is non-`nil`) match any of the patterns in pat.

Function: **deriv** *expr var value symb*

Compute the derivative of expr with respect to variable var (which may actually be any sub-expression). If value is specified, the derivative is evaluated at the value of var; otherwise, the derivative is left in terms of var. If the expression contains functions for which no derivative formula is known, new derivative functions are invented by adding primes to the names; see section Calculus. However, if symb is non-`nil`, the presence of undifferentiable functions in expr instead cancels the whole differentiation, and `deriv` returns `nil` instead.

Derivatives of an n-argument function can be defined by adding a `math-derivative-n` property to the property list of the symbol for the function's derivative, which will be the function name followed by an apostrophe. The value of the property should be a Lisp function; it is called with the same arguments as the original function call that is being differentiated. It should return a formula for the derivative. For example, the derivative of `ln` is defined by

```
(put 'calcFunc-ln\' 'math-derivative-1
     (function (lambda (u) (math-div 1 u))))
```

The two-argument `log` function has two derivatives,

```
(put 'calcFunc-log\' 'math-derivative-2     ; d(log(x,b)) / dx
     (function (lambda (x b) ... )))
(put 'calcFunc-log\'2 'math-derivative-2    ; d(log(x,b)) / db
     (function (lambda (x b) ... )))
```

Function: **tderiv** *expr var value symb*

Compute the total derivative of expr. This is the same as `deriv`, except that variables other than var are not assumed to be constant with respect to var.

Function: **integ** *expr var low high*

Compute the integral of expr with respect to var. See section Calculus, for further details.

Macro: **math-defintegral** *funcs body*

Define a rule for integrating a function or functions of one argument; this macro is very similar in format to `math-defsimplify`. The main difference is that here body is the body of a function with a single argument `u` which is bound to the argument to the function being integrated, not the function call itself. Also, the variable of integration is available as `math-integ-var`. If evaluation of the integral requires doing further integrals,

the body should call `(math-integral x)' to find the integral of x with respect to `math-integ-var'; this function returns `nil' if the integral could not be done. Some examples:

```
(math-defintegral calcFunc-conj
  (let ((int (math-integral u)))
    (and int
         (list 'calcFunc-conj int))))

(math-defintegral calcFunc-cos
  (and (equal u math-integ-var)
       (math-from-radians-2 (list 'calcFunc-sin u))))
```

In the `cos' example, we define only the integral of `cos(x) dx', relying on the general integration-by-substitution facility to handle cosines of more complicated arguments. An integration rule should return `nil' if it can't do the integral; if several rules are defined for the same function, they are tried in order until one returns a non-`nil' result.

Macro: **math-defintegral-2** *funcs body*

Define a rule for integrating a function or functions of two arguments. This is exactly analogous to `math-defintegral', except that body is written as the body of a function with two arguments, u and v.

Function: **solve-for** *lhs rhs var full*

Attempt to solve the equation `lhs = rhs' by isolating the variable var on the lefthand side; return the resulting righthand side, or `nil' if the equation cannot be solved. The variable var must appear at least once in lhs or rhs. Note that the return value is a formula which does not contain var; this is different from the user-level `solve' and `finv' functions, which return a rearranged equation or a functional inverse, respectively. If full is non-`nil', a full solution including dummy signs and dummy integers will be produced. User-defined inverses are provided as properties in a manner similar to derivatives:

```
(put 'calcFunc-ln 'math-inverse
     (function (lambda (x) (list 'calcFunc-exp x))))
```

This function can call `(math-solve-get-sign x)' to create a new arbitrary sign variable, returning x times that sign, and `(math-solve-get-int x)' to create a new arbitrary integer variable multiplied by x. These functions simply return x if the caller requested a non-"full" solution.

Function: **solve-eqn** *expr var full*

This version of `solve-for' takes an expression which will typically be an equation or inequality. (If it is not, it will be interpreted as the equation `expr = 0'.) It returns an equation or inequality, or `nil' if no solution could be found.

Function: **solve-system** *exprs vars full*

This function solves a system of equations. Generally, exprs and vars will be vectors of equal length. See section Solving Systems of Equations, for other options.

Function: **expr-contains** *expr var*

Returns a non-`nil' value if var occurs as a subexpression of expr.

This function might seem at first to be identical to `calc-find-sub-formula`. The key difference is th `expr-contains` uses `equal` to test for matches, whereas `calc-find-sub-formula` uses `eq`. In th formula `f(a, a)', the two `a's will be `equal` but not `eq` to each other.

Function: **expr-contains-count** *expr var*

Returns the number of occurrences of var as a subexpression of expr, or `nil` if there are no occurrences.

Function: **expr-depends** *expr var*

Returns true if expr refers to any variable the occurs in var. In other words, it checks if expr and var have any variables in common.

Function: **expr-contains-vars** *expr*

Return true if expr contains any variables, or `nil` if expr contains only constants and functions with constant arguments.

Function: **expr-subst** *expr old new*

Returns a copy of expr, with all occurrences of old replaced by new. This treats `lambda` forms specially with respect to the dummy argument variables, so that the effect is always to return expr evaluated at old = new.

Function: **multi-subst** *expr old new*

This is like `expr-subst`, except that old and new are lists of expressions to be substituted simultaneously. If one list is shorter than the other, trailing elements of the longer list are ignored.

Function: **expr-weight** *expr*

Returns the "weight" of expr, basically a count of the total number of objects and function calls that appear in expr. For "primitive" objects, this will be one.

Function: **expr-height** *expr*

Returns the "height" of expr, which is the deepest level to which function calls are nested. (Note that `a + b' counts as a function call.) For primitive objects, this returns zero.

Function: **polynomial-p** *expr var*

Check if expr is a polynomial in variable (or sub-expression) var. If so, return the degree of the polynomial, that is, the highest power of var that appears in expr. For example, for `(x^2 + 3)^3 + 4' this would return 6. This function returns `nil` unless expr, when expanded out by a x (`calc-expand`), would consist of a sum of terms in which var appears only raised to nonnegative integer powers. Note that if var does not occur in expr, then expr is considered a polynomial of degree 0.

Function: **is-polynomial** *expr var degree loose*

Check if expr is a polynomial in variable or sub-expression var, and, if so, return a list representation of the polynomial where the elements of the list are coefficients of successive powers of var: `a + b x + c x^3' would produce the list `(a b 0 c)', and `(x + 1)^2' would produce the list `(1 2 1)'. The highest element of the list will be non-zero, with the special exception that if expr is the constant zero, the returned value will be `(0)'. Return `nil` if expr is not a polynomial in var. If degree is specified, this will not consider polynomials of degree higher than that value. This is a good precaution because otherwise an input of `(x+1)^1000' will cause a huge coefficient list to be built. If loose is non-`nil`, then a looser definition of a polynomial is used in which coefficients are no

longer required not to depend on var, but are only required not to take the form of polynomials themselves. For example, `sin(x) x^2 + cos(x)' is a loose polynomial with coefficients `((calcFunc-cos x) 0 (calcFunc-sin x)'. The result will never be `nil` in loose mode, since any expression can be interpreted as a "constant" loose polynomial.

Function: **polynomial-base** *expr pred*

Check if expr is a polynomial in any variable that occurs in it; if so, return that variable. (If expr is a multivariate polynomial, this chooses one variable arbitrarily.) If pred is specified, it should be a Lisp function which is called as `(pred subexpr)', and which should return true if `mpb-top-expr` (a global name for the original expr) is a suitable polynomial in subexpr. The default predicate uses `(polynomial-p mpb-top-expr subexpr)'; you can use pred to specify additional conditions. Or, you could have pred build up a list of every suitable subexpr that is found.

Function: **poly-simplify** *poly*

Simplify polynomial coefficient list poly by (destructively) clipping off trailing zeros.

Function: **poly-mix** *a ac b bc*

Mix two polynomial lists a and b (in the form returned by `is-polynomial`) in a linear combination with coefficient expressions ac and bc. The result is a (not necessarily simplified) polynomial list representing `ac a + bc b'.

Function: **poly-mul** *a b*

Multiply two polynomial coefficient lists a and b. The result will be in simplified form if the inputs were simplified.

Function: **build-polynomial-expr** *poly var*

Construct a Calc formula which represents the polynomial coefficient list poly applied to variable var. The a c (`calc-collect`) command uses `is-polynomial` to turn an expression into a coefficient list, then `build-polynomial-expr` to turn the list back into an expression in regular form.

Function: **check-unit-name** *var*

Check if var is a variable which can be interpreted as a unit name. If so, return the units table entry for that unit. This will be a list whose first element is the unit name (not counting prefix characters) as a symbol and whose second element is the Calc expression which defines the unit. (Refer to the Calc sources for details on the remaining elements of this list.) If var is not a variable or is not a unit name, return `nil`.

Function: **units-in-expr-p** *expr sub-exprs*

Return true if expr contains any variables which can be interpreted as units. If sub-exprs is `t`, the entire expression is searched. If sub-exprs is `nil`, this checks whether expr is directly a units expression.

Function: **single-units-in-expr-p** *expr*

Check whether expr contains exactly one units variable. If so, return the units table entry for the variable. If expr does not contain any units, return `nil`. If expr contains two or more units, return the symbol `wrong`.

Function: **to-standard-units** *expr which*

Convert units expression expr to base units. If which is `nil`, use Calc's native base units. Otherwise, which can

specify a units system, which is a list of two-element lists, where the first element is a Calc base symbol na and the second is an expression to substitute for it.

Function: **remove-units** *expr*

Return a copy of expr with all units variables replaced by ones. This expression is generally normalized before use.

Function: **extract-units** *expr*

Return a copy of expr with everything but units variables replaced by ones.

I/O and Formatting Functions

The functions described here are responsible for parsing and formatting Calc numbers and formulas.

Function: **calc-eval** *str sep arg1 arg2 ...*

This is the simplest interface to the Calculator from another Lisp program. See section Calling Calc from Your Lisp Programs.

Function: **read-number** *str*

If string str contains a valid Calc number, either integer, fraction, float, or HMS form, this function parses and returns that number. Otherwise, it returns `nil`.

Function: **read-expr** *str*

Read an algebraic expression from string str. If str does not have the form of a valid expression, return a list of the form `(error pos msg)' where pos is an integer index into str of the general location of the error, and msg is a string describing the problem.

Function: **read-exprs** *str*

Read a list of expressions separated by commas, and return it as a Lisp list. If an error occurs in any expressions, an error list as shown above is returned instead.

Function: **calc-do-alg-entry** *initial prompt no-norm*

Read an algebraic formula or formulas using the minibuffer. All conventions of regular algebraic entry are observed. The return value is a list of Calc formulas; there will be more than one if the user entered a list of values separated by commas. The result is `nil` if the user presses Return with a blank line. If initial is given, it is a string which the minibuffer will initially contain. If prompt is given, it is the prompt string to use; the default is "Algebraic:". If no-norm is `t`, the formulas will be returned exactly as parsed; otherwise, they will be passed through `calc-normalize` first.

To support the use of $ characters in the algebraic entry, use `let` to bind `calc-dollar-values` to a list of the values to be substituted for $, $$, and so on, and bind `calc-dollar-used` to 0. Upon return, `calc-dollar-used` will have been changed to the highest number of consecutive $s that actually appeared in the input.

Function: **format-number** *a*

Convert the real or complex number or HMS form a to string form.

Function: **format-flat-expr** *a prec*

Convert the arbitrary Calc number or formula a to string form, in the style used by the trail buffer and the `calc-edit` command. This is a simple format designed mostly to guarantee the string is of a form that can be re-parsed by `read-expr`. Most formatting modes, such as digit grouping, complex number format, and point character, are ignored to ensure the result will be re-readable. The prec parameter is normally 0; if you pass a large integer like 1000 instead, the expression will be surrounded by parentheses unless it is a plain number or variable name.

Function: **format-nice-expr** *a width*

This is like `format-flat-expr` (with prec equal to 0), except that newlines will be inserted to keep lines down to the specified width, and vectors that look like matrices or rewrite rules are written in a pseudo-matrix format. The `calc-edit` command uses this when only one stack entry is being edited.

Function: **format-value** *a width*

Convert the Calc number or formula a to string form, using the format seen in the stack buffer. Beware the the string returned may not be re-readable by `read-expr`, for example, because of digit grouping. Multi-line objects like matrices produce strings that contain newline characters to separate the lines. The w parameter, if given, is the target window size for which to format the expressions. If w is omitted, the width of the Calculator window is used.

Function: **compose-expr** *a prec*

Format the Calc number or formula a according to the current language mode, returning a "composition." To learn about the structure of compositions, see the comments in the Calc source code. You can specify the format of a given type of function call by putting a `math-compose-lang` property on the function's symbol, whose value is a Lisp function that takes a and prec as arguments and returns a composition. Here lang is a language mode name, one of `normal`, `big`, `c`, `pascal`, `fortran`, `tex`, `eqn`, `math`, or `maple`. In Big mode, Calc actually tries `math-compose-big` first, then tries `math-compose-normal`. If this property does not exist, or if the function returns `nil`, the function is written in the normal function-call notation for that language.

Function: **composition-to-string** *c w*

Convert a composition structure returned by `compose-expr` into a string. Multi-line compositions convert to strings containing newline characters. The target window size is given by w. The `format-value` function basically calls `compose-expr` followed by `composition-to-string`.

Function: **comp-width** *c*

Compute the width in characters of composition c.

Function: **comp-height** *c*

Compute the height in lines of composition c.

Function: **comp-ascent** *c*

Compute the portion of the height of composition c which is on or above the baseline. For a one-line composition, this will be one.

Function: **comp-descent** *c*

Compute the portion of the height of composition c which is below the baseline. For a one-line composition this will be zero.

Function: **comp-first-char** *c*

If composition c is a "flat" composition, return the first (leftmost) character of the composition as an integer. Otherwise, return `nil`.

Function: **comp-last-char** *c*

If composition c is a "flat" composition, return the last (rightmost) character, otherwise return `nil`.

Hooks

Hooks are variables which contain Lisp functions (or lists of functions) which are called at various times. Calc defines a number of hooks that help you to customize it in various ways. Calc uses the Lisp function `run-hooks` to invoke the hooks shown below. Several other customization-related variables are also described here.

Variable: **calc-load-hook**

This hook is called at the end of `` `calc.el' ``, after the file has been loaded, before any functions in it have been called, but after `calc-mode-map` and similar variables have been set up.

Variable: **calc-ext-load-hook**

This hook is called at the end of `` `calc-ext.el' ``.

Variable: **calc-start-hook**

This hook is called as the last step in a M-x calc command. At this point, the Calc buffer has been created and initialized if necessary, the Calc window and trail window have been created, and the "Welcome to Calc" message has been displayed.

Variable: **calc-mode-hook**

This hook is called when the Calc buffer is being created. Usually this will only happen once per Emacs session. The hook is called after Emacs has switched to the new buffer, the mode-settings file has been read if necessary, and all other buffer-local variables have been set up. After this hook returns, Calc will perform a `calc-refresh` operation, set up the mode line display, then evaluate any deferred `calc-define` properties that have not been evaluated yet.

Variable: **calc-trail-mode-hook**

This hook is called when the Calc Trail buffer is being created. It is called as the very last step of setting up the Trail buffer. Like `calc-mode-hook`, this will normally happen only once per Emacs session.

Variable: **calc-end-hook**

This hook is called by `calc-quit`, generally because the user presses q or M-# c while in Calc. The Calc buffer will be the current buffer. The hook is called as the very first step, before the Calc window is destroyed.

Variable: **calc-window-hook**

If this hook exists, it is called to create the Calc window. Upon return, this new Calc window should be the

current window. (The Calc buffer will already be the current buffer when the hook is called.) If the hook is defined, Calc will generally use `split-window`, `set-window-buffer`, and `select-window` to cr the Calc window.

Variable: **calc-trail-window-hook**

If this hook exists, it is called to create the Calc Trail window. The variable `calc-trail-buffer` will contain the buffer which the window should use. Unlike `calc-window-hook`, this hook must *not* switch into the new window.

Variable: **calc-edit-mode-hook**

This hook is called by `calc-edit` (and the other "edit" commands) when the temporary editing buffer is being created. The buffer will have been selected and set up to be in `calc-edit-mode`, but will not yet have been filled with text. (In fact it may still have leftover text from a previous `calc-edit` command.)

Variable: **calc-mode-save-hook**

This hook is called by the `calc-save-modes` command, after Calc's own mode features have been inserted into the `` `.emacs' `` buffer and just before the "End of mode settings" message is inserted.

Variable: **calc-reset-hook**

This hook is called after M-# 0 (`calc-reset`) has reset all modes. The Calc buffer will be the current buffer.

Variable: **calc-other-modes**

This variable contains a list of strings. The strings are concatenated at the end of the modes portion of the Calc mode line (after standard modes such as "Deg", "Inv" and "Hyp"). Each string should be a short, single word followed by a space. The variable is `nil` by default.

Variable: **calc-mode-map**

This is the keymap that is used by Calc mode. The best time to adjust it is probably in a `calc-mode-hook`. If the Calc extensions package (`` `calc-ext.el' ``) has not yet been loaded, many of these keys will be bound to `calc-missing-key`, which is a command that loads the extensions package and "retypes" the key. If your `calc-mode-hook` rebinds one of these keys, it will probably be overridden when the extensions are loaded.

Variable: **calc-digit-map**

This is the keymap that is used during numeric entry. Numeric entry uses the minibuffer, but this map binds every non-numeric key to `calcDigit-nondigit` which generally calls `exit-minibuffer` and "retypes" the key.

Variable: **calc-alg-ent-map**

This is the keymap that is used during algebraic entry. This is mostly a copy of `minibuffer-local-map`.

Variable: **calc-store-var-map**

This is the keymap that is used during entry of variable names for commands like `calc-store` and `calc-recall`. This is mostly a copy of `minibuffer-local-completion-map`.

Variable: **calc-edit-mode-map**

This is the (sparse) keymap used by `calc-edit` and other temporary editing commands. It binds RET, LFD,

and C-c C-c to `calc-edit-finish`.

Variable: **calc-mode-var-list**

This is a list of variables which are saved by `calc-save-modes`. Each entry is a list of two items, the variable (as a Lisp symbol) and its default value. When modes are being saved, each variable is compared with its default value (using `equal`) and any non-default variables are written out.

Variable: **calc-local-var-list**

This is a list of variables which should be buffer-local to the Calc buffer. Each entry is a variable name (as a Lisp symbol). These variables also have their default values manipulated by the `calc` and `calc-quit` commands; see section Multiple Calculators. Since `calc-mode-hook` is called after this list has been used the first time, your hook should add a variable to the list and also call `make-local-variable` itself.

Go to the previous, next section.

Go to the previous, next section.

Installation

Calc 2.02 comes as a set of GNU Emacs Lisp files, with names like `calc.el' and `calc-ext.el', and also as a `calc.texinfo' file which can be used to generate both on-line and printed documentation.

To install Calc, just follow these simple steps. If you want more information, each step is discussed at length in the sections below.

1. Change (`cd') to the Calc "home" directory. This directory was created when you unbundled the Calc `.tar' or `.shar' file.
2. Type `make' to install Calc privately for your own use, or type `make install' to install Calc system-wide. This will compile all the Calc component files, modify your `.emacs' or the system-wide `lisp/default' file to install Calc as appropriate, and format the on-line Calc manual.

   Both variants are shorthand for the following three steps:

   - `make compile' to run the byte-compiler.
   - `make private' or `make public', corresponding to `make' and `make install', respectively. (If `make public' fails because your system doesn't already have a `default' or `default.el' file, use Emacs or the Unix `touch' command to create a zero-sized one first.)
   - `make info' to format the on-line Calc manual. This first tries to use the `makeinfo' program; if that program is not present, it uses the Emacs `texinfo-format-buffer' command instead.

   The Unix `make' utility looks in the file `Makefile' in the current directory to see what Unix commands correspond to the various "targets" like `install' or `public'. If your system doesn't have `make', you will have to examine the `Makefile' and type in the corresponding commands by hand.
3. If you ever move Calc to a new home directory, just give the `make private' or `make public' command again in the new directory.
4. Test your installation as described at the end of these instructions.
5. (Optional.) To print a hardcopy of the Calc manual (over 500 pages) or just the Calc Summary (about 20 pages), follow the instructions under "Printed Documentation" below.

Calc is now installed and ready to go!

Upgrading from Calc 1.07

If you have Calc version 1.07 or earlier, you will find that Calc 2.00 is organized quite differently. For one, Calc 2.00 is now distributed already split into many parts; formerly this was done as part of the installation procedure. Also, some new functions must be autoloaded and the M-# key must be bound to `calc-dispatch` instead of to `calc`.

The easiest way to upgrade is to delete your old Calc files and then install Calc 2.00 from scratch using the above instructions. You should then go into your `` `.emacs' `` or `` `default' `` file and remove the old `autoload` and `global-set-key` commands for Calc, since `make public'/`make private' has added new, better ones.

See the `` `README' `` and `` `README.prev' `` files in the Calc distribution for more information about what has changed since version 1.07. (`` `README.prev' `` describes changes before 2.00, and is present only in the FTP and tape versions of the distribution.)

The `make public' Command

If you are not the regular Emacs administrator on your system, your account may not be allowed to execute the `make public' command, since the system-wide `` `default' `` file may be write-protected. If this is the case, you will have to ask your Emacs installer to execute this command. (Just `cd` to the Calc home directory and type `make public'.)

The `make private' command adds exactly the same set of commands to your `` `.emacs' `` file as `make public' adds to `` `default' ``. If your Emacs installer is concerned about typing this command out of the blue, you can ask her/him instead to copy the necessary text from your `` `.emacs' `` file. (It will be marked by a comment that says "Commands added by `calc-private-autoloads` on (date and time).")

Compilation

Calc is written in a way that maximizes performance when its code has been byte-compiled; a side effect is that performance is seriously degraded if it *isn't* compiled. Thus, it is essential to compile the Calculator before trying to use it. The function `calc-compile' in the file `` `calc-maint.el' `` runs the Emacs byte-compiler on all the Calc source files. (Specifically, it runs M-x byte-compile-file on all files in the current directory with names of the form `` `calc*.el' ``, and also on the file `` `macedit.el' ``.)

If `calc-compile` finds that certain files have already been compiled and have not been changed since, then it will not bother to recompile those files.

The `calc-compile` command also pre-builds certain tables, such as the units table (see section The Units Table) and the built-in rewrite rules (see section Rearranging Formulas using Selections) which Calc would otherwise need to rebuild every time those features were used.

The `make compile' shell command is simply a convenient way to start an Emacs and give it a

`calc-compile` command.

Auto-loading

To teach Emacs how to load in Calc when you type M-# for the first time, add these lines to your `.emacs' file (if you are installing Calc just for your own use), or the system's `lisp/default' file (if you are installing Calc publicly). The `make private' and `make public' commands, respectively, take care of this. (Note that `make' runs `make private', and `make install' runs `make public'.)

```
(autoload 'calc-dispatch          "calc" "Calculator Options" t)
(autoload 'full-calc              "calc" "Full-screen Calculator" t)
(autoload 'full-calc-keypad       "calc" "Full-screen X Calculator" t)
(autoload 'calc-eval              "calc" "Use Calculator from Lisp")
(autoload 'defmath                "calc" nil t t)
(autoload 'calc                   "calc" "Calculator Mode" t)
(autoload 'quick-calc             "calc" "Quick Calculator" t)
(autoload 'calc-keypad            "calc" "X windows Calculator" t)
(autoload 'calc-embedded          "calc" "Use Calc from any buffer" t)
(autoload 'calc-embedded-activate "calc" "Activate =>'s in buffer" t)
(autoload 'calc-grab-region       "calc" "Grab region of Calc data" t)
(autoload 'calc-grab-rectangle    "calc" "Grab rectangle of data" t)
```

Unless you have installed the Calc files in Emacs' main `lisp/' directory, you will also have to add a command that looks like the following to tell Emacs where to find them. In this example, we have put the files in directory `/usr/gnu/src/calc-2.00'.

```
(setq load-path (append load-path (list "/usr/gnu/src/calc-2.00")))
```

The `make public' and `make private' commands also do this (they use the then-current directory as the name to add to the path). If you move Calc to a new location, just repeat the `make public' or `make private' command to have this new location added to the `load-path'.

The `autoload' command for `calc-dispatch' is what loads `calc.elc' when you type M-#. It is the only `autoload' that is absolutely necessary for Calc to work. The others are for commands and features that you may wish to use before typing M-# for the first time. In particular, `full-calc' and `full-calc-keypad' are autoloaded to support "standalone" operation (see section Standalone Operation), `calc-eval' and `defmath' are autoloaded to allow other Emacs Lisp programs to use Calc facilities (see section Calling Calc from Your Lisp Programs), and `calc-embedded-activate' is autoloaded because some Embedded Mode files may call it as soon as they are read into Emacs (see section Assignments in Embedded Mode).

Finding Component Files

There is no need to write `autoload` commands that point to all the various Calc component files like `` `calc-misc.elc' `` and `` `calc-alg.elc' ``. The main file, `` `calc.elc' ``, contains all the necessary `autoload` commands for these files.

(Actually, to conserve space `` `calc.elc' `` only autoloads a few of the component files, plus `` `calc-ext.elc' ``, which in turn autoloads the rest of the components. This allows Calc to load a little faster in the beginning, but the net effect is the same.)

This autoloading mechanism assumes that all the component files can be found on the `load-path`. The `make public' and `make private' commands take care of this, but Calc has a few other strategies in case you have installed it in an unusual way.

If, when Calc is loaded, it is unable to find its components on the `load-path` it is given, it checks the file name in the original `autoload` command for `calc-dispatch`. If that name included directory information, Calc adds that directory to the `load-path`:

```
(autoload 'calc-dispatch "calc-2.00/calc" "Calculator" t)
```

Suppose the directory `` `/usr/gnu/src/emacs/lisp' `` is on the path, and the above `autoload` allows Emacs to find Calc under the name `` `/usr/gnu/src/emacs/lisp/calc-2.00/calc.elc' ``. Then when Calc starts up it will add `` `/usr/gnu/src/emacs/lisp/calc-2.00' `` to the path so that it will later be able to find its component files.

If the above strategy does not locate the component files, Calc examines the variable `calc-autoload-directory`. This is initially `nil`, but you can store the name of Calc's home directory in it as a sure-fire way of getting Calc to find its components.

Merging Source Files

If the `autoload` mechanism is not managing to load each part of Calc when it is needed, you can concatenate all the `` `.el' `` files into one big file. The order should be `` `calc.el' ``, then `` `calc-ext.el' ``, then all the other files in any order. Byte-compile the resulting big file. This merged Calculator ought to work just like Calc normally does, though it will be *substantially* slower to load.

Key Bindings

Calc is normally bound to the M-# key. To set up this key binding, include the following command in your `` `.emacs' `` or `` `lisp/default' `` file. (This is done automatically by `make private' or `make public', respectively.)

```
(global-set-key "\e#" 'calc-dispatch)
```

Note that `calc-dispatch` actually works as a prefix for various two-key sequences. If you have a convenient unused function key on your keyboard, you may wish to bind `calc-dispatch` to that as well. You may even wish to bind other specific Calc functions like `calc` or `quick-calc` to other handy function keys.

Even if you bind `calc-dispatch` to other keys, it is best to bind it to M-# as well if you possibly can: There are references to M-# all throughout the Calc manual which would confuse novice users if they didn't work as advertised.

Another key binding issue is the DEL key. Some installations use a different key (such as backspace) for this purpose. Calc normally scans the entire keymap and maps all keys defined like DEL to the `calc-pop` command. However, this may be slow. You can set the variable `calc-scan-for-dels` to `nil` to cause only the actual DEL key to be mapped to `calc-pop`; this will speed loading of Calc.

The `macedit' Package

The file `macedit.el' contains another useful Emacs extension called `edit-kbd-macro`. It allows you to edit a keyboard macro in human-readable form. The Z E command in Calc knows how to use it to edit user commands that have been defined by keyboard macros. To autoload it, you will want to include the commands,

```
(autoload 'edit-kbd-macro      "macedit" "Edit Keyboard Macro" t)
(autoload 'edit-last-kbd-macro "macedit" "Edit Keyboard Macro" t)
(autoload 'read-kbd-macro      "macedit" "Read Keyboard Macro" t)
```

The `make public' and `make private' commands do this.

The GNUPLOT Program

Calc's graphing commands use the GNUPLOT program. If you have GNUPLOT but you must type some command other than `gnuplot' to get it, you should add a command to set the Lisp variable `calc-gnuplot-name` to the appropriate file name. You may also need to change the variables `calc-gnuplot-plot-command` and `calc-gnuplot-print-command` in order to get correct displays and hardcopies, respectively, of your plots.

On-Line Documentation

The documentation for Calc (this manual) comes in a file called `calc.texinfo'. To format this for use as an on-line manual, type `make info' (to use the `makeinfo` program), or `make texinfo' (to use the `texinfmt.el` program which runs inside of Emacs). The former command is recommended if it works on your system; it is faster and produces nicer-looking output.

The `makeinfo` program will report inconsistencies involving the nodes "Copying" and "Interactive Tutorial"; these messages should be ignored.

The result will be a collection of files whose names begin with `calc.info'. You may wish to ad reference to the first of these, `calc.info' itself, to your Info system's `dir' file. (This is optio since the M-# i command can access `calc.info' whether or not it appears in the `dir' file.)

There is a Lisp variable called calc-info-filename which holds the name of the Info file containing Calc's on-line documentation. Its default value is "calc.info", which will work correctly if the Info files are stored in Emacs' main `info/' directory, or if they are in any of the directories listed in the load-path. If you keep them elsewhere, you will want to put a command of the form,

```
(setq calc-info-filename ".../calc.info")
```

in your `.emacs' or `lisp/default' file, where `...' represents the directory containing the Info files. This will not be necessary if you follow the normal installation procedures.

The `make info' and `make texinfo' commands compare the dates on the files `calc.texinfo' and `calc.info', and run the appropriate program only if the latter file is older or does not exist.

Printed Documentation

Because the Calc manual is so large, you should only make a printed copy if you really need it. To print the manual, you will need the TeX typesetting program (this is a free program by Donald Knuth at Stanford University) as well as the `texindex' program and `texinfo.tex' file, both of which can be obtained from the FSF as part of the texinfo2 package.

To print the Calc manual in one huge 550 page tome, type `make tex'. This will take care of running the manual through TeX twice so that references to later parts of the manual will have correct page numbers. (Don't worry if you get some "overfull box" warnings.)

The result will be a device-independent output file called `calc.dvi', which you must print in whatever way is right for your system. On many systems, the command is

```
lpr -d calc.dvi
```

Marginal notes for each function and key sequence normally alternate between the left and right sides of the page, which is correct if the manual is going to be bound as double-sided pages. Near the top of the file `calc.texinfo' you will find alternate definitions of the \bumpoddpages macro that put the marginal notes always on the same side, best if you plan to be binding single-sided pages.

Some people find the Calc manual to be too large to handle easily. In fact, some versions of TeX have too little memory to print it. So Calc includes a calc-split-manual command that splits `calc.texinfo' into two volumes, the Calc Tutorial and the Calc Reference. The easiest way to use it is to type `make tex2' instead of `make tex'. The result will be two smaller files, `calctut.dvi' and `calcref.dvi'. The former contains the tutorial part of the manual; the latter contains the reference part. Both volumes include copies of the "Getting Started" chapter and licensing information.

To save disk space, you may wish to delete `calctut.*' and `calcref.*' after you're done. Don't delete `calc.texinfo', because you will need it to install future patches to Calc. The `make

tex2' command takes care of all of this for you.

The `make textut' command formats only the Calc Tutorial volume, producing `calctut.dvi' but not `calcref.dvi'. Likewise, `make texref' formats only the Calc Reference volume.

Finally, there is a `calc-split-summary` command that splits off just the Calc Summary appendix suitable for printing by itself. Type `make summary' instead of `make tex'. The resulting `calcsum.dvi' file will print in less than 20 pages. If the Key Index file `calc.ky' is present, left over from a previous `make tex' command, then `make summary' will insert a column of page numbers into the summary using that information.

The `make isummary' command is like `make summary', but it prints a summary that is designed to be substituted into the regular manual. (The two summaries will be identical except for the additional column of page numbers.) To make a complete manual, run `make tex' and `make isummary', print the two resulting `.dvi' files, then discard the Summary pages that came from `calc.dvi' and insert the ones from `calcsum.dvi' in their place. Also, remember that the table of contents prints at the end of the manual but should generally be moved to the front (after the title and copyright pages).

If you don't have TeX, you can print the summary as a plain text file by going to the "Summary" node in Calc's Info file, then typing M-x print-buffer (see section Calc Summary).

Settings File

Another variable you might want to set is `calc-settings-file`, which holds the file name in which commands like m m and Z P store "permanent" definitions. The default value for this variable is `"~/.emacs"`. If `calc-settings-file` does not contain `".emacs"` as a substring, and if the variable `calc-loaded-settings-file` is `nil`, then Calc will automatically load your settings file (if it exists) the first time Calc is invoked.

Testing the Installation

To test your installation of Calc, start a new Emacs and type M-# c to make sure the autoloads and key bindings work. Type M-# i to make sure Calc can find its Info documentation. Press q to exit the Info system and M-# c to re-enter the Calculator. Type 20 S to compute the sine of 20 degrees; this will test the autoloading of the extensions modules. The result should be 0.342020143326. Finally, press M-# c again to make sure the Calculator can exit.

You may also wish to test the GNUPLOT interface; to plot a sine wave, type ' [0 .. 360], sin(x) RET g f. Type g q when you are done viewing the plot.

Calc is now ready to use. If you wish to go through the Calc Tutorial, press M-# t to begin.

(The above text is included in both the Calc documentation and the file INSTALL in the Calc distribution directory.)

Reporting Bugs

If you find a bug in Calc, send e-mail to Dave Gillespie,

```
daveg@synaptics.com           or
daveg@csvax.cs.caltech.edu
```

While I cannot guarantee that I will have time to work on your bug, I do try to fix bugs quickly whenever I can.

You can obtain a current version of Calc from anonymous FTP on `csvax.cs.caltech.edu' in `pub/calc-version.tar.Z'. Calc is also available on the GNU machine, `prep.ai.mit.edu'. Patches are posted to the `comp.sources.misc' Usenet group, and are also available on `csvax`.

There is an automatic M-x report-calc-bug command which helps you to report bugs. This command prompts you for a brief subject line, then leaves you in a mail editing buffer. Type C-c C-c to send your mail. Make sure your subject line indicates that you are reporting a Calc bug; this command sends mail to my regular mailbox.

If you have suggestions for additional features for Calc, I would love to hear them. Some have dared to suggest that Calc is already top-heavy with features; I really don't see what they're talking about, so, if you have ideas, send them right in. (I may even have time to implement them!)

At the front of the source file, `calc.el', is a list of ideas for future work which I have not had time to do. If any enthusiastic souls wish to take it upon themselves to work on these, I would be delighted. Please let me know if you plan to contribute to Calc so I can coordinate your efforts with mine and those of others. I will do my best to help you in whatever way I can.

Go to the previous, next section.

Go to the previous, next section.

Calc Summary

This section includes a complete list of Calc 2.02 keystroke commands. Each line lists the stack entries used by the command (top-of-stack last), the keystrokes themselves, the prompts asked by the command, and the result of the command (also with top-of-stack last). The result is expressed using the equivalent algebraic function. Commands which put no results on the stack show the full M-x command name in that position. Numbers preceding the result or command name refer to notes at the end.

Algebraic functions and M-x commands that don't have corresponding keystrokes are not listed in this summary. See section Index of Calculator Commands. See section Index of Algebraic Functions.

NOTES

1. Positive prefix arguments apply to n stack entries. Negative prefix arguments apply to the -nth stack entry. A prefix of zero applies to the entire stack. (For LFD and M-DEL, the meaning of the sign is reversed.)
2. Positive prefix arguments apply to n stack entries. Negative prefix arguments apply to the top stack entry and the next -n stack entries.

3. Positive prefix arguments rotate top n stack entries by one. Negative prefix arguments rotate th entire stack by -n. A prefix of zero reverses the entire stack.
4. Prefix argument specifies a repeat count or distance.
5. Positive prefix arguments specify a precision p. Negative prefix arguments reduce the current precision by -p.
6. A prefix argument is interpreted as an additional step-size parameter. A plain C-u prefix means to prompt for the step size.
7. A prefix argument specifies simplification level and depth. 1=Default, 2=like a s, 3=like a e.
8. A negative prefix operates only on the top level of the input formula.
9. Positive prefix arguments specify a word size of w bits, unsigned. Negative prefix arguments specify a word size of w bits, signed.
10. Prefix arguments specify the shift amount n. The w argument cannot be specified in the keyboard version of this command.
11. From the keyboard, d is omitted and defaults to zero.
12. Mode is toggled; a positive prefix always sets the mode, and a negative prefix always clears the mode.
13. Some prefix argument values provide special variations of the mode.
14. A prefix argument, if any, is used for m instead of taking m from the stack. M may take any of these values: {@advance@tableindent10pt

    Integer

        Random integer in the interval [0 .. m).

    Float

        Random floating-point number in the interval [0 .. m).

    0.0

        Gaussian with mean 1 and standard deviation 0.

    Error form

        Gaussian with specified mean and standard deviation.

    Interval

        Random integer or floating-point number in that interval.

    Vector

        Random element from the vector.

    }
15. A prefix argument from 1 to 6 specifies number of date components to remove from the stack. See section Date Conversions.
16. A prefix argument specifies a time zone; C-u says to take the time zone number or name from the top of the stack. See section Time Zones.
17. A prefix argument specifies a day number (0-6, 0-31, or 0-366).
18. If the input has no units, you will be prompted for both the old and the new units.

19. With a prefix argument, collect that many stack entries to form the input data set. Each entry may be a single value or a vector of values.
20. With a prefix argument of 1, take a single @c{$N\times2$} Nx2 matrix from the stack instead of two separate data vectors.
21. The row or column number n may be given as a numeric prefix argument instead. A plain C-u prefix says to take n from the top of the stack. If n is a vector or interval, a subvector/submatrix of the input is created.
22. The op prompt can be answered with the key sequence for the desired function, or with x or z followed by a function name, or with $ to take a formula from the top of the stack, or with ' and a typed formula. In the last two cases, the formula may be a nameless function like `<#1+#2>' or `<x, y : x+y>', or it may include $, $$, etc. (where $ will correspond to the last argument of the created function), or otherwise you will be prompted for an argument list. The number of vectors popped from the stack by V M depends on the number of arguments of the function.
23. One of the mapping direction keys _ (horizontal, i.e., map by rows or reduce across), : (vertical, i.e., map by columns or reduce down), or = (map or reduce by rows) may be used before entering op; these modify the function name by adding the letter `r` for "rows," `c` for "columns," `a` for "across," or `d` for "down."
24. The prefix argument specifies a packing mode. A nonnegative mode is the number of items (for v p) or the number of levels (for v u). A negative mode is as described below. With no prefix argument, the mode is taken from the top of the stack and may be an integer or a vector of integers. {@advance@tableindent-20pt

    -1
        (2) Rectangular complex number.

    -2
        (2) Polar complex number.

-14

(3) Date form (using year, month, day).

-15

(6) Date form (using year, month, day, hour, minute, second).

}

25. A prefix argument specifies the size n of the matrix. With no prefix argument, n is omitted and the size is inferred from the input vector.
26. The prefix argument specifies the starting position n (default 1).
27. Cursor position within stack buffer affects this command.
28. Arguments are not actually removed from the stack by this command.
29. Variable name may be a single digit or a full name.
30. Editing occurs in a separate buffer. Press M-# M-# (or C-c C-c, LFD, or in some cases RET) to finish the edit, or press M-# x to cancel the edit. The LFD key prevents evaluation of the result of the edit.
31. The number prompted for can also be provided as a prefix argument.
32. Press this key a second time to cancel the prefix.
33. With a negative prefix, deactivate all formulas. With a positive prefix, deactivate and then reactivate from scratch.
34. Default is to scan for nearest formula delimiter symbols. With a prefix of zero, formula is delimited by mark and point. With a non-zero prefix, formula is delimited by scanning forward or backward by that many lines.
35. Parse the region between point and mark as a vector. A nonzero prefix parses n lines before or after point as a vector. A zero prefix parses the current line as a vector. A C-u prefix parses the region between point and mark as a single formula.
36. Parse the rectangle defined by point and mark as a matrix. A positive prefix n divides the rectangle into columns of width n. A zero or C-u prefix parses each line as one formula. A negative prefix suppresses special treatment of bracketed portions of a line.
37. A numeric prefix causes the current language mode to be ignored.
38. Responding to a prompt with a blank line answers that and all later prompts by popping additional stack entries.
39. Answer for v may also be of the form v = v_0 or v - v_0.

40. With a positive prefix argument, stack contains many y's and one common x. With a zero prefix, stack contains a vector of ys and a common x. With a negative prefix, stack contains many [x,y] vectors. (For 3D plots, substitute z for y and x,y for x.)
41. With any prefix argument, all curves in the graph are deleted.
42. With a positive prefix, refines an existing plot with more data points. With a negative prefix, forces recomputation of the plot data.
43. With any prefix argument, set the default value instead of the value for this graph.
44. With a negative prefix argument, set the value for the printer.
45. Condition is considered "true" if it is a nonzero real or complex number, or a formula whose value is known to be nonzero; it is "false" otherwise.
46. Several formulas separated by commas are pushed as multiple stack entries. Trailing),], }, >, and " delimiters may be omitted. The notation $$$ refers to the value in stack level three, and causes the formula to replace the top three stack levels. The notation $3 refers to stack level three without causing that value to be removed from the stack. Use LFD in place of RET to prevent evaluation; use M-= in place of RET to evaluate variables.
47. The variable is replaced by the formula shown on the right. The Inverse flag reverses the order of the operands, e.g., I s - x assigns @c{$x \coloneq a-x$} x := a-x.
48. Press ? repeatedly to see how to choose a model. Answer the variables prompt with iv or iv;pv to specify independent and parameter variables. A positive prefix argument takes *N+1* vectors from the stack; a zero prefix takes a matrix and a vector from the stack.
49. With a plain C-u prefix, replace the current region of the destination buffer with the yanked text instead of inserting.
50. All stack entries are reformatted; the H prefix inhibits this. The I prefix sets the mode temporarily, redraws the top stack entry, then restores the original setting of the mode.
51. A negative prefix sets the default 3D resolution instead of the default 2D resolution.
52. This grabs a vector of the form [prec, wsize, ssize, radix, flfmt, ang, frac, symb, polar, matrix, simp, inf]. A prefix argument from 1 to 12 grabs the nth mode value only.

Common Lisp Extensions

Common Lisp Extensions

Overview

Common Lisp is a huge language, and Common Lisp systems tend to be massive and extremely complex. Emacs Lisp, by contrast, is rather minimalist in the choice of Lisp features it offers the programmer. As Emacs Lisp programmers have grown in number, and the applications they write have grown more ambitious, it has become clear that Emacs Lisp could benefit from many of the conveniences of Common Lisp.

The CL package adds a number of Common Lisp functions and control structures to Emacs Lisp. While not a 100% complete implementation of Common Lisp, CL adds enough functionality to make Emacs Lisp programming significantly more convenient.

Some Common Lisp features have been omitted from this package for various reasons:

- Some features are too complex or bulky relative to their benefit to Emacs Lisp programmers. CLOS and Common Lisp streams are fine examples of this group.
- Other features cannot be implemented without modification to the Emacs Lisp interpreter itself, such as multiple return values, lexical scoping, case-insensitive symbols, and complex numbers. The CL package generally makes no attempt to emulate these features.
- Some features conflict with existing things in Emacs Lisp. For example, Emacs' `assoc` function is incompatible with the Common Lisp `assoc`. In such cases, this package usually adds the suffix `*' to the function name of the Common Lisp version of the function (e.g., `assoc*`).

The package described here was written by Dave Gillespie, `daveg@synaptics.com'. It is a total rewrite of the original 1986 `cl.el' package by Cesar Quiroz. Most features of the the Quiroz package have been retained; any incompatibilities are noted in the descriptions below. Care has been taken in this version to ensure that each function is defined efficiently, concisely, and with minimal impact on the rest of the Emacs environment.

Usage

Lisp code that uses features from the CL package should include at the beginning:

```
(require 'cl)
```

If you want to ensure that the new (Gillespie) version of CL is the one that is present, add an additional `(require 'cl-19)` call:

```
(require 'cl)
(require 'cl-19)
```

The second call will fail (with "`cl-19.el' not found") if the old `cl.el' package was in use.

It is safe to arrange to load CL at all times, e.g., in your `.emacs' file. But it's a good idea, for portability, to `(require 'cl)` in your code even if you do this.

Organization

The Common Lisp package is organized into four files:

`cl.el'
: This is the "main" file, which contains basic functions and information about the package. This file is relatively compact--about 700 lines.

`cl-extra.el'
: This file contains the larger, more complex or unusual functions. It is kept separate so that packages which only want to use Common Lisp fundamentals like the `cadr` function won't need to pay the overhead of loading the more advanced functions.

`cl-seq.el'
: This file contains most of the advanced functions for operating on sequences or lists, such as `delete-if` and `assoc*`.

`cl-macs.el'
: This file contains the features of the packages which are macros instead of functions. Macros expand when the caller is compiled, not when it is run, so the macros generally only need to be present when the byte-compiler is running (or when the macros are used in uncompiled code such as a `.emacs' file). Most of the macros of this package are isolated in `cl-macs.el' so that they won't take up memory unless you are compiling.

The file `cl.el' includes all necessary `autoload` commands for the functions and macros in the other three files. All you have to do is `(require 'cl)`, and `cl.el' will take care of pulling in the other files when they are needed.

There is another file, `cl-compat.el', which defines some routines from the older `cl.el' package that are no longer present in the new package. This includes internal routines like `setelt` and `zip-lists`, deprecated features like `defkeyword`, and an emulation of the old-style multiple-values feature. See section Old CL Compatibility.

Installation

Installation of the CL package is simple: Just put the byte-compiled files `cl.elc', `cl-extra.elc', `cl-seq.elc', `cl-macs.elc', and `cl-compat.elc' into a directory on your `load-path`.

There are no special requirements to compile this package: The files do not have to be loaded before they are compiled, nor do they need to be compiled in any particular order.

You may choose to put the files into your main `lisp/' directory, replacing the original `cl.el' file there. Or, you could put them into a directory that comes before `lisp/' on your `load-path` so that the old `cl.el' is effectively hidden.

Also, format the `cl.texinfo' file and put the resulting Info files in the `info/' directory or another suitable place.

You may instead wish to leave this package's components all in their own directory, and then add this

directory to your `load-path` and (Emacs 19 only) `Info-directory-list`. Add the directory to the front of the list so the old CL package and its documentation are hidden.

Naming Conventions

Except where noted, all functions defined by this package have the same names and calling conventions as their Common Lisp counterparts.

Following is a complete list of functions whose names were changed from Common Lisp, usually to avoid conflicts with Emacs. In each case, a `*' has been appended to the Common Lisp name to obtain the Emacs name:

```
defun*          defsubst*       defmacro*       function*
member*         assoc*          rassoc*         get*
remove*         delete*         mapcar*         sort*
floor*          ceiling*        truncate*       round*
mod*            rem*            random*
```

Internal function and variable names in the package are prefixed by `cl-`. Here is a complete list of functions *not* prefixed by `cl-` which were not taken from Common Lisp:

```
member          delete          remove          remq
rassoc          floatp-safe     lexical-let     lexical-let*
callf           callf2          letf            letf*
defsubst*       defalias        add-hook        eval-when-compile
```

(Most of these are Emacs 19 features provided to Emacs 18 users, or introduced, like `remq`, for reasons of symmetry with similar features.)

The following simple functions and macros are defined in `cl.el'; they do not cause other components like `cl-extra' to be loaded.

```
eql             floatp-safe     abs             endp
evenp           oddp            plusp           minusp
last            butlast         nbutlast        caar .. cddddr
list*           ldiff           rest            first .. tenth
member [1]      copy-list       subst           mapcar* [2]
adjoin [3]      acons           pairlis         when
unless          pop [4]         push [4]        pushnew [3,4]
incf [4]        decf [4]        proclaim        declaim
add-hook
```

[1] This is the Emacs 19-compatible function, not `member*`.

[2] Only for one sequence argument or two list arguments.

[3] Only if `:test` is `eq`, `equal`, or unspecified, and `:key` is not used.

[4] Only when place is a plain variable name.

@chapno=4

Program Structure

This section describes features of the CL package which have to do with programs as a whole: advanced argument lists for functions, and the `eval-when` construct.

@secno=1

Argument Lists

Emacs Lisp's notation for argument lists of functions is a subset of the Common Lisp notation. As well as the familiar `&optional` and `&rest` markers, Common Lisp allows you to specify default values for optional arguments, and it provides the additional markers `&key` and `&aux`.

Since argument parsing is built-in to Emacs, there is no way for this package to implement Common Lisp argument lists seamlessly. Instead, this package defines alternates for several Lisp forms which you must use if you need Common Lisp argument lists.

Special Form: **defun*** *name arglist body...*

This form is identical to the regular `defun` form, except that arglist is allowed to be a full Common Lisp argument list. Also, the function body is enclosed in an implicit block called name; see section Blocks and Exits.

Special Form: **defsubst*** *name arglist body...*

This is just like `defun*`, except that the function that is defined is automatically proclaimed `inline`, i.e., calls to it may be expanded into in-line code by the byte compiler. This is analogous to the `defsubst` form in Emacs 19; `defsubst*` uses a different method (compiler macros) which works in all version of Emacs, and also generates somewhat more efficient inline expansions. In particular, `defsubst*` arranges for the processing of keyword arguments, default values, etc., to be done at compile-time whenever possible.

Special Form: **defmacro*** *name arglist body...*

This is identical to the regular `defmacro` form, except that arglist is allowed to be a full Common Lisp argument list. The `&environment` keyword is supported as described in Steele. The `&whole` keyword is supported only within destructured lists (see below); top-level `&whole` cannot be implemented with the current Emacs Lisp interpreter. The macro expander body is enclosed in an implicit block called name.

Special Form: **function*** *symbol-or-lambda*

This is identical to the regular `function` form, except that if the argument is a `lambda` form then that form may use a full Common Lisp argument list.

Also, all forms (such as `defsetf` and `flet`) defined in this package that include arglists in their syntax allow full Common Lisp argument lists.

Note that it is *not* necessary to use `defun*` in order to have access to most CL features in your function.

These features are always present; `defun*`'s only difference from `defun` is its more flexible argument and its implicit block.

The full form of a Common Lisp argument list is

```
(var...
 &optional (var initform svar)...
 &rest var
 &key ((keyword var) initform svar)...
 &aux (var initform)...)
```

Each of the five argument list sections is optional. The svar, initform, and keyword parts are optional; if they are omitted, then `(var)' may be written simply `var'.

The first section consists of zero or more required arguments. These arguments must always be specified in a call to the function; there is no difference between Emacs Lisp and Common Lisp as far as required arguments are concerned.

The second section consists of optional arguments. These arguments may be specified in the function call; if they are not, initform specifies the default value used for the argument. (No initform means to use `nil` as the default.) The initform is evaluated with the bindings for the preceding arguments already established; `(a &optional (b (1+ a)))` matches one or two arguments, with the second argument defaulting to one plus the first argument. If the svar is specified, it is an auxiliary variable which is bound to `t` if the optional argument was specified, or to `nil` if the argument was omitted. If you don't use an svar, then there will be no way for your function to tell whether it was called with no argument, or with the default value passed explicitly as an argument.

The third section consists of a single rest argument. If more arguments were passed to the function than are accounted for by the required and optional arguments, those extra arguments are collected into a list and bound to the "rest" argument variable. Common Lisp's `&rest` is equivalent to that of Emacs Lisp. Common Lisp accepts `&body` as a synonym for `&rest` in macro contexts; this package accepts it all the time.

The fourth section consists of keyword arguments. These are optional arguments which are specified by name rather than positionally in the argument list. For example,

```
(defun* foo (a &optional b &key c d (e 17)))
```

defines a function which may be called with one, two, or more arguments. The first two arguments are bound to `a` and `b` in the usual way. The remaining arguments must be pairs of the form `:c`, `:d`, or `:e` followed by the value to be bound to the corresponding argument variable. (Symbols whose names begin with a colon are called keywords, and they are self-quoting in the same way as `nil` and `t`.)

For example, the call `(foo 1 2 :d 3 :c 4)` sets the five arguments to 1, 2, 4, 3, and 17, respectively. If the same keyword appears more than once in the function call, the first occurrence takes precedence over the later ones. Note that it is not possible to specify keyword arguments without specifying the optional argument `b` as well, since `(foo 1 :c 2)` would bind `b` to the keyword `:c`, then signal an error because `2` is not a valid keyword.

If a keyword symbol is explicitly specified in the argument list as shown in the above diagram, then that keyword will be used instead of just the variable name prefixed with a colon. You can specify a keyword

symbol which does not begin with a colon at all, but such symbols will not be self-quoting; you will have to quote them explicitly with an apostrophe in the function call.

Ordinarily it is an error to pass an unrecognized keyword to a function, e.g., `(foo 1 2 :c 3 :goober 4)`. You can ask Lisp to ignore unrecognized keywords, either by adding the marker `&allow-other-keys` after the keyword section of the argument list, or by specifying an `:allow-other-keys` argument in the call whose value is non-`nil`. If the function uses both `&rest` and `&key` at the same time, the "rest" argument is bound to the keyword list as it appears in the call. For example:

```
(defun* find-thing (thing &rest rest &key need &allow-other-keys)
  (or (apply 'member* thing thing-list :allow-other-keys t rest)
      (if need (error "Thing not found"))))
```

This function takes a `:need` keyword argument, but also accepts other keyword arguments which are passed on to the `member*` function. `allow-other-keys` is used to keep both `find-thing` and `member*` from complaining about each others' keywords in the arguments.

In Common Lisp, keywords are recognized by the Lisp parser itself and treated as special entities. In Emacs, keywords are just symbols whose names begin with colons, which `defun*` has arranged to set equal to themselves so that they will essentially be self-quoting.

As a (significant) performance optimization, this package implements the scan for keyword arguments by calling `memq` to search for keywords in a "rest" argument. Technically speaking, this is incorrect, since `memq` looks at the odd-numbered values as well as the even-numbered keywords. The net effect is that if you happen to pass a keyword symbol as the *value* of another keyword argument, where that keyword symbol happens to equal the name of a valid keyword argument of the same function, then the keyword parser will become confused. This minor bug can only affect you if you use keyword symbols as general-purpose data in your program; this practice is strongly discouraged in Emacs Lisp.

The fifth section of the argument list consists of auxiliary variables. These are not really arguments at all, but simply variables which are bound to `nil` or to the specified initforms during execution of the function. There is no difference between the following two functions, except for a matter of stylistic taste:

```
(defun* foo (a b &aux (c (+ a b)) d)
  body)

(defun* foo (a b)
  (let ((c (+ a b)) d)
    body))
```

Argument lists support destructuring. In Common Lisp, destructuring is only allowed with `defmacro`; this package allows it with `defun*` and other argument lists as well. In destructuring, any argument variable (var in the above diagram) can be replaced by a list of variables, or more generally, a recursive argument list. The corresponding argument value must be a list whose elements match this recursive argument list. For example:

```
(defmacro* dolist ((var listform &optional resultform)
                   &rest body)
  ...)
```

This says that the first argument of `dolist` must be a list of two or three items; if there are other arguments as well as this list, they are stored in `body`. All features allowed in regular argument lists are allowed in these recursive argument lists. In addition, the clause `&whole var' is allowed at the front of a recursive argument list. It binds var to the whole list being matched; thus `(&whole all a b)` matches a list of two things, with `a` bound to the first thing, `b` bound to the second thing, and `all` bound to the list itself. (Common Lisp allows `&whole` in top-level `defmacro` argument lists as well, but Emacs Lisp does not support this usage.)

One last feature of destructuring is that the argument list may be dotted, so that the argument list `(a b . c)` is functionally equivalent to `(a b &rest c)`.

If the optimization quality `safety` is set to 0 (see section Declarations), error checking for wrong number of arguments and invalid keyword arguments is disabled. By default, argument lists are rigorously checked.

Time of Evaluation

Normally, the byte-compiler does not actually execute the forms in a file it compiles. For example, if a file contains `(setq foo t)`, the act of compiling it will not actually set `foo` to `t`. This is true even if the `setq` was a top-level form (i.e., not enclosed in a `defun` or other form). Sometimes, though, you would like to have certain top-level forms evaluated at compile-time. For example, the compiler effectively evaluates `defmacro` forms at compile-time so that later parts of the file can refer to the macros that are defined.

Special Form: **eval-when** *(situations...) forms...*

This form controls when the body forms are evaluated. The situations list may contain any set of the symbols `compile`, `load`, and `eval` (or their long-winded ANSI equivalents, `:compile-toplevel`, `:load-toplevel`, and `:execute`).

The `eval-when` form is handled differently depending on whether or not it is being compiled as a top-level form. Specifically, it gets special treatment if it is being compiled by a command such as `byte-compile-file` which compiles files or buffers of code, and it appears either literally at the top level of the file or inside a top-level `progn`.

For compiled top-level `eval-when`s, the body forms are executed at compile-time if `compile` is in the situations list, and the forms are written out to the file (to be executed at load-time) if `load` is in the situations list.

For non-compiled-top-level forms, only the `eval` situation is relevant. (This includes forms executed by the interpreter, forms compiled with `byte-compile` rather than `byte-compile-file`, and non-top-level forms.) The `eval-when` acts like a `progn` if `eval` is specified, and like `nil` (ignoring the body forms) if not.

The rules become more subtle when `eval-when`s are nested; consult Steele (second edition) for the gruesome details (and some gruesome examples).

Some simple examples:

```
;; Top-level forms in foo.el:
(eval-when (compile)           (setq foo1 'bar))
(eval-when (load)              (setq foo2 'bar))
```

```
(eval-when (compile load)      (setq foo3 'bar))
(eval-when (eval)              (setq foo4 'bar))
(eval-when (eval compile)      (setq foo5 'bar))
(eval-when (eval load)         (setq foo6 'bar))
(eval-when (eval compile load) (setq foo7 'bar))
```

When `foo.el' is compiled, these variables will be set during the compilation itself:

```
foo1  foo3  foo5  foo7      ; `compile'
```

When `foo.elc' is loaded, these variables will be set:

```
foo2  foo3  foo6  foo7      ; `load'
```

And if `foo.el' is loaded uncompiled, these variables will be set:

```
foo4  foo5  foo6  foo7      ; `eval'
```

If these seven `eval-when`s had been, say, inside a `defun`, then the first three would have been equivalent to `nil` and the last four would have been equivalent to the corresponding `setq`s.

Note that `(eval-when (load eval) ...)` is equivalent to `(progn ...)` in all contexts. The compiler treats certain top-level forms, like `defmacro` (sort-of) and `require`, as if they were wrapped in `(eval-when (compile load eval) ...)`.

Emacs 19 includes two special forms related to `eval-when`. One of these, `eval-when-compile`, is not quite equivalent to any `eval-when` construct and is described below. This package defines a version of `eval-when-compile` for the benefit of Emacs 18 users.

The other form, `(eval-and-compile ...)`, is exactly equivalent to `(eval-when (compile load eval) ...)' and so is not itself defined by this package.

Special Form: **eval-when-compile** *forms...*

The forms are evaluated at compile-time; at execution time, this form acts like a quoted constant of the resulting value. Used at top-level, `eval-when-compile` is just like `eval-when (compile eval)'. In other contexts, `eval-when-compile` allows code to be evaluated once at compile-time for efficiency or other reasons.

This form is similar to the `#.' syntax of true Common Lisp.

Special Form: **load-time-value** *form*

The form is evaluated at load-time; at execution time, this form acts like a quoted constant of the resulting value.

Early Common Lisp had a `#,' syntax that was similar to this, but ANSI Common Lisp replaced it with `load-time-value` and gave it more well-defined semantics.

In a compiled file, `load-time-value` arranges for form to be evaluated when the `.elc' file is loaded and then used as if it were a quoted constant. In code compiled by `byte-compile` rather than `byte-compile-file`, the effect is identical to `eval-when-compile`. In uncompiled code, both

`eval-when-compile` and `load-time-value` act exactly like `progn`.

```
(defun report ()
  (insert "This function was executed on: "
          (current-time-string)
          ", compiled on: "
          (eval-when-compile (current-time-string))
          ;; or '#.(current-time-string) in real Common Lisp
          ", and loaded on: "
          (load-time-value (current-time-string))))
```

Byte-compiled, the above defun will result in the following code (or its compiled equivalent, of course) in the `.elc' file:

```
(setq --temp-- (current-time-string))
(defun report ()
  (insert "This function was executed on: "
          (current-time-string)
          ", compiled on: "
          '"Wed Jun 23 18:33:43 1993"
          ", and loaded on: "
          --temp--))
```

Function Aliases

This section describes a feature from GNU Emacs 19 which this package makes available in other versions of Emacs.

Function: **defalias** *symbol function*

This function sets symbol's function cell to function. It is equivalent to `fset`, except that in GNU Emacs 19 it also records the setting in `load-history` so that it can be undone by a later `unload-feature`.

In other versions of Emacs, `defalias` is a synonym for `fset`.

Predicates

This section describes functions for testing whether various facts are true or false.

Type Predicates

The CL package defines a version of the Common Lisp `typep` predicate.

Function: **typep** *object type*

Check if object is of type type, where type is a (quoted) type name of the sort used by Common Lisp. For

example, `(typep foo 'integer)` is equivalent to `(integerp foo)`.

The type argument to the above function is either a symbol or a list beginning with a symbol.

- If the type name is a symbol, Emacs appends `-p' to the symbol name to form the name of a predicate function for testing the type. (Built-in predicates whose names end in `p' rather than `-p' are used when appropriate.)
- The type symbol `t` stands for the union of all types. `(typep object t)` is always true. Likewise, the type symbol `nil` stands for nothing at all, and `(typep object nil)` is always false.
- The type symbol `null` represents the symbol `nil`. Thus `(typep object 'null)` is equivalent to `(null object)`.
- The type symbol `real` is a synonym for `number`, and `fixnum` is a synonym for `integer`.
- The type symbols `character` and `string-char` match integers in the range from 0 to 255.
- The type symbol `float` uses the `floatp-safe` predicate defined by this package rather than `floatp`, so it will work correctly even in Emacs versions without floating-point support.
- The type list `(integer low high)` represents all integers between low and high, inclusive. Either bound may be a list of a single integer to specify an exclusive limit, or a `*` to specify no limit. The type `(integer * *)` is thus equivalent to `integer`.
- Likewise, lists beginning with `float`, `real`, or `number` represent numbers of that type falling in a particular range.
- Lists beginning with `and`, `or`, and `not` form combinations of types. For example, `(or integer (float 0 *))` represents all objects that are integers or non-negative floats.
- Lists beginning with `member` or `member*` represent objects `eql` to any of the following values. For example, `(member 1 2 3 4)` is equivalent to `(integer 1 4)`, and `(member nil)` is equivalent to `null`.
- Lists of the form `(satisfies predicate)` represent all objects for which predicate returns true when called with that object as an argument.

The following function and macro (not technically predicates) are related to `typep`.

Function: **coerce** *object type*

This function attempts to convert object to the specified type. If object is already of that type as determined by `typep`, it is simply returned. Otherwise, certain types of conversions will be made: If type is any sequence type (`string`, `list`, etc.) then object will be converted to that type if possible. If type is `character`, then strings of length one and symbols with one-character names can be coerced. If type is `float`, then integers can be coerced in versions of Emacs that support floats. In all other circumstances, `coerce` signals an error.

Special Form: **deftype** *name arglist forms...*

This macro defines a new type called name. It is similar to `defmacro` in many ways; when name is encountered as a type name, the body forms are evaluated and should return a type specifier that is equivalent to the type. The arglist is a Common Lisp argument list of the sort accepted by `defmacro*`. The type specifier `(name args...)' is expanded by calling the expander with those arguments; the type symbol `name' is expanded by calling the expander with no arguments. The arglist is processed the same as for `defmacro*` except that optional arguments without explicit defaults use `*` instead of `nil` as the "default" default. Some examples:

```
(deftype null () '(satisfies null))    ; predefined
(deftype list () '(or null cons))      ; predefined
(deftype unsigned-byte (&optional bits)
  (list 'integer 0 (if (eq bits '*) bits (1- (lsh 1 bits)))))
(unsigned-byte 8)  ==  (integer 0 255)
(unsigned-byte)  ==  (integer 0 *)
unsigned-byte  ==  (integer 0 *)
```

The last example shows how the Common Lisp `unsigned-byte` type specifier could be implemented if desired; this package does not implement `unsigned-byte` by default.

The `typecase` and `check-type` macros also use type names. See section Conditionals. See section Assertions and Errors. The `map`, `concatenate`, and `merge` functions take type-name arguments to specify the type of sequence to return. See section Sequences.

Equality Predicates

This package defines two Common Lisp predicates, `eql` and `equalp`.

Function: **eql** *a b*

This function is almost the same as `eq`, except that if a and b are numbers of the same type, it compares them for numeric equality (as if by `equal` instead of `eq`). This makes a difference only for versions of Emacs that are compiled with floating-point support, such as Emacs 19. Emacs floats are allocated objects just like cons cells, which means that `(eq 3.0 3.0)` will not necessarily be true--if the two `3.0`s were allocated separately, the pointers will be different even though the numbers are the same. But `(eql 3.0 3.0)` will always be true.

The types of the arguments must match, so `(eql 3 3.0)` is still false.

Note that Emacs integers are "direct" rather than allocated, which basically means `(eq 3 3)` will always be true. Thus `eq` and `eql` behave differently only if floating-point numbers are involved, and are indistinguishable on Emacs versions that don't support floats.

There is a slight inconsistency with Common Lisp in the treatment of positive and negative zeros. Some machines, notably those with IEEE standard arithmetic, represent `+0` and `-0` as distinct values. Normally this doesn't matter because the standard specifies that `(= 0.0 -0.0)` should always be true, and this is indeed what Emacs Lisp and Common Lisp do. But the Common Lisp standard states that `(eql 0.0 -0.0)` and `(equal 0.0 -0.0)` should be false on IEEE-like machines; Emacs Lisp does not do this, and in fact the only known way to distinguish between the two zeros in Emacs Lisp is to `format` them and check for a minus sign.

Function: **equalp** *a b*

This function is a more flexible version of `equal`. In particular, it compares strings case-insensitively, and it compares numbers without regard to type (so that `(equalp 3 3.0)` is true). Vectors and conses are compared recursively. All other objects are compared as if by `equal`.

This function differs from Common Lisp `equalp` in several respects. First, Common Lisp's `equalp` also

compares *characters* case-insensitively, which would be impractical in this package since Emacs does not distinguish between integers and characters. In keeping with the idea that strings are less vector-like in Emacs Lisp, this package's `equalp` also will not compare strings against vectors of integers. Finally, Common Lisp's `equalp` compares hash tables without regard to ordering, whereas this package simply compares hash tables in terms of their underlying structure (which means vectors for Lucid Emacs 19 hash tables, or lists for other hash tables).

Also note that the Common Lisp functions `member` and `assoc` use `eql` to compare elements, whereas Emacs Lisp follows the MacLisp tradition and uses `equal` for these two functions. In Emacs, use `member*` and `assoc*` to get functions which use `eql` for comparisons.

Control Structure

The features described in the following sections implement various advanced control structures, including the powerful `setf` facility and a number of looping and conditional constructs.

Assignment

The `psetq` form is just like `setq`, except that multiple assignments are done in parallel rather than sequentially.

Special Form: **psetq** *[symbol form]...*

This special form (actually a macro) is used to assign to several variables simultaneously. Given only one symbol and form, it has the same effect as `setq`. Given several symbol and form pairs, it evaluates all the forms in advance and then stores the corresponding variables afterwards.

```
(setq x 2 y 3)
(setq x (+ x y)  y (* x y))
x
     => 5
y                       ; y was computed after x was set.
     => 15
(setq x 2 y 3)
(psetq x (+ x y)  y (* x y))
x
     => 5
y                       ; y was computed before x was set.
     => 6
```

The simplest use of `psetq` is `(psetq x y y x)`, which exchanges the values of two variables. (The `rotatef` form provides an even more convenient way to swap two variables; see section Modify Macros.)

`psetq` always returns `nil`.

Generalized Variables

A "generalized variable" or "place form" is one of the many places in Lisp memory where values can be stored. The simplest place form is a regular Lisp variable. But the cars and cdrs of lists, elements of arrays, properties of symbols, and many other locations are also places where Lisp values are stored.

The `setf` form is like `setq`, except that it accepts arbitrary place forms on the left side rather than just symbols. For example, `(setf (car a) b)` sets the car of `a` to `b`, doing the same operation as `(setcar a b)` but without having to remember two separate functions for setting and accessing every type of place.

Generalized variables are analogous to "lvalues" in the C language, where `x = a[i]' gets an element from an array and `a[i] = x' stores an element using the same notation. Just as certain forms like `a[i]` can be lvalues in C, there is a set of forms that can be generalized variables in Lisp.

Basic Setf

The `setf` macro is the most basic way to operate on generalized variables.

Special Form: **setf** *[place form]...*

This macro evaluates form and stores it in place, which must be a valid generalized variable form. If there are several place and form pairs, the assignments are done sequentially just as with `setq`. `setf` returns the value of the last form.

The following Lisp forms will work as generalized variables, and so may legally appear in the place argument of `setf`:

- A symbol naming a variable. In other words, `(setf x y)` is exactly equivalent to `(setq x y)`, and `setq` itself is strictly speaking redundant now that `setf` exists. Many programmers continue to prefer `setq` for setting simple variables, though, purely for stylistic or historical reasons. The macro `(setf x y)` actually expands to `(setq x y)`, so there is no performance penalty for using it in compiled code.
- A call to any of the following Lisp functions:

```
car                 cdr                 caar .. cddddr
nth                 rest                first .. tenth
aref                elt                 nthcdr
symbol-function     symbol-value        symbol-plist
get                 get*                getf
gethash             subseq
```

  Note that for `nthcdr` and `getf`, the list argument of the function must itself be a valid place form. For example, `(setf (nthcdr 0 foo) 7)` will set `foo` itself to 7. Note that `push` and `pop` on an `nthcdr` place can be used to insert or delete at any position in a list. The use of `nthcdr` as a place form is an extension to standard Common Lisp.
- The following Emacs-specific functions are also `setf`-able. (Some of these are defined only in Emacs 19 or only in Lucid Emacs.)

```
buffer-file-name                marker-position
buffer-modified-p               match-data
buffer-name                     mouse-position
buffer-string                   overlay-end
buffer-substring                overlay-get
current-buffer                  overlay-start
current-case-table              point
current-column                  point-marker
current-global-map              point-max
current-input-mode              point-min
current-local-map               process-buffer
current-window-configuration    process-filter
default-file-modes              process-sentinel
default-value                   read-mouse-position
documentation-property          screen-height
extent-data                     screen-menubar
extent-end-position             screen-width
extent-start-position           selected-window
face-background                 selected-screen
face-background-pixmap          selected-frame
face-font                       standard-case-table
face-foreground                 syntax-table
face-underline-p                window-buffer
file-modes                      window-dedicated-p
frame-height                    window-display-table
frame-parameters                window-height
frame-visible-p                 window-hscroll
frame-width                     window-point
get-register                    window-start
getenv                          window-width
global-key-binding              x-get-cut-buffer
keymap-parent                   x-get-cutbuffer
local-key-binding               x-get-secondary-selection
mark                            x-get-selection
mark-marker
```

Most of these have directly corresponding "set" functions, like `use-local-map` for `current-local-map`, or `goto-char` for `point`. A few, like `point-min`, expand to longer sequences of code when they are `setf`'d (`(narrow-to-region x (point-max))` in this case).

- A call of the form `(substring subplace n [m])`, where subplace is itself a legal generalized variable whose current value is a string, and where the value stored is also a string. The new string is spliced into the specified part of the destination string. For example:

```
(setq a (list "hello" "world"))
     => ("hello" "world")
(cadr a)
```

```
     => "world"
(substring (cadr a) 2 4)
     => "rl"
(setf (substring (cadr a) 2 4) "o")
     => "o"
(cadr a)
     => "wood"
a
     => ("hello" "wood")
```

The generalized variable `buffer-substring`, listed above, also works in this way by replacing a portion of the current buffer.

- A call of the form `(apply 'func ...)` or `(apply (function func) ...)`, where func is a `setf`-able function whose store function is "suitable" in the sense described in Steele's book; since none of the standard Emacs place functions are suitable in this sense, this feature is only interesting when used with places you define yourself with `define-setf-method` or the long form of `defsetf`.
- A macro call, in which case the macro is expanded and `setf` is applied to the resulting form.
- Any form for which a `defsetf` or `define-setf-method` has been made.

Using any forms other than these in the place argument to `setf` will signal an error.

The `setf` macro takes care to evaluate all subforms in the proper left-to-right order; for example,

```
(setf (aref vec (incf i)) i)
```

looks like it will evaluate `(incf i)` exactly once, before the following access to `i`; the `setf` expander will insert temporary variables as necessary to ensure that it does in fact work this way no matter what setf-method is defined for `aref`. (In this case, `aset` would be used and no such steps would be necessary since `aset` takes its arguments in a convenient order.)

However, if the place form is a macro which explicitly evaluates its arguments in an unusual order, this unusual order will be preserved. Adapting an example from Steele, given

```
(defmacro wrong-order (x y) (list 'aref y x))
```

the form `(setf (wrong-order a b) 17)` will evaluate b first, then a, just as in an actual call to `wrong-order`.

Modify Macros

This package defines a number of other macros besides `setf` that operate on generalized variables. Many are interesting and useful even when the place is just a variable name.

Special Form: **psetf** *[place form]...*

This macro is to `setf` what `psetq` is to `setq`: When several places and forms are involved, the assignments take place in parallel rather than sequentially. Specifically, all subforms are evaluated from left to right, then all the assignments are done (in an undefined order).

Special Form: **incf** *place &optional x*

This macro increments the number stored in place by one, or by x if specified. The incremented value is returned. For example, `(incf i)` is equivalent to `(setq i (1+ i))`, and `(incf (car x) 2)` is equivalent to `(setcar x (+ (car x) 2))`.

Once again, care is taken to preserve the "apparent" order of evaluation. For example,

```
(incf (aref vec (incf i)))
```

appears to increment `i` once, then increment the element of `vec` addressed by `i`; this is indeed exactly what it does, which means the above form is *not* equivalent to the "obvious" expansion,

```
(setf (aref vec (incf i)) (1+ (aref vec (incf i))))   ; Wrong!
```

but rather to something more like

```
(let ((temp (incf i)))
  (setf (aref vec temp) (1+ (aref vec temp))))
```

Again, all of this is taken care of automatically by `incf` and the other generalized-variable macros.

As a more Emacs-specific example of `incf`, the expression `(incf (point) n)` is essentially equivalent to `(forward-char n)`.

Special Form: **decf** *place &optional x*

This macro decrements the number stored in place by one, or by x if specified.

Special Form: **pop** *place*

This macro removes and returns the first element of the list stored in place. It is analogous to `(prog1 (car place) (setf place (cdr place)))`, except that it takes care to evaluate all subforms only once.

Special Form: **push** *x place*

This macro inserts x at the front of the list stored in place. It is analogous to `(setf place (cons x place))`, except for evaluation of the subforms.

Special Form: **pushnew** *x place* `&key :test :test-not :key`

This macro inserts x at the front of the list stored in place, but only if x was not `eql` to any existing element of the list. The optional keyword arguments are interpreted in the same way as for `adjoin`. See section Lists as Sets.

Special Form: **shiftf** *place... newvalue*

This macro shifts the places left by one, shifting in the value of newvalue (which may be any Lisp expression, not just a generalized variable), and returning the value shifted out of the first place. Thus, `(shiftf a b c d)` is equivalent to

```
(prog1
```

```
   a
 (psetf a b
        b c
        c d))
```

except that the subforms of a, b, and c are actually evaluated only once each and in the apparent order.

Special Form: **rotatef** *place...*

This macro rotates the places left by one in circular fashion. Thus, `(rotatef a b c d)` is equivalent to

```
(psetf a b
       b c
       c d
       d a)
```

except for the evaluation of subforms. `rotatef` always returns `nil`. Note that `(rotatef a b)` conveniently exchanges a and b.

The following macros were invented for this package; they have no analogues in Common Lisp.

Special Form: **letf** *(bindings...) forms...*

This macro is analogous to `let`, but for generalized variables rather than just symbols. Each binding should be of the form `(place value)`; the original contents of the places are saved, the values are stored in them, and then the body forms are executed. Afterwards, the places are set back to their original saved contents. This cleanup happens even if the forms exit irregularly due to a `throw` or an error.

For example,

```
(letf (((point) (point-min))
       (a 17))
  ...)
```

moves "point" in the current buffer to the beginning of the buffer, and also binds `a` to 17 (as if by a normal `let`, since `a` is just a regular variable). After the body exits, `a` is set back to its original value and point is moved back to its original position.

Note that `letf` on `(point)` is not quite like a `save-excursion`, as the latter effectively saves a marker which tracks insertions and deletions in the buffer. Actually, a `letf` of `(point-marker)` is much closer to this behavior. (`point` and `point-marker` are equivalent as `setf` places; each will accept either an integer or a marker as the stored value.)

Since generalized variables look like lists, `let`'s shorthand of using `foo' for `(foo nil)' as a binding would be ambiguous in `letf` and is not allowed.

However, a binding specifier may be a one-element list `(place)', which is similar to `(place place)'. In other words, the place is not disturbed on entry to the body, and the only effect of the `letf` is to restore the original value of place afterwards. (The redundant access-and-store suggested by the `(place place)` example does not actually occur.)

In most cases, the place must have a well-defined value on entry to the `letf` form. The only exceptions are

plain variables and calls to `symbol-value` and `symbol-function`. If the symbol is not bound on entry it is simply made unbound by `makunbound` or `fmakunbound` on exit.

Special Form: **letf*** *(bindings...) forms...*

This macro is to `letf` what `let*` is to `let`: It does the bindings in sequential rather than parallel order.

Special Form: **callf** *function place args...*

This is the "generic" modify macro. It calls function, which should be an unquoted function name, macro name, or lambda. It passes place and args as arguments, and assigns the result back to place. For example, `(incf place n)` is the same as `(callf + place n)`. Some more examples:

```
(callf abs my-number)
(callf concat (buffer-name) "<" (int-to-string n) ">")
(callf union happy-people (list joe bob) :test 'same-person)
```

See section Customizing Setf, for `define-modify-macro`, a way to create even more concise notations for modify macros. Note again that `callf` is an extension to standard Common Lisp.

Special Form: **callf2** *function arg1 place args...*

This macro is like `callf`, except that place is the *second* argument of function rather than the first. For example, `(push x place)` is equivalent to `(callf2 cons x place)`.

The `callf` and `callf2` macros serve as building blocks for other macros like `incf`, `pushnew`, and `define-modify-macro`. The `letf` and `letf*` macros are used in the processing of symbol macros; see section Macro Bindings.

Customizing Setf

Common Lisp defines three macros, `define-modify-macro`, `defsetf`, and `define-setf-method`, that allow the user to extend generalized variables in various ways.

Special Form: **define-modify-macro** *name arglist function [doc-string]*

This macro defines a "read-modify-write" macro similar to `incf` and `decf`. The macro name is defined to take a place argument followed by additional arguments described by arglist. The call

```
(name place args...)
```

will be expanded to

```
(callf func place args...)
```

which in turn is roughly equivalent to

```
(setf place (func place args...))
```

For example:

```
(define-modify-macro incf (&optional (n 1)) +)
(define-modify-macro concatf (&rest args) concat)
```

Note that `&key` is not allowed in arglist, but `&rest` is sufficient to pass keywords on to the function.

Most of the modify macros defined by Common Lisp do not exactly follow the pattern of `define-modify-macro`. For example, `push` takes its arguments in the wrong order, and `pop` is completely irregular. You can define these macros "by hand" using `get-setf-method`, or consult the source file `` `cl-macs.el' `` to see how to use the internal `setf` building blocks.

Special Form: **defsetf** *access-fn update-fn*

This is the simpler of two `defsetf` forms. Where access-fn is the name of a function which accesses a place, this declares update-fn to be the corresponding store function. From now on,

```
(setf (access-fn arg1 arg2 arg3) value)
```

will be expanded to

```
(update-fn arg1 arg2 arg3 value)
```

The update-fn is required to be either a true function, or a macro which evaluates its arguments in a function-like way. Also, the update-fn is expected to return value as its result. Otherwise, the above expansion would not obey the rules for the way `setf` is supposed to behave.

As a special (non-Common-Lisp) extension, a third argument of `t` to `defsetf` says that the `update-fn`'s return value is not suitable, so that the above `setf` should be expanded to something more like

```
(let ((temp value))
  (update-fn arg1 arg2 arg3 temp)
  temp)
```

Some examples of the use of `defsetf`, drawn from the standard suite of setf methods, are:

```
(defsetf car setcar)
(defsetf symbol-value set)
(defsetf buffer-name rename-buffer t)
```

Special Form: **defsetf** *access-fn arglist (store-var) forms...*

This is the second, more complex, form of `defsetf`. It is rather like `defmacro` except for the additional store-var argument. The forms should return a Lisp form which stores the value of store-var into the generalized variable formed by a call to access-fn with arguments described by arglist. The forms may begin with a string which documents the `setf` method (analogous to the doc string that appears at the front of a function).

For example, the simple form of `defsetf` is shorthand for

```
(defsetf access-fn (&rest args) (store)
  (append '(update-fn) args (list store)))
```

The Lisp form that is returned can access the arguments from arglist and store-var in an unrestricted fash macros like `setf` and `incf` which invoke this setf-method will insert temporary variables as needed to make sure the apparent order of evaluation is preserved.

Another example drawn from the standard package:

```
(defsetf nth (n x) (store)
  (list 'setcar (list 'nthcdr n x) store))
```

Special Form: **define-setf-method** *access-fn arglist forms...*

This is the most general way to create new place forms. When a `setf` to access-fn with arguments described by arglist is expanded, the forms are evaluated and must return a list of five items:

1. A list of temporary variables.
2. A list of value forms corresponding to the temporary variables above. The temporary variables will be bound to these value forms as the first step of any operation on the generalized variable.
3. A list of exactly one store variable (generally obtained from a call to `gensym`).
4. A Lisp form which stores the contents of the store variable into the generalized variable, assuming the temporaries have been bound as described above.
5. A Lisp form which accesses the contents of the generalized variable, assuming the temporaries have been bound.

This is exactly like the Common Lisp macro of the same name, except that the method returns a list of five values rather than the five values themselves, since Emacs Lisp does not support Common Lisp's notion of multiple return values.

Once again, the forms may begin with a documentation string.

A setf-method should be maximally conservative with regard to temporary variables. In the setf-methods generated by `defsetf`, the second return value is simply the list of arguments in the place form, and the first return value is a list of a corresponding number of temporary variables generated by `gensym`. Macros like `setf` and `incf` which use this setf-method will optimize away most temporaries that turn out to be unnecessary, so there is little reason for the setf-method itself to optimize.

Function: **get-setf-method** *place &optional env*

This function returns the setf-method for place, by invoking the definition previously recorded by `defsetf` or `define-setf-method`. The result is a list of five values as described above. You can use this function to build your own `incf`-like modify macros. (Actually, it is better to use the internal functions `cl-setf-do-modify` and `cl-setf-do-store`, which are a bit easier to use and which also do a number of optimizations; consult the source code for the `incf` function for a simple example.)

The argument env specifies the "environment" to be passed on to `macroexpand` if `get-setf-method` should need to expand a macro in place. It should come from an `&environment` argument to the macro or setf-method that called `get-setf-method`.

See also the source code for the setf-methods for `apply` and `substring`, each of which works by calling `get-setf-method` on a simpler case, then massaging the result in various ways.

Modern Common Lisp defines a second, independent way to specify the `setf` behavior of a function,

namely "`setf` functions" whose names are lists `(setf name)` rather than symbols. For example, `(defsetf foo ...)` `(setf foo) ...)` defines the function that is used when `setf` is applied to `foo`. This package does currently support `setf` functions. In particular, it is a compile-time error to use `setf` on a form which has not already been `defsetf`'d or otherwise declared; in newer Common Lisps, this would not be an error since the function `(setf func)` might be defined later.

@secno=4

Variable Bindings

These Lisp forms make bindings to variables and function names, analogous to Lisp's built-in `let` form.

See section Modify Macros, for the `letf` and `letf*` forms which are also related to variable bindings.

Dynamic Bindings

The standard `let` form binds variables whose names are known at compile-time. The `progv` form provides an easy way to bind variables whose names are computed at run-time.

Special Form: **progv** *symbols values forms...*

This form establishes `let`-style variable bindings on a set of variables computed at run-time. The expressions symbols and values are evaluated, and must return lists of symbols and values, respectively. The symbols are bound to the corresponding values for the duration of the body forms. If values is shorter than symbols, the last few symbols are made unbound (as if by `makunbound`) inside the body. If symbols is shorter than values, the excess values are ignored.

Lexical Bindings

The CL package defines the following macro which more closely follows the Common Lisp `let` form:

Special Form: **lexical-let** *(bindings...) forms...*

This form is exactly like `let` except that the bindings it establishes are purely lexical. Lexical bindings are similar to local variables in a language like C: Only the code physically within the body of the `lexical-let` (after macro expansion) may refer to the bound variables.

```
(setq a 5)
(defun foo (b) (+ a b))
(let ((a 2)) (foo a))
     => 4
(lexical-let ((a 2)) (foo a))
     => 7
```

In this example, a regular `let` binding of `a` actually makes a temporary change to the global variable `a`, so `foo` is able to see the binding of `a` to 2. But `lexical-let` actually creates a distinct local variable `a` for use within its body, without any effect on the global variable of the same name.

The most important use of lexical bindings is to create closures. A closure is a function object that refers to

an outside lexical variable. For example:

```
(defun make-adder (n)
  (lexical-let ((n n))
    (function (lambda (m) (+ n m)))))
(setq add17 (make-adder 17))
(funcall add17 4)
     => 21
```

The call `(make-adder 17)` returns a function object which adds 17 to its argument. If `let` had been used instead of `lexical-let`, the function object would have referred to the global `n`, which would have been bound to 17 only during the call to `make-adder` itself.

```
(defun make-counter ()
  (lexical-let ((n 0))
    (function* (lambda (&optional (m 1)) (incf n m)))))
(setq count-1 (make-counter))
(funcall count-1 3)
     => 3
(funcall count-1 14)
     => 17
(setq count-2 (make-counter))
(funcall count-2 5)
     => 5
(funcall count-1 2)
     => 19
(funcall count-2)
     => 6
```

Here we see that each call to `make-counter` creates a distinct local variable `n`, which serves as a private counter for the function object that is returned.

Closed-over lexical variables persist until the last reference to them goes away, just like all other Lisp objects. For example, `count-2` refers to a function object which refers to an instance of the variable `n`; this is the only reference to that variable, so after `(setq count-2 nil)` the garbage collector would be able to delete this instance of `n`. Of course, if a `lexical-let` does not actually create any closures, then the lexical variables are free as soon as the `lexical-let` returns.

Many closures are used only during the extent of the bindings they refer to; these are known as "downward funargs" in Lisp parlance. When a closure is used in this way, regular Emacs Lisp dynamic bindings suffice and will be more efficient than `lexical-let` closures:

```
(defun add-to-list (x list)
  (mapcar (function (lambda (y) (+ x y))) list))
(add-to-list 7 '(1 2 5))
     => (8 9 12)
```

Since this lambda is only used while `x` is still bound, it is not necessary to make a true closure out of it.

You can use `defun` or `flet` inside a `lexical-let` to create a named closure. If several closures are created in the body of a single `lexical-let`, they all close over the same instance of the lexical variable.

The `lexical-let` form is an extension to Common Lisp. In true Common Lisp, all bindings are lexical unless declared otherwise.

Special Form: **lexical-let*** *(bindings...) forms...*

This form is just like `lexical-let`, except that the bindings are made sequentially in the manner of `let*`.

Function Bindings

These forms make `let`-like bindings to functions instead of variables.

Special Form: **flet** *(bindings...) forms...*

This form establishes `let`-style bindings on the function cells of symbols rather than on the value cells. Each binding must be a list of the form `(name arglist forms...)', which defines a function exactly as if it were a `defun*` form. The function name is defined accordingly for the duration of the body of the `flet`; then the old function definition, or lack thereof, is restored.

While `flet` in Common Lisp establishes a lexical binding of name, Emacs Lisp `flet` makes a dynamic binding. The result is that `flet` affects indirect calls to a function as well as calls directly inside the `flet` form itself.

You can use `flet` to disable or modify the behavior of a function in a temporary fashion. This will even work on Emacs primitives, although note that some calls to primitive functions internal to Emacs are made without going through the symbol's function cell, and so will not be affected by `flet`. For example,

```
(flet ((message (&rest args) (push args saved-msgs)))
  (do-something))
```

This code attempts to replace the built-in function `message` with a function that simply saves the messages in a list rather than displaying them. The original definition of `message` will be restored after `do-something` exits. This code will work fine on messages generated by other Lisp code, but messages generated directly inside Emacs will not be caught since they make direct C-language calls to the message routines rather than going through the Lisp `message` function.

Functions defined by `flet` may use the full Common Lisp argument notation supported by `defun*`; also, the function body is enclosed in an implicit block as if by `defun*`. See section Program Structure.

Special Form: **labels** *(bindings...) forms...*

The `labels` form is a synonym for `flet`. (In Common Lisp, `labels` and `flet` differ in ways that depend on their lexical scoping; these distinctions vanish in dynamically scoped Emacs Lisp.)

Macro Bindings

These forms create local macros and "symbol macros."

Special Form: **macrolet** *(bindings...) forms...*

This form is analogous to `flet`, but for macros instead of functions. Each binding is a list of the same form as the arguments to `defmacro*` (i.e., a macro name, argument list, and macro-expander forms). The macro is defined accordingly for use within the body of the `macrolet`.

Because of the nature of macros, `macrolet` is lexically scoped even in Emacs Lisp: The `macrolet` binding will affect only calls that appear physically within the body forms, possibly after expansion of other macros in the body.

Special Form: **symbol-macrolet** *(bindings...) forms...*

This form creates symbol macros, which are macros that look like variable references rather than function calls. Each binding is a list `(var expansion)'; any reference to var within the body forms is replaced by expansion.

```
(setq bar '(5 . 9))
(symbol-macrolet ((foo (car bar)))
  (incf foo))
bar
     => (6 . 9)
```

A `setq` of a symbol macro is treated the same as a `setf`. I.e., `(setq foo 4)` in the above would be equivalent to `(setf foo 4)`, which in turn expands to `(setf (car bar) 4)`.

Likewise, a `let` or `let*` binding a symbol macro is treated like a `letf` or `letf*`. This differs from true Common Lisp, where the rules of lexical scoping cause a `let` binding to shadow a `symbol-macrolet` binding. In this package, only `lexical-let` and `lexical-let*` will shadow a symbol macro.

There is no analogue of `defmacro` for symbol macros; all symbol macros are local. A typical use of `symbol-macrolet` is in the expansion of another macro:

```
(defmacro* my-dolist ((x list) &rest body)
  (let ((var (gensym)))
    (list 'loop 'for var 'on list 'do
          (list* 'symbol-macrolet (list (list x (list 'car var)))
                 body))))

(setq mylist '(1 2 3 4))
(my-dolist (x mylist) (incf x))
mylist
     => (2 3 4 5)
```

In this example, the `my-dolist` macro is similar to `dolist` (see section Iteration) except that the variable `x` becomes a true reference onto the elements of the list. The `my-dolist` call shown here expands to

```
(loop for G1234 on mylist do
      (symbol-macrolet ((x (car G1234)))
        (incf x)))
```

which in turn expands to

```
(loop for G1234 on mylist do (incf (car G1234)))
```

See section Loop Facility, for a description of the `loop` macro. This package defines a nonstandard `in-ref` loop clause that works much like `my-dolist`.

Conditionals

These conditional forms augment Emacs Lisp's simple `if`, `and`, `or`, and `cond` forms.

Special Form: **when** *test forms...*

This is a variant of `if` where there are no "else" forms, and possibly several "then" forms. In particular,

```
(when test a b c)
```

is entirely equivalent to

```
(if test (progn a b c) nil)
```

Special Form: **unless** *test forms...*

This is a variant of `if` where there are no "then" forms, and possibly several "else" forms:

```
(unless test a b c)
```

is entirely equivalent to

```
(when (not test) a b c)
```

Special Form: **case** *keyform clause...*

This macro evaluates keyform, then compares it with the key values listed in the various clauses. Whichever clause matches the key is executed; comparison is done by `eql`. If no clause matches, the `case` form returns `nil`. The clauses are of the form

```
(keylist body-forms...)
```

where keylist is a list of key values. If there is exactly one value, and it is not a cons cell or the symbol `nil` or `t`, then it can be used by itself as a keylist without being enclosed in a list. All key values in the `case` form must be distinct. The final clauses may use `t` in place of a keylist to indicate a default clause that should be taken if none of the other clauses match. (The symbol `otherwise` is also recognized in place of `t`. To make a clause that matches the actual symbol `t`, `nil`, or `otherwise`, enclose the symbol in a list.)

For example, this expression reads a keystroke, then does one of four things depending on whether it is an `a', a `b', a RET or LFD, or anything else.

```
(case (read-char)
  (?a (do-a-thing))
```

```
(?b (do-b-thing))
((?\r ?\n) (do-ret-thing))
(t (do-other-thing)))
```

Special Form: **ecase** *keyform clause...*

This macro is just like `case`, except that if the key does not match any of the clauses, an error is signalled rather than simply returning `nil`.

Special Form: **typecase** *keyform clause...*

This macro is a version of `case` that checks for types rather than values. Each clause is of the form `(type body...)'. See section Type Predicates, for a description of type specifiers. For example,

```
(typecase x
  (integer (munch-integer x))
  (float (munch-float x))
  (string (munch-integer (string-to-int x)))
  (t (munch-anything x)))
```

The type specifier `t` matches any type of object; the word `otherwise` is also allowed. To make one clause match any of several types, use an `(or ...)` type specifier.

Special Form: **etypecase** *keyform clause...*

This macro is just like `typecase`, except that if the key does not match any of the clauses, an error is signalled rather than simply returning `nil`.

Blocks and Exits

Common Lisp blocks provide a non-local exit mechanism very similar to `catch` and `throw`, but lexically rather than dynamically scoped. This package actually implements `block` in terms of `catch`; however, the lexical scoping allows the optimizing byte-compiler to omit the costly `catch` step if the body of the block does not actually `return-from` the block.

Special Form: **block** *name forms...*

The forms are evaluated as if by a `progn`. However, if any of the forms execute `(return-from name)`, they will jump out and return directly from the `block` form. The `block` returns the result of the last form unless a `return-from` occurs.

The `block`/`return-from` mechanism is quite similar to the `catch`/`throw` mechanism. The main differences are that block names are unevaluated symbols, rather than forms (such as quoted symbols) which evaluate to a tag at run-time; and also that blocks are lexically scoped whereas `catch`/`throw` are dynamically scoped. This means that functions called from the body of a `catch` can also `throw` to the `catch`, but the `return-from` referring to a block name must appear physically within the forms that make up the body of the block. They may not appear within other called functions, although they may appear within macro expansions or `lambda`s in the body. Block names and `catch` names form independent name-spaces.

In true Common Lisp, `defun` and `defmacro` surround the function or expander bodies with implicit bl with the same name as the function or macro. This does not occur in Emacs Lisp, but this package provi `defun*` and `defmacro*` forms which do create the implicit block.

The Common Lisp looping constructs defined by this package, such as `loop` and `dolist`, also create implicit blocks just as in Common Lisp.

Because they are implemented in terms of Emacs Lisp `catch` and `throw`, blocks have the same overhead as actual `catch` constructs (roughly two function calls). However, Zawinski and Furuseth's optimizing byte compiler (standard in Emacs 19) will optimize away the `catch` if the block does not in fact contain any `return` or `return-from` calls that jump to it. This means that `do` loops and `defun*` functions which don't use `return` don't pay the overhead to support it.

Special Form: **return-from** *name [result]*

This macro returns from the block named name, which must be an (unevaluated) symbol. If a result form is specified, it is evaluated to produce the result returned from the `block`. Otherwise, `nil` is returned.

Special Form: **return** *[result]*

This macro is exactly like `(return-from nil result)`. Common Lisp loops like `do` and `dolist` implicitly enclose themselves in `nil` blocks.

Iteration

The macros described here provide more sophisticated, high-level looping constructs to complement Emacs Lisp's basic `while` loop.

Special Form: **loop** *forms...*

The CL package supports both the simple, old-style meaning of `loop` and the extremely powerful and flexible feature known as the Loop Facility or Loop Macro. This more advanced facility is discussed in the following section; see section Loop Facility. The simple form of `loop` is described here.

If `loop` is followed by zero or more Lisp expressions, then `(loop exprs...)` simply creates an infinite loop executing the expressions over and over. The loop is enclosed in an implicit `nil` block. Thus,

```
(loop (foo)  (if (no-more) (return 72))  (bar))
```

is exactly equivalent to

```
(block nil (while t (foo)  (if (no-more) (return 72))  (bar)))
```

If any of the expressions are plain symbols, the loop is instead interpreted as a Loop Macro specification as described later. (This is not a restriction in practice, since a plain symbol in the above notation would simply access and throw away the value of a variable.)

Special Form: **do** *(spec...) (end-test [result...]) forms...*

This macro creates a general iterative loop. Each spec is of the form

```
(var [init [step]])
```

The loop works as follows: First, each var is bound to the associated init value as if by a `let` form. Then, in each iteration of the loop, the end-test is evaluated; if true, the loop is finished. Otherwise, the body forms are evaluated, then each var is set to the associated step expression (as if by a `psetq` form) and the next iteration begins. Once the end-test becomes true, the result forms are evaluated (with the vars still bound to their values) to produce the result returned by `do`.

The entire `do` loop is enclosed in an implicit `nil` block, so that you can use `(return)` to break out of the loop at any time.

If there are no result forms, the loop returns `nil`. If a given var has no step form, it is bound to its init value but not otherwise modified during the `do` loop (unless the code explicitly modifies it); this case is just a shorthand for putting a `(let ((var init)) ...)` around the loop. If init is also omitted it defaults to `nil`, and in this case a plain `var' can be used in place of `(var)', again following the analogy with `let`.

This example (from Steele) illustrates a loop which applies the function `f` to successive pairs of values from the lists `foo` and `bar`; it is equivalent to the call `(mapcar* 'f foo bar)`. Note that this loop has no body forms at all, performing all its work as side effects of the rest of the loop.

```
(do ((x foo (cdr x))
     (y bar (cdr y))
     (z nil (cons (f (car x) (car y)) z)))
  ((or (null x) (null y))
   (nreverse z)))
```

Special Form: **do*** *(spec...) (end-test [result...]) forms...*

This is to `do` what `let*` is to `let`. In particular, the initial values are bound as if by `let*` rather than `let`, and the steps are assigned as if by `setq` rather than `psetq`.

Here is another way to write the above loop:

```
(do* ((xp foo (cdr xp))
      (yp bar (cdr yp))
      (x (car xp) (car xp))
      (y (car yp) (car yp))
      z)
  ((or (null xp) (null yp))
   (nreverse z))
  (push (f x y) z))
```

Special Form: **dolist** *(var list [result]) forms...*

This is a more specialized loop which iterates across the elements of a list. list should evaluate to a list; the body forms are executed with var bound to each element of the list in turn. Finally, the result form (or `nil`) is evaluated with var bound to `nil` to produce the result returned by the loop. The loop is surrounded by an implicit `nil` block.

Special Form: **dotimes** *(var count [result]) forms...*

This is a more specialized loop which iterates a specified number of times. The body is executed with va bound to the integers from zero (inclusive) to count (exclusive), in turn. Then the `result` form is evalu with var bound to the total number of iterations that were done (i.e., `(max 0 count)`) to get the return value for the loop form. The loop is surrounded by an implicit `nil` block.

Special Form: **do-symbols** *(var [obarray [result]]) forms...*

This loop iterates over all interned symbols. If obarray is specified and is not `nil`, it loops over all symbols in that obarray. For each symbol, the body forms are evaluated with var bound to that symbol. The symbols are visited in an unspecified order. Afterward the result form, if any, is evaluated (with var bound to `nil`) to get the return value. The loop is surrounded by an implicit `nil` block.

Special Form: **do-all-symbols** *(var [result]) forms...*

This is identical to `do-symbols` except that the obarray argument is omitted; it always iterates over the default obarray.

See section Mapping over Sequences, for some more functions for iterating over vectors or lists.

Loop Facility

A common complaint with Lisp's traditional looping constructs is that they are either too simple and limited, such as Common Lisp's `dotimes` or Emacs Lisp's `while`, or too unreadable and obscure, like Common Lisp's `do` loop.

To remedy this, recent versions of Common Lisp have added a new construct called the "Loop Facility" or "`loop` macro," with an easy-to-use but very powerful and expressive syntax.

Loop Basics

The `loop` macro essentially creates a mini-language within Lisp that is specially tailored for describing loops. While this language is a little strange-looking by the standards of regular Lisp, it turns out to be very easy to learn and well-suited to its purpose.

Since `loop` is a macro, all parsing of the loop language takes place at byte-compile time; compiled `loop`s are just as efficient as the equivalent `while` loops written longhand.

Special Form: **loop** *clauses...*

A loop construct consists of a series of clauses, each introduced by a symbol like `for` or `do`. Clauses are simply strung together in the argument list of `loop`, with minimal extra parentheses. The various types of clauses specify initializations, such as the binding of temporary variables, actions to be taken in the loop, stepping actions, and final cleanup.

Common Lisp specifies a certain general order of clauses in a loop:

```
(loop name-clause
      var-clauses...
      action-clauses...)
```

The name-clause optionally gives a name to the implicit block that surrounds the loop. By default, the implicit block is named `nil`. The var-clauses specify what variables should be bound during the loop, and how they should be modified or iterated throughout the course of the loop. The action-clauses are things to be done during the loop, such as computing, collecting, and returning values.

The Emacs version of the `loop` macro is less restrictive about the order of clauses, but things will behave most predictably if you put the variable-binding clauses `with`, `for`, and `repeat` before the action clauses. As in Common Lisp, `initially` and `finally` clauses can go anywhere.

Loops generally return `nil` by default, but you can cause them to return a value by using an accumulation clause like `collect`, an end-test clause like `always`, or an explicit `return` clause to jump out of the implicit block. (Because the loop body is enclosed in an implicit block, you can also use regular Lisp `return` or `return-from` to break out of the loop.)

The following sections give some examples of the Loop Macro in action, and describe the particular loop clauses in great detail. Consult the second edition of Steele's Common Lisp, the Language, for additional discussion and examples of the `loop` macro.

Loop Examples

Before listing the full set of clauses that are allowed, let's look at a few example loops just to get a feel for the `loop` language.

```
(loop for buf in (buffer-list)
      collect (buffer-file-name buf))
```

This loop iterates over all Emacs buffers, using the list returned by `buffer-list`. For each buffer `buf`, it calls `buffer-file-name` and collects the results into a list, which is then returned from the `loop` construct. The result is a list of the file names of all the buffers in Emacs' memory. The words `for`, `in`, and `collect` are reserved words in the `loop` language.

```
(loop repeat 20 do (insert "Yowsa\n"))
```

This loop inserts the phrase "Yowsa" twenty times in the current buffer.

```
(loop until (eobp) do (munch-line) (forward-line 1))
```

This loop calls `munch-line` on every line until the end of the buffer. If point is already at the end of the buffer, the loop exits immediately.

```
(loop do (munch-line) until (eobp) do (forward-line 1))
```

This loop is similar to the above one, except that `munch-line` is always called at least once.

```
(loop for x from 1 to 100
      for y = (* x x)
      until (>= y 729)
      finally return (list x (= y 729)))
```

This more complicated loop searches for a number `x` whose square is 729. For safety's sake it only exam `x` values up to 100; dropping the phrase `to 100' would cause the loop to count upwards with no limit. Th second `for` clause defines `y` to be the square of `x` within the loop; the expression after the `=` sign is reevaluated each time through the loop. The `until` clause gives a condition for terminating the loop, and the `finally` clause says what to do when the loop finishes. (This particular example was written less concisely than it could have been, just for the sake of illustration.)

Note that even though this loop contains three clauses (two `for`s and an `until`) that would have been enough to define loops all by themselves, it still creates a single loop rather than some sort of triple-nested loop. You must explicitly nest your `loop` constructs if you want nested loops.

For Clauses

Most loops are governed by one or more `for` clauses. A `for` clause simultaneously describes variables to be bound, how those variables are to be stepped during the loop, and usually an end condition based on those variables.

The word `as` is a synonym for the word `for`. This word is followed by a variable name, then a word like `from` or `across` that describes the kind of iteration desired. In Common Lisp, the phrase `being the` sometimes precedes the type of iteration; in this package both `being` and `the` are optional. The word `each` is a synonym for `the`, and the word that follows it may be singular or plural: `for x being the elements of y' or `for x being each element of y'. Which form you use is purely a matter of style.

The variable is bound around the loop as if by `let`:

```
(setq i 'happy)
(loop for i from 1 to 10 do (do-something-with i))
i
     => happy
```

`for var from expr1 to expr2 by expr3`

This type of `for` clause creates a counting loop. Each of the three sub-terms is optional, though there must be at least one term so that the clause is marked as a counting clause.

The three expressions are the starting value, the ending value, and the step value, respectively, of the variable. The loop counts upwards by default (expr3 must be positive), from expr1 to expr2 inclusively. If you omit the `from` term, the loop counts from zero; if you omit the `to` term, the loop counts forever without stopping (unless stopped by some other loop clause, of course); if you omit the `by` term, the loop counts in steps of one.

You can replace the word `from` with `upfrom` or `downfrom` to indicate the direction of the loop. Likewise, you can replace `to` with `upto` or `downto`. For example, `for x from 5 downto 1' executes five times with `x` taking on the integers from 5 down to 1 in turn. Also, you can replace `to` with `below` or `above`, which are like `upto` and `downto` respectively except that they are exclusive rather than inclusive limits:

```
(loop for x to 10 collect x)
     => (0 1 2 3 4 5 6 7 8 9 10)
(loop for x below 10 collect x)
```

```
     => (0 1 2 3 4 5 6 7 8 9)
```

The `by` value is always positive, even for downward-counting loops. Some sort of `from` value is required for downward loops; `for x downto 5' is not a legal loop clause all by itself.

`for var in list by function`

This clause iterates var over all the elements of list, in turn. If you specify the `by` term, then function is used to traverse the list instead of `cdr`; it must be a function taking one argument. For example:

```
(loop for x in '(1 2 3 4 5 6) collect (* x x))
     => (1 4 9 16 25 36)
(loop for x in '(1 2 3 4 5 6) by 'cddr collect (* x x))
     => (1 9 25)
```

`for var on list by function`

This clause iterates var over all the cons cells of list.

```
(loop for x on '(1 2 3 4) collect x)
     => ((1 2 3 4) (2 3 4) (3 4) (4))
```

With `by`, there is no real reason that the `on` expression must be a list. For example:

```
(loop for x on first-animal by 'next-animal collect x)
```

where `(next-animal x)` takes an "animal" x and returns the next in the (assumed) sequence of animals, or `nil` if x was the last animal in the sequence.

`for var in-ref list by function`

This is like a regular `in` clause, but var becomes a `setf`-able "reference" onto the elements of the list rather than just a temporary variable. For example,

```
(loop for x in-ref my-list do (incf x))
```

increments every element of `my-list` in place. This clause is an extension to standard Common Lisp.

`for var across array`

This clause iterates var over all the elements of array, which may be a vector or a string.

```
(loop for x across "aeiou"
      do (use-vowel (char-to-string x)))
```

`for var across-ref array`

This clause iterates over an array, with var a `setf`-able reference onto the elements; see `in-ref` above.

`for var being the elements of sequence`

This clause iterates over the elements of sequence, which may be a list, vector, or string. Since the type must be determined at run-time, this is somewhat less efficient than `in` or `across`. The clause may be followed by the additional term `using (index var2)' to cause var2 to be bound to the successive indices (starting at 0) of the elements.

This clause type is taken from older versions of the `loop` macro, and is not present in modern Common Lisp. The `using (sequence ...)' term of the older macros is not supported.

`for var being the elements of-ref sequence`

This clause iterates over a sequence, with var a `setf`-able reference onto the elements; see `in-ref` above.

`for var being the symbols [of obarray]`

This clause iterates over symbols, either over all interned symbols or over all symbols in obarray. The loop is executed with var bound to each symbol in turn. The symbols are visited in an unspecified order.

As an example,

```
(loop for sym being the symbols
      when (fboundp sym)
      when (string-match "^map" (symbol-name sym))
      collect sym)
```

returns a list of all the functions whose names begin with `map'.

The Common Lisp words `external-symbols` and `present-symbols` are also recognized but are equivalent to `symbols` in Emacs Lisp.

Due to a minor implementation restriction, it will not work to have more than one `for` clause iterating over symbols, hash tables, keymaps, overlays, or intervals in a given `loop`. Fortunately, it would rarely if ever be useful to do so. It *is* legal to mix one of these types of clauses with other clauses like `for ... to` or `while`.

`for var being the hash-keys of hash-table`

This clause iterates over the entries in hash-table. For each hash table entry, var is bound to the entry's key. If you write `the hash-values' instead, var is bound to the values of the entries. The clause may be followed by the additional term `using (hash-values var2)' (where `hash-values` is the opposite word of the word following `the`) to cause var and var2 to be bound to the two parts of each hash table entry.

`for var being the key-codes of keymap`

This clause iterates over the entries in keymap. In GNU Emacs 18 and 19, keymaps are either alists or vectors, and key-codes are integers or symbols. In Lucid Emacs 19, keymaps are a special new data type, and key-codes are symbols or lists of symbols. The iteration does not enter nested keymaps or inherited (parent) keymaps. You can use `the key-bindings' to access the commands bound to the keys rather than the key codes, and you can add a `using` clause to access both the codes and the bindings together.

`for var being the key-seqs of keymap`

This clause iterates over all key sequences defined by keymap and its nested keymaps, where var takes on values which are strings in Emacs 18 or vectors in Emacs 19. The strings or vectors are reused for each iteration, so you must copy them if you wish to keep them permanently. You can add a `using (key-bindings ...)' clause to get the command bindings as well.

`for var being the overlays [of buffer] ...`

This clause iterates over the Emacs 19 "overlays" or Lucid Emacs "extents" of a buffer (the clause

`extents` is synonymous with `overlays`). Under Emacs 18, this clause iterates zero times. If th term is omitted, the current buffer is used. This clause also accepts optional `from pos' and `to pos' terms, limiting the clause to overlays which overlap the specified region.

`for var being the intervals [of buffer] ...`

This clause iterates over all intervals of a buffer with constant text properties. The variable var will be bound to conses of start and end positions, where one start position is always equal to the previous end position. The clause allows `of`, `from`, `to`, and `property` terms, where the latter term restricts the search to just the specified property. The `of` term may specify either a buffer or a string. This clause is useful only in GNU Emacs 19; in other versions, all buffers and strings consist of a single interval.

`for var being the frames`

This clause iterates over all frames, i.e., X window system windows open on Emacs files. This clause works only under Emacs 19. The clause `screens` is a synonym for `frames`. The frames are visited in `next-frame` order starting from `selected-frame`.

`for var being the windows [of frame]`

This clause iterates over the windows (in the Emacs sense) of the current frame, or of the specified frame. (In Emacs 18 there is only ever one frame, and the `of` term is not allowed there.)

`for var being the buffers`

This clause iterates over all buffers in Emacs. It is equivalent to `for var in (buffer-list)'.

`for var = expr1 then expr2`

This clause does a general iteration. The first time through the loop, var will be bound to expr1. On the second and successive iterations it will be set by evaluating expr2 (which may refer to the old value of var). For example, these two loops are effectively the same:

```
(loop for x on my-list by 'cddr do ...)
(loop for x = my-list then (cddr x) while x do ...)
```

Note that this type of `for` clause does not imply any sort of terminating condition; the above example combines it with a `while` clause to tell when to end the loop.

If you omit the `then` term, expr1 is used both for the initial setting and for successive settings:

```
(loop for x = (random) when (> x 0) return x)
```

This loop keeps taking random numbers from the `(random)` function until it gets a positive one, which it then returns.

If you include several `for` clauses in a row, they are treated sequentially (as if by `let*` and `setq`). You can instead use the word `and` to link the clauses, in which case they are processed in parallel (as if by `let` and `psetq`).

```
(loop for x below 5 for y = nil then x collect (list x y))
     => ((0 nil) (1 1) (2 2) (3 3) (4 4))
(loop for x below 5 and y = nil then x collect (list x y))
     => ((0 nil) (1 0) (2 1) (3 2) (4 3))
```

In the first loop, `y` is set based on the value of `x` that was just set by the previous clause; in the second loop, `x`

and `y` are set simultaneously so `y` is set based on the value of `x` left over from the previous time through the loop.

Another feature of the `loop` macro is destructuring, similar in concept to the destructuring provided by `defmacro`. The var part of any `for` clause can be given as a list of variables instead of a single variable. The values produced during loop execution must be lists; the values in the lists are stored in the corresponding variables.

```
(loop for (x y) in '((2 3) (4 5) (6 7)) collect (+ x y))
     => (5 9 13)
```

In loop destructuring, if there are more values than variables the trailing values are ignored, and if there are more variables than values the trailing variables get the value `nil`. If `nil` is used as a variable name, the corresponding values are ignored. Destructuring may be nested, and dotted lists of variables like `(x . y)` are allowed.

Iteration Clauses

Aside from `for` clauses, there are several other loop clauses that control the way the loop operates. They might be used by themselves, or in conjunction with one or more `for` clauses.

`repeat integer`

This clause simply counts up to the specified number using an internal temporary variable. The loops

```
(loop repeat n do ...)
(loop for temp to n do ...)
```

are identical except that the second one forces you to choose a name for a variable you aren't actually going to use.

`while condition`

This clause stops the loop when the specified condition (any Lisp expression) becomes `nil`. For example, the following two loops are equivalent, except for the implicit `nil` block that surrounds the second one:

```
(while cond forms...)
(loop while cond do forms...)
```

`until condition`

This clause stops the loop when the specified condition is true, i.e., non-`nil`.

`always condition`

This clause stops the loop when the specified condition is `nil`. Unlike `while`, it stops the loop using `return nil` so that the `finally` clauses are not executed. If all the conditions were non-`nil`, the loop returns `t`:

```
(if (loop for size in size-list always (> size 10))
    (some-big-sizes)
  (no-big-sizes))
```

`never condition`

This clause is like `always`, except that the loop returns `t` if any conditions were false, or `nil` otherwise.

`thereis condition`

This clause stops the loop when the specified form is non-`nil`; in this case, it returns that non-`nil` value. If all the values were `nil`, the loop returns `nil`.

Accumulation Clauses

These clauses cause the loop to accumulate information about the specified Lisp form. The accumulated result is returned from the loop unless overridden, say, by a `return` clause.

`collect form`

This clause collects the values of form into a list. Several examples of `collect` appear elsewhere in this manual.

The word `collecting` is a synonym for `collect`, and likewise for the other accumulation clauses.

`append form`

This clause collects lists of values into a result list using `append`.

`nconc form`

This clause collects lists of values into a result list by destructively modifying the lists rather than copying them.

`concat form`

This clause concatenates the values of the specified form into a string. (It and the following clause are extensions to standard Common Lisp.)

`vconcat form`

This clause concatenates the values of the specified form into a vector.

`count form`

This clause counts the number of times the specified form evaluates to a non-`nil` value.

`sum form`

This clause accumulates the sum of the values of the specified form, which must evaluate to a number.

`maximize form`

This clause accumulates the maximum value of the specified form, which must evaluate to a number. The return value is undefined if `maximize` is executed zero times.

`minimize form`

This clause accumulates the minimum value of the specified form.

Accumulation clauses can be followed by `into var' to cause the data to be collected into variable var (which is automatically `let`-bound during the loop) rather than an unnamed temporary variable. Also, `into` accumulations do not automatically imply a return value. The loop must use some explicit mechanism, such as `finally return`, to return the accumulated result.

It is legal for several accumulation clauses of the same type to accumulate into the same place. From Steele:

```
(loop for name in '(fred sue alice joe june)
      for kids in '((bob ken) () () (kris sunshine) ())
      collect name
      append kids)
     => (fred bob ken sue alice joe kris sunshine june)
```

Other Clauses

This section describes the remaining loop clauses.

`with var = value`

This clause binds a variable to a value around the loop, but otherwise leaves the variable alone during the loop. The following loops are basically equivalent:

```
(loop with x = 17 do ...)
(let ((x 17)) (loop do ...))
(loop for x = 17 then x do ...)
```

Naturally, the variable var might be used for some purpose in the rest of the loop. For example:

```
(loop for x in my-list  with res = nil  do (push x res)
      finally return res)
```

This loop inserts the elements of `my-list` at the front of a new list being accumulated in `res`, then returns the list `res` at the end of the loop. The effect is similar to that of a `collect` clause, but the list gets reversed by virtue of the fact that elements are being pushed onto the front of `res` rather than the end.

If you omit the `=` term, the variable is initialized to `nil`. (Thus the `= nil' in the above example is unnecessary.)

Bindings made by `with` are sequential by default, as if by `let*`. Just like `for` clauses, `with` clauses can be linked with `and` to cause the bindings to be made by `let` instead.

`if condition clause`

This clause executes the following loop clause only if the specified condition is true. The following clause should be an accumulation, `do`, `return`, `if`, or `unless` clause. Several clauses may be linked by separating them with `and`. These clauses may be followed by `else` and a clause or clauses to execute if the condition was false. The whole construct may optionally be followed by the word `end` (which may be used to disambiguate an `else` or `and` in a nested `if`).

The actual non-`nil` value of the condition form is available by the name `it` in the "then" part. For example:

```
(setq funny-numbers '(6 13 -1))
     => (6 13 -1)
(loop for x below 10
      if (oddp x)
        collect x into odds
```

```
          and if (memq x funny-numbers) return (cdr it) end
        else
          collect x into evens
        finally return (vector odds evens))
     => [(1 3 5 7 9) (0 2 4 6 8)]
(setq funny-numbers '(6 7 13 -1))
     => (6 7 13 -1)
(loop <same thing again>)
     => (13 -1)
```

Note the use of `and` to put two clauses into the "then" part, one of which is itself an `if` clause. Note also that `end`, while normally optional, was necessary here to make it clear that the `else` refers to the outermost `if` clause. In the first case, the loop returns a vector of lists of the odd and even values of x. In the second case, the odd number 7 is one of the `funny-numbers` so the loop returns early; the actual returned value is based on the result of the `memq` call.

`when condition clause`

This clause is just a synonym for `if`.

`unless condition clause`

The `unless` clause is just like `if` except that the sense of the condition is reversed.

`named name`

This clause gives a name other than `nil` to the implicit block surrounding the loop. The name is the symbol to be used as the block name.

`initially [do] forms...`

This keyword introduces one or more Lisp forms which will be executed before the loop itself begins (but after any variables requested by `for` or `with` have been bound to their initial values). `initially` clauses can appear anywhere; if there are several, they are executed in the order they appear in the loop. The keyword `do` is optional.

`finally [do] forms...`

This introduces Lisp forms which will be executed after the loop finishes (say, on request of a `for` or `while`). `initially` and `finally` clauses may appear anywhere in the loop construct, but they are executed (in the specified order) at the beginning or end, respectively, of the loop.

`finally return form`

This says that form should be executed after the loop is done to obtain a return value. (Without this, or some other clause like `collect` or `return`, the loop will simply return `nil`.) Variables bound by `for`, `with`, or `into` will still contain their final values when form is executed.

`do forms...`

The word `do` may be followed by any number of Lisp expressions which are executed as an implicit `progn` in the body of the loop. Many of the examples in this section illustrate the use of `do`.

`return form`

This clause causes the loop to return immediately. The following Lisp form is evaluated to give the return value of the `loop` form. The `finally` clauses, if any, are not executed. Of course, `return` is generally used inside an `if` or `unless`, as its use in a top-level loop clause would mean the loop would never get to "loop" more than once.

The clause `return form' is equivalent to `do (return form)' (or `return-from` if the loop was nam
The `return` clause is implemented a bit more efficiently, though.

While there is no high-level way to add user extensions to `loop` (comparable to `defsetf` for `setf`, say), this package does offer two properties called `cl-loop-handler` and `cl-loop-for-handler` which are functions to be called when a given symbol is encountered as a top-level loop clause or `for` clause, respectively. Consult the source code in file `` `cl-macs.el' `` for details.

This package's `loop` macro is compatible with that of Common Lisp, except that a few features are not implemented: `loop-finish` and data-type specifiers. Naturally, the `for` clauses which iterate over keymaps, overlays, intervals, frames, windows, and buffers are Emacs-specific extensions.

Multiple Values

Common Lisp functions can return zero or more results. Emacs Lisp functions, by contrast, always return exactly one result. This package makes no attempt to emulate Common Lisp multiple return values; Emacs versions of Common Lisp functions that return more than one value either return just the first value (as in `compiler-macroexpand`) or return a list of values (as in `get-setf-method`). This package *does* define placeholders for the Common Lisp functions that work with multiple values, but in Emacs Lisp these functions simply operate on lists instead. The `values` form, for example, is a synonym for `list` in Emacs.

Special Form: **multiple-value-bind** *(var...) values-form forms...*

This form evaluates values-form, which must return a list of values. It then binds the vars to these respective values, as if by `let`, and then executes the body forms. If there are more vars than values, the extra vars are bound to `nil`. If there are fewer vars than values, the excess values are ignored.

Special Form: **multiple-value-setq** *(var...) form*

This form evaluates form, which must return a list of values. It then sets the vars to these respective values, as if by `setq`. Extra vars or values are treated the same as in `multiple-value-bind`.

The older Quiroz package attempted a more faithful (but still imperfect) emulation of Common Lisp multiple values. The old method "usually" simulated true multiple values quite well, but under certain circumstances would leave spurious return values in memory where a later, unrelated `multiple-value-bind` form would see them.

Since a perfect emulation is not feasible in Emacs Lisp, this package opts to keep it as simple and predictable as possible.

Macros

This package implements the various Common Lisp features of `defmacro`, such as destructuring, `&environment`, and `&body`. Top-level `&whole` is not implemented for `defmacro` due to technical difficulties. See section Argument Lists.

Destructuring is made available to the user by way of the following macro:

Special Form: **destructuring-bind** *arglist expr forms...*

This macro expands to code which executes forms, with the variables in arglist bound to the list of values returned by expr. The arglist can include all the features allowed for `defmacro` argument lists, including destructuring. (The `&environment` keyword is not allowed.) The macro expansion will signal an error if expr returns a list of the wrong number of arguments or with incorrect keyword arguments.

This package also includes the Common Lisp `define-compiler-macro` facility, which allows you to define compile-time expansions and optimizations for your functions.

Special Form: **define-compiler-macro** *name arglist forms...*

This form is similar to `defmacro`, except that it only expands calls to name at compile-time; calls processed by the Lisp interpreter are not expanded, nor are they expanded by the `macroexpand` function.

The argument list may begin with a `&whole` keyword and a variable. This variable is bound to the macro-call form itself, i.e., to a list of the form `(name args...)'. If the macro expander returns this form unchanged, then the compiler treats it as a normal function call. This allows compiler macros to work as optimizers for special cases of a function, leaving complicated cases alone.

For example, here is a simplified version of a definition that appears as a standard part of this package:

```
(define-compiler-macro member* (&whole form a list &rest keys)
  (if (and (null keys)
           (eq (car-safe a) 'quote)
           (not (floatp-safe (cadr a))))
      (list 'memq a list)
    form))
```

This definition causes `(member* a list)` to change to a call to the faster `memq` in the common case where a is a non-floating-point constant; if a is anything else, or if there are any keyword arguments in the call, then the original `member*` call is left intact. (The actual compiler macro for `member*` optimizes a number of other cases, including common `:test` predicates.)

Function: **compiler-macroexpand** *form*

This function is analogous to `macroexpand`, except that it expands compiler macros rather than regular macros. It returns form unchanged if it is not a call to a function for which a compiler macro has been defined, or if that compiler macro decided to punt by returning its `&whole` argument. Like `macroexpand`, it expands repeatedly until it reaches a form for which no further expansion is possible.

See section Macro Bindings, for descriptions of the `macrolet` and `symbol-macrolet` forms for making "local" macro definitions.

Declarations

Common Lisp includes a complex and powerful "declaration" mechanism that allows you to give the compiler special hints about the types of data that will be stored in particular variables, and about the ways those variables and functions will be used. This package defines versions of all the Common Lisp declaration forms: `declare`, `locally`, `proclaim`, `declaim`, and `the`.

Most of the Common Lisp declarations are not currently useful in Emacs Lisp, as the byte-code system provides little opportunity to benefit from type information, and `special` declarations are redundant in a fully dynamically-scoped Lisp. A few declarations are meaningful when the optimizing Emacs 19 byte compiler is being used, however. Under the earlier non-optimizing compiler, these declarations will effectively be ignored.

Function: **proclaim** *decl-spec*

This function records a "global" declaration specified by decl-spec. Since `proclaim` is a function, decl-spec is evaluated and thus should normally be quoted.

Special Form: **declaim** *decl-specs...*

This macro is like `proclaim`, except that it takes any number of decl-spec arguments, and the arguments are unevaluated and unquoted. The `declaim` macro also puts an `(eval-when (compile load eval) ...)` around the declarations so that they will be registered at compile-time as well as at run-time. (This is vital, since normally the declarations are meant to influence the way the compiler treats the rest of the file that contains the `declaim` form.)

Special Form: **declare** *decl-specs...*

This macro is used to make declarations within functions and other code. Common Lisp allows declarations in various locations, generally at the beginning of any of the many "implicit `progn`s" throughout Lisp syntax, such as function bodies, `let` bodies, etc. Currently the only declaration understood by `declare` is `special`.

Special Form: **locally** *declarations... forms...*

In this package, `locally` is no different from `progn`.

Special Form: **the** *type form*

Type information provided by `the` is ignored in this package; in other words, `(the type form)` is equivalent to form. Future versions of the optimizing byte-compiler may make use of this information.

For example, `mapcar` can map over both lists and arrays. It is hard for the compiler to expand `mapcar` into an in-line loop unless it knows whether the sequence will be a list or an array ahead of time. With `(mapcar 'car (the vector foo))`, a future compiler would have enough information to expand the loop in-line. For now, Emacs Lisp will treat the above code as exactly equivalent to `(mapcar 'car foo)`.

Each decl-spec in a `proclaim`, `declaim`, or `declare` should be a list beginning with a symbol that says what kind of declaration it is. This package currently understands `special`, `inline`, `notinline`, `optimize`, and `warn` declarations. (The `warn` declaration is an extension of standard Common Lisp.) Other Common Lisp declarations, such as `type` and `ftype`, are silently ignored.

`special`

Since all variables in Emacs Lisp are "special" (in the Common Lisp sense), `special` declarations are only advisory. They simply tell the optimizing byte compiler that the specified variables are intentionally being referred to without being bound in the body of the function. The compiler normally emits warnings for such references, since they could be typographical errors for references to local variables.

The declaration `(declare (special var1 var2))` is equivalent to `(defvar var1)` `(defvar var2)` in the optimizing compiler, or to nothing at all in older compilers (which do not warn for non-local references).

In top-level contexts, it is generally better to write `(defvar var)` than `(declaim (special var))`, since `defvar` makes your intentions clearer. But the older byte compilers can not handle `defvar`s appearing inside of functions, while `(declare (special var))` takes care to work correctly with all compilers.

`inline`

The `inline` decl-spec lists one or more functions whose bodies should be expanded "in-line" into calling functions whenever the compiler is able to arrange for it. For example, the Common Lisp function `cadr` is declared `inline` by this package so that the form `(cadr x)` will expand directly into `(car (cdr x))` when it is called in user functions, for a savings of one (relatively expensive) function call.

The following declarations are all equivalent. Note that the `defsubst` form is a convenient way to define a function and declare it inline all at once, but it is available only in Emacs 19.

```
(declaim (inline foo bar))
(eval-when (compile load eval) (proclaim '(inline foo bar)))
(proclaim-inline foo bar)      ; Lucid Emacs only
(defsubst foo (...) ...)       ; instead of defun; Emacs 19 only
```

Note: This declaration remains in effect after the containing source file is done. It is correct to use it to request that a function you have defined should be inlined, but it is impolite to use it to request inlining of an external function.

In Common Lisp, it is possible to use `(declare (inline ...))` before a particular call to a function to cause just that call to be inlined; the current byte compilers provide no way to implement this, so `(declare (inline ...))` is currently ignored by this package.

`notinline`

The `notinline` declaration lists functions which should not be inlined after all; it cancels a previous `inline` declaration.

`optimize`

This declaration controls how much optimization is performed by the compiler. Naturally, it is ignored by the earlier non-optimizing compilers.

The word `optimize` is followed by any number of lists like `(speed 3)` or `(safety 2)`. Common Lisp defines several optimization "qualities"; this package ignores all but `speed` and `safety`. The value of a quality should be an integer from 0 to 3, with 0 meaning "unimportant" and 3

meaning "very important." The default level for both qualities is 1.

In this package, with the Emacs 19 optimizing compiler, the `speed` quality is tied to the `byte-compile-optimize` flag, which is set to `nil` for `(speed 0)` and to `t` for higher settings; and the `safety` quality is tied to the `byte-compile-delete-errors` flag, which is set to `t` for `(safety 3)` and to `nil` for all lower settings. (The latter flag controls whether the compiler is allowed to optimize out code whose only side-effect could be to signal an error, e.g., rewriting `(progn foo bar)` to `bar` when it is not known whether `foo` will be bound at run-time.)

Note that even compiling with `(safety 0)`, the Emacs byte-code system provides sufficient checking to prevent real harm from being done. For example, barring serious bugs in Emacs itself, Emacs will not crash with a segmentation fault just because of an error in a fully-optimized Lisp program.

The `optimize` declaration is normally used in a top-level `proclaim` or `declaim` in a file; Common Lisp allows it to be used with `declare` to set the level of optimization locally for a given form, but this will not work correctly with the current version of the optimizing compiler. (The `declare` will set the new optimization level, but that level will not automatically be unset after the enclosing form is done.)

`warn`

This declaration controls what sorts of warnings are generated by the byte compiler. Again, only the optimizing compiler generates warnings. The word `warn` is followed by any number of "warning qualities," similar in form to optimization qualities. The currently supported warning types are `redefine`, `callargs`, `unresolved`, and `free-vars`; in the current system, a value of 0 will disable these warnings and any higher value will enable them. See the documentation for the optimizing byte compiler for details.

Symbols

This package defines several symbol-related features that were missing from Emacs Lisp.

Property Lists

These functions augment the standard Emacs Lisp functions `get` and `put` for operating on properties attached to symbols. There are also functions for working with property lists as first-class data structures not attached to particular symbols.

Function: **get*** *symbol property &optional default*

This function is like `get`, except that if the property is not found, the default argument provides the return value. (The Emacs Lisp `get` function always uses `nil` as the default; this package's `get*` is equivalent to Common Lisp's `get`.)

The `get*` function is `setf`-able; when used in this fashion, the default argument is allowed but ignored.

Function: **remprop** *symbol property*

This function removes the entry for property from the property list of symbol. It returns a true value if the

property was indeed found and removed, or `nil` if there was no such property. (This function was proba omitted from Emacs originally because, since `get` did not allow a default, it was very difficult to disting between a missing property and a property whose value was `nil`; thus, setting a property to `nil` was close enough to `remprop` for most purposes.)

Function: **getf** *place property &optional default*

This function scans the list place as if it were a property list, i.e., a list of alternating property names and values. If an even-numbered element of place is found which is `eq` to property, the following odd-numbered element is returned. Otherwise, default is returned (or `nil` if no default is given).

In particular,

```
(get sym prop)  ==  (getf (symbol-plist sym) prop)
```

It is legal to use `getf` as a `setf` place, in which case its place argument must itself be a legal `setf` place. The default argument, if any, is ignored in this context. The effect is to change (via `setcar`) the value cell in the list that corresponds to property, or to cons a new property-value pair onto the list if the property is not yet present.

```
(put sym prop val)  ==  (setf (getf (symbol-plist sym) prop) val)
```

The `get` and `get*` functions are also `setf`-able. The fact that `default` is ignored can sometimes be useful:

```
(incf (get* 'foo 'usage-count 0))
```

Here, symbol `foo`'s `usage-count` property is incremented if it exists, or set to 1 (an incremented 0) otherwise.

When not used as a `setf` form, `getf` is just a regular function and its place argument can actually be any Lisp expression.

Special Form: **remf** *place property*

This macro removes the property-value pair for property from the property list stored at place, which is any `setf`-able place expression. It returns true if the property was found. Note that if property happens to be first on the list, this will effectively do a `(setf place (cddr place))`, whereas if it occurs later, this simply uses `setcdr` to splice out the property and value cells.

@secno=2

Creating Symbols

These functions create unique symbols, typically for use as temporary variables.

Function: **gensym** *&optional x*

This function creates a new, uninterned symbol (using `make-symbol`) with a unique name. (The name of an uninterned symbol is relevant only if the symbol is printed.) By default, the name is generated from an

increasing sequence of numbers, `G1000', `G1001', `G1002', etc. If the optional argument x is a string, th string is used as a prefix instead of `G'. Uninterned symbols are used in macro expansions for temporary variables, to ensure that their names will not conflict with "real" variables in the user's code.

Variable: ***gensym-counter***

This variable holds the counter used to generate `gensym` names. It is incremented after each use by `gensym`. In Common Lisp this is initialized with 0, but this package initializes it with a random (time-dependent) value to avoid trouble when two files that each used `gensym` in their compilation are loaded together. (Uninterned symbols become interned when the compiler writes them out to a file and the Emacs loader loads them, so their names have to be treated a bit more carefully than in Common Lisp where uninterned symbols remain uninterned after loading.)

Function: **gentemp** *&optional x*

This function is like `gensym`, except that it produces a new *interned* symbol. If the symbol that is generated already exists, the function keeps incrementing the counter and trying again until a new symbol is generated.

The Quiroz `cl.el' package also defined a `defkeyword` form for creating self-quoting keyword symbols. This package automatically creates all keywords that are called for by `&key` argument specifiers, and discourages the use of keywords as data unrelated to keyword arguments, so the `defkeyword` form has been discontinued.

@chapno=11

Numbers

This section defines a few simple Common Lisp operations on numbers which were left out of Emacs Lisp.

@secno=1

Predicates on Numbers

These functions return `t` if the specified condition is true of the numerical argument, or `nil` otherwise.

Function: **plusp** *number*

This predicate tests whether number is positive. It is an error if the argument is not a number.

Function: **minusp** *number*

This predicate tests whether number is negative. It is an error if the argument is not a number.

Function: **oddp** *integer*

This predicate tests whether integer is odd. It is an error if the argument is not an integer.

Function: **evenp** *integer*

This predicate tests whether integer is even. It is an error if the argument is not an integer.

Function: **floatp-safe** *object*

This predicate tests whether object is a floating-point number. On systems that support floating-point, this is equivalent to `floatp`. On other systems, this always returns `nil`.

@secno=3

Numerical Functions

These functions perform various arithmetic operations on numbers.

Function: **abs** *number*

This function returns the absolute value of number. (Newer versions of Emacs provide this as a built-in function; this package defines `abs` only for Emacs 18 versions which don't provide it as a primitive.)

Function: **expt** *base power*

This function returns base raised to the power of number. (Newer versions of Emacs provide this as a built-in function; this package defines `expt` only for Emacs 18 versions which don't provide it as a primitive.)

Function: **gcd** *&rest integers*

This function returns the Greatest Common Divisor of the arguments. For one argument, it returns the absolute value of that argument. For zero arguments, it returns zero.

Function: **lcm** *&rest integers*

This function returns the Least Common Multiple of the arguments. For one argument, it returns the absolute value of that argument. For zero arguments, it returns one.

Function: **isqrt** *integer*

This function computes the "integer square root" of its integer argument, i.e., the greatest integer less than or equal to the true square root of the argument.

Function: **floor*** *number &optional divisor*

This function implements the Common Lisp `floor` function. It is called `floor*` to avoid name conflicts with the simpler `floor` function built-in to Emacs 19.

With one argument, `floor*` returns a list of two numbers: The argument rounded down (toward minus infinity) to an integer, and the "remainder" which would have to be added back to the first return value to yield the argument again. If the argument is an integer x, the result is always the list `(x 0)`. If the argument is an Emacs 19 floating-point number, the first result is a Lisp integer and the second is a Lisp float between 0 (inclusive) and 1 (exclusive).

With two arguments, `floor*` divides number by divisor, and returns the floor of the quotient and the corresponding remainder as a list of two numbers. If `(floor* x y)` returns `(q r)`, then `q*y + r = x`, with r between 0 (inclusive) and r (exclusive). Also, note that `(floor* x)` is exactly equivalent to `(floor* x 1)`.

This function is entirely compatible with Common Lisp's `floor` function, except that it returns the two

results in a list since Emacs Lisp does not support multiple-valued functions.

Function: **ceiling*** *number &optional divisor*

This function implements the Common Lisp `ceiling` function, which is analogous to `floor` except that it rounds the argument or quotient of the arguments up toward plus infinity. The remainder will be between 0 and minus r.

Function: **truncate*** *number &optional divisor*

This function implements the Common Lisp `truncate` function, which is analogous to `floor` except that it rounds the argument or quotient of the arguments toward zero. Thus it is equivalent to `floor*` if the argument or quotient is positive, or to `ceiling*` otherwise. The remainder has the same sign as number.

Function: **round*** *number &optional divisor*

This function implements the Common Lisp `round` function, which is analogous to `floor` except that it rounds the argument or quotient of the arguments to the nearest integer. In the case of a tie (the argument or quotient is exactly halfway between two integers), it rounds to the even integer.

Function: **mod*** *number divisor*

This function returns the same value as the second return value of `floor`.

Function: **rem*** *number divisor*

This function returns the same value as the second return value of `truncate`.

These definitions are compatible with those in the Quiroz `` `cl.el' `` package, except that this package appends `*' to certain function names to avoid conflicts with existing Emacs 19 functions, and that the mechanism for returning multiple values is different.

@secno=8

Random Numbers

This package also provides an implementation of the Common Lisp random number generator. It uses its own additive-congruential algorithm, which is much more likely to give statistically clean random numbers than the simple generators supplied by many operating systems.

Function: **random*** *number &optional state*

This function returns a random nonnegative number less than number, and of the same type (either integer or floating-point). The state argument should be a `random-state` object which holds the state of the random number generator. The function modifies this state object as a side effect. If state is omitted, it defaults to the variable `*random-state*`, which contains a pre-initialized `random-state` object.

Variable: ***random-state***

This variable contains the system "default" `random-state` object, used for calls to `random*` that do not specify an alternative state object. Since any number of programs in the Emacs process may be accessing `*random-state*` in interleaved fashion, the sequence generated from this variable will be irreproducible for all intents and purposes.

Function: **make-random-state** *&optional state*

This function creates or copies a `random-state` object. If state is omitted or `nil`, it returns a new copy of `*random-state*`. This is a copy in the sense that future sequences of calls to `(random* n)` and `(random* n s)` (where s is the new random-state object) will return identical sequences of random numbers.

If state is a `random-state` object, this function returns a copy of that object. If state is `t`, this function returns a new `random-state` object seeded from the date and time. As an extension to Common Lisp, state may also be an integer in which case the new object is seeded from that integer; each different integer seed will result in a completely different sequence of random numbers.

It is legal to print a `random-state` object to a buffer or file and later read it back with `read`. If a program wishes to use a sequence of pseudo-random numbers which can be reproduced later for debugging, it can call `(make-random-state t)` to get a new sequence, then print this sequence to a file. When the program is later rerun, it can read the original run's random-state from the file.

Function: **random-state-p** *object*

This predicate returns `t` if object is a `random-state` object, or `nil` otherwise.

Implementation Parameters

This package defines several useful constants having to with numbers.

Variable: **most-positive-fixnum**

This constant equals the largest value a Lisp integer can hold. It is typically `2^23-1` or `2^25-1`.

Variable: **most-negative-fixnum**

This constant equals the smallest (most negative) value a Lisp integer can hold.

The following parameters have to do with floating-point numbers. This package determines their values by exercising the computer's floating-point arithmetic in various ways. Because this operation might be slow, the code for initializing them is kept in a separate function that must be called before the parameters can be used.

Function: **cl-float-limits**

This function makes sure that the Common Lisp floating-point parameters like `most-positive-float` have been initialized. Until it is called, these parameters will be `nil`. If this version of Emacs does not support floats (e.g., most versions of Emacs 18), the parameters will remain `nil`. If the parameters have already been initialized, the function returns immediately.

The algorithm makes assumptions that will be valid for most modern machines, but will fail if the machine's arithmetic is extremely unusual, e.g., decimal.

Since true Common Lisp supports up to four different floating-point precisions, it has families of constants like `most-positive-single-float`, `most-positive-double-float`, `most-positive-long-float`, and so on. Emacs has only one floating-point precision, so this package omits the precision word from the constants' names.

TOC

Variable: **most-positive-float**

This constant equals the largest value a Lisp float can hold. For those systems whose arithmetic supports infinities, this is the largest *finite* value. For IEEE machines, the value is approximately `1.79e+308`.

Variable: **most-negative-float**

This constant equals the most-negative value a Lisp float can hold. (It is assumed to be equal to `(-most-positive-float)`.)

Variable: **least-positive-float**

This constant equals the smallest Lisp float value greater than zero. For IEEE machines, it is about `4.94e-324` if denormals are supported or `2.22e-308` if not.

Variable: **least-positive-normalized-float**

This constant equals the smallest *normalized* Lisp float greater than zero, i.e., the smallest value for which IEEE denormalization will not result in a loss of precision. For IEEE machines, this value is about `2.22e-308`. For machines that do not support the concept of denormalization and gradual underflow, this constant will always equal `least-positive-float`.

Variable: **least-negative-float**

This constant is the negative counterpart of `least-positive-float`.

Variable: **least-negative-normalized-float**

This constant is the negative counterpart of `least-positive-normalized-float`.

Variable: **float-epsilon**

This constant is the smallest positive Lisp float that can be added to 1.0 to produce a distinct value. Adding a smaller number to 1.0 will yield 1.0 again due to roundoff. For IEEE machines, epsilon is about `2.22e-16`.

Variable: **float-negative-epsilon**

This is the smallest positive value that can be subtracted from 1.0 to produce a distinct value. For IEEE machines, it is about `1.11e-16`.

@chapno=13

Sequences

Common Lisp defines a number of functions that operate on sequences, which are either lists, strings, or vectors. Emacs Lisp includes a few of these, notably `elt` and `length`; this package defines most of the rest.

Sequence Basics

Many of the sequence functions take keyword arguments; see section Argument Lists. All keyword arguments are optional and, if specified, may appear in any order.

The `:key` argument should be passed either `nil`, or a function of one argument. This key function is used as a filter through which the elements of the sequence are seen; for example, `(find x y :key 'car)` is similar to `(assoc* x y)`: It searches for an element of the list whose `car` equals `x`, rather than for an element which equals `x` itself. If `:key` is omitted or `nil`, the filter is effectively the identity function.

The `:test` and `:test-not` arguments should be either `nil`, or functions of two arguments. The test function is used to compare two sequence elements, or to compare a search value with sequence elements. (The two values are passed to the test function in the same order as the original sequence function arguments from which they are derived, or, if they both come from the same sequence, in the same order as they appear in that sequence.) The `:test` argument specifies a function which must return true (non-`nil`) to indicate a match; instead, you may use `:test-not` to give a function which returns *false* to indicate a match. The default test function is `:test 'eql`.

Many functions which take item and `:test` or `:test-not` arguments also come in `-if` and `-if-not` varieties, where a predicate function is passed instead of item, and sequence elements match if the predicate returns true on them (or false in the case of `-if-not`). For example:

```
(remove* 0 seq :test '=)  ==  (remove-if 'zerop seq)
```

to remove all zeros from sequence `seq`.

Some operations can work on a subsequence of the argument sequence; these function take `:start` and `:end` arguments which default to zero and the length of the sequence, respectively. Only elements between start (inclusive) and end (exclusive) are affected by the operation. The end argument may be passed `nil` to signify the length of the sequence; otherwise, both start and end must be integers, with `0 <= start <= end <= (length seq)`. If the function takes two sequence arguments, the limits are defined by keywords `:start1` and `:end1` for the first, and `:start2` and `:end2` for the second.

A few functions accept a `:from-end` argument, which, if non-`nil`, causes the operation to go from right-to-left through the sequence instead of left-to-right, and a `:count` argument, which specifies an integer maximum number of elements to be removed or otherwise processed.

The sequence functions make no guarantees about the order in which the `:test`, `:test-not`, and `:key` functions are called on various elements. Therefore, it is a bad idea to depend on side effects of these functions. For example, `:from-end` may cause the sequence to be scanned actually in reverse, or it may be scanned forwards but computing a result "as if" it were scanned backwards. (Some functions, like `mapcar*` and `every`, *do* specify exactly the order in which the function is called so side effects are perfectly acceptable in those cases.)

Strings in GNU Emacs 19 may contain "text properties" as well as character data. Except as noted, it is undefined whether or not text properties are preserved by sequence functions. For example, `(remove* ?A str)` may or may not preserve the properties of the characters copied from str into the result.

Mapping over Sequences

These functions "map" the function you specify over the elements of lists or arrays. They are all variations on the theme of the built-in function `mapcar`.

Function: **mapcar*** *function seq &rest more-seqs*

This function calls function on successive parallel sets of elements from its argument sequences. Given a single seq argument it is equivalent to `mapcar`; given n sequences, it calls the function with the first elements of each of the sequences as the n arguments to yield the first element of the result list, then with the second elements, and so on. The mapping stops as soon as the shortest sequence runs out. The argument sequences may be any mixture of lists, strings, and vectors; the return sequence is always a list.

Common Lisp's `mapcar` accepts multiple arguments but works only on lists; Emacs Lisp's `mapcar` accepts a single sequence argument. This package's `mapcar*` works as a compatible superset of both.

Function: **map** *result-type function seq &rest more-seqs*

This function maps function over the argument sequences, just like `mapcar*`, but it returns a sequence of type result-type rather than a list. result-type must be one of the following symbols: `vector`, `string`, `list` (in which case the effect is the same as for `mapcar*`), or `nil` (in which case the results are thrown away and `map` returns `nil`).

Function: **maplist** *function list &rest more-lists*

This function calls function on each of its argument lists, then on the `cdr`s of those lists, and so on, until the shortest list runs out. The results are returned in the form of a list. Thus, `maplist` is like `mapcar*` except that it passes in the list pointers themselves rather than the `car`s of the advancing pointers.

Function: **mapc** *function seq &rest more-seqs*

This function is like `mapcar*`, except that the values returned by function are ignored and thrown away rather than being collected into a list. The return value of `mapc` is seq, the first sequence.

Function: **mapl** *function list &rest more-lists*

This function is like `maplist`, except that it throws away the values returned by function.

Function: **mapcan** *function seq &rest more-seqs*

This function is like `mapcar*`, except that it concatenates the return values (which must be lists) using `nconc`, rather than simply collecting them into a list.

Function: **mapcon** *function list &rest more-lists*

This function is like `maplist`, except that it concatenates the return values using `nconc`.

Function: **some** *predicate seq &rest more-seqs*

This function calls predicate on each element of seq in turn; if predicate returns a non-`nil` value, `some` returns that value, otherwise it returns `nil`. Given several sequence arguments, it steps through the sequences in parallel until the shortest one runs out, just as in `mapcar*`. You can rely on the left-to-right order in which the elements are visited, and on the fact that mapping stops immediately as soon as predicate

returns non-`nil`.

Function: **every** *predicate seq &rest more-seqs*

This function calls predicate on each element of the sequence(s) in turn; it returns `nil` as soon as predicate returns `nil` for any element, or `t` if the predicate was true for all elements.

Function: **notany** *predicate seq &rest more-seqs*

This function calls predicate on each element of the sequence(s) in turn; it returns `nil` as soon as predicate returns a non-`nil` value for any element, or `t` if the predicate was `nil` for all elements.

Function: **notevery** *predicate seq &rest more-seqs*

This function calls predicate on each element of the sequence(s) in turn; it returns a non-`nil` value as soon as predicate returns `nil` for any element, or `t` if the predicate was true for all elements.

Function: **reduce** *function seq* `&key :from-end :start :end :initial-value :key`

This function combines the elements of seq using an associative binary operation. Suppose function is `*` and seq is the list `(2 3 4 5)`. The first two elements of the list are combined with `(* 2 3) = 6`; this is combined with the next element, `(* 6 4) = 24`, and that is combined with the final element: `(* 24 5) = 120`. Note that the `*` function happens to be self-reducing, so that `(* 2 3 4 5)` has the same effect as an explicit call to `reduce`.

If `:from-end` is true, the reduction is right-associative instead of left-associative:

```
(reduce '- '(1 2 3 4))
     == (- (- (- 1 2) 3) 4) => -8
(reduce '- '(1 2 3 4) :from-end t)
     == (- 1 (- 2 (- 3 4))) => -2
```

If `:key` is specified, it is a function of one argument which is called on each of the sequence elements in turn.

If `:initial-value` is specified, it is effectively added to the front (or rear in the case of `:from-end`) of the sequence. The `:key` function is *not* applied to the initial value.

If the sequence, including the initial value, has exactly one element then that element is returned without ever calling function. If the sequence is empty (and there is no initial value), then function is called with no arguments to obtain the return value.

All of these mapping operations can be expressed conveniently in terms of the `loop` macro. In compiled code, `loop` will be faster since it generates the loop as in-line code with no function calls.

Sequence Functions

This section describes a number of Common Lisp functions for operating on sequences.

Function: **subseq** *sequence start &optional end*

This function returns a given subsequence of the argument sequence, which may be a list, string, or vector.

The indices start and end must be in range, and start must be no greater than end. If end is omitted, it de to the length of the sequence. The return value is always a copy; it does not share structure with sequenc

As an extension to Common Lisp, start and/or end may be negative, in which case they represent a distance back from the end of the sequence. This is for compatibility with Emacs' `substring` function. Note that `subseq` is the *only* sequence function that allows negative start and end.

You can use `setf` on a `subseq` form to replace a specified range of elements with elements from another sequence. The replacement is done as if by `replace`, described below.

Function: **concatenate** *result-type &rest seqs*

This function concatenates the argument sequences together to form a result sequence of type result-type, one of the symbols `vector`, `string`, or `list`. The arguments are always copied, even in cases such as `(concatenate 'list '(1 2 3))` where the result is identical to an argument.

Function: **fill** *seq item* `&key :start :end`

This function fills the elements of the sequence (or the specified part of the sequence) with the value item.

Function: **replace** *seq1 seq2* `&key :start1 :end1 :start2 :end2`

This function copies part of seq2 into part of seq1. The sequence seq1 is not stretched or resized; the amount of data copied is simply the shorter of the source and destination (sub)sequences. The function returns seq1.

If seq1 and seq2 are `eq`, then the replacement will work correctly even if the regions indicated by the start and end arguments overlap. However, if seq1 and seq2 are lists which share storage but are not `eq`, and the start and end arguments specify overlapping regions, the effect is undefined.

Function: **remove*** *item seq* `&key :test :test-not :key :count :start :end :from-end`

This returns a copy of seq with all elements matching item removed. The result may share storage with or be `eq` to seq in some circumstances, but the original seq will not be modified. The `:test`, `:test-not`, and `:key` arguments define the matching test that is used; by default, elements `eql` to item are removed. The `:count` argument specifies the maximum number of matching elements that can be removed (only the leftmost count matches are removed). The `:start` and `:end` arguments specify a region in seq in which elements will be removed; elements outside that region are not matched or removed. The `:from-end` argument, if true, says that elements should be deleted from the end of the sequence rather than the beginning (this matters only if count was also specified).

Function: **delete*** *item seq* `&key :test :test-not :key :count :start :end :from-end`

This deletes all elements of seq which match item. It is a destructive operation. Since Emacs Lisp does not support stretchable strings or vectors, this is the same as `remove*` for those sequence types. On lists, `remove*` will copy the list if necessary to preserve the original list, whereas `delete*` will splice out parts of the argument list. Compare `append` and `nconc`, which are analogous non-destructive and destructive list operations in Emacs Lisp.

The predicate-oriented functions `remove-if`, `remove-if-not`, `delete-if`, and `delete-if-not` are defined similarly.

Function: **delete** *item list*

This MacLisp-compatible function deletes from list all elements which are `equal` to item. The `delete` function is built-in to Emacs 19; this package defines it equivalently in Emacs 18.

Function: **remove** *item list*

This function removes from list all elements which are `equal` to item. This package defines it for symmetry with `delete`, even though `remove` is not built-in to Emacs 19.

Function: **remq** *item list*

This function removes from list all elements which are `eq` to item. This package defines it for symmetry with `delq`, even though `remq` is not built-in to Emacs 19.

Function: **remove-duplicates** *seq* `&key :test :test-not :key :start :end :from-end`

This function returns a copy of seq with duplicate elements removed. Specifically, if two elements from the sequence match according to the `:test`, `:test-not`, and `:key` arguments, only the rightmost one is retained. If `:from-end` is true, the leftmost one is retained instead. If `:start` or `:end` is specified, only elements within that subsequence are examined or removed.

Function: **delete-duplicates** *seq* `&key :test :test-not :key :start :end :from-end`

This function deletes duplicate elements from seq. It is a destructive version of `remove-duplicates`.

Function: **substitute** *new old seq* `&key :test :test-not :key :count :start :end :from-end`

This function returns a copy of seq, with all elements matching old replaced with new. The `:count`, `:start`, `:end`, and `:from-end` arguments may be used to limit the number of substitutions made.

Function: **nsubstitute** *new old seq* `&key :test :test-not :key :count :start :end :from-end`

This is a destructive version of `substitute`; it performs the substitution using `setcar` or `aset` rather than by returning a changed copy of the sequence.

The `substitute-if`, `substitute-if-not`, `nsubstitute-if`, and `nsubstitute-if-not` functions are defined similarly. For these, a predicate is given in place of the old argument.

Searching Sequences

These functions search for elements or subsequences in a sequence. (See also `member*` and `assoc*`; see section Lists.)

Function: **find** *item seq* `&key :test :test-not :key :start :end :from-end`

This function searches seq for an element matching item. If it finds a match, it returns the matching element. Otherwise, it returns `nil`. It returns the leftmost match, unless `:from-end` is true, in which case it returns the rightmost match. The `:start` and `:end` arguments may be used to limit the range of elements that are searched.

Function: **position** *item seq* `&key :test :test-not :key :start :end :from-end`

This function is like `find`, except that it returns the integer position in the sequence of the matching item rather than the item itself. The position is relative to the start of the sequence as a whole, even if `:start` is non-zero. The function returns `nil` if no matching element was found.

Function: **count** *item seq* `&key :test :test-not :key :start :end`

This function returns the number of elements of seq which match item. The result is always a nonnegative integer.

The `find-if`, `find-if-not`, `position-if`, `position-if-not`, `count-if`, and `count-if-not` functions are defined similarly.

Function: **mismatch** *seq1 seq2* `&key :test :test-not :key :start1 :end1 :start2 :end2 :from-end`

This function compares the specified parts of seq1 and seq2. If they are the same length and the corresponding elements match (according to `:test`, `:test-not`, and `:key`), the function returns `nil`. If there is a mismatch, the function returns the index (relative to seq1) of the first mismatching element. This will be the leftmost pair of elements which do not match, or the position at which the shorter of the two otherwise-matching sequences runs out.

If `:from-end` is true, then the elements are compared from right to left starting at `(1- end1)` and `(1- end2)`. If the sequences differ, then one plus the index of the rightmost difference (relative to seq1) is returned.

An interesting example is `(mismatch str1 str2 :key 'upcase)`, which compares two strings case-insensitively.

Function: **search** *seq1 seq2* `&key :test :test-not :key :from-end :start1 :end1 :start2 :end2`

This function searches seq2 for a subsequence that matches seq1 (or part of it specified by `:start1` and `:end1`.) Only matches which fall entirely within the region defined by `:start2` and `:end2` will be considered. The return value is the index of the leftmost element of the leftmost match, relative to the start of seq2, or `nil` if no matches were found. If `:from-end` is true, the function finds the *rightmost* matching subsequence.

Sorting Sequences

Function: **sort*** *seq predicate* `&key :key`

This function sorts seq into increasing order as determined by using predicate to compare pairs of elements. predicate should return true (non-`nil`) if and only if its first argument is less than (not equal to) its second argument. For example, `<` and `string-lessp` are suitable predicate functions for sorting numbers and strings, respectively; `>` would sort numbers into decreasing rather than increasing order.

This function differs from Emacs' built-in `sort` in that it can operate on any type of sequence, not just lists. Also, it accepts a `:key` argument which is used to preprocess data fed to the predicate function. For example,

```
(setq data (sort data 'string-lessp :key 'downcase))
```

sorts data, a sequence of strings, into increasing alphabetical order without regard to case. A `:key` function of `car` would be useful for sorting association lists.

The `sort*` function is destructive; it sorts lists by actually rearranging the `cdr` pointers in suitable fashion.

Function: **stable-sort** *seq predicate* `&key :key`

This function sorts seq stably, meaning two elements which are equal in terms of predicate are guaranteed not to be rearranged out of their original order by the sort.

In practice, `sort*` and `stable-sort` are equivalent in Emacs Lisp because the underlying `sort` function is stable by default. However, this package reserves the right to use non-stable methods for `sort*` in the future.

Function: **merge** *type seq1 seq2 predicate* `&key :key`

This function merges two sequences seq1 and seq2 by interleaving their elements. The result sequence, of type type (in the sense of `concatenate`), has length equal to the sum of the lengths of the two input sequences. The sequences may be modified destructively. Order of elements within seq1 and seq2 is preserved in the interleaving; elements of the two sequences are compared by predicate (in the sense of `sort`) and the lesser element goes first in the result. When elements are equal, those from seq1 precede those from seq2 in the result. Thus, if seq1 and seq2 are both sorted according to predicate, then the result will be a merged sequence which is (stably) sorted according to predicate.

Lists

The functions described here operate on lists.

List Functions

This section describes a number of simple operations on lists, i.e., chains of cons cells.

Function: **caddr** *x*

This function is equivalent to `(car (cdr (cdr x)))`. Likewise, this package defines all 28 `cxxxr` functions where xxx is up to four `a's and/or `d's. All of these functions are `setf`-able, and calls to them are expanded inline by the byte-compiler for maximum efficiency.

Function: **first** *x*

This function is a synonym for `(car x)`. Likewise, the functions `second`, `third`, ..., through `tenth` return the given element of the list x.

Function: **rest** *x*

This function is a synonym for `(cdr x)`.

Function: **endp** *x*

Common Lisp defines this function to act like `null`, but signalling an error if `x` is neither a `nil` nor a c cell. This package simply defines `endp` as a synonym for `null`.

Function: **list-length** *x*

This function returns the length of list x, exactly like `(length x)`, except that if x is a circular list (where the cdr-chain forms a loop rather than terminating with `nil`), this function returns `nil`. (The regular `length` function would get stuck if given a circular list.)

Function: **last** *x &optional n*

This function returns the last cons, or the nth-to-last cons, of the list x. If n is omitted it defaults to 1. The "last cons" means the first cons cell of the list whose `cdr` is not another cons cell. (For normal lists, the `cdr` of the last cons will be `nil`.) This function returns `nil` if x is `nil` or shorter than n. Note that the last *element* of the list is `(car (last x))`.

Function: **butlast** *x &optional n*

This function returns the list x with the last element, or the last n elements, removed. If n is greater than zero it makes a copy of the list so as not to damage the original list. In general, `(append (butlast x n) (last x n))` will return a list equal to x.

Function: **nbutlast** *x &optional n*

This is a version of `butlast` that works by destructively modifying the `cdr` of the appropriate element, rather than making a copy of the list.

Function: **list*** *arg &rest others*

This function constructs a list of its arguments. The final argument becomes the `cdr` of the last cell constructed. Thus, `(list* a b c)` is equivalent to `(cons a (cons b c))`, and `(list* a b nil)` is equivalent to `(list a b)`.

(Note that this function really is called `list*` in Common Lisp; it is not a name invented for this package like `member*` or `defun*`.)

Function: **ldiff** *list sublist*

If sublist is a sublist of list, i.e., is `eq` to one of the cons cells of list, then this function returns a copy of the part of list up to but not including sublist. For example, `(ldiff x (cddr x))` returns the first two elements of the list `x`. The result is a copy; the original list is not modified. If sublist is not a sublist of list, a copy of the entire list is returned.

Function: **copy-list** *list*

This function returns a copy of the list list. It copies dotted lists like `(1 2 . 3)` correctly.

Function: **copy-tree** *x &optional vecp*

This function returns a copy of the tree of cons cells x. Unlike `copy-sequence` (and its alias `copy-list`), which copies only along the `cdr` direction, this function copies (recursively) along both the `car` and the `cdr` directions. If x is not a cons cell, the function simply returns x unchanged. If the optional vecp argument is true, this function copies vectors (recursively) as well as cons cells.

Function: **tree-equal** *x y* `&key :test :test-not :key`

This function compares two trees of cons cells. If x and y are both cons cells, their `car`s and `cdr`s are compared recursively. If neither x nor y is a cons cell, they are compared by `eql`, or according to the specified test. The `:key` function, if specified, is applied to the elements of both trees. See section Sequences.

@secno=3

Substitution of Expressions

These functions substitute elements throughout a tree of cons cells. (See section Sequence Functions, for the `substitute` function, which works on just the top-level elements of a list.)

Function: **subst** *new old tree* `&key :test :test-not :key`

This function substitutes occurrences of old with new in tree, a tree of cons cells. It returns a substituted tree, which will be a copy except that it may share storage with the argument tree in parts where no substitutions occurred. The original tree is not modified. This function recurses on, and compares against old, both `car`s and `cdr`s of the component cons cells. If old is itself a cons cell, then matching cells in the tree are substituted as usual without recursively substituting in that cell. Comparisons with old are done according to the specified test (`eql` by default). The `:key` function is applied to the elements of the tree but not to old.

Function: **nsubst** *new old tree* `&key :test :test-not :key`

This function is like `subst`, except that it works by destructive modification (by `setcar` or `setcdr`) rather than copying.

The `subst-if`, `subst-if-not`, `nsubst-if`, and `nsubst-if-not` functions are defined similarly.

Function: **sublis** *alist tree* `&key :test :test-not :key`

This function is like `subst`, except that it takes an association list alist of old-new pairs. Each element of the tree (after applying the `:key` function, if any), is compared with the `car`s of alist; if it matches, it is replaced by the corresponding `cdr`.

Function: **nsublis** *alist tree* `&key :test :test-not :key`

This is a destructive version of `sublis`.

Lists as Sets

These functions perform operations on lists which represent sets of elements.

Function: **member** *item list*

This MacLisp-compatible function searches list for an element which is `equal` to item. The `member` function is built-in to Emacs 19; this package defines it equivalently in Emacs 18. See the following function for a Common-Lisp compatible version.

Function: **member*** *item list* `&key :test :test-not :key`

This function searches list for an element matching item. If a match is found, it returns the cons cell whose `car` was the matching element. Otherwise, it returns `nil`. Elements are compared by `eql` by default; you can use the `:test`, `:test-not`, and `:key` arguments to modify this behavior. See section Sequences.

Note that this function's name is suffixed by `*' to avoid the incompatible `member` function defined in Emacs 19. (That function uses `equal` for comparisons; it is equivalent to `(member* item list :test 'equal)`.)

The `member-if` and `member-if-not` functions analogously search for elements which satisfy a given predicate.

Function: **tailp** *sublist list*

This function returns `t` if sublist is a sublist of list, i.e., if sublist is `eql` to list or to any of its `cdr`s.

Function: **adjoin** *item list* `&key :test :test-not :key`

This function conses item onto the front of list, like `(cons item list)`, but only if item is not already present on the list (as determined by `member*`). If a `:key` argument is specified, it is applied to item as well as to the elements of list during the search, on the reasoning that item is "about" to become part of the list.

Function: **union** *list1 list2* `&key :test :test-not :key`

This function combines two lists which represent sets of items, returning a list that represents the union of those two sets. The result list will contain all items which appear in list1 or list2, and no others. If an item appears in both list1 and list2 it will be copied only once. If an item is duplicated in list1 or list2, it is undefined whether or not that duplication will survive in the result list. The order of elements in the result list is also undefined.

Function: **nunion** *list1 list2* `&key :test :test-not :key`

This is a destructive version of `union`; rather than copying, it tries to reuse the storage of the argument lists if possible.

Function: **intersection** *list1 list2* `&key :test :test-not :key`

This function computes the intersection of the sets represented by list1 and list2. It returns the list of items which appear in both list1 and list2.

Function: **nintersection** *list1 list2* `&key :test :test-not :key`

This is a destructive version of `intersection`. It tries to reuse storage of list1 rather than copying. It does *not* reuse the storage of list2.

Function: **set-difference** *list1 list2* `&key :test :test-not :key`

This function computes the "set difference" of list1 and list2, i.e., the set of elements that appear in list1 but *not* in list2.

Function: **nset-difference** *list1 list2* `&key :test :test-not :key`

This is a destructive `set-difference`, which will try to reuse list1 if possible.

Function: **set-exclusive-or** *list1 list2* `&key :test :test-not :key`

This function computes the "set exclusive or" of list1 and list2, i.e., the set of elements that appear in exactly one of list1 and list2.

Function: **nset-exclusive-or** *list1 list2* `&key :test :test-not :key`

This is a destructive `set-exclusive-or`, which will try to reuse list1 and list2 if possible.

Function: **subsetp** *list1 list2* `&key :test :test-not :key`

This function checks whether list1 represents a subset of list2, i.e., whether every element of list1 also appears in list2.

Association Lists

An association list is a list representing a mapping from one set of values to another; any list whose elements are cons cells is an association list.

Function: **assoc*** *item a-list* `&key :test :test-not :key`

This function searches the association list a-list for an element whose `car` matches (in the sense of `:test`, `:test-not`, and `:key`, or by comparison with `eql`) a given item. It returns the matching element, if any, otherwise `nil`. It ignores elements of a-list which are not cons cells. (This corresponds to the behavior of `assq` and `assoc` in Emacs Lisp; Common Lisp's `assoc` ignores `nil`s but considers any other non-cons elements of a-list to be an error.)

Function: **rassoc*** *item a-list* `&key :test :test-not :key`

This function searches for an element whose `cdr` matches item. If a-list represents a mapping, this applies the inverse of the mapping to item.

Function: **rassoc** *item a-list*

This function searches like `rassoc*` with a `:test` argument of `equal`. It is analogous to Emacs Lisp's standard `assoc` function, which derives from the MacLisp rather than the Common Lisp tradition.

The `assoc-if`, `assoc-if-not`, `rassoc-if`, and `rassoc-if-not` functions are defined similarly.

Two simple functions for constructing association lists are:

Function: **acons** *key value alist*

This is equivalent to `(cons (cons key value) alist)`.

Function: **pairlis** *keys values &optional alist*

This is equivalent to `(nconc (mapcar* 'cons keys values) alist)`.

Hash Tables

A hash table is a data structure that maps "keys" onto "values." Keys and values can be arbitrary Lisp data objects. Hash tables have the property that the time to search for a given key is roughly constant; simpler data structures like association lists take time proportional to the number of entries in the list.

Function: **make-hash-table** *&key :test :size*

This function creates and returns a hash-table object whose function for comparing elements is `:test` (`eql` by default), and which is allocated to fit about `:size` elements. The `:size` argument is purely advisory; the table will stretch automatically if you store more elements in it. If `:size` is omitted, a reasonable default is used.

Common Lisp allows only `eq`, `eql`, `equal`, and `equalp` as legal values for the `:test` argument. In this package, any reasonable predicate function will work, though if you use something else you should check the details of the hashing function described below to make sure it is suitable for your predicate.

Some versions of Emacs (like Lucid Emacs 19) include a built-in hash table type; in these versions, `make-hash-table` with a test of `eq` will use these built-in hash tables. In all other cases, it will return a hash-table object which takes the form of a list with an identifying "tag" symbol at the front. All of the hash table functions in this package can operate on both types of hash table; normally you will never know which type is being used.

This function accepts the additional Common Lisp keywords `:rehash-size` and `:rehash-threshold`, but it ignores their values.

Function: **gethash** *key table &optional default*

This function looks up key in table. If key exists in the table, in the sense that it matches any of the existing keys according to the table's test function, then the associated value is returned. Otherwise, default (or `nil`) is returned.

To store new data in the hash table, use `setf` on a call to `gethash`. If key already exists in the table, the corresponding value is changed to the stored value. If key does not already exist, a new entry is added to the table and the table is reallocated to a larger size if necessary. The default argument is allowed but ignored in this case. The situation is exactly analogous to that of `get*`; see section Property Lists.

Function: **remhash** *key table*

This function removes the entry for key from table. If an entry was removed, it returns `t`. If key does not appear in the table, it does nothing and returns `nil`.

Function: **clrhash** *table*

This function removes all the entries from table, leaving an empty hash table.

Function: **maphash** *function table*

This function calls function for each entry in table. It passes two arguments to function, the key and the value of the given entry. The return value of function is ignored; maphash itself returns `nil`. See section Loop Facility, for an alternate way of iterating over hash tables.

Function: **hash-table-count** *table*

This function returns the number of entries in table. **Warning:** The current implementation of Lucid Emacs 19 hash-tables does not decrement the stored `count` when `remhash` removes an entry. Therefore, the return value of this function is not dependable if you have used `remhash` on the table and the table's test is `eq`. A slower, but reliable, way to count the entries is `(loop for x being the hash-keys of table count t)`.

Function: **hash-table-p** *object*

This function returns `t` if object is a hash table, `nil` otherwise. It recognizes both types of hash tables (both Lucid Emacs built-in tables and tables implemented with special lists.)

Sometimes when dealing with hash tables it is useful to know the exact "hash function" that is used. This package implements hash tables using Emacs Lisp "obarrays," which are the same data structure that Emacs Lisp uses to keep track of symbols. Each hash table includes an embedded obarray. Key values given to `gethash` are converted by various means into strings, which are then looked up in the obarray using `intern` and `intern-soft`. The symbol, or "bucket," corresponding to a given key string includes as its `symbol-value` an association list of all key-value pairs which hash to that string. Depending on the test function, it is possible for many entries to hash to the same bucket. For example, if the test is `eql`, then the symbol `foo` and two separately built strings `"foo"` will create three entries in the same bucket. Search time is linear within buckets, so hash tables will be most effective if you arrange not to store too many things that hash the same.

The following algorithm is used to convert Lisp objects to hash strings:

- Strings are used directly as hash strings. (However, if the test function is `equalp`, strings are `downcase`d first.)
- Symbols are hashed according to their `symbol-name`.
- Integers are hashed into one of 16 buckets depending on their value modulo 16. Floating-point numbers are truncated to integers and hashed modulo 16.
- Cons cells are hashed according to their `car`s; nonempty vectors are hashed according to their first element.
- All other types of objects hash into a single bucket named `"*"`.

Thus, for example, searching among many buffer objects in a hash table will devolve to a (still fairly fast) linear-time search through a single bucket, whereas searching for different symbols will be very fast since each symbol will, in general, hash into its own bucket.

The size of the obarray in a hash table is automatically adjusted as the number of elements increases.

As a special case, `make-hash-table` with a `:size` argument of 0 or 1 will create a hash-table object that uses a single association list rather than an obarray of many lists. For very small tables this structure will be more efficient since lookup does not require converting the key to a string or looking it up in an obarray. However, such tables are guaranteed to take time proportional to their size to do a search.

@chapno=18

Structures

The Common Lisp structure mechanism provides a general way to define data types similar to C's `struct` types. A structure is a Lisp object containing some number of slots, each of which can hold any Lisp data object. Functions are provided for accessing and setting the slots, creating or copying structure objects, and recognizing objects of a particular structure type.

In true Common Lisp, each structure type is a new type distinct from all existing Lisp types. Since the underlying Emacs Lisp system provides no way to create new distinct types, this package implements structures as vectors (or lists upon request) with a special "tag" symbol to identify them.

Special Form: **defstruct** *name slots...*

The `defstruct` form defines a new structure type called name, with the specified slots. (The slots may begin with a string which documents the structure type.) In the simplest case, name and each of the slots are symbols. For example,

```
(defstruct person name age sex)
```

defines a struct type called `person` which contains three slots. Given a `person` object p, you can access those slots by calling `(person-name p)`, `(person-age p)`, and `(person-sex p)`. You can also change these slots by using `setf` on any of these place forms:

```
(incf (person-age birthday-boy))
```

You can create a new `person` by calling `make-person`, which takes keyword arguments `:name`, `:age`, and `:sex` to specify the initial values of these slots in the new object. (Omitting any of these arguments leaves the corresponding slot "undefined," according to the Common Lisp standard; in Emacs Lisp, such uninitialized slots are filled with `nil`.)

Given a `person`, `(copy-person p)` makes a new object of the same type whose slots are `eq` to those of p.

Given any Lisp object x, `(person-p x)` returns true if x looks like a `person`, false otherwise. (Again, in Common Lisp this predicate would be exact; in Emacs Lisp the best it can do is verify that x is a vector of the correct length which starts with the correct tag symbol.)

Accessors like `person-name` normally check their arguments (effectively using `person-p`) and signal an error if the argument is the wrong type. This check is affected by `(optimize (safety ...))` declarations. Safety level 1, the default, uses a somewhat optimized check that will detect all incorrect arguments, but may use an uninformative error message (e.g., "expected a vector" instead of "expected a `person`"). Safety level 0 omits all checks except as provided by the underlying `aref` call; safety levels 2 and 3 do rigorous checking that will always print a descriptive error message for incorrect inputs. See section Declarations.

```
(setq dave (make-person :name "Dave" :sex 'male))
     => [cl-struct-person "Dave" nil male]
(setq other (copy-person dave))
```

```
     => [cl-struct-person "Dave" nil male]
(eq dave other)
     => nil
(eq (person-name dave) (person-name other))
     => t
(person-p dave)
     => t
(person-p [1 2 3 4])
     => nil
(person-p "Bogus")
     => nil
(person-p '[cl-struct-person counterfeit person object])
     => t
```

In general, name is either a name symbol or a list of a name symbol followed by any number of struct options; each slot is either a slot symbol or a list of the form `(slot-name default-value slot-options...)'. The default-value is a Lisp form which is evaluated any time an instance of the structure type is created without specifying that slot's value.

Common Lisp defines several slot options, but the only one implemented in this package is `:read-only`. A non-`nil` value for this option means the slot should not be `setf`-able; the slot's value is determined when the object is created and does not change afterward.

```
(defstruct person
  (name nil :read-only t)
  age
  (sex 'unknown))
```

Any slot options other than `:read-only` are ignored.

For obscure historical reasons, structure options take a different form than slot options. A structure option is either a keyword symbol, or a list beginning with a keyword symbol possibly followed by arguments. (By contrast, slot options are key-value pairs not enclosed in lists.)

```
(defstruct (person (:constructor create-person)
                   (:type list)
                   :named)
  name age sex)
```

The following structure options are recognized.

@itemmax=0 in @advance@leftskip-.5@tableindent

`:conc-name`

The argument is a symbol whose print name is used as the prefix for the names of slot accessor functions. The default is the name of the struct type followed by a hyphen. The option `(:conc-name p-)` would change this prefix to `p-`. Specifying `nil` as an argument means no prefix, so that the slot names themselves are used to name the accessor functions.

`:constructor`

In the simple case, this option takes one argument which is an alternate name to use for the constructor function. The default is `make-name`, e.g., `make-person`. The above example changes this to `create-person`. Specifying `nil` as an argument means that no standard constructor should be generated at all.

In the full form of this option, the constructor name is followed by an arbitrary argument list. See section Program Structure, for a description of the format of Common Lisp argument lists. All options, such as `&rest` and `&key`, are supported. The argument names should match the slot names; each slot is initialized from the corresponding argument. Slots whose names do not appear in the argument list are initialized based on the default-value in their slot descriptor. Also, `&optional` and `&key` arguments which don't specify defaults take their defaults from the slot descriptor. It is legal to include arguments which don't correspond to slot names; these are useful if they are referred to in the defaults for optional, keyword, or `&aux` arguments which *do* correspond to slots.

You can specify any number of full-format `:constructor` options on a structure. The default constructor is still generated as well unless you disable it with a simple-format `:constructor` option.

```
(defstruct
 (person
  (:constructor nil)   ; no default constructor
  (:constructor new-person (name sex &optional (age 0)))
  (:constructor new-hound (&key (name "Rover")
                                (dog-years 0)
                          &aux (age (* 7 dog-years))
                                (sex 'canine))))
 name age sex)
```

The first constructor here takes its arguments positionally rather than by keyword. (In official Common Lisp terminology, constructors that work By Order of Arguments instead of by keyword are called "BOA constructors." No, I'm not making this up.) For example, `(new-person "Jane" 'female)` generates a person whose slots are `"Jane"`, 0, and `female`, respectively.

The second constructor takes two keyword arguments, `:name`, which initializes the `name` slot and defaults to `"Rover"`, and `:dog-years`, which does not itself correspond to a slot but which is used to initialize the `age` slot. The `sex` slot is forced to the symbol `canine` with no syntax for overriding it.

`:copier`

The argument is an alternate name for the copier function for this type. The default is `copy-name`. `nil` means not to generate a copier function. (In this implementation, all copier functions are simply synonyms for `copy-sequence`.)

`:predicate`

The argument is an alternate name for the predicate which recognizes objects of this type. The default is `name-p`. `nil` means not to generate a predicate function. (If the `:type` option is used without the `:named` option, no predicate is ever generated.)

In true Common Lisp, `typep` is always able to recognize a structure object even if `:predicate` was used. In this package, `typep` simply looks for a function called `typename-p`, so it will work for

structure types only if they used the default predicate name.

`:include`

This option implements a very limited form of C++-style inheritance. The argument is the name of another structure type previously created with `defstruct`. The effect is to cause the new structure type to inherit all of the included structure's slots (plus, of course, any new slots described by this struct's slot descriptors). The new structure is considered a "specialization" of the included one. In fact, the predicate and slot accessors for the included type will also accept objects of the new type.

If there are extra arguments to the `:include` option after the included-structure name, these options are treated as replacement slot descriptors for slots in the included structure, possibly with modified default values. Borrowing an example from Steele:

```
(defstruct person name (age 0) sex)
     => person
(defstruct (astronaut (:include person (age 45)))
  helmet-size
  (favorite-beverage 'tang))
     => astronaut

(setq joe (make-person :name "Joe"))
     => [cl-struct-person "Joe" 0 nil]
(setq buzz (make-astronaut :name "Buzz"))
     => [cl-struct-astronaut "Buzz" 45 nil nil tang]

(list (person-p joe) (person-p buzz))
     => (t t)
(list (astronaut-p joe) (astronaut-p buzz))
     => (nil t)

(person-name buzz)
     => "Buzz"
(astronaut-name joe)
     => error: "astronaut-name accessing a non-astronaut"
```

Thus, if `astronaut` is a specialization of `person`, then every `astronaut` is also a `person` (but not the other way around). Every `astronaut` includes all the slots of a `person`, plus extra slots that are specific to astronauts. Operations that work on people (like `person-name`) work on astronauts just like other people.

`:print-function`

In full Common Lisp, this option allows you to specify a function which is called to print an instance of the structure type. The Emacs Lisp system offers no hooks into the Lisp printer which would allow for such a feature, so this package simply ignores `:print-function`.

`:type`

The argument should be one of the symbols `vector` or `list`. This tells which underlying Lisp data type should be used to implement the new structure type. Vectors are used by default, but `(:type list)` will cause structure objects to be stored as lists instead.

The vector representation for structure objects has the advantage that all structure slots can be acc quickly, although creating vectors is a bit slower in Emacs Lisp. Lists are easier to create, but take relatively long time accessing the later slots.

`:named`

This option, which takes no arguments, causes a characteristic "tag" symbol to be stored at the front of the structure object. Using `:type` without also using `:named` will result in a structure type stored as plain vectors or lists with no identifying features.

The default, if you don't specify `:type` explicitly, is to use named vectors. Therefore, `:named` is only useful in conjunction with `:type`.

```
(defstruct (person1) name age sex)
(defstruct (person2 (:type list) :named) name age sex)
(defstruct (person3 (:type list)) name age sex)

(setq p1 (make-person1))
     => [cl-struct-person1 nil nil nil]
(setq p2 (make-person2))
     => (person2 nil nil nil)
(setq p3 (make-person3))
     => (nil nil nil)

(person1-p p1)
     => t
(person2-p p2)
     => t
(person3-p p3)
     => error: function person3-p undefined
```

Since unnamed structures don't have tags, `defstruct` is not able to make a useful predicate for recognizing them. Also, accessors like `person3-name` will be generated but they will not be able to do any type checking. The `person3-name` function, for example, will simply be a synonym for `car` in this case. By contrast, `person2-name` is able to verify that its argument is indeed a `person2` object before proceeding.

`:initial-offset`

The argument must be a nonnegative integer. It specifies a number of slots to be left "empty" at the front of the structure. If the structure is named, the tag appears at the specified position in the list or vector; otherwise, the first slot appears at that position. Earlier positions are filled with `nil` by the constructors and ignored otherwise. If the type `:includes` another type, then `:initial-offset` specifies a number of slots to be skipped between the last slot of the included type and the first new slot.

Except as noted, the `defstruct` facility of this package is entirely compatible with that of Common Lisp.

@chapno=23

Assertions and Errors

This section describes two macros that test assertions, i.e., conditions which must be true if the program is operating correctly. Assertions never add to the behavior of a Lisp program; they simply make "sanity checks" to make sure everything is as it should be.

If the optimization property `speed` has been set to 3, and `safety` is less than 3, then the byte-compiler will optimize away the following assertions. Because assertions might be optimized away, it is a bad idea for them to include side-effects.

Special Form: **assert** *test-form [show-args string args...]*

This form verifies that test-form is true (i.e., evaluates to a non-`nil` value). If so, it returns `nil`. If the test is not satisfied, `assert` signals an error.

A default error message will be supplied which includes test-form. You can specify a different error message by including a string argument plus optional extra arguments. Those arguments are simply passed to `error` to signal the error.

If the optional second argument show-args is `t` instead of `nil`, then the error message (with or without string) will also include all non-constant arguments of the top-level form. For example:

```
(assert (> x 10) t "x is too small: %d")
```

This usage of show-args is an extension to Common Lisp. In true Common Lisp, the second argument gives a list of places which can be `setf`'d by the user before continuing from the error. Since Emacs Lisp does not support continuable errors, it makes no sense to specify places.

Special Form: **check-type** *form type [string]*

This form verifies that form evaluates to a value of type type. If so, it returns `nil`. If not, `check-type` signals a `wrong-type-argument` error. The default error message lists the erroneous value along with type and form themselves. If string is specified, it is included in the error message in place of type. For example:

```
(check-type x (integer 1 *) "a positive integer")
```

See section Type Predicates, for a description of the type specifiers that may be used for type.

Note that in Common Lisp, the first argument to `check-type` must be a place suitable for use by `setf`, because `check-type` signals a continuable error that allows the user to modify place.

The following error-related macro is also defined:

Special Form: **ignore-errors** *forms...*

This executes forms exactly like a `progn`, except that errors are ignored during the forms. More precisely, if an error is signalled then `ignore-errors` immediately aborts execution of the forms and returns `nil`. If the forms complete successfully, `ignore-errors` returns the result of the last form.

Efficiency Concerns

Macros

Many of the advanced features of this package, such as `defun*`, `loop`, and `setf`, are implemented as Lisp macros. In byte-compiled code, these complex notations will be expanded into equivalent Lisp code which is simple and efficient. For example, the forms

```
(incf i n)
(push x (car p))
```

are expanded at compile-time to the Lisp forms

```
(setq i (+ i n))
(setcar p (cons x (car p)))
```

which are the most efficient ways of doing these respective operations in Lisp. Thus, there is no performance penalty for using the more readable `incf` and `push` forms in your compiled code.

Interpreted code, on the other hand, must expand these macros every time they are executed. For this reason it is strongly recommended that code making heavy use of macros be compiled. (The features labelled "Special Form" instead of "Function" in this manual are macros.) A loop using `incf` a hundred times will execute considerably faster if compiled, and will also garbage-collect less because the macro expansion will not have to be generated, used, and thrown away a hundred times.

You can find out how a macro expands by using the `cl-prettyexpand` function.

Function: **cl-prettyexpand** *form &optional full*

This function takes a single Lisp form as an argument and inserts a nicely formatted copy of it in the current buffer (which must be in Lisp mode so that indentation works properly). It also expands all Lisp macros which appear in the form. The easiest way to use this function is to go to the `*scratch*` buffer and type, say,

```
(cl-prettyexpand '(loop for x below 10 collect x))
```

and type C-x C-e immediately after the closing parenthesis; the expansion

```
(block nil
  (let* ((x 0)
         (G1004 nil))
    (while (< x 10)
      (setq G1004 (cons x G1004))
      (setq x (+ x 1)))
    (nreverse G1004)))
```

will be inserted into the buffer. (The `block` macro is expanded differently in the interpreter and compiler, so

`cl-prettyexpand` just leaves it alone. The temporary variable `G1004` was created by `gensym`.)

If the optional argument full is true, then *all* macros are expanded, including `block`, `eval-when`, and compiler macros. Expansion is done as if form were a top-level form in a file being compiled. For example,

```
(cl-prettyexpand '(pushnew 'x list))
     -| (setq list (adjoin 'x list))
(cl-prettyexpand '(pushnew 'x list) t)
     -| (setq list (if (memq 'x list) list (cons 'x list)))
(cl-prettyexpand '(caddr (member* 'a list)) t)
     -| (car (cdr (cdr (memq 'a list))))
```

Note that `adjoin`, `caddr`, and `member*` all have built-in compiler macros to optimize them in common cases.

Error Checking

Common Lisp compliance has in general not been sacrificed for the sake of efficiency. A few exceptions have been made for cases where substantial gains were possible at the expense of marginal incompatibility. One example is the use of `memq` (which is treated very efficiently by the byte-compiler) to scan for keyword arguments; this can become confused in rare cases when keyword symbols are used as both keywords and data values at once. This is extremely unlikely to occur in practical code, and the use of `memq` allows functions with keyword arguments to be nearly as fast as functions that use `&optional` arguments.

The Common Lisp standard (as embodied in Steele's book) uses the phrase "it is an error if" to indicate a situation which is not supposed to arise in complying programs; implementations are strongly encouraged but not required to signal an error in these situations. This package sometimes omits such error checking in the interest of compactness and efficiency. For example, `do` variable specifiers are supposed to be lists of one, two, or three forms; extra forms are ignored by this package rather than signalling a syntax error. The `endp` function is simply a synonym for `null` in this package. Functions taking keyword arguments will accept an odd number of arguments, treating the trailing keyword as if it were followed by the value `nil`.

Argument lists (as processed by `defun*` and friends) *are* checked rigorously except for the minor point just mentioned; in particular, keyword arguments are checked for validity, and `&allow-other-keys` and `:allow-other-keys` are fully implemented. Keyword validity checking is slightly time consuming (though not too bad in byte-compiled code); you can use `&allow-other-keys` to omit this check. Functions defined in this package such as `find` and `member*` do check their keyword arguments for validity.

Optimizing Compiler

The byte-compiler that comes with Emacs 18 normally fails to expand macros that appear in top-level positions in the file (i.e., outside of `defun`s or other enclosing forms). This would have disastrous consequences to programs that used such top-level macros as `defun*`, `eval-when`, and `defstruct`. To work around this problem, the CL package patches the Emacs 18 compiler to expand top-level macros. This patch will apply to your own macros, too, if they are used in a top-level context. The patch will not harm versions of the Emacs 18 compiler which have already had a similar patch applied, nor will it affect the

optimizing Emacs 19 byte-compiler written by Jamie Zawinski and Hallvard Furuseth. The patch is appl to the byte compiler's code in Emacs' memory, *not* to the `bytecomp.elc' file stored on disk.

The Emacs 19 compiler (for Emacs 18) is available from various Emacs Lisp archive sites such as `archive.cis.ohio-state.edu`. Its use is highly recommended; many of the Common Lisp macros emit code which can be improved by optimization. In particular, `block`s (whether explicit or implicit in constructs like `defun*` and `loop`) carry a fair run-time penalty; the optimizing compiler removes `block`s which are not actually referenced by `return` or `return-from` inside the block.

Common Lisp Compatibility

Following is a list of all known incompatibilities between this package and Common Lisp as documented in Steele (2nd edition).

Certain function names, such as `member`, `assoc`, and `floor`, were already taken by (incompatible) Emacs Lisp functions; this package appends `*' to the names of its Common Lisp versions of these functions.

The word `defun*` is required instead of `defun` in order to use extended Common Lisp argument lists in a function. Likewise, `defmacro*` and `function*` are versions of those forms which understand full-featured argument lists. The `&whole` keyword does not work in `defmacro` argument lists (except inside recursive argument lists).

In order to allow an efficient implementation, keyword arguments use a slightly cheesy parser which may be confused if a keyword symbol is passed as the *value* of another keyword argument. (Specifically, `(memq :keyword rest-of-arguments)` is used to scan for `:keyword` among the supplied keyword arguments.)

The `eql` and `equal` predicates do not distinguish between IEEE floating-point plus and minus zero. The `equalp` predicate has several differences with Common Lisp; see section Predicates.

The `setf` mechanism is entirely compatible, except that setf-methods return a list of five values rather than five values directly. Also, the new "`setf` function" concept (typified by `(defun (setf foo) ...)`) is not implemented.

The `do-all-symbols` form is the same as `do-symbols` with no obarray argument. In Common Lisp, this form would iterate over all symbols in all packages. Since Emacs obarrays are not a first-class package mechanism, there is no way for `do-all-symbols` to locate any but the default obarray.

The `loop` macro is complete except that `loop-finish` and type specifiers are unimplemented.

The multiple-value return facility treats lists as multiple values, since Emacs Lisp cannot support multiple return values directly. The macros will be compatible with Common Lisp if `values` or `values-list` is always used to return to a `multiple-value-bind` or other multiple-value receiver; if `values` is used without `multiple-value-...` or vice-versa the effect will be different from Common Lisp.

Many Common Lisp declarations are ignored, and others match the Common Lisp standard in concept but not in detail. For example, local `special` declarations, which are purely advisory in Emacs Lisp, do not rigorously obey the scoping rules set down in Steele's book.

The variable `*gensym-counter*` starts out with a pseudo-random value rather than with zero. This is to

cope with the fact that generated symbols become interned when they are written to and loaded back fro file.

The `defstruct` facility is compatible, except that structures are of type `:type vector :named` by default rather than some special, distinct type. Also, the `:type` slot option is ignored.

The second argument of `check-type` is treated differently.

Old CL Compatibility

Following is a list of all known incompatibilities between this package and the older Quiroz `` `cl.el' `` package.

This package's emulation of multiple return values in functions is incompatible with that of the older package. That package attempted to come as close as possible to true Common Lisp multiple return values; unfortunately, it could not be 100% reliable and so was prone to occasional surprises if used freely. This package uses a simpler method, namely replacing multiple values with lists of values, which is more predictable though more noticeably different from Common Lisp.

The `defkeyword` form and `keywordp` function are not implemented in this package.

The `member`, `floor`, `ceiling`, `truncate`, `round`, `mod`, and `rem` functions are suffixed by `*' in this package to avoid collision with existing functions in Emacs 18 or Emacs 19. The older package simply redefined these functions, overwriting the built-in meanings and causing serious portability problems with Emacs 19. (Some more recent versions of the Quiroz package changed the names to `cl-member`, etc.; this package defines the latter names as aliases for `member*`, etc.)

Certain functions in the old package which were buggy or inconsistent with the Common Lisp standard are incompatible with the conforming versions in this package. For example, `eql` and `member` were synonyms for `eq` and `memq` in that package, `setf` failed to preserve correct order of evaluation of its arguments, etc.

Finally, unlike the older package, this package is careful to prefix all of its internal names with `cl-`. Except for a few functions which are explicitly defined as additional features (such as `floatp-safe` and `letf`), this package does not export any non-`cl-' symbols which are not also part of Common Lisp.

The `cl-compat` package

The CL package includes emulations of some features of the old `` `cl.el' ``, in the form of a compatibility package `cl-compat`. To use it, put `(require 'cl-compat)` in your program.

The old package defined a number of internal routines without `cl-` prefixes or other annotations. Call to these routines may have crept into existing Lisp code. `cl-compat` provides emulations of the following internal routines: `pair-with-newsyms`, `zip-lists`, `unzip-lists`, `reassemble-arglists`, `duplicate-symbols-p`, `safe-idiv`.

Some `setf` forms translated into calls to internal functions that user code might call directly. The functions `setnth`, `setnthcdr`, and `setelt` fall in this category; they are defined by `cl-compat`, but the best fix is to change to use `setf` properly.

The `cl-compat` file defines the keyword functions `keywordp`, `keyword-of`, and `defkeyword`, which are not defined by the new CL package because the use of keywords as data is discouraged.

The `build-klist` mechanism for parsing keyword arguments is emulated by `cl-compat`; the `with-keyword-args` macro is not, however, and in any case it's best to change to use the more natural keyword argument processing offered by `defun*`.

Multiple return values are treated differently by the two Common Lisp packages. The old package's method was more compatible with true Common Lisp, though it used heuristics that caused it to report spurious multiple return values in certain cases. The `cl-compat` package defines a set of multiple-value macros that are compatible with the old CL package; again, they are heuristic in nature, but they are guaranteed to work in any case where the old package's macros worked. To avoid name collision with the "official" multiple-value facilities, the ones in `cl-compat` have capitalized names: `Values`, `Values-list`, `Multiple-value-bind`, etc.

The functions `cl-floor`, `cl-ceiling`, `cl-truncate`, and `cl-round` are defined by `cl-compat` to use the old-style multiple-value mechanism, just as they did in the old package. The newer `floor*` and friends return their two results in a list rather than as multiple values. Note that older versions of the old package used the unadorned names `floor`, `ceiling`, etc.; `cl-compat` cannot use these names because they conflict with Emacs 19 built-ins.

Porting Common Lisp

This package is meant to be used as an extension to Emacs Lisp, not as an Emacs implementation of true Common Lisp. Some of the remaining differences between Emacs Lisp and Common Lisp make it difficult to port large Common Lisp applications to Emacs. For one, some of the features in this package are not fully compliant with ANSI or Steele; see section Common Lisp Compatibility. But there are also quite a few features that this package does not provide at all. Here are some major omissions that you will want watch out for when bringing Common Lisp code into Emacs.

- Case-insensitivity. Symbols in Common Lisp are case-insensitive by default. Some programs refer to a function or variable as `foo` in one place and `Foo` or `FOO` in another. Emacs Lisp will treat these as three distinct symbols.

  Some Common Lisp code is written in all upper-case. While Emacs is happy to let the program's own functions and variables use this convention, calls to Lisp builtins like `if` and `defun` will have to be changed to lower-case.

- Lexical scoping. In Common Lisp, function arguments and `let` bindings apply only to references physically within their bodies (or within macro expansions in their bodies). Emacs Lisp, by contrast, uses dynamic scoping wherein a binding to a variable is visible even inside functions called from the body.

  Variables in Common Lisp can be made dynamically scoped by declaring them `special` or using `defvar`. In Emacs Lisp it is as if all variables were declared `special`.

  Often you can use code that was written for lexical scoping even in a dynamically scoped Lisp, but not always. Here is an example of a Common Lisp code fragment that would fail in Emacs Lisp:

```
(defun map-odd-elements (func list)
  (loop for x in list
        for flag = t then (not flag)
        collect (if flag x (funcall func x))))

(defun add-odd-elements (list x)
  (map-odd-elements (function (lambda (a) (+ a x))) list))
```

In Common Lisp, the two functions' usages of `x` are completely independent. In Emacs Lisp, the binding to `x` made by `add-odd-elements` will have been hidden by the binding in `map-odd-elements` by the time the `(+ a x)` function is called.

(This package avoids such problems in its own mapping functions by using names like `cl-x` instead of `x` internally; as long as you don't use the `cl-` prefix for your own variables no collision can occur.)

See section Lexical Bindings, for a description of the `lexical-let` form which establishes a Common Lisp-style lexical binding, and some examples of how it differs from Emacs' regular `let`.

- Common Lisp allows the shorthand `#'x` to stand for `(function x)`, just as `'x` stands for `(quote x)`. In Common Lisp, one traditionally uses `#'` notation when referring to the name of a function. In Emacs Lisp, it works just as well to use a regular quote:

```
(loop for x in y by #'cddr collect (mapcar #'plusp x))  ; Common Lisp
(loop for x in y by 'cddr collect (mapcar 'plusp x))    ; Emacs Lisp
```

When `#'` introduces a `lambda` form, it is best to write out `(function ...)` longhand in Emacs Lisp. You can use a regular quote, but then the byte-compiler won't know that the `lambda` expression is code that can be compiled.

```
(mapcar #'(lambda (x) (* x 2)) list)            ; Common Lisp
(mapcar (function (lambda (x) (* x 2))) list)   ; Emacs Lisp
```

Lucid Emacs supports `#'` notation starting with version 19.8.

- The "backquote" feature uses a different syntax in Emacs Lisp.

```
(defmacro foo (v &rest body) `(let ((,v 0)) @,body))  ; Common Lisp
(defmacro foo (v &rest body) (` (let (((, v) 0)) (@, body)))  ; Emacs
```

- Reader macros. Common Lisp includes a second type of macro that works at the level of individual characters. For example, Common Lisp implements the quote notation by a reader macro called `'`, whereas Emacs Lisp's parser just treats quote as a special case. Some Lisp packages use reader macros to create special syntaxes for themselves, which the Emacs parser is incapable of reading.

  The lack of reader macros, incidentally, is the reason behind Emacs Lisp's unusual backquote syntax. Since backquotes are implemented as a Lisp package and not built-in to the Emacs parser, they are forced to use a regular macro named ` which is used with the standard function/macro call notation.

- Other syntactic features. Common Lisp provides a number of notations beginning with # that the Emacs Lisp parser won't understand. For example, `#| ... |#' is an alternate comment notation, and `#+lucid (foo)' tells the parser to ignore the `(foo)` except in Lucid Common Lisp.

- Packages. In Common Lisp, symbols are divided into packages. Symbols that are Lisp built-ins are typically stored in one package; symbols that are vendor extensions are put in another, and each application program would have a package for its own symbols. Certain symbols are "exported" by a package and others are internal; certain packages "use" or import the exported symbols of other packages. To access symbols that would not normally be visible due to this importing and exporting, Common Lisp provides a syntax like `package:symbol` or `package::symbol`.

  Emacs Lisp has a single namespace for all interned symbols, and then uses a naming convention of putting a prefix like `cl-` in front of the name. Some Emacs packages adopt the Common Lisp-like convention of using `cl:` or `cl::` as the prefix. However, the Emacs parser does not understand colons and just treats them as part of the symbol name. Thus, while `mapcar` and `lisp:mapcar` may refer to the same symbol in Common Lisp, they are totally distinct in Emacs Lisp. Common Lisp programs which refer to a symbol by the full name sometimes and the short name other times will not port cleanly to Emacs.

  Emacs Lisp does have a concept of "obarrays," which are package-like collections of symbols, but this feature is not strong enough to be used as a true package mechanism.

- Keywords. The notation `:test-not` in Common Lisp really is a shorthand for `keyword:test-not`; keywords are just symbols in a built-in `keyword` package with the special property that all its symbols are automatically self-evaluating. Common Lisp programs often use keywords liberally to avoid having to use quotes.

  In Emacs Lisp a keyword is just a symbol whose name begins with a colon; since the Emacs parser does not treat them specially, they have to be explicitly made self-evaluating by a statement like `(setq :test-not ':test-not)`. This package arranges to execute such a statement whenever `defun*` or some other form sees a keyword being used as an argument. Common Lisp code that assumes that a symbol `:mumble` will be self-evaluating even though it was never introduced by a `defun*` will have to be fixed.

- The `format` function is quite different between Common Lisp and Emacs Lisp. It takes an additional "destination" argument before the format string. A destination of `nil` means to format to a string as in Emacs Lisp; a destination of `t` means to write to the terminal (similar to `message` in Emacs). Also, format control strings are utterly different; `~` is used instead of `%` to introduce format codes, and the set of available codes is much richer. There are no notations like `\n` for string literals; instead, `format` is used with the "newline" format code, `~%`. More advanced formatting codes provide such features as paragraph filling, case conversion, and even loops and conditionals.

  While it would have been possible to implement most of Common Lisp `format` in this package (under the name `format*`, of course), it was not deemed worthwhile. It would have required a huge amount of code to implement even a decent subset of `format*`, yet the functionality it would provide over Emacs Lisp's `format` would rarely be useful.

- Vector constants use square brackets in Emacs Lisp, but `#(a b c)` notation in Common Lisp. To further complicate matters, Emacs 19 introduces its own `#(` notation for something entirely different--strings with properties.

- Characters are distinct from integers in Common Lisp. The notation for character constants is also different: `#\A` instead of `?A`. Also, `string=` and `string-equal` are synonyms in Emacs Lisp whereas the latter is case-insensitive in Common Lisp.

- Data types. Some Common Lisp data types do not exist in Emacs Lisp. Rational numbers and complex

numbers are not present, nor are large integers (all integers are "fixnums"). All arrays are one-dimensional. There are no readtables or pathnames; streams are a set of existing data types rat than a new data type of their own. Hash tables, random-states, structures, and packages (obarrays) ar built from Lisp vectors or lists rather than being distinct types.

- The Common Lisp Object System (CLOS) is not implemented, nor is the Common Lisp Condition System.
- Common Lisp features that are completely redundant with Emacs Lisp features of a different name generally have not been implemented. For example, Common Lisp writes `defconstant` where Emacs Lisp uses `defconst`. Similarly, `make-list` takes its arguments in different ways in the two Lisps but does exactly the same thing, so this package has not bothered to implement a Common Lisp-style `make-list`.
- A few more notable Common Lisp features not included in this package: `compiler-let`, `tagbody`, `prog`, `ldb/dpb`, `parse-integer`, `cerror`.
- Recursion. While recursion works in Emacs Lisp just like it does in Common Lisp, various details of the Emacs Lisp system and compiler make recursion much less efficient than it is in most Lisps. Some schools of thought prefer to use recursion in Lisp over other techniques; they would sum a list of numbers using something like

```
(defun sum-list (list)
  (if list
      (+ (car list) (sum-list (cdr list)))
    0))
```

where a more iteratively-minded programmer might write one of these forms:

```
(let ((total 0)) (dolist (x my-list) (incf total x)) total)
(loop for x in my-list sum x)
```

While this would be mainly a stylistic choice in most Common Lisps, in Emacs Lisp you should be aware that the iterative forms are much faster than recursion. Also, Lisp programmers will want to note that the current Emacs Lisp compiler does not optimize tail recursion.

Overview

Common Lisp is a huge language, and Common Lisp systems tend to be massive and extremely complex. Emacs Lisp, by contrast, is rather minimalist in the choice of Lisp features it offers the programmer. As Emacs Lisp programmers have grown in number, and the applications they write have grown more ambitious, it has become clear that Emacs Lisp could benefit from many of the conveniences of Common Lisp.

The CL package adds a number of Common Lisp functions and control structures to Emacs Lisp. While not a 100% complete implementation of Common Lisp, CL adds enough functionality to make Emacs Lisp programming significantly more convenient.

Some Common Lisp features have been omitted from this package for various reasons:

- Some features are too complex or bulky relative to their benefit to Emacs Lisp programmers. CLOS and Common Lisp streams are fine examples of this group.
- Other features cannot be implemented without modification to the Emacs Lisp interpreter itself, such as multiple return values, lexical scoping, case-insensitive symbols, and complex numbers. The CL package generally makes no attempt to emulate these features.
- Some features conflict with existing things in Emacs Lisp. For example, Emacs' `assoc` function is incompatible with the Common Lisp `assoc`. In such cases, this package usually adds the suffix `*' to the function name of the Common Lisp version of the function (e.g., `assoc*`).

The package described here was written by Dave Gillespie, `daveg@synaptics.com'. It is a total rewrite of the original 1986 `cl.el' package by Cesar Quiroz. Most features of the the Quiroz package have been retained; any incompatibilities are noted in the descriptions below. Care has been taken in this version to ensure that each function is defined efficiently, concisely, and with minimal impact on the rest of the Emacs environment.

Usage

Lisp code that uses features from the CL package should include at the beginning:

```
(require 'cl)
```

If you want to ensure that the new (Gillespie) version of CL is the one that is present, add an additional `(require 'cl-19)` call:

```
(require 'cl)
(require 'cl-19)
```

The second call will fail (with "`cl-19.el' not found") if the old `cl.el' package was in use.

It is safe to arrange to load CL at all times, e.g., in your `.emacs' file. But it's a good idea, for

portability, to `(require 'cl)` in your code even if you do this.

Organization

The Common Lisp package is organized into four files:

`cl.el'
: This is the "main" file, which contains basic functions and information about the package. This file is relatively compact--about 700 lines.

`cl-extra.el'
: This file contains the larger, more complex or unusual functions. It is kept separate so that packages which only want to use Common Lisp fundamentals like the `cadr` function won't need to pay the overhead of loading the more advanced functions.

`cl-seq.el'
: This file contains most of the advanced functions for operating on sequences or lists, such as `delete-if` and `assoc*`.

`cl-macs.el'
: This file contains the features of the packages which are macros instead of functions. Macros expand when the caller is compiled, not when it is run, so the macros generally only need to be present when the byte-compiler is running (or when the macros are used in uncompiled code such as a `.emacs' file). Most of the macros of this package are isolated in `cl-macs.el' so that they won't take up memory unless you are compiling.

The file `cl.el' includes all necessary `autoload` commands for the functions and macros in the other three files. All you have to do is `(require 'cl)`, and `cl.el' will take care of pulling in the other files when they are needed.

There is another file, `cl-compat.el', which defines some routines from the older `cl.el' package that are no longer present in the new package. This includes internal routines like `setelt` and `zip-lists`, deprecated features like `defkeyword`, and an emulation of the old-style multiple-values feature. See section Old CL Compatibility.

Installation

Installation of the CL package is simple: Just put the byte-compiled files `cl.elc', `cl-extra.elc', `cl-seq.elc', `cl-macs.elc', and `cl-compat.elc' into a directory on your `load-path`.

There are no special requirements to compile this package: The files do not have to be loaded before they are compiled, nor do they need to be compiled in any particular order.

You may choose to put the files into your main `lisp/' directory, replacing the original `cl.el' file there. Or, you could put them into a directory that comes before `lisp/' on your `load-path` so that the old `cl.el' is effectively hidden.

Also, format the `cl.texinfo' file and put the resulting Info files in the `info/' directory or another suitable place.

You may instead wish to leave this package's components all in their own directory, and then add this directory to your `load-path' and (Emacs 19 only) `Info-directory-list'. Add the directory to the front of the list so the old CL package and its documentation are hidden.

Naming Conventions

Except where noted, all functions defined by this package have the same names and calling conventions as their Common Lisp counterparts.

Following is a complete list of functions whose names were changed from Common Lisp, usually to avoid conflicts with Emacs. In each case, a `*' has been appended to the Common Lisp name to obtain the Emacs name:

```
defun*          defsubst*       defmacro*       function*
member*         assoc*          rassoc*         get*
remove*         delete*         mapcar*         sort*
floor*          ceiling*        truncate*       round*
mod*            rem*            random*
```

Internal function and variable names in the package are prefixed by `cl-'. Here is a complete list of functions *not* prefixed by `cl-' which were not taken from Common Lisp:

```
member          delete          remove          remq
rassoc          floatp-safe     lexical-let     lexical-let*
callf           callf2          letf            letf*
defsubst*       defalias        add-hook        eval-when-compile
```

(Most of these are Emacs 19 features provided to Emacs 18 users, or introduced, like `remq', for reasons of symmetry with similar features.)

The following simple functions and macros are defined in `cl.el'; they do not cause other components like `cl-extra' to be loaded.

```
eql             floatp-safe     abs             endp
evenp           oddp            plusp           minusp
last            butlast         nbutlast        caar .. cddddr
list*           ldiff           rest            first .. tenth
member [1]      copy-list       subst           mapcar* [2]
adjoin [3]      acons           pairlis         when
unless          pop [4]         push [4]        pushnew [3,4]
incf [4]        decf [4]        proclaim        declaim
add-hook
```

[1] This is the Emacs 19-compatible function, not `member*`.

[2] Only for one sequence argument or two list arguments.

[3] Only if `:test` is `eq`, `equal`, or unspecified, and `:key` is not used.

[4] Only when place is a plain variable name.

@chapno=4

Program Structure

This section describes features of the CL package which have to do with programs as a whole: advanced argument lists for functions, and the `eval-when` construct.

@secno=1

Argument Lists

Emacs Lisp's notation for argument lists of functions is a subset of the Common Lisp notation. As well as the familiar `&optional` and `&rest` markers, Common Lisp allows you to specify default values for optional arguments, and it provides the additional markers `&key` and `&aux`.

Since argument parsing is built-in to Emacs, there is no way for this package to implement Common Lisp argument lists seamlessly. Instead, this package defines alternates for several Lisp forms which you must use if you need Common Lisp argument lists.

Special Form: **defun*** *name arglist body...*

This form is identical to the regular `defun` form, except that arglist is allowed to be a full Common Lisp argument list. Also, the function body is enclosed in an implicit block called name; see section Blocks and Exits.

Special Form: **defsubst*** *name arglist body...*

This is just like `defun*`, except that the function that is defined is automatically proclaimed `inline`, i.e., calls to it may be expanded into in-line code by the byte compiler. This is analogous to the `defsubst` form in Emacs 19; `defsubst*` uses a different method (compiler macros) which works in all version of Emacs, and also generates somewhat more efficient inline expansions. In particular, `defsubst*` arranges for the processing of keyword arguments, default values, etc., to be done at compile-time whenever possible.

Special Form: **defmacro*** *name arglist body...*

This is identical to the regular `defmacro` form, except that arglist is allowed to be a full Common Lisp argument list. The `&environment` keyword is supported as described in Steele. The `&whole` keyword is supported only within destructured lists (see below); top-level `&whole` cannot be implemented with the current Emacs Lisp interpreter. The macro expander body is enclosed in an implicit block called

name.

Special Form: **function*** *symbol-or-lambda*

This is identical to the regular `function` form, except that if the argument is a `lambda` form then that form may use a full Common Lisp argument list.

Also, all forms (such as `defsetf` and `flet`) defined in this package that include arglists in their syntax allow full Common Lisp argument lists.

Note that it is *not* necessary to use `defun*` in order to have access to most CL features in your function. These features are always present; `defun*`'s only difference from `defun` is its more flexible argument lists and its implicit block.

The full form of a Common Lisp argument list is

```
(var...
 &optional (var initform svar)...
 &rest var
 &key ((keyword var) initform svar)...
 &aux (var initform)...)
```

Each of the five argument list sections is optional. The svar, initform, and keyword parts are optional; if they are omitted, then `(var)' may be written simply `var'.

The first section consists of zero or more required arguments. These arguments must always be specified in a call to the function; there is no difference between Emacs Lisp and Common Lisp as far as required arguments are concerned.

The second section consists of optional arguments. These arguments may be specified in the function call; if they are not, initform specifies the default value used for the argument. (No initform means to use `nil` as the default.) The initform is evaluated with the bindings for the preceding arguments already established; `(a &optional (b (1+ a)))` matches one or two arguments, with the second argument defaulting to one plus the first argument. If the svar is specified, it is an auxiliary variable which is bound to `t` if the optional argument was specified, or to `nil` if the argument was omitted. If you don't use an svar, then there will be no way for your function to tell whether it was called with no argument, or with the default value passed explicitly as an argument.

The third section consists of a single rest argument. If more arguments were passed to the function than are accounted for by the required and optional arguments, those extra arguments are collected into a list and bound to the "rest" argument variable. Common Lisp's `&rest` is equivalent to that of Emacs Lisp. Common Lisp accepts `&body` as a synonym for `&rest` in macro contexts; this package accepts it all the time.

The fourth section consists of keyword arguments. These are optional arguments which are specified by name rather than positionally in the argument list. For example,

```
(defun* foo (a &optional b &key c d (e 17)))
```

defines a function which may be called with one, two, or more arguments. The first two arguments are bound to `a` and `b` in the usual way. The remaining arguments must be pairs of the form `:c`, `:d`, or `:e` followed by the value to be bound to the corresponding argument variable. (Symbols whose names begin with a colon are called keywords, and they are self-quoting in the same way as `nil` and `t`.)

For example, the call `(foo 1 2 :d 3 :c 4)` sets the five arguments to 1, 2, 4, 3, and 17, respectively. If the same keyword appears more than once in the function call, the first occurrence takes precedence over the later ones. Note that it is not possible to specify keyword arguments without specifying the optional argument `b` as well, since `(foo 1 :c 2)` would bind `b` to the keyword `:c`, then signal an error because `2` is not a valid keyword.

If a keyword symbol is explicitly specified in the argument list as shown in the above diagram, then that keyword will be used instead of just the variable name prefixed with a colon. You can specify a keyword symbol which does not begin with a colon at all, but such symbols will not be self-quoting; you will have to quote them explicitly with an apostrophe in the function call.

Ordinarily it is an error to pass an unrecognized keyword to a function, e.g., `(foo 1 2 :c 3 :goober 4)`. You can ask Lisp to ignore unrecognized keywords, either by adding the marker `&allow-other-keys` after the keyword section of the argument list, or by specifying an `:allow-other-keys` argument in the call whose value is non-`nil`. If the function uses both `&rest` and `&key` at the same time, the "rest" argument is bound to the keyword list as it appears in the call. For example:

```
(defun* find-thing (thing &rest rest &key need &allow-other-keys)
  (or (apply 'member* thing thing-list :allow-other-keys t rest)
      (if need (error "Thing not found"))))
```

This function takes a `:need` keyword argument, but also accepts other keyword arguments which are passed on to the `member*` function. `allow-other-keys` is used to keep both `find-thing` and `member*` from complaining about each others' keywords in the arguments.

In Common Lisp, keywords are recognized by the Lisp parser itself and treated as special entities. In Emacs, keywords are just symbols whose names begin with colons, which `defun*` has arranged to set equal to themselves so that they will essentially be self-quoting.

As a (significant) performance optimization, this package implements the scan for keyword arguments by calling `memq` to search for keywords in a "rest" argument. Technically speaking, this is incorrect, since `memq` looks at the odd-numbered values as well as the even-numbered keywords. The net effect is that if you happen to pass a keyword symbol as the *value* of another keyword argument, where that keyword symbol happens to equal the name of a valid keyword argument of the same function, then the keyword parser will become confused. This minor bug can only affect you if you use keyword symbols as general-purpose data in your program; this practice is strongly discouraged in Emacs Lisp.

The fifth section of the argument list consists of auxiliary variables. These are not really arguments at all, but simply variables which are bound to `nil` or to the specified initforms during execution of the function. There is no difference between the following two functions, except for a matter of stylistic taste:

```
(defun* foo (a b &aux (c (+ a b)) d)
  body)

(defun* foo (a b)
  (let ((c (+ a b)) d)
    body))
```

Argument lists support destructuring. In Common Lisp, destructuring is only allowed with `defmacro`; this package allows it with `defun*` and other argument lists as well. In destructuring, any argument variable (var in the above diagram) can be replaced by a list of variables, or more generally, a recursive argument list. The corresponding argument value must be a list whose elements match this recursive argument list. For example:

```
(defmacro* dolist ((var listform &optional resultform)
                   &rest body)
  ...)
```

This says that the first argument of `dolist` must be a list of two or three items; if there are other arguments as well as this list, they are stored in `body`. All features allowed in regular argument lists are allowed in these recursive argument lists. In addition, the clause `&whole var' is allowed at the front of a recursive argument list. It binds var to the whole list being matched; thus `(&whole all a b)` matches a list of two things, with `a` bound to the first thing, `b` bound to the second thing, and `all` bound to the list itself. (Common Lisp allows `&whole` in top-level `defmacro` argument lists as well, but Emacs Lisp does not support this usage.)

One last feature of destructuring is that the argument list may be dotted, so that the argument list `(a b . c)` is functionally equivalent to `(a b &rest c)`.

If the optimization quality `safety` is set to 0 (see section Declarations), error checking for wrong number of arguments and invalid keyword arguments is disabled. By default, argument lists are rigorously checked.

Time of Evaluation

Normally, the byte-compiler does not actually execute the forms in a file it compiles. For example, if a file contains `(setq foo t)`, the act of compiling it will not actually set `foo` to `t`. This is true even if the `setq` was a top-level form (i.e., not enclosed in a `defun` or other form). Sometimes, though, you would like to have certain top-level forms evaluated at compile-time. For example, the compiler effectively evaluates `defmacro` forms at compile-time so that later parts of the file can refer to the macros that are defined.

Special Form: **eval-when** *(situations...) forms...*

This form controls when the body forms are evaluated. The situations list may contain any set of the symbols `compile`, `load`, and `eval` (or their long-winded ANSI equivalents, `:compile-toplevel`, `:load-toplevel`, and `:execute`).

The `eval-when` form is handled differently depending on whether or not it is being compiled as a top-level form. Specifically, it gets special treatment if it is being compiled by a command such as `byte-compile-file` which compiles files or buffers of code, and it appears either literally at the top level of the file or inside a top-level `progn`.

For compiled top-level `eval-when`s, the body forms are executed at compile-time if `compile` is in the situations list, and the forms are written out to the file (to be executed at load-time) if `load` is in the situations list.

For non-compiled-top-level forms, only the `eval` situation is relevant. (This includes forms executed by the interpreter, forms compiled with `byte-compile` rather than `byte-compile-file`, and non-top-level forms.) The `eval-when` acts like a `progn` if `eval` is specified, and like `nil` (ignoring the body forms) if not.

The rules become more subtle when `eval-when`s are nested; consult Steele (second edition) for the gruesome details (and some gruesome examples).

Some simple examples:

```
;; Top-level forms in foo.el:
(eval-when (compile)           (setq foo1 'bar))
(eval-when (load)              (setq foo2 'bar))
(eval-when (compile load)      (setq foo3 'bar))
(eval-when (eval)              (setq foo4 'bar))
(eval-when (eval compile)      (setq foo5 'bar))
(eval-when (eval load)         (setq foo6 'bar))
(eval-when (eval compile load) (setq foo7 'bar))
```

When `` `foo.el' `` is compiled, these variables will be set during the compilation itself:

```
foo1  foo3  foo5  foo7      ; `compile'
```

When `` `foo.elc' `` is loaded, these variables will be set:

```
foo2  foo3  foo6  foo7      ; `load'
```

And if `` `foo.el' `` is loaded uncompiled, these variables will be set:

```
foo4  foo5  foo6  foo7      ; `eval'
```

If these seven `eval-when`s had been, say, inside a `defun`, then the first three would have been equivalent to `nil` and the last four would have been equivalent to the corresponding `setq`s.

Note that `(eval-when (load eval) ...)` is equivalent to `(progn ...)` in all contexts. The compiler treats certain top-level forms, like `defmacro` (sort-of) and `require`, as if they were wrapped in `(eval-when (compile load eval) ...)`.

Emacs 19 includes two special forms related to `eval-when`. One of these, `eval-when-compile`, is

not quite equivalent to any `eval-when` construct and is described below. This package defines a version of `eval-when-compile` for the benefit of Emacs 18 users.

The other form, `(eval-and-compile ...)`, is exactly equivalent to `(eval-when (compile load eval) ...)' and so is not itself defined by this package.

Special Form: **eval-when-compile** *forms...*

The forms are evaluated at compile-time; at execution time, this form acts like a quoted constant of the resulting value. Used at top-level, `eval-when-compile` is just like `eval-when (compile eval)'. In other contexts, `eval-when-compile` allows code to be evaluated once at compile-time for efficiency or other reasons.

This form is similar to the `#.' syntax of true Common Lisp.

Special Form: **load-time-value** *form*

The form is evaluated at load-time; at execution time, this form acts like a quoted constant of the resulting value.

Early Common Lisp had a `#,' syntax that was similar to this, but ANSI Common Lisp replaced it with `load-time-value` and gave it more well-defined semantics.

In a compiled file, `load-time-value` arranges for form to be evaluated when the `.elc' file is loaded and then used as if it were a quoted constant. In code compiled by `byte-compile` rather than `byte-compile-file`, the effect is identical to `eval-when-compile`. In uncompiled code, both `eval-when-compile` and `load-time-value` act exactly like `progn`.

```
(defun report ()
  (insert "This function was executed on: "
          (current-time-string)
          ", compiled on: "
          (eval-when-compile (current-time-string))
          ;; or '#.(current-time-string) in real Common Lisp
          ", and loaded on: "
          (load-time-value (current-time-string))))
```

Byte-compiled, the above defun will result in the following code (or its compiled equivalent, of course) in the `.elc' file:

```
(setq --temp-- (current-time-string))
(defun report ()
  (insert "This function was executed on: "
          (current-time-string)
          ", compiled on: "
          '"Wed Jun 23 18:33:43 1993"
          ", and loaded on: "
          --temp--))
```

Function Aliases

This section describes a feature from GNU Emacs 19 which this package makes available in other versions of Emacs.

Function: **defalias** *symbol function*

This function sets symbol's function cell to function. It is equivalent to `fset`, except that in GNU Emacs 19 it also records the setting in `load-history` so that it can be undone by a later `unload-feature`.

In other versions of Emacs, `defalias` is a synonym for `fset`.

Go to the next section.

Go to the previous, next section.

Predicates

This section describes functions for testing whether various facts are true or false.

Type Predicates

The CL package defines a version of the Common Lisp `typep` predicate.

Function: **typep** *object type*

Check if object is of type type, where type is a (quoted) type name of the sort used by Common Lisp. For example, `(typep foo 'integer)` is equivalent to `(integerp foo)`.

The type argument to the above function is either a symbol or a list beginning with a symbol.

- If the type name is a symbol, Emacs appends `-p' to the symbol name to form the name of a predicate function for testing the type. (Built-in predicates whose names end in `p' rather than `-p' are used when appropriate.)
- The type symbol `t` stands for the union of all types. `(typep object t)` is always true. Likewise, the type symbol `nil` stands for nothing at all, and `(typep object nil)` is always false.
- The type symbol `null` represents the symbol `nil`. Thus `(typep object 'null)` is equivalent to `(null object)`.
- The type symbol `real` is a synonym for `number`, and `fixnum` is a synonym for `integer`.
- The type symbols `character` and `string-char` match integers in the range from 0 to 255.
- The type symbol `float` uses the `floatp-safe` predicate defined by this package rather than `floatp`, so it will work correctly even in Emacs versions without floating-point support.
- The type list `(integer low high)` represents all integers between low and high, inclusive. Either bound may be a list of a single integer to specify an exclusive limit, or a `*` to specify no limit. The type `(integer * *)` is thus equivalent to `integer`.
- Likewise, lists beginning with `float`, `real`, or `number` represent numbers of that type falling in a particular range.
- Lists beginning with `and`, `or`, and `not` form combinations of types. For example, `(or integer (float 0 *))` represents all objects that are integers or non-negative floats.
- Lists beginning with `member` or `member*` represent objects `eql` to any of the following values. For example, `(member 1 2 3 4)` is equivalent to `(integer 1 4)`, and `(member nil)` is equivalent to `null`.
- Lists of the form `(satisfies predicate)` represent all objects for which predicate returns true when called with that object as an argument.

The following function and macro (not technically predicates) are related to `typep`.

Function: **coerce** *object type*

This function attempts to convert object to the specified type. If object is already of that type as determined by `typep`, it is simply returned. Otherwise, certain types of conversions will be made: If type is any sequence type (`string`, `list`, etc.) then object will be converted to that type if possible. If type is `character`, then strings of length one and symbols with one-character names can be coerced. If type is `float`, then integers can be coerced in versions of Emacs that support floats. In all other circumstances, `coerce` signals an error.

Special Form: **deftype** *name arglist forms...*

This macro defines a new type called name. It is similar to `defmacro` in many ways; when name is encountered as a type name, the body forms are evaluated and should return a type specifier that is equivalent to the type. The arglist is a Common Lisp argument list of the sort accepted by `defmacro*`. The type specifier `(name args...)' is expanded by calling the expander with those arguments; the type symbol `name' is expanded by calling the expander with no arguments. The arglist is processed the same as for `defmacro*` except that optional arguments without explicit defaults use `*` instead of `nil` as the "default" default. Some examples:

```
(deftype null () '(satisfies null))    ; predefined
(deftype list () '(or null cons))      ; predefined
(deftype unsigned-byte (&optional bits)
  (list 'integer 0 (if (eq bits '*) bits (1- (lsh 1 bits)))))
(unsigned-byte 8)  ==  (integer 0 255)
(unsigned-byte)  ==  (integer 0 *)
unsigned-byte  ==  (integer 0 *)
```

The last example shows how the Common Lisp `unsigned-byte` type specifier could be implemented if desired; this package does not implement `unsigned-byte` by default.

The `typecase` and `check-type` macros also use type names. See section Conditionals. See section Assertions and Errors. The `map`, `concatenate`, and `merge` functions take type-name arguments to specify the type of sequence to return. See section Sequences.

Equality Predicates

This package defines two Common Lisp predicates, `eql` and `equalp`.

Function: **eql** *a b*

This function is almost the same as `eq`, except that if a and b are numbers of the same type, it compares them for numeric equality (as if by `equal` instead of `eq`). This makes a difference only for versions of Emacs that are compiled with floating-point support, such as Emacs 19. Emacs floats are allocated objects just like cons cells, which means that `(eq 3.0 3.0)` will not necessarily be true--if the two `3.0`s were allocated separately, the pointers will be different even though the numbers are the same. But `(eql 3.0 3.0)` will always be true.

The types of the arguments must match, so `(eql 3 3.0)` is still false.

Note that Emacs integers are "direct" rather than allocated, which basically means `(eq 3 3)` will always be true. Thus `eq` and `eql` behave differently only if floating-point numbers are involved, and are indistinguishable on Emacs versions that don't support floats.

There is a slight inconsistency with Common Lisp in the treatment of positive and negative zeros. Some machines, notably those with IEEE standard arithmetic, represent `+0` and `-0` as distinct values. Normally this doesn't matter because the standard specifies that `(= 0.0 -0.0)` should always be true, and this is indeed what Emacs Lisp and Common Lisp do. But the Common Lisp standard states that `(eql 0.0 -0.0)` and `(equal 0.0 -0.0)` should be false on IEEE-like machines; Emacs Lisp does not do this, and in fact the only known way to distinguish between the two zeros in Emacs Lisp is to `format` them and check for a minus sign.

Function: **equalp** *a b*

This function is a more flexible version of `equal`. In particular, it compares strings case-insensitively, and it compares numbers without regard to type (so that `(equalp 3 3.0)` is true). Vectors and conses are compared recursively. All other objects are compared as if by `equal`.

This function differs from Common Lisp `equalp` in several respects. First, Common Lisp's `equalp` also compares *characters* case-insensitively, which would be impractical in this package since Emacs does not distinguish between integers and characters. In keeping with the idea that strings are less vector-like in Emacs Lisp, this package's `equalp` also will not compare strings against vectors of integers. Finally, Common Lisp's `equalp` compares hash tables without regard to ordering, whereas this package simply compares hash tables in terms of their underlying structure (which means vectors for Lucid Emacs 19 hash tables, or lists for other hash tables).

Also note that the Common Lisp functions `member` and `assoc` use `eql` to compare elements, whereas Emacs Lisp follows the MacLisp tradition and uses `equal` for these two functions. In Emacs, use `member*` and `assoc*` to get functions which use `eql` for comparisons.

Go to the previous, next section.

Go to the previous, next section.

Control Structure

The features described in the following sections implement various advanced control structures, including the powerful `setf` facility and a number of looping and conditional constructs.

Assignment

The `psetq` form is just like `setq`, except that multiple assignments are done in parallel rather than sequentially.

Special Form: **psetq** *[symbol form]...*

This special form (actually a macro) is used to assign to several variables simultaneously. Given only one symbol and form, it has the same effect as `setq`. Given several symbol and form pairs, it evaluates all the forms in advance and then stores the corresponding variables afterwards.

```
(setq x 2 y 3)
(setq x (+ x y)  y (* x y))
x
     => 5
y                       ; y was computed after x was set.
     => 15
(setq x 2 y 3)
(psetq x (+ x y)  y (* x y))
x
     => 5
y                       ; y was computed before x was set.
     => 6
```

The simplest use of `psetq` is `(psetq x y y x)`, which exchanges the values of two variables. (The `rotatef` form provides an even more convenient way to swap two variables; see section Modify Macros.)

`psetq` always returns `nil`.

Generalized Variables

A "generalized variable" or "place form" is one of the many places in Lisp memory where values can be stored. The simplest place form is a regular Lisp variable. But the cars and cdrs of lists, elements of arrays, properties of symbols, and many other locations are also places where Lisp values are stored.

The `setf` form is like `setq`, except that it accepts arbitrary place forms on the left side rather than just

symbols. For example, `(setf (car a) b)` sets the car of `a` to `b`, doing the same operation as `(setcar a b)` but without having to remember two separate functions for setting and accessing each type of place.

Generalized variables are analogous to "lvalues" in the C language, where `x = a[i]' gets an element from an array and `a[i] = x' stores an element using the same notation. Just as certain forms like `a[i]` can be lvalues in C, there is a set of forms that can be generalized variables in Lisp.

Basic Setf

The `setf` macro is the most basic way to operate on generalized variables.

Special Form: **setf** *[place form]...*

This macro evaluates form and stores it in place, which must be a valid generalized variable form. If there are several place and form pairs, the assignments are done sequentially just as with `setq`. `setf` returns the value of the last form.

The following Lisp forms will work as generalized variables, and so may legally appear in the place argument of `setf`:

- A symbol naming a variable. In other words, `(setf x y)` is exactly equivalent to `(setq x y)`, and `setq` itself is strictly speaking redundant now that `setf` exists. Many programmers continue to prefer `setq` for setting simple variables, though, purely for stylistic or historical reasons. The macro `(setf x y)` actually expands to `(setq x y)`, so there is no performance penalty for using it in compiled code.
- A call to any of the following Lisp functions:

```
car                 cdr                 caar .. cddddr
nth                 rest                first .. tenth
aref                elt                 nthcdr
symbol-function     symbol-value        symbol-plist
get                 get*                getf
gethash             subseq
```

  Note that for `nthcdr` and `getf`, the list argument of the function must itself be a valid place form. For example, `(setf (nthcdr 0 foo) 7)` will set `foo` itself to 7. Note that `push` and `pop` on an `nthcdr` place can be used to insert or delete at any position in a list. The use of `nthcdr` as a place form is an extension to standard Common Lisp.
- The following Emacs-specific functions are also `setf`-able. (Some of these are defined only in Emacs 19 or only in Lucid Emacs.)

```
buffer-file-name                marker-position
buffer-modified-p               match-data
buffer-name                     mouse-position
buffer-string                   overlay-end
buffer-substring                overlay-get
```

```
current-buffer                  overlay-start
current-case-table              point
current-column                  point-marker
current-global-map              point-max
current-input-mode              point-min
current-local-map               process-buffer
current-window-configuration    process-filter
default-file-modes              process-sentinel
default-value                   read-mouse-position
documentation-property          screen-height
extent-data                     screen-menubar
extent-end-position             screen-width
extent-start-position           selected-window
face-background                 selected-screen
face-background-pixmap          selected-frame
face-font                       standard-case-table
face-foreground                 syntax-table
face-underline-p                window-buffer
file-modes                      window-dedicated-p
frame-height                    window-display-table
frame-parameters                window-height
frame-visible-p                 window-hscroll
frame-width                     window-point
get-register                    window-start
getenv                          window-width
global-key-binding              x-get-cut-buffer
keymap-parent                   x-get-cutbuffer
local-key-binding               x-get-secondary-selection
mark                            x-get-selection
mark-marker
```

Most of these have directly corresponding "set" functions, like `use-local-map` for `current-local-map`, or `goto-char` for `point`. A few, like `point-min`, expand to longer sequences of code when they are `setf`'d (`(narrow-to-region x (point-max))` in this case).

- A call of the form `(substring subplace n [m])`, where subplace is itself a legal generalized variable whose current value is a string, and where the value stored is also a string. The new string is spliced into the specified part of the destination string. For example:

```
(setq a (list "hello" "world"))
     => ("hello" "world")
(cadr a)
     => "world"
(substring (cadr a) 2 4)
     => "rl"
```

```
(setf (substring (cadr a) 2 4) "o")
     => "o"
(cadr a)
     => "wood"
a
     => ("hello" "wood")
```

The generalized variable `buffer-substring`, listed above, also works in this way by replacing a portion of the current buffer.

- A call of the form `(apply 'func ...)` or `(apply (function func) ...)`, where func is a `setf`-able function whose store function is "suitable" in the sense described in Steele's book; since none of the standard Emacs place functions are suitable in this sense, this feature is only interesting when used with places you define yourself with `define-setf-method` or the long form of `defsetf`.
- A macro call, in which case the macro is expanded and `setf` is applied to the resulting form.
- Any form for which a `defsetf` or `define-setf-method` has been made.

Using any forms other than these in the place argument to `setf` will signal an error.

The `setf` macro takes care to evaluate all subforms in the proper left-to-right order; for example,

```
(setf (aref vec (incf i)) i)
```

looks like it will evaluate `(incf i)` exactly once, before the following access to `i`; the `setf` expander will insert temporary variables as necessary to ensure that it does in fact work this way no matter what setf-method is defined for `aref`. (In this case, `aset` would be used and no such steps would be necessary since `aset` takes its arguments in a convenient order.)

However, if the place form is a macro which explicitly evaluates its arguments in an unusual order, this unusual order will be preserved. Adapting an example from Steele, given

```
(defmacro wrong-order (x y) (list 'aref y x))
```

the form `(setf (wrong-order a b) 17)` will evaluate b first, then a, just as in an actual call to `wrong-order`.

Modify Macros

This package defines a number of other macros besides `setf` that operate on generalized variables. Many are interesting and useful even when the place is just a variable name.

Special Form: **psetf** *[place form]...*

This macro is to `setf` what `psetq` is to `setq`: When several places and forms are involved, the assignments take place in parallel rather than sequentially. Specifically, all subforms are evaluated from left to right, then all the assignments are done (in an undefined order).

Special Form: **incf** *place &optional x*

This macro increments the number stored in place by one, or by x if specified. The incremented value is returned. For example, `(incf i)` is equivalent to `(setq i (1+ i))`, and `(incf (car x) 2)` is equivalent to `(setcar x (+ (car x) 2))`.

Once again, care is taken to preserve the "apparent" order of evaluation. For example,

```
(incf (aref vec (incf i)))
```

appears to increment `i` once, then increment the element of `vec` addressed by `i`; this is indeed exactly what it does, which means the above form is *not* equivalent to the "obvious" expansion,

```
(setf (aref vec (incf i)) (1+ (aref vec (incf i))))   ; Wrong!
```

but rather to something more like

```
(let ((temp (incf i)))
  (setf (aref vec temp) (1+ (aref vec temp))))
```

Again, all of this is taken care of automatically by `incf` and the other generalized-variable macros.

As a more Emacs-specific example of `incf`, the expression `(incf (point) n)` is essentially equivalent to `(forward-char n)`.

Special Form: **decf** *place &optional x*

This macro decrements the number stored in place by one, or by x if specified.

Special Form: **pop** *place*

This macro removes and returns the first element of the list stored in place. It is analogous to `(prog1 (car place) (setf place (cdr place)))`, except that it takes care to evaluate all subforms only once.

Special Form: **push** *x place*

This macro inserts x at the front of the list stored in place. It is analogous to `(setf place (cons x place))`, except for evaluation of the subforms.

Special Form: **pushnew** *x place* `&key :test :test-not :key`

This macro inserts x at the front of the list stored in place, but only if x was not `eql` to any existing element of the list. The optional keyword arguments are interpreted in the same way as for `adjoin`. See section Lists as Sets.

Special Form: **shiftf** *place... newvalue*

This macro shifts the places left by one, shifting in the value of newvalue (which may be any Lisp expression, not just a generalized variable), and returning the value shifted out of the first place. Thus, `(shiftf a b c d)` is equivalent to

```
(prog1
    a
  (psetf a b
         b c
         c d))
```

except that the subforms of a, b, and c are actually evaluated only once each and in the apparent order.

Special Form: **rotatef** *place...*

This macro rotates the places left by one in circular fashion. Thus, `(rotatef a b c d)` is equivalent to

```
(psetf a b
       b c
       c d
       d a)
```

except for the evaluation of subforms. `rotatef` always returns `nil`. Note that `(rotatef a b)` conveniently exchanges a and b.

The following macros were invented for this package; they have no analogues in Common Lisp.

Special Form: **letf** *(bindings...) forms...*

This macro is analogous to `let`, but for generalized variables rather than just symbols. Each binding should be of the form `(place value)`; the original contents of the places are saved, the values are stored in them, and then the body forms are executed. Afterwards, the places are set back to their original saved contents. This cleanup happens even if the forms exit irregularly due to a `throw` or an error.

For example,

```
(letf (((point) (point-min))
       (a 17))
  ...)
```

moves "point" in the current buffer to the beginning of the buffer, and also binds `a` to 17 (as if by a normal `let`, since `a` is just a regular variable). After the body exits, `a` is set back to its original value and point is moved back to its original position.

Note that `letf` on `(point)` is not quite like a `save-excursion`, as the latter effectively saves a marker which tracks insertions and deletions in the buffer. Actually, a `letf` of `(point-marker)` is much closer to this behavior. (`point` and `point-marker` are equivalent as `setf` places; each will accept either an integer or a marker as the stored value.)

Since generalized variables look like lists, `let`'s shorthand of using `foo' for `(foo nil)' as a binding would be ambiguous in `letf` and is not allowed.

However, a binding specifier may be a one-element list `(place)', which is similar to `(place place)'. In other words, the place is not disturbed on entry to the body, and the only effect of the `letf' is to restore the original value of place afterwards. (The redundant access-and-store suggested by the `(place place)' example does not actually occur.)

In most cases, the place must have a well-defined value on entry to the `letf' form. The only exceptions are plain variables and calls to `symbol-value' and `symbol-function'. If the symbol is not bound on entry, it is simply made unbound by `makunbound' or `fmakunbound' on exit.

Special Form: **letf*** *(bindings...) forms...*

This macro is to `letf' what `let*' is to `let': It does the bindings in sequential rather than parallel order.

Special Form: **callf** *function place args...*

This is the "generic" modify macro. It calls function, which should be an unquoted function name, macro name, or lambda. It passes place and args as arguments, and assigns the result back to place. For example, `(incf place n)' is the same as `(callf + place n)'. Some more examples:

```
(callf abs my-number)
(callf concat (buffer-name) "<" (int-to-string n) ">")
(callf union happy-people (list joe bob) :test 'same-person)
```

See section Customizing Setf, for `define-modify-macro', a way to create even more concise notations for modify macros. Note again that `callf' is an extension to standard Common Lisp.

Special Form: **callf2** *function arg1 place args...*

This macro is like `callf', except that place is the *second* argument of function rather than the first. For example, `(push x place)' is equivalent to `(callf2 cons x place)'.

The `callf' and `callf2' macros serve as building blocks for other macros like `incf', `pushnew', and `define-modify-macro'. The `letf' and `letf*' macros are used in the processing of symbol macros; see section Macro Bindings.

Customizing Setf

Common Lisp defines three macros, `define-modify-macro', `defsetf', and `define-setf-method', that allow the user to extend generalized variables in various ways.

Special Form: **define-modify-macro** *name arglist function [doc-string]*

This macro defines a "read-modify-write" macro similar to `incf' and `decf'. The macro name is defined to take a place argument followed by additional arguments described by arglist. The call

```
(name place args...)
```

will be expanded to

```
(callf func place args...)
```

which in turn is roughly equivalent to

```
(setf place (func place args...))
```

For example:

```
(define-modify-macro incf (&optional (n 1)) +)
(define-modify-macro concatf (&rest args) concat)
```

Note that `&key` is not allowed in arglist, but `&rest` is sufficient to pass keywords on to the function.

Most of the modify macros defined by Common Lisp do not exactly follow the pattern of `define-modify-macro`. For example, `push` takes its arguments in the wrong order, and `pop` is completely irregular. You can define these macros "by hand" using `get-setf-method`, or consult the source file `` `cl-macs.el' `` to see how to use the internal `setf` building blocks.

Special Form: **defsetf** *access-fn update-fn*

This is the simpler of two `defsetf` forms. Where access-fn is the name of a function which accesses a place, this declares update-fn to be the corresponding store function. From now on,

```
(setf (access-fn arg1 arg2 arg3) value)
```

will be expanded to

```
(update-fn arg1 arg2 arg3 value)
```

The update-fn is required to be either a true function, or a macro which evaluates its arguments in a function-like way. Also, the update-fn is expected to return value as its result. Otherwise, the above expansion would not obey the rules for the way `setf` is supposed to behave.

As a special (non-Common-Lisp) extension, a third argument of `t` to `defsetf` says that the `update-fn`'s return value is not suitable, so that the above `setf` should be expanded to something more like

```
(let ((temp value))
  (update-fn arg1 arg2 arg3 temp)
  temp)
```

Some examples of the use of `defsetf`, drawn from the standard suite of setf methods, are:

```
(defsetf car setcar)
(defsetf symbol-value set)
(defsetf buffer-name rename-buffer t)
```

Special Form: **defsetf** *access-fn arglist (store-var) forms...*

This is the second, more complex, form of `defsetf`. It is rather like `defmacro` except for the additional store-var argument. The forms should return a Lisp form which stores the value of store-var into the generalized variable formed by a call to access-fn with arguments described by arglist. The forms may begin with a string which documents the `setf` method (analogous to the doc string that appears at the front of a function).

For example, the simple form of `defsetf` is shorthand for

```
(defsetf access-fn (&rest args) (store)
  (append '(update-fn) args (list store)))
```

The Lisp form that is returned can access the arguments from arglist and store-var in an unrestricted fashion; macros like `setf` and `incf` which invoke this setf-method will insert temporary variables as needed to make sure the apparent order of evaluation is preserved.

Another example drawn from the standard package:

```
(defsetf nth (n x) (store)
  (list 'setcar (list 'nthcdr n x) store))
```

Special Form: **define-setf-method** *access-fn arglist forms...*

This is the most general way to create new place forms. When a `setf` to access-fn with arguments described by arglist is expanded, the forms are evaluated and must return a list of five items:

1. A list of temporary variables.
2. A list of value forms corresponding to the temporary variables above. The temporary variables will be bound to these value forms as the first step of any operation on the generalized variable.
3. A list of exactly one store variable (generally obtained from a call to `gensym`).
4. A Lisp form which stores the contents of the store variable into the generalized variable, assuming the temporaries have been bound as described above.
5. A Lisp form which accesses the contents of the generalized variable, assuming the temporaries have been bound.

This is exactly like the Common Lisp macro of the same name, except that the method returns a list of five values rather than the five values themselves, since Emacs Lisp does not support Common Lisp's notion of multiple return values.

Once again, the forms may begin with a documentation string.

A setf-method should be maximally conservative with regard to temporary variables. In the setf-methods generated by `defsetf`, the second return value is simply the list of arguments in the place form, and the first return value is a list of a corresponding number of temporary variables generated by `gensym`. Macros like `setf` and `incf` which use this setf-method will optimize away most temporaries that turn out to be unnecessary, so there is little reason for the setf-method itself to optimize.

Function: **get-setf-method** *place &optional env*

This function returns the setf-method for place, by invoking the definition previously recorded by `defsetf` or `define-setf-method`. The result is a list of five values as described above. You can use this function to build your own `incf`-like modify macros. (Actually, it is better to use the internal functions `cl-setf-do-modify` and `cl-setf-do-store`, which are a bit easier to use and which also do a number of optimizations; consult the source code for the `incf` function for a simple example.)

The argument env specifies the "environment" to be passed on to `macroexpand` if `get-setf-method` should need to expand a macro in place. It should come from an `&environment` argument to the macro or setf-method that called `get-setf-method`.

See also the source code for the setf-methods for `apply` and `substring`, each of which works by calling `get-setf-method` on a simpler case, then massaging the result in various ways.

Modern Common Lisp defines a second, independent way to specify the `setf` behavior of a function, namely "`setf` functions" whose names are lists `(setf name)` rather than symbols. For example, `(defun (setf foo) ...)` defines the function that is used when `setf` is applied to `foo`. This package does not currently support `setf` functions. In particular, it is a compile-time error to use `setf` on a form which has not already been `defsetf`'d or otherwise declared; in newer Common Lisps, this would not be an error since the function `(setf func)` might be defined later.

@secno=4

Variable Bindings

These Lisp forms make bindings to variables and function names, analogous to Lisp's built-in `let` form.

See section Modify Macros, for the `letf` and `letf*` forms which are also related to variable bindings.

Dynamic Bindings

The standard `let` form binds variables whose names are known at compile-time. The `progv` form provides an easy way to bind variables whose names are computed at run-time.

Special Form: **progv** *symbols values forms...*

This form establishes `let`-style variable bindings on a set of variables computed at run-time. The expressions symbols and values are evaluated, and must return lists of symbols and values, respectively. The symbols are bound to the corresponding values for the duration of the body forms. If values is shorter than symbols, the last few symbols are made unbound (as if by `makunbound`) inside the body. If symbols is shorter than values, the excess values are ignored.

Lexical Bindings

The CL package defines the following macro which more closely follows the Common Lisp `let` form:

Special Form: **lexical-let** *(bindings...) forms...*

This form is exactly like `let` except that the bindings it establishes are purely lexical. Lexical bindings

are similar to local variables in a language like C: Only the code physically within the body of the `lexical-let` (after macro expansion) may refer to the bound variables.

```
(setq a 5)
(defun foo (b) (+ a b))
(let ((a 2)) (foo a))
     => 4
(lexical-let ((a 2)) (foo a))
     => 7
```

In this example, a regular `let` binding of `a` actually makes a temporary change to the global variable `a`, so `foo` is able to see the binding of `a` to 2. But `lexical-let` actually creates a distinct local variable `a` for use within its body, without any effect on the global variable of the same name.

The most important use of lexical bindings is to create closures. A closure is a function object that refers to an outside lexical variable. For example:

```
(defun make-adder (n)
  (lexical-let ((n n))
    (function (lambda (m) (+ n m)))))
(setq add17 (make-adder 17))
(funcall add17 4)
     => 21
```

The call `(make-adder 17)` returns a function object which adds 17 to its argument. If `let` had been used instead of `lexical-let`, the function object would have referred to the global `n`, which would have been bound to 17 only during the call to `make-adder` itself.

```
(defun make-counter ()
  (lexical-let ((n 0))
    (function* (lambda (&optional (m 1)) (incf n m)))))
(setq count-1 (make-counter))
(funcall count-1 3)
     => 3
(funcall count-1 14)
     => 17
(setq count-2 (make-counter))
(funcall count-2 5)
     => 5
(funcall count-1 2)
     => 19
(funcall count-2)
     => 6
```

Here we see that each call to `make-counter` creates a distinct local variable `n`, which serves as a private counter for the function object that is returned.

Closed-over lexical variables persist until the last reference to them goes away, just like all other Lisp objects. For example, `count-2` refers to a function object which refers to an instance of the variable `n`; this is the only reference to that variable, so after `(setq count-2 nil)` the garbage collector would be able to delete this instance of `n`. Of course, if a `lexical-let` does not actually create any closures, then the lexical variables are free as soon as the `lexical-let` returns.

Many closures are used only during the extent of the bindings they refer to; these are known as "downward funargs" in Lisp parlance. When a closure is used in this way, regular Emacs Lisp dynamic bindings suffice and will be more efficient than `lexical-let` closures:

```
(defun add-to-list (x list)
  (mapcar (function (lambda (y) (+ x y))) list))
(add-to-list 7 '(1 2 5))
     => (8 9 12)
```

Since this lambda is only used while `x` is still bound, it is not necessary to make a true closure out of it.

You can use `defun` or `flet` inside a `lexical-let` to create a named closure. If several closures are created in the body of a single `lexical-let`, they all close over the same instance of the lexical variable.

The `lexical-let` form is an extension to Common Lisp. In true Common Lisp, all bindings are lexical unless declared otherwise.

Special Form: **lexical-let*** *(bindings...) forms...*

This form is just like `lexical-let`, except that the bindings are made sequentially in the manner of `let*`.

Function Bindings

These forms make `let`-like bindings to functions instead of variables.

Special Form: **flet** *(bindings...) forms...*

This form establishes `let`-style bindings on the function cells of symbols rather than on the value cells. Each binding must be a list of the form `(name arglist forms...)', which defines a function exactly as if it were a `defun*` form. The function name is defined accordingly for the duration of the body of the `flet`; then the old function definition, or lack thereof, is restored.

While `flet` in Common Lisp establishes a lexical binding of name, Emacs Lisp `flet` makes a dynamic binding. The result is that `flet` affects indirect calls to a function as well as calls directly inside the `flet` form itself.

You can use `flet` to disable or modify the behavior of a function in a temporary fashion. This will even work on Emacs primitives, although note that some calls to primitive functions internal to Emacs are made without going through the symbol's function cell, and so will not be affected by `flet`. For example,

```
(flet ((message (&rest args) (push args saved-msgs)))
  (do-something))
```

This code attempts to replace the built-in function `message` with a function that simply saves the messages in a list rather than displaying them. The original definition of `message` will be restored after `do-something` exits. This code will work fine on messages generated by other Lisp code, but messages generated directly inside Emacs will not be caught since they make direct C-language calls to the message routines rather than going through the Lisp `message` function.

Functions defined by `flet` may use the full Common Lisp argument notation supported by `defun*`; also, the function body is enclosed in an implicit block as if by `defun*`. See section Program Structure.

Special Form: **labels** *(bindings...) forms...*

The `labels` form is like `flet`, except that it makes lexical bindings of the function names rather than dynamic bindings. (In true Common Lisp, both `flet` and `labels` make lexical bindings of slightly different sorts; since Emacs Lisp is dynamically bound by default, it seemed more appropriate for `flet` also to use dynamic binding. The `labels` form, with its lexical binding, is fully compatible with Common Lisp.)

Lexical scoping means that all references to the named functions must appear physically within the body of the `labels` form. References may appear both in the body forms of `labels` itself, and in the bodies of the functions themselves. Thus, `labels` can define local recursive functions, or mutually-recursive sets of functions.

A "reference" to a function name is either a call to that function, or a use of its name quoted by `quote` or `function` to be passed on to, say, `mapcar`.

Macro Bindings

These forms create local macros and "symbol macros."

Special Form: **macrolet** *(bindings...) forms...*

This form is analogous to `flet`, but for macros instead of functions. Each binding is a list of the same form as the arguments to `defmacro*` (i.e., a macro name, argument list, and macro-expander forms). The macro is defined accordingly for use within the body of the `macrolet`.

Because of the nature of macros, `macrolet` is lexically scoped even in Emacs Lisp: The `macrolet` binding will affect only calls that appear physically within the body forms, possibly after expansion of other macros in the body.

Special Form: **symbol-macrolet** *(bindings...) forms...*

This form creates symbol macros, which are macros that look like variable references rather than function calls. Each binding is a list `(var expansion)'; any reference to var within the body forms is replaced by expansion.

```
(setq bar '(5 . 9))
```

```
(symbol-macrolet ((foo (car bar)))
  (incf foo))
bar
     => (6 . 9)
```

A `setq` of a symbol macro is treated the same as a `setf`. I.e., `(setq foo 4)` in the above would be equivalent to `(setf foo 4)`, which in turn expands to `(setf (car bar) 4)`.

Likewise, a `let` or `let*` binding a symbol macro is treated like a `letf` or `letf*`. This differs from true Common Lisp, where the rules of lexical scoping cause a `let` binding to shadow a `symbol-macrolet` binding. In this package, only `lexical-let` and `lexical-let*` will shadow a symbol macro.

There is no analogue of `defmacro` for symbol macros; all symbol macros are local. A typical use of `symbol-macrolet` is in the expansion of another macro:

```
(defmacro* my-dolist ((x list) &rest body)
  (let ((var (gensym)))
    (list 'loop 'for var 'on list 'do
          (list* 'symbol-macrolet (list (list x (list 'car var)))
                 body))))

(setq mylist '(1 2 3 4))
(my-dolist (x mylist) (incf x))
mylist
     => (2 3 4 5)
```

In this example, the `my-dolist` macro is similar to `dolist` (see section Iteration) except that the variable `x` becomes a true reference onto the elements of the list. The `my-dolist` call shown here expands to

```
(loop for G1234 on mylist do
      (symbol-macrolet ((x (car G1234)))
        (incf x)))
```

which in turn expands to

```
(loop for G1234 on mylist do (incf (car G1234)))
```

See section Loop Facility, for a description of the `loop` macro. This package defines a nonstandard `in-ref` loop clause that works much like `my-dolist`.

Conditionals

These conditional forms augment Emacs Lisp's simple `if`, `and`, `or`, and `cond` forms.

Special Form: **when** *test forms...*

This is a variant of `if` where there are no "else" forms, and possibly several "then" forms. In particular,

```
(when test a b c)
```

is entirely equivalent to

```
(if test (progn a b c) nil)
```

Special Form: **unless** *test forms...*

This is a variant of `if` where there are no "then" forms, and possibly several "else" forms:

```
(unless test a b c)
```

is entirely equivalent to

```
(when (not test) a b c)
```

Special Form: **case** *keyform clause...*

This macro evaluates keyform, then compares it with the key values listed in the various clauses. Whichever clause matches the key is executed; comparison is done by `eql`. If no clause matches, the `case` form returns `nil`. The clauses are of the form

```
(keylist body-forms...)
```
